Currently, public perception is critical for obtaining and maintaining a social license, as it directly influences societal support and acceptance. A positive public perception can strengthen community relations, while negative ones can generate conflict and resistance. Companies can develop and maintain a social license by demonstrating their commitment to transparency and communication, being open and honest with the community about their operations and impact. Likewise, they gain social legitimacy by respecting community norms and interacting with local stakeholders, providing reliable information and fulfilling commitments, thus building trust based on respect and mutual understanding. Specifically, this paper presents an experience with a regulatory and environmental compliance program, with a pilot program that included an academic third-party reviewer. The program aims to strengthen a commitment to sustainable practices and minimize the environmental impact of a salmon farming company's activities.

Traditionally, the Chilean salmon farming industry operated under a regulatory mechanism known as "command and control," where the environmental monitoring and regulatory support area, rather than a second line of defense, was an auditor of compliance with procedures or regulations. This auditing system is similar to that used by government authorities.

With the implementation of this pilot program, the goal is to identify and consolidate the different lines of defense in the company's environmental risk management and regulatory compliance. The above implies an original framework that emphasizes the transversality of environmental and regulatory risk management, directly including operational areas, as well as making it part of the company's strategic plan for sustainability. The challenge is to generate a true cultural change within the company. This means that all operational, administrative, and commercial teams, among others, are committed to this new system and understand their role as risk managers. They begin to understand themselves, measure themselves, and report on their risks, incorporating this new variable into their routine decision-making framework.

The progress made so far has included reviewing critical points of the company's compliance model that fall within Chilean regulatory and environmental aspects, as well as their relevance to the established risk needs and verifying the effective execution of the monitoring and improvement actions described in the compliance matrix.

The challenge for the future is to foster academic spaces that promote the training of new professionals and technicians, incorporating aspects of regulatory and environmental compliance, to generate competencies in both production and operational tasks, as well as support and governance, thus incorporating capabilities and value into companies in the face of the challenges and opportunities that arise, within a sustainable productive ecosystem connected to society.

# GENOMIC STRATEGIES FOR CLIMATE-RESILIENT MUSSEL FARMING: TOXIN ACCUMULATION IN *Mytilus galloprovincialis*

## Introduction

The Mediterranean mussel (*Mytilus galloprovincialis*) is a cornerstone of European shellfish farming, particularly along the Atlantic coast, where Galicia (NW-Spain) alone produces approximately 220,000 tons annually. However, the increasing frequency of harmful microalgae blooms, caused by climate change, poses a major challenge to mussel aquaculture due to toxin accumulation and prolonged commercialization bans. In this study, we conducted genome-wide association studies (GWAS) on a large number of families, using a multispecies SNP Axiom Array (60K) to investigate the genetic basis of toxin accumulation following exposure to okadaic acid, the main diarrheic toxin. A chromosome-level genome assembly of *M. galloprovincialis* (1.8 Gb) was developed, and SNPs from the array were mapped to the annotated genome. Chromosomal regions showing significant association with toxin accumulation were analyzed for candidate genes, revealing a major quantitative trait locus (QTL) on chromosome 1. This locus appears to underlie the moderate heritability of the trait ($h^2 = 0.39$) and offers promising targets for selective breeding. These genomic tools represent a critical step toward more sustainable and climate-resilient mussel aquaculture.

## Materials and Methods

A population of 1138 mussel samples, belonging to the toxin accumulation group (APG group) described in Pino-Querido et al., 2015, was genotyped using a custom 60K multispecies SNP Axiom array, developed in collaboration with the University of Exeter. Genomic DNA was analyzed using standard GWAS pipelines, including quality filtering with PLINK 1.9 software (Chang et al., 2015). A chromosome-level genome assembly (1.8 Gb) was constructed using Oxford Nanopore (50x) and Illumina (120x) sequencing, resulting in 1,207 contigs (N50 = 2.4 Mb). The genome was scaffolded using a medium-density linkage map (11,540 loci in 14 LGs) and Omni-C data.

## Results

After quality control, a total of 22,499 high-confidence SNPs were retained, of which 8,891 were successfully aligned to the reference genome. Genome-wide association analysis revealed seven SNPs significantly associated with okadaic acid accumulation, supporting the presence of quantitative trait loci (QTL) with moderate heritability ($h^2 = 0.39$). The majority of these SNPs were localized on chromosome 1, delineating a key genomic region potentially involved in the trait; one SNP mapped to chromosome 4, while another did not align to the genome. A detailed annotation of the chromosome 1 QTL region showed that two of the significant SNPs are located within coding sequences of annotated genes. Further investigation of the intergenic region between these two SNPs revealed a tightly linked gene cluster, including candidate genes functionally associated with transport processes and immune response mechanisms.

## Discussion

This study highlights the utility of SNP genotyping arrays to identify genetic regions involved in toxin accumulation. The identification of QTLs offers valuable targets for selective breeding, aiming to develop toxin-resilient mussel lines and mitigate the socio-economic impact of harmful algal blooms on aquaculture.

## Introduction

The intensification of aquaculture production has raised increasing concern regarding the environmental impacts of nutrient-rich effluents, particularly those containing high concentrations of nitrogen and phosphorus compounds. A sustainable alternative for mitigating these impacts involves the use of microalgae, such as *Desmodesmus armatus*, which are capable of growing in wastewater while simultaneously assimilating excess nutrients. This study evaluated the growth performance of *D. armatus* in synthetic aquaculture effluents formulated with varying concentrations of carbon (C), nitrogen (N), and phosphorus (P), aiming to assess its efficacy as a bioremediation agent. Additionally, the approach aligns with circular economy principles by integrating nutrient recovery with the generation of high-value algal biomass, with potential application as aquafeed.

## Material and methods

The experimental design followed a two-factor factorial arrangement, investigating the effects of carbon (C) and macronutrient (nitrogen and phosphorus) concentrations on the growth of *Desmodesmus armatus* and its nutrient bioremediation performance. Four levels of C-glucose (4.2, 2.8, 1.4, and 0 mM) were combined with four dilution levels of nitrogen (N) and phosphorus (P) (100%, 67%, 33%, and 10%), with the highest concentrations corresponding to 8.6 mM N and 0.64 mM P. The synthetic effluent medium was based on the formulation proposed by Visvanathan et al. (2008), with modifications to C, N, and P concentrations and the inclusion of ammonia and nitrite as nitrogen sources. Bold's Basal Medium (BBM) was used as the control, resulting in a total of 17 treatments, each with two replicates. Cultures were conducted in 250 mL Erlenmeyer flasks containing 100 mL of working volume, maintained under orbital shaking (100 rpm), at 24 °C, with a 12:12 h light: dark photoperiod and an irradiance of 300 $\mu E\ m^{-2}\ s^{-1}$. The cultivation protocol consisted of an initial inoculation phase followed by three consecutive subcultures, each lasting 12 days. Daily monitoring included measurements of optical density at 720 nm and cell concentration determined by flow cytometry. On days 0, 6, and 12, additional analyses were performed to assess photosynthetic efficiency (Fv/Fm), pH, total ammoniacal nitrogen, nitrite-nitrogen ($NO^{2-}$), nitrate-nitrogen ($NO^{3-}$), phosphate-phosphorus ($PO_4^{3-}$), and total organic carbon (TOC) (2017). Statistical analysis included two-way ANOVA followed by Tukey's post hoc test. Principal Component Analysis (PCA) was employed to identify treatment effects and multivariate trends.

## Results and Discussion

Desmodesmus armatus exhibited growth under all tested conditions, with significant variation in response to the availability of organic carbon. Higher C-glucose concentrations (4.2 and 2.8 mM) consistently promoted algal growth that was greater than the control, resulting in increased biomass productivity regardless of nitrogen and phosphorus dilution levels. The principal component analysis (fig. 1) revealed a clear separation among treatments with different C-glucose concentrations (0, 1.4, 2.8 and 4.2 mM), indicating a strong influence of carbon availability on system performance. Dimension 1 (Dim1), which accounts for 44.7% of the total variance, distinctly separates the carbon-free treatments from those with higher concentrations (particularly 4.2 mM), while Dimension 2 (Dim2), explaining 36.5%, further discriminates intermediate groups. Variables associated with bioremediation, such as the consumption of ammonium (ConsNH4), nitrite (ConsNO2), and nitrate (ConsNO3), along with the initial nitrogen concentration (N0), were more closely related to treatments with low or no carbon supplementation. In contrast, variables linked to cultivation performance, including final productivity (Pr_final), final relative productivity (Pr_rel_final), and carbon consumption (ConsC), showed a positive association with treatments receiving higher glucose concentrations. These findings suggest that increased carbon availability enhances the growth of Desmodesmus armatus and is associated with changes in the consumption patterns of nutrients derived from aquaculture effluents.

*(Continued on next page)*

**Conclusion**

The results demonstrate that higher C-glucose concentrations significantly enhance the growth and biomass productivity of *Desmodesmus armatus*. Carbon supplementation also influenced nutrient consumption patterns, highlighting the key role of this microalga not only in optimizing high-value biomass production for potential use in aquafeed, but also in bioremediation through the efficient removal of nutrients from aquaculture effluents.

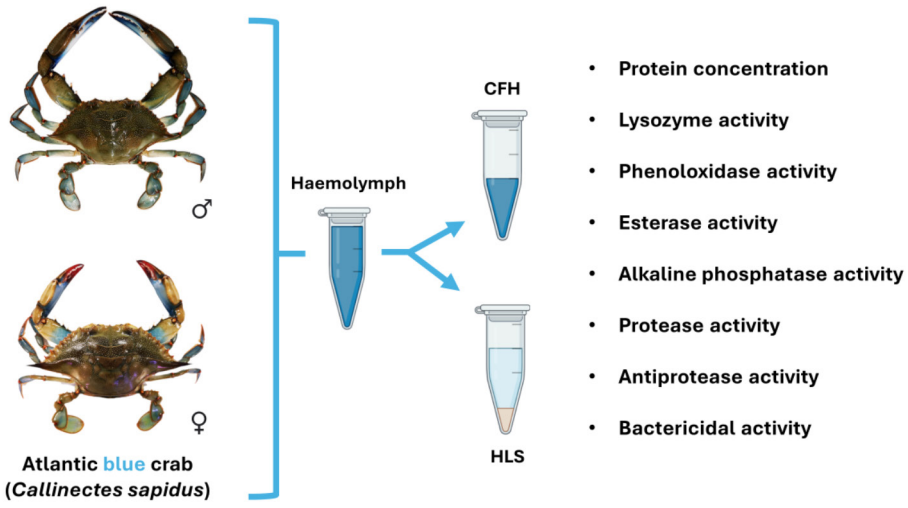
Despite their economic significance, brachyurans are relatively understudied among invertebrate groups compared to other decapods, with numerous fields remaining to be explored, including the immune response. Therefore, the aim of this study was to characterize several immune-related enzymes and activities of the Atlantic blue crab (*Callinectes sapidus*) in cell-free haemolymph (CFH) and in the haemocyte lysate supernatant (HLS), considering the gender factor and the suitability of measuring each activity in CFH or HLS. Data were expressed by millilitres of haemolymph or milligrams of protein to identify which of these units would be more robust and informative. For this, haemolymph from crabs of each gender was collected, and centrifuged to obtain CFH samples, whilst the cells were sonicated to get the HLS. Our results revealed that the protein concentration was higher in CFH compared to HLS. Considering milligrams of protein as units, phenoloxidase and esterase activities were lower in CFH regarding to HLS in both genders. Similarly, the lysozyme and phosphatase activities were lower in CFH compared to HLS but only in females. The values of lysozyme activity were higher in HLS of females compared to males. Studying millilitre of haemolymph as units, lysozyme activity exhibited higher activity in CFH compared to HLS in both genders, whilst phenoloxidase and esterase activities were higher in HLS, showing variations only in males. Interestingly, alkaline phosphatase activity was undetected in CFH male. Any variation was observed between the activities measured in both genders. Protease and antiprotease activities were higher and lower in CFH compared to HLS values, respectively, whilst any variation was observed between genders. Bactericidal activity against *V. harveyi*, *V. alginolyticus* and *V. anguillarum,* exhibited stronger values in HLS than in CFH, independently of gender, as well as against *P. damselae* in females. Considering gender factor, the bactericidal activity against *V. alginolyticus*, *V. anguillarum* and *P. damselae* was higher in HLS of females than in males. However, the bactericidal activity against *V. alginolyticus* and *P. damselae* was higher in CFH of males compared to females. Our results could contribute to gender selection in future brachyurans studies considering the variability between males and females due to their distinct biology. Additionally, we provide data regarding the baseline values of several immune-related activities, establishing the most appropriate units from the biological point of view.



# MEASURE OF PHAGOCYTIC ACTIVITY IN THE HAEMOCYTES OF THE ATLANTIC BLUE CRAB *(Callinectes sapidus)* USING LABELLED *Vibrio alginolyticus*

## Introduction

Phagocytosis represents one of the most important cellular defence mechanisms in crustaceans, being essential for the elimination of pathogens and the activation of other immune processes (Sunjial et al., 2014). Despite its biological significance, the study of phagocytic activity in brachyuran crabs is still limited, with scarce information available for the Atlantic blue crab (*Callinectes sapidus*), a species of growing ecological and economic importance. Previous studies in crustaceans have employed several approaches to assess phagocytosis, often relying on microscopy or the use of yeast particles as model organisms. However, these techniques generally lack sensitivity and quantification accuracy. Flow cytometry offers a powerful tool to overcome these limitations, enabling a rapid and reproducible analysis of large numbers of cells, with the possibility to discriminate between cellular subpopulations. In this work, we aimed to develop and standardise a reliable method for the evaluation of phagocytic activity in Atlantic blue crab haemocytes by using fluorescein isothiocyanate (FITC)-labelled *Vibrio alginolyticus* as target particles and flow cytometry as the analytical platform.

## Materials and Methods

For bacterial preparation, *V. alginolyticus* was cultured in Tryptic Soy Broth supplemented with 1.5% NaCl at 25 °C until the exponential growth phase was reached. Bacteria were adjusted to $1 \times 10^9$ CFU $mL^{-1}$, inactivated with 3% formalin, and fluorescently labelled with FITC following a modified version of the method described by Yang et al (2020). Labelled bacteria were washed thoroughly and stored at –80 °C until use. For measuring the phagocytic activity, the method described by Esteban et al. (1998) was employed with some modifications. Haemolymph was extracted from six crabs using Alsever's solution with ethylenediamine tetraacetic acid (EDTA) as anticoagulant, and haemocytes were adjusted to $5 \times 10^6$ cells $mL^{-1}$. Each individual and time point, aliquots were prepared as positive (25 °C) and negative (4 °C) controls and incubated with FITC-labelled *V. alginolyticus* at a ratio of 50 bacteria per haemocyte. An additional aliquot from each crab was reserved for electronic transmission microscopic analysis. After centrifugation and incubation in the dark, extracellular fluorescence was quenched with trypan blue before analysis by flow cytometry (FACSCalibur, Becton Dickinson). A total of 10,000 events were recorded per sample. Forward scatter (FSC), side scatter (SSC) and green fluorescence (FL1) were collected. Phagocytic ability was defined as the percentage of haemocytes displaying green fluorescence, while phagocytic capacity was expressed as the mean fluorescence intensity (MFI) of positive cells. All experiments were carried out in triplicate and measurements were taken every 30 minutes from 0 to 180 minutes.

## Results

The method developed allowed a clear and reproducible quantification of phagocytic activity in Atlantic blue crab haemocytes. Haemocytes incubated at 25 °C (positive control) exhibited a progressive and significant increase in phagocytic ability over time, with the highest values observed between 120 and 180 minutes compared with earlier time points (0, 30, 60 and 90 minutes). In contrast, haemocytes incubated at 4 °C (negative control), where metabolic activity is reduced, did not show variations in phagocytic ability throughout the experimental period. Regarding phagocytic capacity, both positive and negative controls showed an increase in MFI over time compared with baseline values, but no variations were detected between the two conditions. These results suggest that the optimal time point for measuring this activity is between 120 and 180 minutes and also that cold reduces the metabolism of the cells and reduces drastically the phagocytic ability. Although, phagocytic

*(Continued on next page)*

capacity was not affected by cold treatment. The data obtained by flow cytometry were corroborated by transmission electron microscopy, which confirmed the internalisation of bacterial particles by haemocytes, providing complementary evidence to support the reliability of the method.

**Conclusion**

The present study establishes a reproducible and sensitive method for assessing haemocyte phagocytic activity in the Atlantic blue crab by combining FITC-labelled *V. alginolyticus* and flow cytometry. This protocol allows for the discrimination between phagocytic ability and phagocytic capacity, two complementary aspects of immune function, and contributes to the standardisation of methodologies for studying crustacean cellular immunity. The validation of results by electron microscopy further strengthens the robustness of the approach. Overall, this technique represents a valuable tool for the investigation of crustacean immune responses and could be adapted to other brachyuran and decapod species.

**Introduction**

The concept of animal welfare has traditionally been associated with vertebrate species, leaving aquatic invertebrates relatively understudied despite their ecological relevance and considerable economic value in aquaculture and fisheries. The lack of standardised methodologies for assessing welfare in these animals has hindered both the implementation of best practices and the establishment of regulatory frameworks. In recent years, there has been a growing recognition of the need to identify and validate species-specific biomarkers that may serve as reliable indicators of welfare status in aquatic invertebrates. Brachyuran crabs, due to their physiological and immunological characteristics, represent promising models in this regard. The Atlantic blue crab (*Callinectes sapidus*), an invasive species in the Mediterranean but also a species of commercial interest, provides an ideal experimental model to explore potential biomarkers of welfare. Parameters such as lactate and glucose have been commonly used as metabolic indicators in crustaceans (Albalat et al., 2009), while haemocyte-based assays, including viability, phagocytosis, and phenoloxidase activity, are frequently employed as markers of immune competence (Lightner et al., 2021). However, comprehensive studies combining these markers under controlled experimental conditions are scarce. This study aimed to assess a range of physiological, cellular, and humoral parameters in Atlantic blue crab over different time intervals following capture, in order to evaluate their potential as welfare biomarkers.

**Materials and Methods**

A total of 42 male of Atlantic blue crab (315 ± 62 g) were obtained from the fish market in Lo Pagán (Murcia, Spain) captured by traditional fishing methods. Crabs were transported in sealed dry containers, mimicking commercial conditions, and transferred to the marine facilities of the University of Murcia. Animals were placed separately in rack system tanks (35 L each compartment), each with a 10 cm sand substrate to allow burying behaviour. Animals were not fed during the experimental period. Haemolymph was collected from six crabs per time point (0, 6, 24, 48, 72 h, 7 and 14 days post-capture). From each 5 mL sample, 1 mL was centrifuged to obtain plasma for glucose and protein analysis. Lactate was measured *in situ* using a portable analyser (MARCA) with specific strips. The remaining haemolymph was diluted 1:3 in modified Alsever's solution, adjusted to 1,200 mOsm $Kg^{-1}$, and kept on ice. Haemocytes were washed and resuspended in Alsever's buffer for subsequent assays. Plasma glucose was quantified using a commercial hexokinase kit, and protein concentration was measured following the method described by Bradford (1976). Haemocyte counts were performed using an automated cell counter, and samples were adjusted to 5 × 106 cells $mL^{-1}$. Viability was assessed by flow cytometry using propidium iodide. Phagocytic activity (ability and capacity) was evaluated using FITC-labelled *Vibrio alginolyticus*. For humoral parameters, haemocyte suspensions were sonicated to obtain lysates, which were used to determine total intracellular protein concentration and phenoloxidase activity employing the method described by Gálvez et al. (2025).

**Results**

Metabolic indicators showed clear temporal variation. Lactate and glucose levels in haemolymph decreased significantly at all experimental times compared with baseline (0 h), indicating a recovery from fishing-related stress. Cellular markers revealed more complex dynamics. Haemocyte counts decreased only at 24 h, with the values stabilising thereafter. Haemocyte viability remained constant across all time points, suggesting that handling and transport did not compromise membrane integrity. However, phagocytic activity displayed marked fluctuations. In the case of phagocytic ability, the values decreased significantly

E-mail: paolo.gamberoni@awi.de

## Introduction

According to FAO [1], *Litopenaeus vannamei* production is rapidly expanding (6.8 million tons) due to its palatability, high nutritional value, disease resistance, and rapid growth. To enhance environmental sustainability and biosecurity, indoor aquaculture systems are emerging, minimizing water discharge, but increasing total suspended solids, ammonia, nitrite, and nitrate. Although nitrate originating from the oxidation of ammonia and nitrite is less harmful, it is often disregarded in farm management. In chronic stress conditions, the safe level threshold for Whiteleg shrimp is set to 177 mg/L and [2], with its toxicity depending on factors such as concentration, salinity and duration of exposure [3]. With increasing aquaculture production, consumer concerns about animal welfare have grown. Physiological and morphological changes provide valuable insights into the effects of stress on shrimp welfare, as markers of compromised health [4]. Currently, limited information is available regarding *L. vannamei* chronic nitrate stress, with a lack of knowledge about its impact on welfare. This study investigates the effects of chronic nitrate induced stress on *L. vannamei*, adopting a comprehensive approach that includes growth performance, physiological responses, and overall health.

**Table 1.** Survival rates, growth performance indices, and physiological values (Mean +/- SD) for treatments for LN and HN.

| Parameter | LN | HN |
|---|---|---|
| Survival (%) | 98.75 ± 2.5 | 95 ± 4.30 |
| Initial Weight (g) | 15.68 ± 3.15 | 15.68 ± 3.15 |

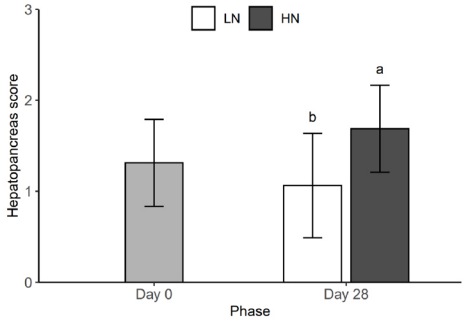

**Figure 1.** Mean value and standard deviation (n = 24) for shrimp hepatopancreas.

## Materials and methods

The experiment was conducted in 8 separate stand-alone tanks filled with 600 L of saltwater (20 ppt). An airlift-operated biofilter with 30L bio-carriers was installed in each tank to establish biofiltration, water movement and gas exchange. Nitrate concentrations were adjusted to two treatment concentration, low: 50 mg/L (LN) and high: 400 mg/L (HN) $NO_3$-N, using sodium nitrate (Carl Roth GmbH, Germany) with four replicates per treatment, for a duration of 4 weeks. Nitrate was measured using a nitrate analyzer probe (subCtech GmbH, Kiel, Germany) and adjusted twice a week to the nominal concentration. Shrimp were counted and weighed for the calculation of biometric indices and growth performance, including survival rate (SR), daily weight gain (DWG), specific growth rate (SGR), feed conversion ratio (FCR), condition factor (CF), and hepatosomatic index (HSI). Hemolymph samples were analysed for glucose and protein in a Fuji DRI-Chem NX500i (Fujifilm Europe) blood analysis system. Plasma lactate levels were quantified with an enzymatic kit (L-lactate, Megazyme). Hemocyte count was done using a light microscope and Neubauer chamber. Hemocyanin was measured following the methods of Chen and Cheng (1993). Hepatopancreas samples were diluted, homogenized in a phosphate buffer and superoxide dismutase (SOD) activity was measured with a SOD determination kit (no. 19160, Sigma-Aldrich, St. Louis, MO). Health parameters were assessed using a non-invasive scoring system for different body areas, originated from literature with slight modifications. Independent sample t-tests, Wilcoxon test, Welch's T-test, Mood median test were used to analyse the difference between the 2 treatments according to the assumptions.

*(Continued on next page)*

**Results and Discussion**

No difference was detected in the survival rate between treatments. Variations with other studies may be attributed to differences in salinity, exposure duration, and size which are key factors influencing chronic nitrate toxicity in *L. vannamei* [3]. However, HN impacted the growth performance (SGR, biomass, DWG) and FCR. The growth performance was in line with data reported from this species. As such, reduced feed utilization related to chronic nitrate stress suggests that energy is shifted from growth related processes towards restoration of homeostasis and acclimatization to the altered environment. No significant differences were observed in the physiological parameters analyzed in the hemolymph (glucose, lactate, total proteins, hemocyanin, and hemocyte count) and in the hepatopancreas (SOD activity). These values were comparable to those from unstressed shrimps in other studies. The health index revealed no significant differences, with only the hepatopancreas quality mildly impaired between LN ($1.06 \pm 0.62$) and HN ($1.69 \pm 0.79$). The visual observation of hepatopancreas quality was associated with a change in color from dark brown to pale and a shift in tecture from firm to mushy.

# INTEGRATED NUMERICAL AND FIELD ANALYSIS OF WATER ENVIRONMENT CONTROL INSIDE A MARINE SEMI-CLOSED RECIRCULATING FLEXIBLE FISH CAGE

H. Gao [*1], J. Zhou [1], S. Dong [2], K. Wang [3], D. Kitazawa [1]

1 Institute of Industrial Science, The University of Tokyo
2 Department of Marine Bioresources, Tokyo University of Marine Science and Technology
3 Graduate School of Engineering, The University of Tokyo
5-1-5 Kashiwanoha, Kashiwa, Chiba 2778574, Japan
hxgao@iis.u-tokyo.ac.jp

## Introduction

The offshore net cage aquaculture industry is increasingly challenged by environmental stressors such as red tides, parasites, and elevated surface water temperatures (Price et al., 2015; Sun et al., 2024). Semi-closed recirculating fish cages are gaining attention as a promising solution to mitigate these issues by physically isolating the cultured environment from surrounding seawater and introducing cooler water from deeper layers. However, understanding and controlling the internal water environment, including water temperature, dissolved oxygen, and salinity—is crucial for improving fish welfare and farming sustainability.

This study focuses on numerical simulation with field experiments to investigate the environmental control performance of a semi-closed recirculating flexible fish cage. The findings aim to provide a scientific basis for optimizing system design and operational strategies.

## Materials and methods

A three-dimensional numerical simulation was conducted by using the MEC (Marine Environmental Committee) Ocean model (Zhang and Kitazawa, 2015), incorporating surface radiative heat exchange and wall heat conduction effects, to investigate the internal temperature distribution of a semi-closed fish cage. The simulation domain is a sub-scale semi-closed fish cage measuring 5 m × 5 m × 3.5 m, with the lower 3 m shaped into a conical structure to facilitate waste accumulation and flow convergence. A structured grid with a uniform resolution of 25 cm was applied both horizontally and vertically.

Water inflow was applied at the top of the cage, while outflow occurred naturally through an open bottom without forced pumping. The temperature of the inflow water was set at 18°C, representing cold water conditions. Seawater properties were assumed with a density of 1025 kg/m³ and a specific heat capacity of 4170 J/kg/K. At the surface boundary, radiative heat exchange was considered. The cage wall boundaries accounted for heat conduction between the internal water body and the external sea water.

Meanwhile, a field experiment was conducted using the same cage configuration in a coastal bay. Cold water (water temperature about 18°C) was pumped from 3 m depth and injected continuously at 250 L/min. Water temperature was monitored at multiple depths.

## Results

Numerical simulation results demonstrate that as the outside seawater temperature increased from 20 °C to 28 °C, the temperature difference between inside and the outside of the cage also increased (Fig. 1). This highlights the system's strong temperature adjust capacity under high-temperature conditions.

Field experiments further validated this performance. In a real coastal expetiment, we compared water temperature inside a semi-closed cage with that of a traditional open-net cage. The semi-closed cage maintained consistently lower temperatures than the open-net cage(Fig. 2). This experimental evidence confirms the system's ability to mitigate heat stress and support a more stable thermal environment for cultured fish.

*(Continued on next page)*

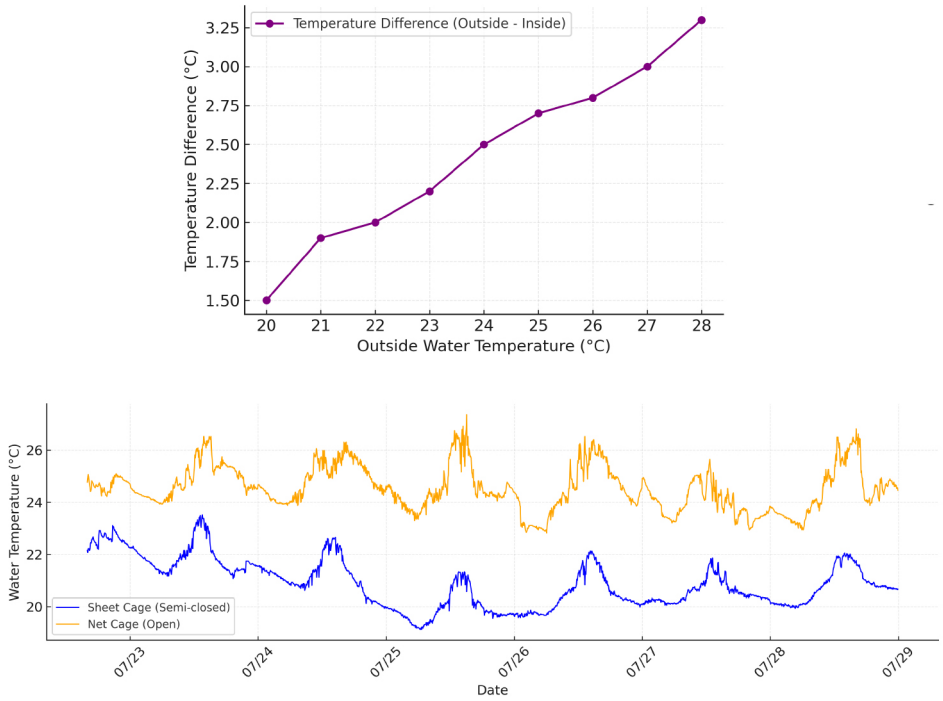

Fig. 2 Water temperature comparison between semi-closed fish cage and open net cage.

## Conclusion

This study evaluated the environmental control performance of a semi-closed fish cage system through both numerical simulations and field experiments. The results revealed that the semi-closed cage effectively maintained a cooler and more stable internal environment. This temperature-buffering capability not only helps mitigate the risks associated with high summer temperatures but also supports a more consistent water environment to fish growth. These findings demonstrate the system's potential for improving environmental stability in marine aquaculture.

# EFFECTS OF FOOD AVAILABILITY ON THE DYNAMICS OF BIOACCUMULATION AND CLEARANCE OF *Escherichia COLI* IN MUSSELS (*Mytilus galloprovincialis*) AT DIFFERENT TEMPERATURES

L. García-Sanmartín[1]
lgarcia@iim.csic.es*

**Introduction**

The coasts of Galicia (NW Spain) are the main production area for bivalves molluscs in the European Union, and mussels (*Mytilus galloprovincilis*) account for about 95% of the production. The Galician coastline is highly populated and industrialized, and huge volumes of wastewater are discharged daily into the rías, which may cause food safety problems due to the consumption of bivalves (Braga et al., 2023; Olalemi et al., 2016).

Official control programs in production areas include the determination of *Escherichia coli* in bivalves. However, monitoring is widely spaced in time (1-2 samplings per month), so that fecal contamination events are usually far from early detection. This would require high-frequency monitoring, but this approach is not possible by sampling of bivalves. However, it might be feasible if water column sample were taken instead, provided that the *E. coli* load in the water could be linked to that bioaccumulated by bivalve molluscs.

The bioaccumulation of *E. coli* in mussels and its subsequent clearance depend on both the concentration of *E. coli* in the water and the time of exposure, but a number of environmental factors can also condition the dynamics of these processes (Braga et al., 2023; Oliveira et al., 2011). The Galician rías are noticeably affected by the northern boundary of the Canary upwelling system (Alvarez et al., 2005), so that mussels are exposed to significant seasonal variations in factors such as food availability and temperature throughout the year, and under these different environmental conditions may be subject to faecal contamination.

Therefore, a pilot-sales study was performed to study the effects of temperature and food availability on the dynamics of *E. coli* accumulation and elimination in mussels, as well as their relationship with physiological, metabolic and behavioural responses.

**Methods**

Non-depurated mussels (*Mytilus galloprovincilis)* farmed in rafts in the Ría de Arousa were placed in a number of 25 L polypropylene tanks. Seawater was supplied in an open-flow circuit (300 mL/min) with a secondary constant supply of seston (10 mL/min) throughout all the experiments. After a 10-day acclimation period, mussels were additionally exposed to a continuous supply of 1000 CFU/ 100 mL of *E. coli* during 48 h in the same flow of seston. Next, the dosage of *E. coli* was stopped and a 48 h-clearance phase was started.

The uptake of *E. coli* by mussels was determined at different periods under different conditions of food availability and temperature found in the Galician Rias. Two consecutive experiments were carried out for that, one at 15 ºC with two simultaneous diets (optimal and suboptimal), and the other with water at 22 ºC and four simultaneous diets (two optimal and two suboptimal). The dynamics of bioaccumulation and depuration of *E. coli* in mussels were defined by monitoring the concentrations of the microorganism in mussels and water throughout the experimental period. Additionally, the filtration and respiration rates of mussels were measured on a daily basis.

*(Continued on next page)*

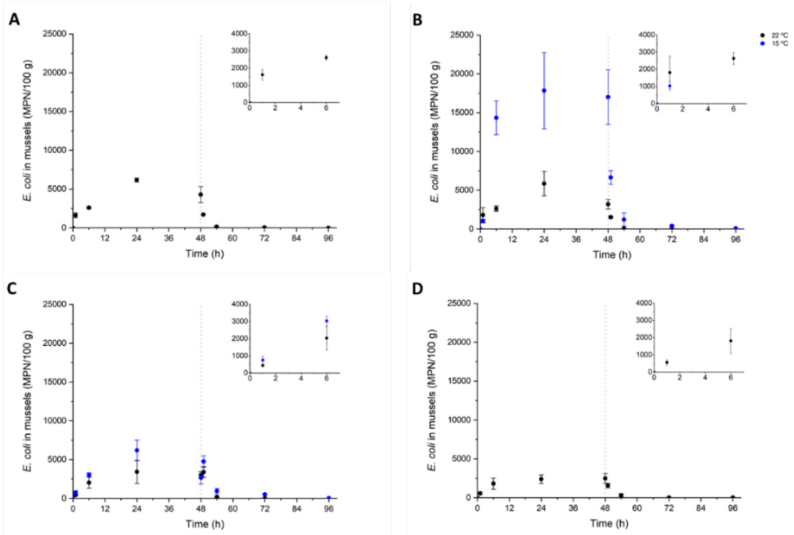

Figure 3. Bioaccumulation and clearance of *E. coli* by mussels as a function of diet and temperature. *E. coli* load in mussels (MPN/100g) fed seston a the following levels: (A) 40.000 cells/mL; (B) 20.000 cells/mL; (C) 2.000 cells/mL; (D) no exogenous input. Data points represent means ± SE (n = 3). Dotted lines at 48 h indicate the end of exposure and the beginning of clearance, The upper window in each graph is the zoom of the first 6 hours of the experiment.

**Results and discussion**

The bioaccumulation of *E. coli* in mussels is a dynamic process in which the bacterial load increases drastically immediately after exposure, reaching concentrations far above those present in the water.

Food availability as well as water temperature and time of exposure were found to have a significant effect on *E.coli* uptake. In the first set of experiments at 15°C, bioaccumulation patterns were similar between treatments, but was observed to reach significantly higher *E.coli* loads in mussels fed the optimal diet from 6 h of exposure to contaminated water. The same way, bioaccumulation profiles obtained at 22 °C showed higher loads of *E. coli* in mussels fed optimal diets than in those fed sub-optimal diets. However, the differences between temperatures were only observed for mussels fed optimal diets, with higher loads of *E. coli* for mussels kept at 15 ºC.

The highest bioaccumulation was observed for mussels with higher filtration activity, corresponding to the optimal diet, especially at 15°C. Seasonal variations in food availability and temperature have a direct effect on the filtration rate and, therefore, to the efficiency of accumulation and purification of microbiological contaminants present in the water column. On the other hand, the higher respiration rates were observed under optimal diets and high temperature, in accordance with the seasonal character of the metabolic activity and the ectothermic condition of the bivalves.

**Introduction**

The gilthead seabream is one of the most valuable species in the Mediterranean basin both for fisheries and aquaculture.

Flesh quality traits, such as fillet fat content and its fatty acids are very important traits for the consumer from a nutritional point of view and the benefits for health. Several studies have confirmed that these parameters are different in farmed and wild fish (Alasalvar et al. 2002).The aim of this study was to determine the fat content in wild and farmed sea bream fillets using different methods (non-invasive vs. invasive) in order to propose a reliable measurement method for use in aquaculture production and breeding programs.

# MODULATION OF THE DIFFERENTIAL PROTEOME OF GILTHEAD SEABREAM (*Sparus aurata*) BRAIN AND SKIN CAUSED BY AN INTRAMUSCULAR INJECTION OF THE HOST DEFENCE PEPTIDE HEPCIDIN 1 (HAMP1)

Population growth and the declining efficiency of traditional fisheries necessitate an increase in both the production and diversity of cultured species. This drives the application of multiomic molecular techniques to study the immune response of fish, with proteomics being one such technique. Proteomics offers a precise and comprehensive view of the proteome and the changes it may undergo due to intrinsic or extrinsic factors affecting the animal. In this context, we have examined the impact of hepcidin 1 (Hamp1) on the proteome of the brain and skin of sea bream (*Sparus aurata*), a significant species for marine aquaculture in temperate and warm waters [1]. Hamp1 is a host defense peptide (HDP) [2]. HDPs are small, mostly cationic peptides with potent biocidal and immunomodulatory effects. Studying them could enhance fish health in aquaculture, thereby improving fish production and quality. Consequently, in this study, we intramuscularly injected synthetic Hamp1 peptide (50 μL at 25 μM in sterile phosphate buffer). Brain and skin samples were collected for protein extraction using RIPA Buffer and trypsin digestion at 4 and 10 days post-injection. The proteome in the samples was then analyzed by HPLC-MS/MS. Data analysis with Spectrum Mill MS Proteomics software revealed that Hamp1 injection induced changes in the sea bream proteome, as observed in the PCA and PLS-DA, in the brain at 4 days post-injection and in the skin at both 4 and 10 days post-injection.

Among the proteins whose expression varied most in the brain of seabream, sampled four days after peptide injection, were helicase-like transcription factor (HLTF), myelin basic protein (LOC115578167), and α-2-HS-glycoprotein 2 (A0A671UQD9). Additionally, ten days post-injection, RYR3 and α-1,6-mannosyl-glycoprotein 6-β-N-acetylglucosaminyltransferase (MGAT5B) showed increased levels in this organ. Curiously, in the brain, Hamp1 elevated the concentration of proteins within the nucleus, such as HLTF, which plays a role in DNA repair, ATP binding, or helicase/hydrolase activity, as well as proteins in the myelin membrane that serve a structural function.

In contrast, the skin exhibited a greater increase in protein expression compared to the brain. Notably, protein disulfide isomerase (A0A671Y1J8, which is involved in the endoplasmic reticulum stress response), Galectin (LOC115574816), and Alsin Rho guanine guanine (LOC115574816) were elevated four days after injection. Furthermore, Alsin Rho guanine nucleotide exchange factor ALS2 b (ALS2, which is found in the centrosome and plays an active role in cell division) and Peptidyl-prolyl cis-trans isomerase (Ppib, which is associated with RNA polymerase II, protein folding, and isomerase activity) increased at four days, pression of proteins located in the lumen of the endoplasmic reticulum. The protein Galectin, which binds to carbohydrates, galactosides, and laminin and is present in the extracellular matrix or collagen-containing protein, also showed increased expression. Finally, in the skin, we detected an enhanced response to Hamp1 at 10 days post-injection, resulting in a significant increase in proteins while α-1,4 glucan phosphorylase (A0A671V311), Phosphoglycerate kinase (A0A671UGW5), and Rabphilin 3A homolog (mouse), b (RPH3A), among others. A0A671V311 and A0A671UGW5 are present in the cytoplasm and involved in the cell's energy metabolism, including carbohydrate storage, glycogen catabolic process, carbohydrate degradation, glycolysis, pyruvate metabolism, and gluconeogenesis, among others. Furthermore, the expression of RPH3, a protein capable of binding metal ions, GTPase, and involved in intracellular protein transport, exocytosis, and spontaneous neurotransmitter secretion, was also greatly increased. This protein is present in the synaptic vesicle membrane and neurons.

*(Continued on next page)*

The findings indicate that the impact of each host defense peptide (HDP) is contingent upon the specific organ under investigation. Furthermore, the results suggest the involvement of certain proteins, either directly or indirectly, in the immunomodulatory effects of HDPs, which may differ depending on the organ. To the best of our knowledge, this study presents the inaugural findings on the effects of HDPs in the brain of a commercially significant fish species. The administration of Hamp1 induces alterations in the proteome of the seabream brain, with more pronounced changes observed at 4 days compared to 10 days. Notably, many of the upregulated proteins are localized within the cell nucleus and are associated with DNA. Conversely, in the skin, the effects of Hamp1 are evident at both 4 and 10 days, with a more substantial proteomic alteration occurring at 10 days. This is characterized by the overexpression of proteins within the endoplasmic reticulum and cytoplasm, facilitating processes such as cell division and neuronal signaling.

**Introduction**

Welfare of farmed fish is crucial for production efficiency and economic benefits of aquaculture industry (Jerez-Cepa et al., 2019). However, procedures such as netting, weighing, sorting, vaccination, blood sampling or transport, which are routine practices in aquaculture, can produce stress in fish and compromise their welfare. In this context, anaesthetic agents are widely used during routine practices in order to reduce stress response and improve fish welfare, decreasing physiological damage and susceptibility to pathogens and infections (Martins et al., 2019). Nevertheless, anaesthetic agents may activate and induce by themselves a stress response in fish and compromise their health and welfare (Martins et al., 2019; Soltanian et al., 2018). For this reason and due the few studies where the physiological, immunological and pathological effects of anaesthetic agents have been analyzed in fish, in this work we analyzed the effect of exposition to three anaesthetics, clove oil (CO), tricaine methanesulfonate (MS-222) and chlorobutanol (CB) on immune, stress and antioxidant status of gilthead seabream (*Sparus aurata*) and greater amberjack (*Seriola dumerili*) specimens.

**Material and methods**

Gilthead seabream and greater amberjack specimens were completely anesthetized with different anaesthetic agents and recovered in water without anaesthetics and plenty of oxygenation. Blood samples were taken at 0, 1 and 24 hours after recovery. For that fish were slaughtered by anaesthetic overdose. Water samples were taken at 0, 5, 30 and 60 min. The control group was only slaughtered in a similar manner. Immune response and antioxidant activities, as well as stress status, were measured according to previous studies (García-Beltrán et al., 2024).

**Results**

Regarding results in gilthead seabream, CO increased serum protease activity at 0 and 1 hours while decreased lactate level at every sampled time. For its part, MS-222 increased serum cortisol level at every sampled time, as well as glucose and lactate levels at 1 hour.

As to greater amberjack, similarly to gilthead seabream, CO decreased serum glucose and lactate level at 24 hours as well as cortisol level in water at 1 hour. Meanwhile, MS-222 decreased serum bactericidal activity at 0 hours while increased cortisol and lactate levels at 0 and 1 hours and decreased them at 24 hours. Finally, CB increased serum cortisol level at every sampled time and decreased lactate level at 1 and 24 hours, as well as total antioxidant activity at every sampled time.

**Discussion**

Anaesthesia, which includes partial or total loss of sensation, voluntary neuromotor control, mobility, equilibrium and consciousness through depression of the central and peripheral nervous system (Zahl et al., 2012; Martins et al., 2019) is a common practice in fish aquaculture during handling routine procedures in order to reduce fish stress response and susceptibility to pathogens and infections. However, fish response to anaesthetic agents is species-specific and dependent on compounds chemical properties (Jerez-Cepa et al., 2019). Thus, anaesthetic agents may activate and induce by themselves a stress response in fish and compromise their health and welfare (Martins et al., 2019) and induce negative effect on growth, physiology, haematology and biochemistry of fish and appearance of disease outbreaks which can lead to mortality (Soltanian et al., 2018). Therefore, in order to obtain the best efficacy of anaesthesia avoiding negative effects on fish it is necessary to select the correct anaesthetic agent, dose and duration, which vary between and within species (Zahl et al., 2012; Martins et al., 2019).

*(Continued on next page)*

In this work, we study the effect of anaesthetic agents on immune activities, on fish stress status and on antioxidant activity of fish. Considering, all results, we can conclude that MS-222 and CB caused a short acute stress situation in fish which returned to normal level after a few hours and did not negatively affect to fish immune system. However, exposition of greater amberjack to CB negatively affected antioxidant status. For its part, any negative effect was observed in immune, antioxidant or stress status in fish exposed to CO. Therefore, it can be concluded that CO and MS-222 can be considered safe for gilthead seabream and greater amberjack specimens and precautions should be taken when using CB.

**Introduction**

Microalgae represent a natural and sustainable alternative to the use of antibiotics in aquaculture, both due to their nutritional characteristics and their potential as immunostimulants (Charoomart et al., 2018). These microalgae have the ability to combat pathogens, diseases and stress due to the large number of bioactive compounds they present, including antimicrobial peptides (AMPs) which play a crucial role in the immune system of living organisms as the first line of defence against a wide variety of pathogens. These AMPs can directly lyse microorganisms, act as regulators of the immune system in pathogen elimination and inflammation and exhibit antioxidant activity (Zhang et al., 2022). Therefore, in this study, the antioxidant, antibacterial and immunostimulatory activities of microalgae treated or not (with or without cell wall disruption), and AMPs from microalgae were analysed.

**Material and methods**

Microalgae (*Chlorella vulgaris*, *Dunaliella salina*, *Haematococcus pluvialis*, *Nannochloropsis gaditana*, *Tisochrysis lutea* and *Schizochytrium* sp.), macroalga *Alaria esculenta* and cyanobacteria *Arthrospira platensis* cells were harvested and lysed by enzymatic hydrolysis to release soluble cytoplasmic proteins (Galafat et al., 2020). Controls were included by incubating cells in the hydrolysis buffer in the absence of enzymes. After centrifugation, the soluble fraction and the cellular fraction were obtained, the latter being homogenized. Moreover, five AMPs from microalgae were selected and synthetized for *in vitro* studies (AP1, AP2 and NV14 from *A. platensis*, APWP from *C. vulgaris* and DS1 from *D. salina*).

Antioxidant, antibacterial and immunostimulant activities of microalgae and AMPs were studied *in vitro* as previous studies (García Beltrán et al. 2018). The capacity of samples to reduce the radical cation $ABTS^{+}$ was used to determine antioxidant activity. Antibacterial activity was tested by measuring the inhibition of growth of three fish-pathogenic bacteria: *Vibrio anguillarum* (Va), *Vibrio harveyi* (Vh) and *Photobacterium damselae* subp. *piscicida* (Phb). Finally, the ability to stimulate peroxidase (formation of bactericidal hypochlorous acid) and respiratory burst (activation and production of reactive oxygen species, ROS) activities by head-kidney (HK) leucocytes of gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*) was studied.

**Results**

Microalgae *D. salina*, *T. lutea* and macroalgae *A. esculenta* showed the highest antioxidant activity. As to antibacterial activity, *D. salina*, *T. lutea* and *Schizochytrium* sp. showed the best activity as well as *H. pluvialis* and *N. gaditana* against Vh and Va and Phb respectively. For its part, *C. vulgaris*, *H. pluvialis* and *A. platensis* showed the highest activity against Vh. Interestingly, all AMPs showed antioxidant and antibacterial activity, except DS1 which did not show antibacterial activity against any bacteria. AP1 and APWP showed the best antioxidant activity, while AP1 and AP2 showed the best antibacterial activity. However, NV14 and APWP did not show activity against Phb, and Vh respectively, but did against Va.

As to immunostimulant activity, cellular fractions of all microalgae as well as supernatant fractions of *A. platensis* and *A. esculenta* increased peroxidase activity of gilthead seabream and European seabass HK leucocytes. Concerning respiratory burst activity, in the case of gilthead seabream HK leucocytes, all supernatant fractions of microalgae increased values while most of cellular fractions decreased this parameter. For European seabass HK leucocytes, cellular fraction of *Schizochytrium* sp. increased it while cellular fractions of *C. vulgaris*, *N. gaditana* and *A. platensis* and supernatant fraction of *A. esculenta*

*(Continued on next page)*

showed the opposite effect. Finally, all AMPs increased the peroxidase activity in both gilthead seabream and European seabass HK leucocytes. Moreover, AP1, AP2 and NV14 increased the respiratory burst activity of both gilthead seabream and European seabass HK leucocytes, while APWP and DS1 decreased values in gilthead seabream cells and had no effect on European seabass HK leucocytes.

**Discussion**

Microalgae have great potential as a source of bioactive molecules capable of regulating immune, antioxidant and antibacterial responses. However, research about these activities directly from microalgae or through the release of their bioactive compounds is needed (Charoonnart et al., 2018).

Regarding antioxidant and antibacterial activity, enzymatic hydrolysis generally increased the activities of both fractions studied compared to the data obtained for untreated biomass. Moreover, supernatant fractions of microalgae showed higher activity than cellular fractions, especially in the case of antioxidant activity. Therefore, results indicate that both microalgal biomass processing method and fractioning affect bioactive compounds activity, thus explaining the wide variability of effects described in the literature (Charoonnart et al., 2018). AMPs also exhibited both activities, especially AP1, AP2, and APWP. As to immunostimulatory activity, both microalgae and AMPs increased the peroxidase activity of gilthead seabream and European seabass HK leucocytes. However, increased and decreased respiratory burst activity observed could be due to the antioxidant activity of both microalgae and AMPs, which are able to stimulate HK leucocytes and, at the same time, eliminate ROS created by this activation. Therefore, both microalgae and AMPs are showed as potential tools for use in aquaculture.

## Introduction

Improved growth and disease resistance are crucial in aquaculture production (Houston et al., 2020). During their life cycle, fish release their eggs into the environment, and after fertilization, they hatch in an environment with pathogens and with their immune system in the early stages of development (Mulero et al., 2007). Therefore, there is a relationship between and effective immune system of embryos and their survival rate (Mulero et al., 2007; Cordero et al., 2016). However, there is little information on the ontogeny of the immune system in gilthead seabream (*Sparus aurata*) and nothing is known about how these ontogenetic processes may be affected by growth-based genetic selection (Cordero et al., 2016). For this reason, in this work we performed a miRNA transcriptomic analysis of gilthead seabream eggs and larvae from two different populations of breeders differentially selected for growth from the genetic selection program of PROGENSA and Centro Oceanográfico de Murcia (COMU-IEO), CSIC.

## Material and methods

Two distinct groups (A1 and A2) of gilthead seabream breeding stock from different sources were used. One was from the PROGENSA breeding program and maintained at the COMU-IEO, CSIC facilities (A1, specimens of 4-5 years old), and the other was from the Mediterranean Sea and maintained at the COMU-IEO, CSIC facilities (A2, specimens of around 15 years old).

Eggs from three different clutches and 66-day-old larvae of A1 or A2 spawns were sampled for transcriptome analysis (García-Beltrán et al., 2024; Kanehisa et al., 2025).

## Results

Significantly greater differences in expression patterns (KEGG pathways) were observed in larvae than in eggs from different breeders.

The main differences in gene expression patterns in eggs are related to metabolism of lipid (glycerophospholipid), fatty acids (linoleic acid, α-linolenic acid and arachidonic acid), amino acids (arginine, proline, glycine, serine and threonine) and nucleic acid (pyrimidine), immune system (herpes simplex virus 1 infection, intestinal immune network for IgA production and phagosome), signalling pathways (MAPK, calcium and adrenergic signalling pathways), apoptosis, cellular and focal adhesion molecules, and ligand-receptor interactions (ECM-receptor and neuroactive ligand-receptor interaction). Meanwhile, the main differences in expression patterns in larvae from different breeders are related to important signalling pathways involved in energy homeostasis and cell metabolism, development, apoptosis, migration and proliferation (PPAR, adipocytokine, mTOR, VEFG, wnt and GnRH) and immune response regulation (PPAR, erbB and c-type lectin receptor). Moreover, differences in expression of genes related with endocytosis, cellular and focal adhesion molecules (tight junction, adherents' junction and focal adhesion), energy metabolism (oxidative phosphorylation), lipid metabolism (glycerophospholipid), general metabolism (glyoxylate and dicarboxylate) and xenobiotics and drugs metabolism (cytochrome P450) were also observed.

*(Continued on next page)*

## Discussion

The study of fish ontogeny is a key knowledge to understand how embryos develop and which genes related to survival are expressed from the moment of eggs fertilization (Houston et al., 2020). The embryos of fish, when released into a hostile environment, have to provide defense mechanisms that allow them to survive and grow as quickly as possible (Mulero et al., 2007). A quick growth is also important for aquaculture sector purposes. As gilthead seabream (*Sparus aurata*) is one of the most cultivated species in
Spain and in the European Union, genetic selection for growth is being established (Vallecillos et al., 2021).

In this work, eggs from different breeders showed more significant differences in the expression patterns of a smaller number of genes than larvae, which showed less significant differences but in a larger number of genes. Therefore, results obtained in this work revealed that studying the ontogeny of gilthead seabream is key to understanding the development of the species and individual survival, identifying key genes at each stage of the process.

Infectious diseases pose a significant challenge to aquaculture, resulting in significant economic losses. Treatment options for viral infections in particular are limited. The use of chemotherapeutic agents has several drawbacks, including adverse health and environmental effects. Therefore, there is an urgent need for new antiviral or therapeutic agents that are effective, affordable and sustainable [1]. This study proposes the use of plant extracts as sources of antivirals that not only contribute to more sustainable aquaculture practices but also utilise by-products from terrestrial industries such as agriculture for the development of these treatments.

This study focuses on RGNNV, the most widespread strain affecting numerous fish species, with European seabass being highly susceptible. RGNNV causes up to 100% mortality in larvae and juveniles [2] and significant losses in adult fish by targeting central nervous tissue, particularly the retina and brain, resulting in extensive vacuolization and neuronal degeneration. Symptoms include erratic swimming, loss of appetite and hyperinflation of the swim bladder [3].

In this study, we evaluated the in vivo antiviral activity and immunomodulatory capacity of five plant extracts encapsulated and formulated in the feed. First, we assessed the health status of the individuals fed with the supplemented feeds, for 3, 10 and 28 days. We evaluated parameters such as growth, blood biochemistry, haematology and gene expression in various tissues including anterior kidney, intestine and erythrocytes. Results showed a slight increase in growth parameters in the groups fed with the feed supplemented with the plant extracts in comparison with the control. However, blood biochemistry and haematology profiles results varied depending on the treatment and the days on which it was analysed. In addition, the antiviral capacity of the feeds supplemented with the plant extracts was assessed *in vivo* by means of a challenge with RGNNV. Results showed that some plant extracts increased the survival of the fish by up to 20%. Regarding immunoglobulin titration, we observed an increment in the production of specific IgMs against RGNNV in the case of some plant extracts.

## Introduction

As aquaculture expands to meet global food demands, the need for innovative tools to monitor fish welfare and wellbeing is growing. Biological age (BA), unlike chronological age, offers a more accurate measure of overall welfare by reflecting the cumulative effects of internal and external stressors. Consequently, BA markers can serve as highly informative welfare indicators since their activity is highly influenced by the environment (Colditz *et al*., 2023). In a previous multi-omics study in farmed gilthead sea bream, we applied an integrative transcriptomic and epigenetic approach to target BA in skeletal muscle, focusing on genes with an opposite trend of DNA methylation and expression (Belenguer *et al*., 2024). From an initial list of 102 genes, 10 top candidate markers were retrieved based on their multifunctionality and differential methylation in regulatory regions. As a result of this, the up-regulation of *sirt1*, *smad1*, *ramp1* and *psmd2,* in combination with the down-regulation of the other six genes *(col5a1*, *calcrl*, *bmp1*, *thrb*, *spred2*, *atp1a2)* was related to an older phenotype. The present study aims to validate these selected markers of BA under varying independent aquaculture conditions, evaluating their potential utility as generic molecular indicators of fish welfare.

## Materials and methods

Four independent trials were conducted to assess how different environmental and nutritional challenges modulate the gene expression patterns of BA selected candidate markers. In the first trial (HD), 2-year-old fish (~480 g) were stocked at two different densities and water [$O_2$] levels: control (8.5 kg/m$^3$; 5–6 ppm) and high density (HD, 25 kg/m$^3$; 3–4 ppm) for 8 weeks (Holhorea *et al.*, 2023). In the remaining trials, 9–12-month-old fish (50–105 g) were fed different experimental diets to evaluate their potential benefits under either thermal stress (TS) or standard conditions. In the TS trial, the experimental diet was supplemented with a hydrophilic emulsifier administered during the extreme heat episode in the summer of 2022 (Domingo-Bretón *et al*., 2025). In the other trials, the potential benefits of a porcine protein hydrolysate enriched in bioactive peptides (PHS trial, 5% inclusion level), and microalgae biomass (*Nannochloropsis oceanica*) derived from the valorisation of brewery waste (NCHL trial, 14% inclusion level) were assessed over 10–14 weeks in fast-growing fish. RNA was extracted from white skeletal muscle (500 ng) and reverse transcribed prior to gene expression analysis by RT-qPCR. All pipetting operations were carried out using an EpMotion 5070 Liquid Handling Robot. β-actin was used as the housekeeping gene, and multigene expression data were normalised to *smad1* expression in control fish of each trial, which was arbitrarily set to 1. Gene expression differences ($p < 0.05$) were assessed using a non-parametric Kruskal–Wallis test followed by Holm–Sidak *post hoc* analysis. Clustering of gene fold changes was performed using complete linkage. Biological process categories from Gene Ontology (GO-BP) associated with each gene were retrieved from Belenguer *et al*. (2024).

## Results and discussion

As shown in Figure 1, all 10 candidate genes responded to at least one of the four experimental conditions, validating their sensitivity to both environmental and nutritional challenges. In the HD trial, six genes were either up-regulated or down-regulated, reflecting an older phenotype associated with impaired welfare and wellbeing due to the stressful condition. Conversely, in the other trials, the observed changes, 5 up- and 2 down-regulated genes, revealed a younger phenotype, likely resulting from improved performance following dietary supplementation with a hydrophobic emulsifier (TS trial), protein hydrolysate (PHS trial) or microalgae biomass derived from the brewery by-product valorisation (NCHL trial). When clustering the gene expression fold-changes, the trials grouped according to the direction and magnitude of their transcriptional responses. Trials yielding a younger phenotype (TS, PHS, and NCHL) clustered together, while HD emerged as an outlier due to its distinct stress-related expression profile, indicative of an older phenotype. Functionally, the tested genes were associated with

*(Continued on next page)*

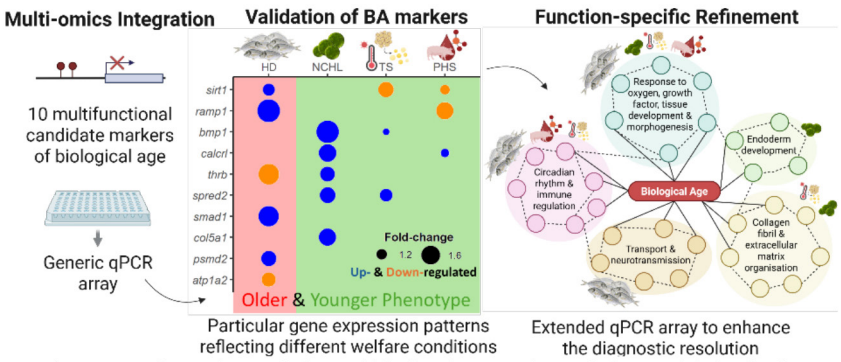

**Figure 1.** Overview of the validation/annotation of the 10 biological age candidate markers in gilthead sea bream.

71 GO-BP terms, which were categorised into challenge-specific and shared responses. Challenge-specific terms included transport and neurotransmission in the HD trial, and endoderm development in the NCHL trial. Shared functions across all four trials included tissue development (especially vascular development), morphogenesis, growth factor signalling, and responses to oxygen-containing compounds. Additional overlaps were observed: HD, TS, and NCHL were linked to sensory and skeletal development; HD, PHS, and NCHL to cell signalling and heart development; HD, PHS, and TS to circadian rhythm and immune regulation; TS and NCHL to collagen fibril and extracellular matrix organization; HD and NCHL to early embryonic development. These biological functions are tightly regulated during development but become progressively dysregulated with ageing under stressful conditions due to cumulative molecular damage, altered signalling, and impaired tissue maintenance and repair (La Mesa and Eastman, 2024). The sensitivity of these genes to environmental stressors further underscores their value as markers for tracking BA beyond chronological age.

## Conclusions

This study confirms the potential of a set of 10 candidate genes as versatile biomarkers of BA in gilthead sea bream. By incorporating function-specific refinements, the validated qPCR array can be further customised with challenge-responsive markers, significantly boosting its diagnostic power. This innovative approach paves the way for a reliable and forward-looking tool to support the certification and auditing of animal welfare and wellbeing in aquaculture systems.

## Introduction

Digestion in shellfish occurs extracellularly and intracellularly. The main site of intracellular digestion is the digestive cells located in the tubules of the digestive gland. During each digestion process, these cells go through four phases (resting, absorption, degradation, and reconstitution), and the diameter of the lumen of the digestive tubules also changes (Gavrilović, 2011). Determination of the digestive tubule index can indicate a lack of food or unfavorable (stressful) conditions in the culture environment in which filtration is reduced (Winstead, 1995; 1998). Given the rhythmic changes in the digestive cells, sampling should be carried out at shorter time intervals within a day to obtain relevant data. Considering that *Ostrea edulis* is often grown in areas near estuaries and/or underground fresh water sources, the aim of this research was to determine whether reduced salinity (hypoosmotic) affects food ingestion, i.e. the digestion process to optimize the gonad conditioning process in the hatchery.

## Materials and Methods

Immediately before the start of the month-long experiment, two recirculating oyster conditioning systems were set up. Each system was stocked with 200 oysters from a farm in Mali Ston Bay. The basic parameters of the culture medium (oxygen saturation, temperature, salinity and pH) were kept constant and regularly monitored. Salinity in both systems was maintained at 35 psu during the first seven days of adaptation to the new breeding environment. After this period, in the first experimental group it was maintained at the same value, while the second experimental group was gradually acclimatized to 20 psu over the course of seven days. Feeding was carried out by giving an algae mixture in the amount of 3% of the dry mass of the soft oyster tissue. Four species of unicellular algae were used as feed: *Isochrysis galbana, Pavlova lutheri, Tetraselmis suecica* and *Cylindrotheca closterium.* The ratio of the listed algae species in the diet was 20%: 20% : 20% : 40%. The required volume of algae suspension was calculated according to Gavrilović et al. (2021). After one month of the experiment, 30 individuals from each system were sampled five times at one and a half hour intervals (total 150 per system). All oysters were opened and the soft tissue was fixed in Davidson fixative for routine histological processing. Hematoxylin-oezoin was used for staining. After microscopic examination, the digestive tubules index was calculated according to the method described by Winstead (1995). The mean value of the tubule index was calculated for each individual and then the mean value for each experimental group. ANOVA test was used to compare the values of tubule condition index at different sampling times of the same experimental group. After this test, the similarity of the mentioned groups was analyzed using MRT (Multiple range test). A statistical comparison of the values of the digestive tubule index between the group kept at 35 psu and 20 psu salinity was performed using the Chi square test.

## Results and Discussion

The results of a microscopic examination of the digestive gland of both groups have shown that there is a rhythmical exchange of phases in the digestive tubules (Table 1), where in a single oyster the exchange was not synchronous in all of the digestive tubules, but they were in phases that were close to one another. Depending on the sampling interval all four phases of digestive tubules were found: resting, absorption, degradation, and reconstitution. Within the same experimental group ANOVA test has shown a significant statistical difference between individual sampling intervals ($p<0,05$), which confirms the existence of a rhythmical exchange in the digestive rhythm in the tubules. The results of a statistical comparison using a CHI SQUARE test showed that there was no significant statistical difference in the values measured between the two salinity groups ($\chi^2<0.711$, $p<0,05$). Winstead (1995; 1998) found that lower salinity affects intercellular digestion in *Crassostrea virginica*. Horedesky et. al (2019) reported optimal salinity for *Crassostrea gasar* in the range of 4 to 40 psu. From our results it can be concluded that *O. edulis* can gradually adapt to a 20 psu salinity, with no significant changes in the feeding rhythm, digestion rhythm and the digestive tubules index regarding the tested salinity value.

## Introduction

Swim bladder inflation (SBI) is a fundamental step in larval development for both physostome and physoclist fish species (Balon, 1975; Price and Mager, 2020). Failure of the SBI triggers higher energy expenditures of the individual, which negatively affects swimming ability, growth rate, feeding efficiency, susceptibility to predation, and survival rate (McElman and Balon, 1979; Summerfelt, 1996). In aquaculture, the SBI failure is caused by different factors including: (a) water contamination with oil increasing the surface water tension and preventing the larvae from gulping air bubbles for inflation, and (b) bacterial aerocystitis of the swim bladder caused by gulped organic debris (Summerfelt, 2013). Hence, novel and effective water treatment technologies such as nanobubbles can be employed in aquaculture to reduce the risk of low SBI. This study aimed to apply the air nanobubbles alone and in combination with conventional water treatment technologies, *i.e.* spray and water skimmers to promote swim bladder inflation success in European perch larvae under aquaculture rearing conditions.

## Materials and methods

Four experimental treatments were conducted in a triplicate design to investigate the effect on SBI of European perch larvae: (a) surface spray covering one-third of the tank diameter and skimmers (SS); (b) air nanobubbles (ANBs); (c) surface spray covering one-third of the tank diameter, skimmers and air nanobubbles (ANBsSS); and (d) control with no water treatment technology. To prevent cross-contamination of NBs between treatments and control groups, the experiment was done in two recirculating aquaculture systems (RASs). Larvae from all four experimental conditions were sampled at the $6^{th}$, $9^{th}$, $12^{th}$, $15^{th}$, $18^{th}$, and $21^{st}$ dph. For each sampling point, 30 individuals per tank (90 ind. per treatment) were killed by a lethal dose of clove oil (Hamackova et al. 2006) and weighed to the nearest 0.10 mg. Measuring the individual standard length (SL), counting larvae with inflated and non-inflated swim bladder and determining the swim bladder length (SBL) were done. Swim bladder inflation efficiency (SBIE) was calculated as the number of larvae with inflated swim bladder/total larvae examined x 100. Survival rate (SR) was determined as the percentage of surviving larvae in relation to the total number of stocked larvae in each sample. Viability was calculated as the SR × SBI /100 = (S × GBI )/100, where SR is the percent survival rate, and SBI is the percentage of the survivors that had an inflated swim bladder (Clayton and Summerfelt, 2010). The yield presents the number of harvested juveniles with inflated swim bladder in the total water volume of the rearing tank (Ljubobratović, et al., 2019). the nanobubble generator was connected to the RAS system with the respective experimental treatments, *i.e.* ANBs and ANBsSS. Water from the retention tank was pumped into the nanobubble generator and then to tanks once per hour for 15 min.

## Results

At the end of the experiment, the final SBL and SL of the larvae were not significantly different ($p \leq 0.05$) across all treatments. The final BW was approximately 1.5-fold higher in all treatment groups compared to the control groups. The low BW of the control groups seems to be in line with the final SBIE that is 2.2- to 2.4-fold higher in SS- and ANBsSS larvae with SBI compared to the control groups. In contrast, the SR was 2-fold higher in individuals from SS and ANBsSS groups compared to the control groups. A very low final SR (19.57%) was also recorded in the ANBs treatment group, although final SBIE and BW were in comparable ranges. The viability and yield were significantly higher in ANBsSS group, followed by SS group, while ANBs and control groups did not differ.

*(Continued on next page)*

**Discussion and conclusion**

All treatments showed higher SBI efficiency compared to the control, where no water treatment technology was employed. Higher SR and SBIE and consequebtly higher viability and yield were found in individuals from SS and ANBsSS groups. This may be explained by the beneficial combination of SS and ANBsSS to remove the oil film layer on the water surface. The resulting enhanced SBIE observed in our study, invariably achieved better larvae growth gain, what was also shown for ANBs but with lower SR. A higher SR in the ANBsSS group could be achieved by the Brownian motion of the air NBs, which produce an "up-welling" effect and stirs up small and passively swimming larvae in the water suspension, thus minimizing their swimming requirements(Kolkovski et al.,2004). However, applying ANBs alone resulted in an unexcepted low SR especially in early larval stage. Hence, appling NBs later in the larval stage can result in an additive effect to already used technology such as surface sprays, skimmers and upwelling. Moreover, different types of cannibalism should be also explored in future studies to get an overall picture of the NBs effect.This puzzling observation remains to be investigated in the future because there are still gaps in the effects of ANBs on larvae's SB inflammation processes.The current study offers the first investigation of the nanobubbles' effect on SBI promotion in larvae of European perch and gives motivation for future optimizations.

# MOBILE LICE DETACH DURING CROWDING BUT CAN BE RETAINED BY FINE-MESHED CROWDING NET

L. Geitung[1*], L. T. Barrett[2], S. Dalvin[1], M. Harvey[2], V. Nola[1], C. Eichner[3], F. Sambraus[1], L. V. Martinsen[1], A. Dahlgren[1], F. Oppedal[1]

## Introduction

Crowding is a common practice in salmon aquaculture during operations such as sea lice treatments and harvesting. Sea lice, particularly *Lepeophtheirus salmonis,* remain one of the most significant parasitic challenges in Atlantic salmon farming. A growing concern is that during crowding events, mobile lice detach from their hosts and spread into the surrounding environment where they may pose a reinfestation risk for both farmed and wild fish. Despite these concerns, the extent to which lice detach and are lost during these events is still not well understood. The aim for this project was therefore to quantify lice detachment, determine the mesh size needed to capture all lice stages, and assess the feasibility of using a fine-meshed net to collect detached lice during crowding.

## Methods

Replicate crowding trials were conducted in small research cages, using either a standard coarse-mesh crowding net or a fine-meshed crowding net intended to retain detached lice. The trials varied in crowding duration (10 min – 2 h), fish size and number, as well as louse density. Detached lice that passed through the crowding nets were captured using a plankton net, allowing direct quantification of lice that were 'lost' during the crowding process. Additionally, a benchtop physical model was made simulating the retention of detached lice using various mesh types and sizes (0.8–2.0 mm) as well as precise measurements of each louse stage size metrics.

## Results and discussion

Mobile lice that detached during crowding varied from 2 to 38%, with higher detachment rates during longer crowding duration (up to 2 h) and with larger fish. Smaller pre-adult lice detached more frequently than adult lice. Laboratory studies demonstrated that a nominal mesh size of 0.8 mm effectively captured all lice stages, 1.6 mm retained most pre-adults and adult males, while adult females required a 2.0 mm mesh for successful collection. The maximum mesh opening size (diagonally) corresponded to the cephalothorax width of the louse stage captured. In cage trials, the fine-meshed crowding net successfully retained 75% of adult female lice and improved fish welfare. Overall, these findings show that significant lice loss can occur during handling of salmon and that collecting lice during crowding operations could be an effective management strategy to limit their release into the environment and thereby lower the reinfestation risks for both farmed and wild fish.

# ASSESSING THE POPULATION GENETIC STRUCTURE OF WILD GILTHEAD SEABREAM (*Sparus aurata* Linnaeus, 1758) OVER THE PAST 3 DECADES

G. Geladakis[1]*, M. Anastasiadi[1], C. Papaioannou[1], G. Koumoundouros[2], E. Dimitriou[1], C. Koutsikopoulos[1] and C. Batargias[1]

## Introduction

Marine aquaculture has expanded rapidly in Greece and the Mediterranean in recent decades, with Gilthead seabream (*Sparus aurata* Linnaeus, 1758) being one of the two most extensively farmed species (Greece: 66,000 tonnes in 2022; HAPO 2024). As a result, fish escapes from aquaculture facilities may have significant ecological impacts on local wild populations, including disease transmission, competition for resources, and the introgression of foreign genetic material (Arechavala et al. 2018). Gilthead seabream is distributed from the Black Sea and the Mediterranean to the eastern Atlantic. Existing literature shows either an absence or very weak genetic differentiation among populations, with Greek stocks demonstrating genetic homogeneity (Geladakis et al. 2023 and references therein). However, wild populations are typically characterized by higher genetic diversity compared to farmed populations (Geladakis et al. 2023 and references therein). The objective of this study is to investigate the potential genetic effects of aquaculture escapees on the genetic diversity of wild Gilthead seabream populations in Greece by comparing samples from the early aquaculture period (1993–1997, annual production of 5–18 thousand tonnes; Dimitriou et al. 2007) to contemporary populations (2015-2024).

## Material and Methods

Total genomic DNA was isolated from historical scale samples of 86 Gilthead seabream individuals (1993–1997, Messolonghi Lagoon, Western Greece) and from tissue samples of 227 individuals collected between 2015 and 2024 in the Messolonghi Lagoon and the Ionian Sea. Building on the findings of Geladakis et al. (2023), which indicate that the likelihood of aquaculture escapees increases proportionally to the degree of scale regeneration (SRD, % regenerated scales), SRD was used as a criterion to assess potential impacts of escapees on the wild gene pool. Accordingly, wild fish were classified into two predefined categories based on their SRD values: (a) individuals with SRD $\leq$ 30% (L30) and (b) individuals with SRD > 30% (M30). In addition, DNA was isolated from three groups of reared samples serving as reference points: (i) 48 fish from the Ionian Sea collected in 2012, (ii) 27 fish from the Ionian Sea collected in 2016, and (iii) 16 fish from the Northwestern Aegean Sea collected in 2015. All individuals were genotyped for 15 microsatellite loci. Genetic diversity and genetic differentiation among groups ($F_{ST}$ values) were estimated using GenAlEx (v. 6.5) whereas the effective population sizes ($N_e$) were estimated with NeEstimator (v. 1.3). The population structure was inferred through Bayesian clustering analysis using STRUCTURE software (v. 2.3.4).

## Results & Discussion

Genetic analyses revealed no significant differentiation ($F_{ST}$ = 0.003–0.024, p > 0.05; Figure 1B) between historical (1993–1997) and contemporary (2015–2024) Gilthead seabream samples from the Ionian Sea, exhibited long-term stability in the genetic structure of wild populations. Similarly, no genetic differences were detected among wild fish classified by their degree of scale regeneration (SRD), used here as a proxy for the potential presence of aquaculture escapees (p > 0.05; Figure 1B). Interestingly, the $N_e$ remain high, comparable to recent studies of contemporary groups of Gilthead seabream (Žužul et al., 2019). These findings suggest that large effective population sizes, widespread larval dispersal, and adult migratory behavior maintain panmictic population dynamics of large breeding populations, preventing detectable temporal genetic shifts. Consequently, the detrimental interaction of aquaculture to the natural resources of the species cannot be documented.

In contrast, a small but statistically significant differentiation was observed between wild and farmed stocks ($F_{ST}$ = 0.016–0.044, p < 0.05), with wild populations consistently displaying higher levels of genetic variance (Figure 1A, 1B). Reared fish retain only a small subset of the natural genetic diversity, often further diminished by artificial selection and intensive breeding practices (Arachevala et al., 2018. The Ne of the farmed fish is 20 (from the 1995 population) to >400 (from the contemporary populations) times smaller than the wild (Figure 1A). Despite recurrent escape events from offshore aquaculture facilities (Dempster et al., 2018), introgression of farmed genotypes into wild populations appears to be minimal. This likely reflects the large effective population size of wild seabream stocks and/or the reduced survival and reproductive success of escapees under natural conditions.

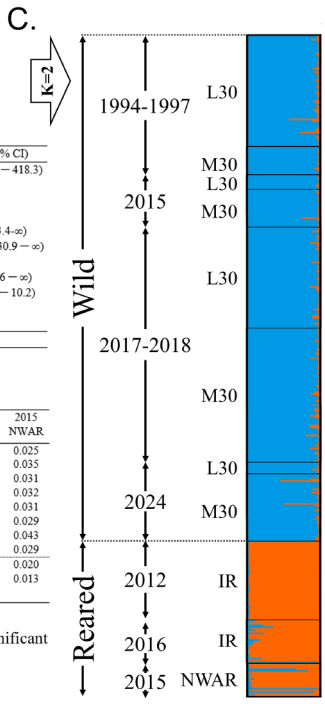

Figure 1. (A) Genetic diversity parameters for wild and farmed Gilthead seabream groups. n: number of individuals; *A*: mean number of alleles (±SD); *Ae*: effective number of alleles (±SE); *Ar*: allelic richness (±SD); *Ho* and *He* (±SD): observed and expected heterozygosity; $F_{IS}$: inbreeding coefficient; *Ne*: effective population size (CI: confidence interval). (B) Pairwise $F_{ST}$ values between wild and farmed groups. (C) Bayesian clustering analysis of genotypes based on 15 microsatellite loci with K = 2 (see text for details). L30: wild fish with degree of scale regeneration (SRD, % regenerated scales) ≤30%; M30: wild fish with SRD >30%; NWAR: farmed fish from the Northwestern Aegean Sea; IR: farmed fish from the Ionian Sea. Sample sizes smaller than 30 individuals were not used for the estimation of *Ne*.

Bayesian clustering analysis (STRUCTURE, K = 2) identified two distinct genetic clusters, clearly separating wild and farmed individuals, with no significant assignment of wild samples to the farmed cluster (Figure 1C). Overall, these results suggest that current escape events exert minimal detectable genetic impact on wild Gilthead seabream populations in the Ionian Sea.

## Introduction

Viral encephalopathy and retinopathy (VER), caused by nervous necrosis virus (NNV), is one of the main viral diseases affecting Senegalese sole (*Solea senegalensis*) in Southern Europe aquaculture. This virus (genus *Betanodavirus*, family *Nodaviridae*) is classified into four species: SJNNV, RGNNV, TPNNV and BFNNV (Sahul Hameed *et al*., 2019). In addition, highly virulent reassortants (RGNNV/SJNNV) have been identified in VER outbreaks in sole (Olveira *et al.,* 2009). Recently, NNV reassortant strain SsNNV19 was isolated from farmed Senegalese sole during an NNV outbreak in Southwestern Spain. Various prophylactic methods are being developed to reduce NNV infections in sole, including vaccines, supplemented functional feeds, and a combination of both treatments, among others. The *Allium* spp extracts propyl propane thiosulfinate (PTS) and propyl propane thiosulfonate (PTSO) are key compounds for the control of pathogenic microorganisms in livestock (Liu *et al.,* 2013), and their potential use in the aquaculture industry have been tested (Cabello-Gómez *et al.,* 2022). In this study, different sole feed supplemented with PTS or PTSO were developed, and its VER protective capacity was evaluated by measuring post-infection mortality and the study of host oxidative stress and inflammatory response after the feeding regime.

## Materials and methods

Sole (0.5g) were divided into three groups and fed with different WinFlat (SPAROS) based feed formulations: Control (WinFlat), PTS (WinFlat + PTS), and PTSO (WinFlat + PTSO) at 6% of biomass for 30 days. At the end of the feeding period, six fish from each experimental group were sacrificed, and gene expression related to oxidative stress in the liver and inflammatory response and apoptosis in the intestine were analysed by qPCR. After feeding, the fish were experimentally infected with the SsNNV19 strain by intramuscular injection at $10^5$ $TCID_{50}$/g of fish. Mortality was recorded for 30 days.

## Results

In Senegalese sole specimens fed with PTSO-supplemented diet, downregulation of the *hsp90* (-3.32) and *nos* (-2.89) genes was observed, as well as upregulation of the *sod* (1.17) gene in the liver. In the case of the specimens fed with PTS-supplemented diet, only the differential expression of *sod* (1.035) gene was observed, being upregulated (Figure 1).

In the intestine, no significant differences were observed in the expression of genes related to the inflammatory process. However, in specimens fed with both supplemented diets (PTSO and PTS), upregulation of *casp9* (0.88 and 0.83) gene, related to the cell apoptosis process, was observed (Figure 2).

During the first days of the challenge, mortality registered in fish fed with the supplemented diets was lower than in the control group, but from 9 dpi onward, mortality increased similarly in all groups, ending with 100% mortality at 19 days post-challenge.

## Conclusions

Dietary supplementation with PTS and, in particular, PTSO modulates the expression of genes related to oxidative stress in the liver, which could lead to an improvement in the health status of Senegalese sole specimens.

In intestinal samples, no induction of genes related to the inflammatory response was observed after 30 days of feeding with the supplemented diets. Nevertheless, the induction of the gene encoding caspase-9, associated with apoptosis, in both diets could indicate a certain degree of intestinal toxicity of these compounds.

Although these compounds do not confer direct protection, they may be used in conjunction with other strategies, such as vaccination, since the mitigation of oxidative stress, together with the reduction of early mortality, can potentiate the efficacy of vaccines.

# ENHANCING IMMUNITY, HEALTH AND PERFORMANCE IN ATLANTIC SALMON (*Salmo salar*) FRY AND REDUCING THERMAL STRESS IN RAINBOW TROUT (*Oncorhynchus mykiss*) THROUGH DIETARY SUPPLEMENTATION WITH ALGAL 1,3-β-GLUCAN: INSIGHTS INTO SUSTAINABLE AQUACULTURE PRACTICES

Edward Gnana Jothi George[1], Koen Meynen[2] and Rajalekhmi Mukkalil[1]

Email: Edward.george@kemin.com

**Introduction**

The intensification of aquaculture practices has heightened the need for sustainable strategies to improve fish health and reduce dependency on antibiotics. Atlantic salmon (*Salmo salar*), a cornerstone species in global aquaculture, is particularly susceptible to stress and disease under intensive farming conditions. Recent research has highlighted the immunomodulatory potential of natural compounds, such as 1,3-β-glucans derived from microalgae, which may enhance host defense mechanisms and overall physiological resilience. As a functional feed additive, algal 1,3-β-glucan (ABG) represents a promising approach to improve immune responses, growth performance, and survival rates in salmon aquaculture, aligning with the industry's shift toward more sustainable and health-oriented production systems.

This study evaluated the effects of dietary algae-derived 1,3-β-glucan supplementation on growth performance, immune response, and disease resistance in Atlantic salmon (*Salmo salar*). A total of 360 fish were assigned to control and treatment groups receiving 250–1000 g/ton of algal 1,3-β-glucan over six months. Key parameters assessed included condition factor, immune activity, and resistance to *Aeromonas salmonicida* (Furunculosis). In addition, effect of algal 1,3-β-glucan on chronic thermal stress in rainbow trout (*Onchorhynchus mykiss*) have been assessed.

**Materials and methods**

This six-month study evaluated the effects of dietary algal 1,3-β-glucan supplementation on growth, immunity, and disease resistance in Atlantic salmon fry (6–8 inches). All experiments were conducted at 10–12°C in a controlled environmental chamber.

Phase I (Days 0–14): Fish (n=360) were acclimated in twelve 30-gallon tanks (30 fish/tank), with standard feed provided twice daily. Length and weight measurements were recorded on days 0 and 14 to assess baseline condition.

Phase II (Days 15–45): Fish were divided into four treatment groups: Control (no β-glucan), and three algal 1,3-β-glucan doses - 250, 500, and 1000 mg/kg feed. Condition factors, immune parameters, and hematological indices were assessed on days 30 and 45.
Phase III (Days 46–75): Fish were challenged with *Aeromonas salmonicida* ($1 \times 10^5$ CFU/fish) via intraperitoneal injection. Positive controls received the pathogen, while negative controls received PBS. Daily mortality was recorded for 30 days. Additional immune and hematological assessments were conducted on days 60 and 75.

Health and Immune Assessment: Growth and condition were monitored via weight gain, length:weight ratio, and condition factor. Hematological parameters including red and white blood cell counts, hematocrit, and hemoglobin were measured using hematological assays.

Thermal stress study: Efficacy of algal 1,3-β-glucan on reducing heat stress was assessed by measuring the scale cortisol level. Treatment groups involved negative control, cortisol control (CORT 500), 250 ppm water soluble (WS) algal 1,3-β-glucan.

**Results**

Survival rate was linearly correlated with increasing doses of algal 1,3-β-glucan. The highest survivability was observed in the algal 1,3-β-glucan at 1000 g/MT (90%), compared to 46% in the control group.

*(Continued on next page)*

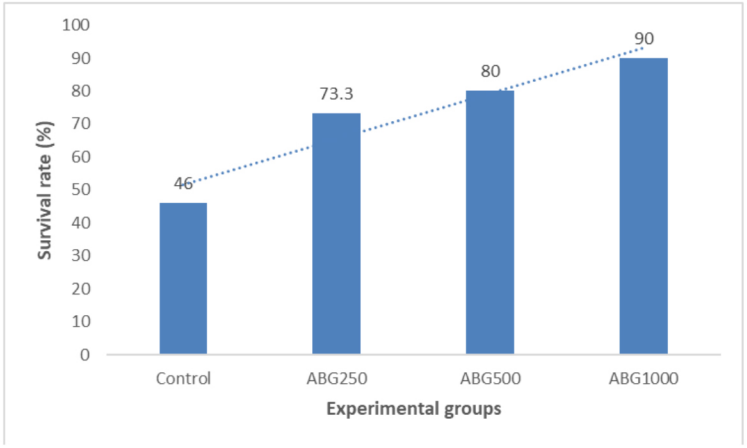

**Fig. 1: Survival rates among control and algal 1,3-β-glucan (ABG) treated groups**

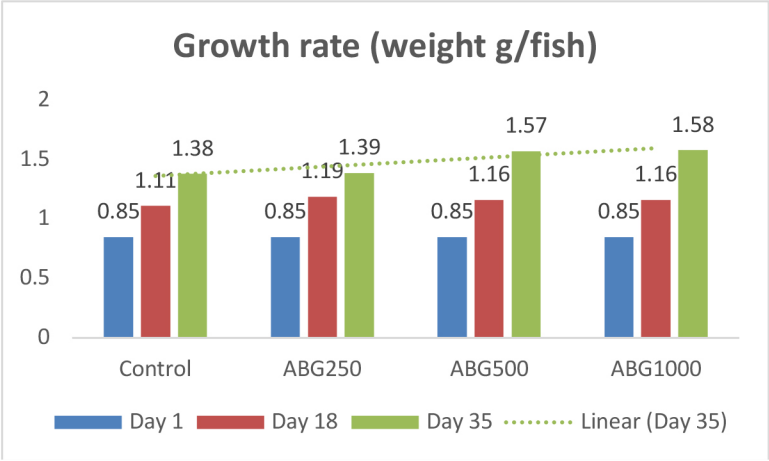

**Fig. 2: Growth rate of fish among control and algal 1,3-β-glucan (ABG) treated groups**

A significant improvement in the growth was observed in the algal 1,3-β-glucan treated groups (500g/MT and 1000g/MT). There were no statistically significant differences observed in hematocrit, or red blood cell counts among treatment groups. These findings support the potential of algal 1,3-β-glucan as a functional feed additive in sustainable salmon aquaculture.

The scale cortisol level at the start was on average 0.056±0.040 µg/kg. After 3 weeks, the scale cortisol in CORT500 group had increased. The variation in scale cortisol between individual fish is smaller in the groups given WS 1,3-β-glucan than in the control or CORT 500 group. This is an indication that the algal beta-glucan helps tuning the HPI axis activation during the first three weeks.

**Conclusion**

The study demonstrates that algal-derived 1,3-β-glucan is an effective immunostimulant and growth promoter in Atlantic salmon and thermal stress management tool in trouts. Its incorporation into commercial diets has the potential to improve fish health and performance while reducing reliance on chemotherapeutics. These findings support the broader adoption of microalgal bioactive in sustainable aquafeed formulations.

## Introduction

The aquaculture industry has grown substantially over the past 25 years, with production increasing by 200% and global fish trade by 300% since 1995 (FAO, 2021). As the fastest-growing food production sector, aquaculture requires efficient and sustainable practices that support both productivity and animal welfare. Key anatomical features such as the pectoral fins, tail, and skin are critical for fish locomotion, posture, and health, yet are highly vulnerable to damage caused by handling, high stocking densities, and underlying health issues. Such impairments can adversely impact welfare, feeding efficiency, and growth. Despite their importance, the condition of these features remains largely under-monitored due to the reliance on manual assessment methods, which are time-consuming, labor-intensive, and potentially harmful to fish. This work aims to develop and validate non-invasive computer vision models for automatically monitoring fish morphometric traits—including fins, tails, and skin—and for classifying their condition as 'good' or 'bad.' The objective is to provide an efficient and reliable tool to improve health monitoring and welfare management in aquaculture systems.

## Materials and methods

Two YOLO architectures—YOLOv8 and YOLOv12—were trained to detect three morphometric characteristics (tail, pectoral fin, and red skin spots) in two fish species: European seabass and gilthead seabream. Data were collected using a stereo vision system (1080p resolution) with a patented software (Voskakis et al., 2021) in circular polyester cages (40 m diameter, 9 m depth) at HCMR's pilot farm in Souda Bay, Crete (certified: GR94FISH0001). Images were annotated into "good" and "bad" classes for tails and fins, and a single class for red skin spots. Training datasets included 2,383 fin images (gilthead seabream), 1,414 fin images (European seabass), 5,041 tail images (gilthead seabream), 4,276 tail images (European seabass), and 584 skin images with red spots for both species. Models were trained using Python on an NVIDIA RTX 4080 GPU (batch size: 12, image size: 640×640), with early stopping (patience = 30) to prevent overfitting. Extensive data augmentation strategies for underwater object detection were tested. A total of over 125 training runs were conducted as datasets were incrementally expanded.

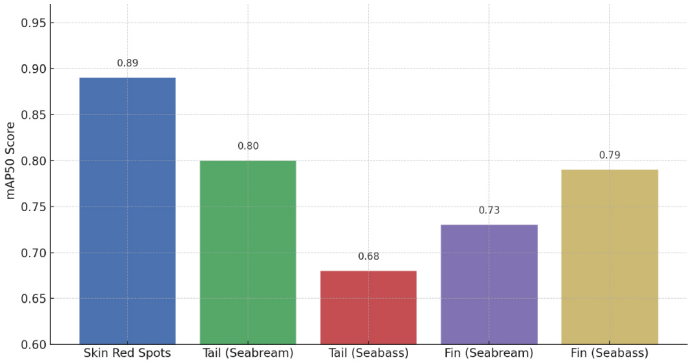

Fig. 1. Yolov12 detection performance by morphometric feature and species.

*(Continued on next page)*

**Results**

YOLOv8 and YOLOv12 both performed well in detecting morphometric features across species, with YOLOv12 showing superior computational efficiency and less overfitting. Transitioning from YOLOv8 Large to YOLOv12 Small model led to a **78.7% reduction in parameters** (43.7M → 9.3M) (Jocher et al., 2021; Tian et al., 2025) without loss in detection accuracy. Despite its smaller size, YOLOv12 Small matched or outperformed YOLOv8 Large. In terms of detection performance, detection of red skin spots achieved the highest accuracy, with a **mean Average Precision at IoU 0.5 (mAP50)** of **0.89**. Tail condition classification in **gilthead seabream** reached **mAP50 = 0.80**, while in **European seabass**, it achieved **0.68** (Figure 1). For **pectoral fin classification**, the seabream model reached **mAP50 = 0.73**, whereas the **seabass model performed better**, achieving **mAP50 = 0.79**.

**Conclusion**

Overall, detection accuracy varied across species, morphometric traits but also from differences in image quality due variable environmental conditions. Red skin spots were the most accurately detected feature, while tail condition in European seabass showed the greatest need for further improvement. Both YOLO models performed reliably; YOLOv12 demonstrated advantages in computational efficiency. Future steps include to test the system on large scale aquaculture farms by estimating the percentage of damaged morphometric features.

## Introduction

Animal welfare is a growing public concern, especially for the emerging field of octopus aquaculture. The common octopus, *Octopus vulgaris,* is a commercial valuable species, and an excellent candidate for aquaculture diversification (1). Overfishing of natural stocks and high market demand make sustainable octopus aquaculture essential to reduce fishing pressure and protect natural populations. To achieve this, optimizing and standardizing practices to control and safeguard animal welfare is crucial. Welfare assessment should prioritize aspects such as diet, appropriate housing conditions, environmental enrichment, behavior, and health. In this context, the early detection of pathogens, particularly the protozoan parasite *Aggregata octopiana* and bacteria of the *Vibrio* genus, is essential to prevent disease outbreaks and reduce animal suffering (2-3). Moreover, the identification of protein- or microbiota- based welfare markers from non-invasive samples, such as skin mucus, could provide powerful tools for routine health monitoring, offering insight into the physiological status of the animals without compromising their welfare. This study identifies specific octopus welfare markers, defined as biological Operational Welfare Indicators (OWIs), to be integrated into monitoring plans for good aquaculture practices.

## Material and methods

Quantitative PCR (qPCR) assays were developed for the absolute quantification of the coccidian *A. octopiana* in fecal samples, using standard curves based on a plasmid-cloned target 18S rDNA sequence with known copy numbers. qPCR results were correlated with microscopic examination of fecal smears, applying an optimized algorithm in Python 3.11.8 that selected threshold pairs from qPCR Ct values and microscopy count, allowing the establishment of different infection ranges of infection. A similar qPCR approach was used to quantify *Vibrio* spp. from tank seawater and skin mucus samples, employing genus-specific primers, and results were validated through colony counts on selective TCBS agar. A shotgun proteomics approach combined with liquid chromatography coupled with tandem mass spectrometry (LC-ESI-MS/MS) using an Orbitrap-Elite instrument was used to create a reference dataset from octopus skin mucus including wild and aquarium maintained octopus, as well as adult and senescent ones. The final proteome compilation was investigated by integrated *in silico* studies, including Gene Ontology (GO), the Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway, network studies, and prediction and characterization analysis of potential bioactive peptides. Additionally, tank seawater and skin samples from individuals showing external lesions were subjected to shotgun metagenomics sequencing (RNA-seq Illumina) to analyze microbial community structure and potential pathogens associated with compromised skin integrity. All samples were collected from octopuses under aquaculture conditions.

## Results

Absolute quantifications of *A.octopiana* and *Vibrio* spp by qPCR enabled rapid, reliable, and low-impact monitoring of infection in aquarium-maintained octopuses, supporting early diagnosis and improved animal welfare. The quantification of *A. octopiana* 18S rDNA by qPCR using plasmid-based standard curves achieved a high efficiency (97%, $R^2 = 0.995$) and a detection limit of $10^2$ copies/µL. The assay showed strong repeatability (CV = 0.01) and high specificity. The comparison between data obtained by qPCR and those obtained with microscopy counts using an optimized algorithm let to define three infection levels (low, medium, high), yielding a good correlation (r = 0.723) between both methods. This allowed reliable, quantitative categorization of parasite load in non-invasively collected samples. In addition, absolute quantification of *Vibrio* spp. was successfully implemented using genus-conserved primers in a qPCR assay. The correlation between Ct values obtained by qPCR and colony counts on selective TCBS agar validated the method and enabled the identification of potentially pathogenic

*(Continued on next page)*

*Vibrio* colonies in culture conditions. Proteomic analysis revealed a different pattern between conditions. Although similar profiles were observed, differences in relative abundances led to the identification of potential biomarkers, including caspase-3-like, protocadherin 4, deleted in malignant brain tumors, thioredoxin, papilin, annexin, cofilin and mucin-4 proteins. Some of these proteins also revealed potential as bioactive peptides, with several displaying antibacterial and antiviral activities in skin mucus, as identified using the CAMP (Collection of Anti-Microbial Peptides) database. The metagenomics analysis identified different bacterial species corresponding mainly to the genus Vibrio as causative of skin ulcerations.

**Discussion**

Ensuring animal welfare in aquaculture systems is essential, and the identification of reliable OWIs is key to achieving this goal. Although octopus farming is not yet established at an industrial scale, preserving welfare in aquarium-maintained individuals is crucial, both for ethical husbandry and as a base for future large-scale aquaculture practices. This study highlights the effectiveness of non-invasive molecular tools for monitoring the health and welfare of *O. vulgaris* under aquarium conditions. The validated qPCR assays for *A. octopiana* and *Vibrio* spp. enabled sensitive, repeatable, and early detection of infections, supporting their use as practical OWIs. The strong correlation between molecular and traditional diagnostic methods further reinforces their reliability.

Similar approaches using absolute qPCR have proven effective in other species for pathogen detection and infection level assessment (4-5), further supporting the value of these tools for developing standardized, cross-species welfare monitoring protocols in aquaculture. Additionally, while metagenomics analysis provided insights into microbial communities associated with skin lesions, proteomic profiling of skin mucus allowed exploration of how aquarium maintenance conditions and senescence alter the mucus proteome. Also, it revealed a wide array of bioactive peptides with potential antimicrobial and immunological roles, which, similar to findings in fish and other molluscs, can serve as reliable indicators of physiological status and stress (6), supporting their potential use as OWIs in octopus. These findings highlight skin mucus as a promising, non-invasive source of biomarkers for health and welfare monitoring in octopus aquaculture.

## Introduction

Seawater transfer (SWT) represents a critical phase in Atlantic salmon aquaculture, often accompanied by high stress and susceptibility to infections, which are influenced by various environmental factors, including seasonality. The gut microbiome is essential for fish health, influencing digestion, immunity, and barrier functions. Nevertheless, the impact of the season at seawater transfer on microbiome composition and subsequent fish performance in flow-through systems remains understudied. This research investigates seasonal effects (spring vs autumn) at the time of SWT on gut microbiome dynamics and their implications for salmon performance.

## Materials and methods

Atlantic salmon smolts were transferred from freshwater to seawater during two different seasons: spring and autumn. Sampling occurred at multiple timepoints: just before SWT (Code 3 for spring; Code 7 for autumn), one week after SWT (Code 4 spring; Code 8 autumn), and six months post-transfer (Code 5 spring; Code 9 autumn). Feces samples were collected from the posterior intestine, and genomic DNA was extracted. Microbiome composition was assessed via 16S rRNA gene sequencing (V3-V4 regions), using Illumina technology. Bioinformatic analyses included quality filtering, ASV assignment (DADA2), taxonomic classification (SILVA138.1 database), and diversity analyses (Shannon and Bray-Curtis indices).

## Results

Gut microbiota showed significant seasonal differences at seawater transfer, with higher microbial diversity observed during autumn compared to spring (Shannon index, $p<0.05$). In spring-transferred smolts, low diversity correlated with increased abundance of the genus *Brevinema*. Bray-Curtis analysis indicated distinct microbiota compositions between seasons (MANOVA, $p.adj < 0.001$), suggesting a more specialized microbiota over time in autumn cohorts. At later stages, *Malacoplasma* emerged as the dominant genus in both seasonal cohorts. Furthermore, specific taxa such as *Photobacterium* and *Carnobacterium* varied significantly between seasonal transfers, implicating potential functional implications for fish health.

## Discussion and conclusion

Our findings indicate clear seasonal effects on gut microbiome composition at seawater transfer, with autumn transfers supporting higher microbiota diversity and specialization. Such microbiota differences may underlie differential performance outcomes and disease resistance. Seasonal variation in microbial communities underscores the importance of considering environmental timing in aquaculture practices. Future studies should investigate functional implications and potential microbial biomarkers such as *Brevinema* for optimizing salmon production in flow-through systems.

# EFFECT OF RAS ON ATLANTIC SALMON GUT MICROBIOME AND ITS INTERACTION WITH PERFORMANCE AFTER SEAWATER TRANSFER

Neda Gilannejad [1,*], Simon Menanteau-Ledouble [1], Patrik Tang [1], Marius Nilsen [1], Marcos Parras-Moltó[2], Marnix Gorissen [3], Miriam Emilie Donovan [4], Harald Sveier [4], Naouel Gharbi [1], Lars Ebbesson [1], Pablo Sánchez-Cueto [2], Radu Ghemis [2]

## Introduction

Recirculating Aquaculture Systems (RAS) are increasingly common land-based production systems, however, biological requirements of the fish are not always considered, contributing to the high mortalities observed, notably following the seawater transfer (SWT). SWT is a challenging production phase associated with stress, impaired welfare, and elevated susceptibility to opportunistic infections (Sommerset et al., 2023). The gut microbiome plays an array of critical roles in fish biology, not only during digestion but also in the immune and barrier functions with large implications for the fish's health. Importantly, little work has been conducted to investigate how farming procedures can alter the fish' microbiome and the health of the holobiont. This study aims to characterize the effects of different RAS protocols (size at SWT) on gut microbiome, in relation to fish health and welfare.

## Materials and methods

A fish cohort from a commercial production facility was monitored from the parr stage in freshwater (FW) RAS through transfer to brackish water (BW) RAS. Two transfer strategies were applied: release of small (150 g) or large (500 g) smolts to sea cages (SC). Sampling points are depicted in Fig. 1 and were as follows: A) FW RAS: parr at 50 g **(Code 0)** and 100 g just before transfer to BW **(Code 1)**; B) BW RAS: one week after transfer **(Code 2)** and just before seawater transfer (SWT) at either 100 g **(Code 3)** or 500 g **(Code 6)**; and C) SC: at one week **(Codes 4 & 7)** and six months after SWT **(Codes 5 & 8)**. Fish weight and somatic indexes were recorded. Three sample sets were collected: plasma for general welfare assessments and water and feces for microbiome analysis. Feces were collected from the posterior intestine. Total genomic DNA was extracted for metataxonomic, DNA amplicon libraries were generated targeting the V3-V4 regions (341F/R805) of the 16S rRNA gene, and the sequencing was performed on the Illumina platform. Analysis of the sequences was performed following standards pipelines for metataxonomic analysis. Clean sequences chimeric detection and deletion, followed by Amplicon Sequence Variant (ASV) assignment was completed using the DADA2 plugin. Taxonomy was assigned with a 99% similarity level using the q2-feature-classifier plugin with the SILVA138 database. Alpha (Shannon) and beta (Bray Curtis) diversity indices were calculated using the vegan R package.

## Results

Alpha-diversity was low in the salmon gut microbiota at the early parr stage (Code 0) (Fig. 2A) and closely resembled the RAS water, being largely dominated by *Aurantimicrobium* (data not shown). From the smolt stage onwards (Code 1), the microbiota became more diverse and increasingly distinct from the surrounding water, despite the BW being less diverse than the FW. Beta-diversity revealed significant differences among Codes 0, 1, and 2, with the most pronounced difference observed between Codes 1 and 2 (Fig. 2C).

In the remaining samples, alpha-diversity was significantly different between salmon gut microbiota one week after SWT in fish transferred at 150 g and 500 g (Codes 4 and 7; Fig. 2B). According to beta-diversity analysis, significant differences existed between small and large smolts during the BW phase (Codes 3 and 6; Fig. 2D). SWT of smaller fish was associated with higher gut microbiota diversity compared to fish transferred at bigger size. Gut microbiome differences were most pronounced one week after sea transfer (Codes 4 and 7). By the end of the sea-cage phase (Codes 5 and 8), differences were less marked but remained significant (Fig. 2D) with *Mycoplasma* emerging as the dominant genus (data not shown). Correlation analysis

*(Continued on next page)*

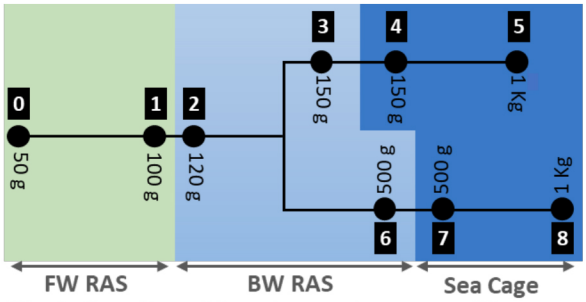

Fig. 1. Sampling of the salmon cohort across life stages and production environments. Sampling codes are marked with black squares

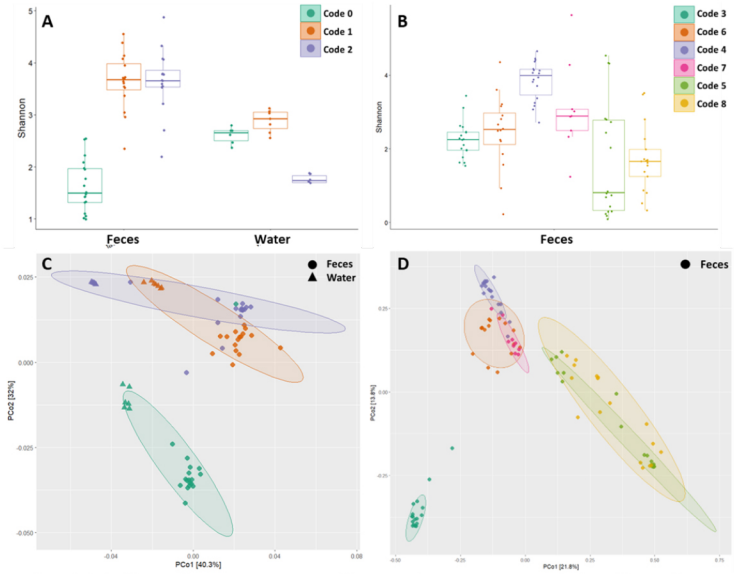

Fig. 2. Microbial diversity across sampling points. (A, B) Alpha-diversity measured by the Shannon index. (C, D) Beta-diversity based on Bray-Curtis dissimilarity.

between gut microbiota and fish weight revealed significant associations, particularly in the cohort transferred at smaller size (data not shown). Most correlations were positive (e.g., *Prochlorococcus*, *Aeriscardovia*, and *Mycoplasma*), while a few were negative (e.g., *Francisella*). Correlation with other biological aspects is in progress and will be updated at a later stage before the presentation.

**Discussion and conclusion**

Our findings show that the salmon gut microbiota gradually diverges from the surrounding environment and becomes specialized over time. Although gut communities converged by the end of the sea production cycle, differences in body weight at SWT appear to shape microbial composition of the early SW phase, likely contributing to the heightened vulnerability and mortality often observed at this stage. Notably, the association between microbiota profiles and fish size at SWT suggests a potential link to performance. Further research is needed to clarify how microbial shifts over time relate to other biological factors. Overall, our results highlight life stage–dependent changes in gut microbiome and suggest functional relevance, an area still underexplored in fish microbiome research.

# BLACK SPOT INHIBITION AND FRESHNESS PRESERVATION USING A SULFITE-FREE ADDITIVE IN HARVESTED SHRIMP

Daniel Gilaranz

Xyrex Ltd, 65 Rodney St
Glasgow G4 9SQ, UK
Email: daniel@xyrex.com

This study evaluates the efficacy of PrawnFresh™ , a sulfite-free antimelanosic agent developed by Xyrex Ltd, in preserving the appearance and freshness of Penaeus vannamei and Penaeus monodon. Comparative trials were conducted to assess melanosis inhibition, microbiological quality, and overall shelf life in shrimp treated with PrawnFresh™ versus untreated controls. Results demonstrated that PrawnFresh™ effectively inhibited melanosis, maintaining 0% discoloration after 90 days of frozen storage at -18°C, whereas untreated samples exhibited melanosis levels exceeding 40%. Additionally, microbiological assessments indicated that PrawnFresh™ extended shrimp shelf life by 6–8 days beyond conventional methods, without compromising sensory attributes. These findings suggest that PrawnFresh™ is a viable and sustainable alternative to sulfite-based treatments, aligning with regulatory requirements and industry demands for improved seafood preservation.

**Introduction**

Melanosis is a major post-harvest challenge in shrimp and other crustaceans, leading to product degradation and reduced consumer appeal. This enzymatic process is primarily catalyzed by polyphenol oxidase (PPO), which, upon exposure to oxygen, oxidizes phenolic compounds to quinones that polymerize into dark pigments. While melanosis does not pose a food safety risk, its occurrence negatively impacts the seafood industry by decreasing product value and shelf life. Sulfite-based treatments, particularly sodium metabisulfite (SMS), have traditionally been employed to inhibit PPO activity; however, their use raises several concerns. SMS can produce toxic fumes, cause allergic reactions in sensitive individuals, corrode processing equipment, and contribute to aquatic contamination through processing effluents. Regulatory shifts and consumer demand for cleaner-label alternatives have driven the exploration of novel sulfite-free melanosis inhibitors. PrawnFresh™, a proprietary additive formulated by Xyrex Ltd, presents an innovative solution that mitigates these drawbacks while ensuring high-quality shrimp preservation.

**Objective**

- To evaluate the efficacy of PrawnFresh™ in inhibiting melanosis in harvested shrimp.
- To compare the effects of PrawnFresh™ with traditional sulfite treatments and untreated controls.
- To assess the microbiological impact of PrawnFresh™ on shrimp quality and shelf life.

**Methodology**

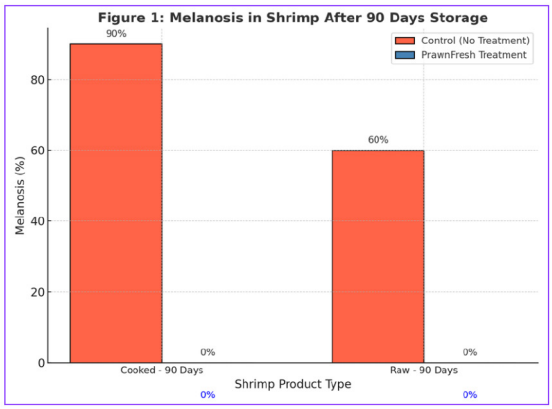
Post-harvest trials were conducted using Penaeus vannamei and Penaeus monodon. Shrimp were subjected to a chill-kill process immediately after harvest, immersed in an ice-water slurry containing PrawnFresh™, and maintained under strict cold chain conditions. Samples were divided into treatment and control groups, with the control group receiving no antimelanosic agent.

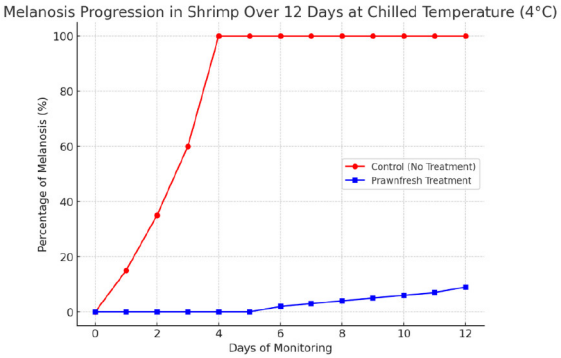
Melanosis progression and microbiological quality were evaluated at 48 hours, 15 days, 30 days, 60 days, and 90 days of frozen storage at -18°C. Additionally, a subset of samples was stored at 4°C for up to 12 days to assess melanosis under refrigerated conditions. Each treatment group was analyzed in triplicate to ensure statistical reliability. Microbiological assessments focused on total viable count (TVC), psychrotrophic bacteria, and specific spoilage organisms.

**Results**

- PrawnFresh™ -treated shrimp exhibited complete inhibition of melanosis (0%) after 90 days at -18°C, whereas untreated samples showed melanosis levels exceeding 40%.
- Under chilled storage at 4°C, melanosis in untreated samples reached 100% by day 4, while PrawnFresh™ -treated shrimp displayed minimal browning until day 12.
- Microbiological analysis indicated that PrawnFresh™ extended shrimp shelf life by an additional 6–8 days compared to untreated samples, maintaining acceptable TVC levels and sensory attributes.

*(Continued on next page)*





Figures:

1. **Melanosis inhibition in frozen shrimp:** Comparison of control and PrawnFresh™-treated samples over 90 days of storage at -18°C. ***Figure 1 illustrates*** the effectiveness of PrawnFresh in preventing melanosis in shrimp after 90 days of storage. The control group (A) shows high melanosis levels (90% in cooked shrimp and 60% in raw shrimp), whereas the treated group (B) exhibited no melanosis (0%) in both conditions
2. **Melanosis progression in chilled shrimp:** Monitoring of black spot development in treated vs. untreated samples at 4°C over 12 days. Melanosis progression monitored over 12 days at a chilled temperature of 4°C for two treatments: a control group (no treatment) and a Prawnfresh-treated group. The control group exhibited a rapid increase in melanosis, reaching 100% by day 4 and remaining stable until day 12. In contrast, the Prawnfresh treatment effectively delayed melanosis,

**Discussion**

The results demonstrate that PrawnFresh™ effectively inhibits melanosis in shrimp, offering a sulfite-free alternative that meets industry and regulatory standards. The absence of melanosis in treated samples after prolonged frozen storage underscores its potential as a superior preservation method compared to conventional SMS treatments. Furthermore, the observed extension of microbiological shelf life suggests that PrawnFresh™ functions as both an antimelanosic and a preservative, improving overall product stability.

From a commercial perspective, PrawnFresh™ addresses several industry challenges, including worker safety, environmental sustainability, and regulatory compliance. Its adoption could enhance operational efficiency by reducing corrosion-related equipment maintenance and minimizing chemical waste in aquaculture environments.

**Conclusion**

PrawnFresh™ emerges as a promising sulfite-free alternative for shrimp melanosis inhibition and quality preservation. By effectively preventing black spot formation and extending shelf life without adverse sensory or microbiological effects, it provides a sustainable and regulatory-compliant solution for seafood processors. These findings support the broader adoption of sulfite-free treatments in response to evolving industry demands and environmental concerns.

# BIOCHEMICAL RESPONSE OF JUVENILE *Dicentrarchus labrax* TO NOISE GENERATED BY MARITIME TRAFFIC

Pablo Giner Tarazona*, Isabel Pérez Arjona, Jaime Ramis Soriano, Víctor Espinosa Roselló, Miguel Jover Cerdá, Pedro Poveda Martínez, Manuela Mauro

Universitat Politècnica de València
Universidad de Alicante
Università degli Studi di Palermo
E-mail: pgintar@epsg.upv.es

**Introduction**

Aquaculture plays a key role in global food security and is expanding rapidly to meet the demands of a growing population (Verdegem et al., 2023). However, its sustainability is challenged by environmental impacts and stressors affecting fish welfare. Among these, underwater noise—often overlooked—can disrupt fish physiology, behavior, and immune function (Wysocki et al., 2007; Kunc et al., 2016; Filiciotto et al., 2017). Despite increasing awareness, data on its effects in aquaculture settings remain scarce (Duan et al., 2025).

In the Mediterranean, European seabass (*Dicentrarchus labrax*) is a key aquaculture species due to its adaptability and commercial value (Varsamos et al., 2001). This study examines the short- and long-term physiological impacts of acoustic exposure on juvenile *D. labrax*, aiming to support more welfare-focused and sustainable farming practices.

**Material and Methods**

The experiment was conducted at the facilities os the Universitat Politécnica de Valencia in the port of Gandia. Using a total of 144 juvenile of Dicentrarchus labrax, placed in tanks (147 cm x 118 cm x 89 cm). The animals were subjected to acoustic stress for 30 minutes, 3 hours, 24 hours, and 7 days. For each time point, three replicates were performed.

An electroacoustic setup was developed to generate underwater noise within the tanks, comprising a digital acquisition card (DAQ), a Sony FA-TE370 amplifier, and a custom UA-UPV speaker positioned inside the tank without contact with the walls. The speaker was calibrated using a reference hydrophone. Acoustic stimuli consisted of randomized recordings from four fishing vessels (10–15 m distance), lasting 90–150 s, with 10–30 s silent intervals. Emissions were primarily in the low-frequency range (50–2000 Hz).

At each sampling time, fish were stored at −20 °C. Whole-body extracts in PBS were analyzed for cortisol, HSP70, SOD, GPx, and ACTH via ELISA. Glucose was measured with a glucometer, while alkaline phosphatase and esterase activities were determined using modified colorimetric protocols. Enzymatic reactions were run at 30 °C, monitored at 405 nm, and expressed as U/μg protein.

**Results**

Short-term acoustic exposure (30 minutes) led to significant increases in all measured stress and oxidative biomarkers. HSP70, SOD, GSH-PX, ACTH, cortisol, esterase, alkaline phosphatase, and glucose levels all rose markedly in response to the initial acoustic stimulus.

HSP70 and ACTH levels remained significantly elevated after 3 hours but returned to baseline after 24 hours and 7 days. SOD and GSH-PX also showed elevated values at 30 minutes and 3 hours, with only GSH-PX remaining significantly higher at 24 hours; both returned to control levels by day 7.

Cortisol levels peaked at 3 hours post-exposure—unlike the other parameters—and normalized by day 7. Glucose levels also peaked at 30 minutes, remained elevated at 3 hours and 7 days, but returned to control levels at 24 hours.

Esterase activity showed an early increase at 30 minutes, followed by a decline to baseline levels from 3 hours onwards. Alkaline phosphatase peaked at 30 minutes and gradually decreased at subsequent time points, but did not return to control levels even after 7 days.

*(Continued on next page)*

**Conclusion and Discussion**

Early life stages of fish are highly sensitive to environmental stressors, making the study of acoustic pollution particularly relevant. In Mediterranean aquaculture, where *Dicentrarchus labrax* is economically important, assessing physiological responses to sound can inform welfare-oriented practices. Whole-body analyses of juvenile seabass revealed short- to medium-term changes in key cellular markers, indicating a strong acute stress response to acoustic exposure, with varying recovery times depending on the biomarker evaluated and potential compensatory mechanisms that enhance coping capacity.

**Introduction**
The SONORA project aims to evaluate the effects of underwater noise on commercially relevant fish species, focusing on growth, biochemical parameters, and behavior. Behavioral analysis requires processing large volumes of video recordings, which makes manual evaluation impractical and resource-intensive. This study explores the potential of artificial intelligence (AI) and computer vision to automate the detection and tracking of fish, enabling large-scale and precise behavioral analysis in aquaculture and ecological experiments.

**Material and Methods**
Multiple publicly available dorsal-view fish datasets were compiled, totaling approximately 35,000 images and 1 million annotations. A baseline fish detection model was trained using YOLOv8, achieving a mean Average Precision (mAP) of 0.94 for dorsal-view detection. An experimental setup was then implemented with 20 juvenile European seabass (*Dicentrarchus labrax*), in which 5 hours of video footage were recorded. The model was fine-tuned using only 20 annotated images from this setup.

**Results**
The fine-tuned YOLOv8 model achieved a detection accuracy of 0.98 mAP in our experimental setup. The high detection performance enabled robust fish tracking with the BoT-SORT algorithm, allowing for the automatic computation of first- and second-order behavioral metrics: detection distribution maps, distance to the sound source, shoal cohesion, 2D swimming speed, and swimming direction. This metrics allows us to observe differences between fish exposed to different acoustic stimuli and control groups.

The system is being applied in a 3-month behavioral experiment with 6 tanks equipped with a multi-camera recording system, capturing 8-10 hours of video daily.

**Conclusion and Discussion**
This study approximates the use of AI-based computer vision systems to automate the detection, tracking, and behavioral analysis of fish in aquaculture tanks. The main limitations are related to detecting very small individuals (larvae or early juveniles) and high-water turbidity, which can compromise second-order metrics such as swimming speed and direction. These limitations could be mitigated with higher-resolution imaging systems, albeit at higher cost and computational requirements. Ongoing work focuses on refining and validating behavioral metrics and integrating the detection and tracking pipeline into a user-friendly graphical interface to facilitate its adoption in aquaculture and ecological research.

# PHYTOBIOTIC-ENRICHED AQUAFEED: HARNESSING EUCALYPTUS ESSENTIAL OIL TO ENHANCE HEALTH AND IMMUNITY IN JOUVENILE SEA BASS (*Dicentrarchus labrax*)

## Introduction

Aquaculture, the fastest-growing production sector globally, provides essential protein and nutrients but faces productivity and sustainability challenges due to disease outbreaks in intensive systems, worsened by climate change (Liao et al., 2024). The excessive use of antibiotics has raised concerns about antimicrobial resistance and environmental safety, prompting the need for alternative approaches to health management (Reverter et al., 2021). Phytobiotics—natural bioactive compounds from plants—are emerging as effective immunostimulants, with *Eucalyptus globulus* essential oil showing notable antimicrobial and immune-enhancing effects in fish (Lin et al., 2025). This research aims to develop a novel functional aquafeed enriched with eucalyptus essential oil to enhance immune function in juvenile European seabass (*Dicentrarchus labrax*).

## Materials and Methods

Bioactive compounds with immunoenhancing properties in the essential oil were identified using GC-MS. Analysis was performed with a Shimadzu GC-2030 system and GCMS-QP2020 NX detector, using an SP-2340 capillary column. Helium was the carrier gas (1 mL/min, splitless mode). The oven temperature was programmed from 43 °C to 230 °C, then held for 12 min, followed by a post-run at 240 °C for 5 min. A 96-well plate microdilution method was used to evaluate the antibacterial activity of the extract against four marine pathogens: *Listonella (Vibrio) anguillarum* serotype O1, *Edwardsiella anguillarum*, *Vibrio harveyi*, and *Aeromonas veronii* biovar *sobria*. The extract was mixed with sterile BHIB at a 1:1 v/v ratio, and 10 µl of each bacterial culture was added. Plates were incubated at 25°C for 72 hrs. Optical density (OD) at 610 nm was measured at 12, 24, 48, and 72 hours using a TECAN Infinite® M Plex microplate reader. For the in vivo feeding trial, 200 juvenile *D. labrax* of 27.6 ± 0.1 g initial mean weight were randomly distributed into closed seawater circulation system tanks of 500 L capacity. The groups were fed two different isonitrogenous and isoenergetic diets. The Control diet was formulated to resemble a commercial diet for sea bass, without phytobiotic, and the experimental diet was formulated to contain 0.1% *E. globulus* essential oil. Fish were fed at a feeding rate of 1.5% of their body weight per day, six days per week for a total of 8 weeks. Water conditions were monitored daily: temperature (19–21°C), salinity (37± 0.2‰), pH (8.0 ± 0.1), and dissolved oxygen (>5.5 mg/ml).

## Results and Discussion

The resulting chromatogram is shown in Figure 1, illustrating the major constituents of the oil based on their retention times and relative intensities. The chemical composition of eucalyptus essential oil was determined via GC-MS analysis. The GC-MS analysis of eucalyptus essential oil identified eucalyptol (1,8-cineole) as the major component (68.9 ± 0.27%), with d-limonene (1.53%) and p-cymene (1.01%) as minor constituents. These results align with previous findings showing eucalyptol as the dominant compound in *E. globulus* oil. Its high eucalyptol content supports its potential use as a natural phytobiotic in aquaculture, offering antimicrobial and anti-inflammatory benefits that promote fish health. (Mączka et al., 2021; Lin et al., 2025).

*(Continued on next page)*

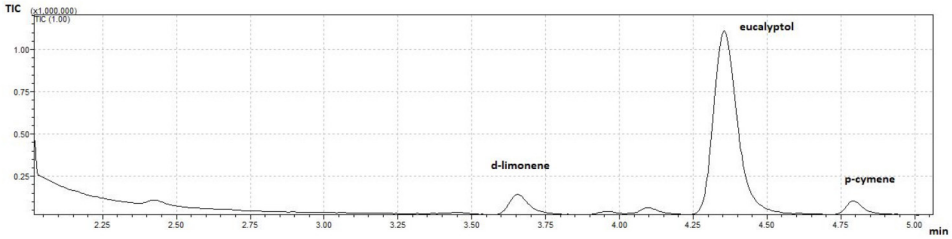

**Figure 1.** Representative chromatogram of eucalyptus essential oil obtained by GC-MS analysis.

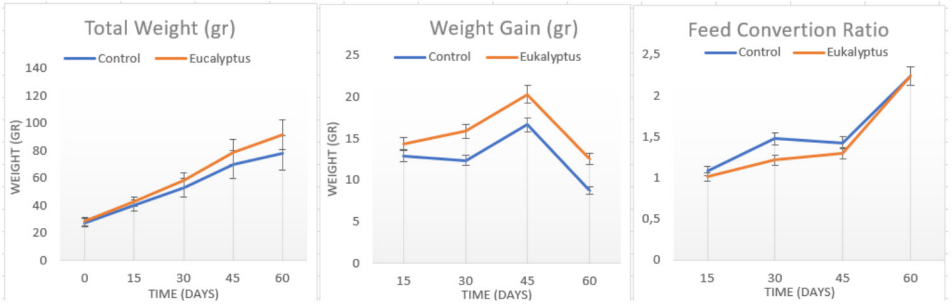

The extract significantly inhibited the growth of all tested pathogens (*L. anguillarum* O1, *E. anguillarum*, *V. harveyi*, and *A. veronii* bv *sobria*) throughout the 3-day incubation. The supplemented feed was well accepted, with no mortalities or behavioral changes observed. Fish fed the supplemented diet showed significantly higher ($P<0.05$) total weight from the first month onward, with noticeable weight gain starting at day 15. The feed conversion ratio was lower for the experimental group, particularly during the first 45 days.

The enhanced growth performance that was observed along with the efficient feed utilization shown by the lower feed conversion ratio is a possible indicator for an enhanced gut health and overall good fish health condition provided by the feed supplementation.

## Introduction

Aquafeed, as major input in aquaculture still relies upon conventional plant protein source like soy. However, the use of soy in aquafeeds are associated with ecological concerns, price volatility, and reduces its availability for direct human consumption (Wang et al., 2023). Brewers spent grain (BSG) is a major agro-industrial byproduct and a potential alternative protein source for soy with the annual production of 40 million tonnes. However, BSG utilization in aquafeed in its raw form is limited due to very low digestibility associated with high fibre content (Karlsen & Skov, 2022). These limitations can be overcome by extracting BSG protein isolate (PI), leaving behind fibre and other anti-nutritional compounds. Evaluating the digestibility of extracted BSG PI is essential to ensure its nutritional viability. In this study, both *in vitro* and *in vivo* digestibility of BSG PI are determined for rainbow trout in comparison with soybean meal to validate the BSG PI as a potential alternative protein source in rainbow diet.

## Materials and methods

BSG and protein extraction

Raw BSG was procured from San Miguel Mahou Brewery Ltd., Lleida. Protein extraction was carried out in pilot food industry of IRTA, Monells. Initially, wet BSG biomass was mixed with water at 1:4 (w/w) and heated to 50 $^{0}$C. Protein extraction was carried out at pH 11.5 using 2M NaOH 2 hours with constant stirring. The slurry was decanted to separate the liquid phase and reduced the pH to iso-electric point (3.8) The precipitated protein was separated using industrial centrifuge and washed with water to remove excess solutes and neutralized to pH 7 before freeze drying.

*(Continued on next page)*

*In vitro* and *in vivo* Digestibility

For *in vitro* assay, the stomach and intestine sections of rainbow trout (350 g BW) after 6 hours post-ingestion were used to prepare functional extracts. The acid and alkaline phases of protein hydrolysis was simulated in a two-chambered bioreactor separated by a semi-permeable dialysis membrane with a molecular weight cut of 3,500 Da as described by Lewis et al. (2019). Measurement of acid and alkaline protease by tyrosine release from hydrolysis of haemoglobin (pH 2.5) (Anson 1938) and casein (pH 8.5) (Walter, 1984) respectively. The duration of the acid and alkaline phases of digestion were 1.5 and 4.5 hours respectively. Samples of BSG protein isolates (58.7% CP) and soy protein concentrate, SPC (61.5% CP) were used for comparison. All assays were performed in quadruplicate. *In vivo* assay is conducted as part of ongoing replacement trial on rainbow trout. Five diets were prepared by replacing gradient levels of SPC using BSG PI with the addition of inert marker. The in vivo digestibility will be analysed by measuring the ratio of nutrients and marker in the diet and faecal matter.

**Results and discussion**

The dynamics of amino acid release during protein hydrolysis of BSG PI and SPC is detailed in Figure 1.

Figure 1 shows hydrolysis profiles of SPC and BSG PI that are generally characterized by a strong initial effect of acid hydrolysis, followed by a stable phase at the beginning of the alkaline phase and a second increase in the release of amino acids after 3 h of alkaline digestion. However, the hydrolysis profile of the BSG PI was clearly different in both acid alkaline digestion phases. It showed slightly lower values than SPC during the acid digestion phase. But the drastic effect of hydrolysis was observed at alkaline phase without any increase in amino acid liberation after 3 hours of alkaline digestion.

The final hydrolysis values of BSG PI and SPC after *in vitro* digestion with rainbow trout digestive enzyme extract were presented in Figure 2. Overall, final hydrolysis value of BSG PI (17.3% ± 1.05) was significantly lower ($P<0.05$) compared to SPC (29.78% ± 0.84). It is difficult to directly predict the actual *in vivo* digestibility of the BSG PI via *in vitro* hydrolysis. Because various factors play role in a digestibility in the live organism such as interactions with feed matrix, actual digestion duration, effect of intestinal microbiota etc (Moyano et al., 2015). This is especially obvious in ingredients containing complex polysaccharides. Lower *in vitro* digestibility of BSG PI in the present study will be validated in *in vivo* by an ongoing feeding trial in terms of key performance indicators associated to growth performance, feed efficiency.

## Introduction

Sea urchin populations have dramatically declined due to continuous alterations in ocean conditions caused by global climate change. Elevated temperatures increase the energetic cost of maintaining essential physiological functions and consequently disrupt defense mechanisms against reactive oxygen species (ROS) in marine invertebrates. This leads to oxidative stress and lipid peroxidation, ultimately reducing their fitness and increasing their susceptibility to mortality (Leiva et al., 2022). Recent research highlights that sea urchins can alter their physiological responses through phenotypic plasticity after acclimation. Dietary carotenoids can help counteract oxidative damage, protecting cellular components and potentially improving the efficiency of the immune response and reproductive success. Major yolk protein (MYP) is the nutritional reserve in oocytes, and it is essential for embryonic development. Temperature-induced reproductive disruptions inevitably affect the availability and function of MYP. Conversely, heat shock proteins (HSPs) are activated under thermal stress, act as molecular chaperones to protect and refold denatured proteins, and play an important role in thermal adaptation. Understanding the interplay between these factors is crucial for developing effective strategies for the sustainable production and conservation of sea urchins in a changing environment. The present study aimed at evaluating the impact of high and low carotenoid diets on the reproductive performance, oxidative stress, and gene expression of *myp* and heat shock proteins (*hsp70, hsp90, hsp60*, and *hsp56*) in the sea urchin *Paracentrotus lividus* (Lamarck, 1816) under high temperature.

## Materials and Methods

*P. lividus* broodstock was acclimated in recirculating aquaculture systems (RAS) and starved for one month before the experimental conditions. Sea urchins (N=168) were reared for four months on two temperature scenarios: local environmental temperature (18°C) and warming temperature (+3.5°C), following IPCC 2023 predictions for 2100. During conditioning, the individuals were fed with two isoproteic and isolipidic jellified diets: a high carotenoid diet (HC) and a low carotenoid diet (LC). The microalgae *Nannochloropsis* sp. was used as a source of carotenoids since it enhances gonad development and immune function **(**Tsushima et al., 1991**).** During acclimation, a 12L:12D photoperiod was used to mimic natural light conditions. The temperature was digitally controlled, simulating the two scenarios. By the end of the trial, several physiological parameters were assessed, including maturity level, gonadosomatic index (GSI), and oxidative stress markers such as superoxide dismutase (SOD) and catalase (CAT) activity, as well as lipid peroxidation (LPO). Subsequently, total RNA was extracted from gonad tissue and used to perform RT-qPCR for gene expression analysis of *myp* and the heat shock protein genes *hsp70, hsp90, hsp60*, and *hsp56*.

*(Continued on next page)*

**Results**

Conditioning temperature significantly influenced gonad development. Sea urchins maintained at +3.5ºC and fed with both diets presented a higher proportion of advanced stages of gonad development (mature; partly spawned; spent). GSI was significantly affected by temperature, with lower values observed in sea urchins exposed to +3.5°C and fed the HC diet (7 %). The activities of antioxidant enzymes (SOD and CAT) and the level of LPO were affected by temperature and dietary treatments. SOD activity showed a decrease of over 10% when sea urchins were exposed to +3.5°C and fed with both diets, with no significant differences observed between the HC and LC diets at this temperature. In contrast, CAT activity significantly increased (39 Umg/protein) in sea urchins fed the LC diet and exposed to +3.5°C, compared to those kept at 18°C (11 Umg/protein). When the sea urchins were fed by the HC diet, no significant differences in CAT activity were observed between the two temperature treatments, with activity levels remaining relatively stable (between 10-16 Umg/protein). A similar trend was observed for LPO. Significantly higher LPO levels (0.05 nmol/g wet weight) were detected in sea urchins exposed to +3.5°C and fed the LC diet. The expression of *myp* was significantly up regulated in sea urchins exposed to the +3.5°C temperature, regardless of the dietary treatment. Conversely, the expression of heat shock protein genes (*hsp70*, *hsp90*, *hsp60*, and *hsp56*) increased in sea urchins exposed to +3.5°C, particularly in those fed the LC diet.

**Discussion**

Sea urchins fed the HC diet demonstrated the strongest antioxidant defense when exposed to a higher temperature. These individuals exhibited high SOD concentration and significantly reduced CAT activity, resulting in low LPO values. Tsushima et al. (1991) reported that the carotenoid supplementation in a diet improves the immune function of sea urchins. Although CAT activity was higher when sea urchins were exposed to a higher temperature and fed with LC diet, it was insufficient to prevent lipid peroxidation, resulting in the highest LPO values. The expression of the heat shock protein genes was up regulated when the individuals were exposed to higher temperatures and fed with an LC diet. The combination of high temperature and a low carotenoid diet creates a synergistic stress effect. The high temperature directly induces protein misfolding and ROS production, while the low carotenoid diet weakens the sea urchins' ability to counteract the resulting oxidative stress. The up regulation of *myp* gene expression indicates that sea urchins were responding to higher temperatures by enhancing their reproductive processes, specifically egg development. The increase of nutrient accumulation in the gonads could be a mechanism to increase the offspring's resilience and maximize the reproductive success in a changing environment.

# EVALUATION OF AEROBIC MINERALIZATION AS A TREATMENT FOR EFFLUENTS FROM AN AQUAPONIC SYSTEM

E. Gómez Ramírez, P. D. Lara Escobar, L. F. Suárez Villamil

Ecotoxicology, Evolution, Environment and Conservation Research Group
Applied Biology Program
Universidad Militar Nueva Granada
Km 2, Cajicá-Zipaquirá Road, Colombia
Edwin.gomez@unimilitar.edu.co

Aquaponics is a sustainable production system that integrated techniques from both hydroponics and aquaculture. Although aquaponic systems are water-efficient, the cleaning of the clarifier leads to the loss of essential plant nutrients. Therefore, the mineralization of aquaponic effluents has been increasingly studied as a strategy to recover both water and nutrients. In this context, implementing mineralization processes in aquaponics allows the transformation of solid wastes into inorganic compounds that are highly available and efficient for plant growth. This study aimed to evaluate aerobic mineralization as a treatment for effluents from an aquaponic system by determining nutrient dynamics and water quality parameters. Two treatments were evaluated, each with five replicates: aerobic mineralization using filtered and unfiltered water collected from the clarifier of an aquaponic system with different lettuce varieties and Nile tilapia. Water samples were collected over a one-month period on days 0, 7, 15, 23, and 30. The following nutrients and water quality parameters were analyzed: ammonium, nitrite, nitrate, iron, phosphate, calcium, potassium, manganese, magnesium, molybdenum, zinc, sulfate, copper, total hardness, temperature (°C), pH, dissolved oxygen (% and ppm), turbidity (FNU), conductivity (µS/cm), and total dissolved solids. The results showed significant differences in macro- and micronutrient dynamics between the filtered and unfiltered treatments during mineralization. Between the days 15 and 23, an increase in pH from acidic to alkaline values was recorded, enhancing nutrient solubility and mineralization rates. Nitrogen mineralization showed efficient conversion from ammonium to nitrite and subsequently to nitrate, the preferred nitrogen form for plant absorption. Phosphate levels initially increased under acidic conditions but decreased as pH became alkaline. Magnesium and molybdenum concentrations were higher at low pH, while calcium, potassium, zinc, and total hardness increased under neutral to alkaline conditions. Aerobic mineralization with filtered water resulted in improved nutrient concentrations and higher nitrification rates, leading to greater nitrate availability. This study highlights that the implementation of aerobic mineralization processes in aquaponic wastewater management enhances nutrient transformation and recovery, simultaneously improving water use efficiency. CIAS 4164.

# EFFECT OF BIOFLOC CONSERVATION ON BACTERIAL POPULATIONS AND EVALUATION OF THEIR EVOLUTION FOLLOWING BIOFLOC REINOCULATION

Javier Gómez-Aguilera*, Sara Ferrando-Juan, Macarena M. Jurado, Miguel Rodilla, Silvia Falco, Ana Tomás, Silvia Martínez Llorens, Miguel Jover, Francisco J. Moyano, Juan A. López-González, David S. Peñaranda

## Introduction

Biofloc technology (BFT) is a proven production system that enables the cultivation of aquatic animals at high densities while maintaining water quality through the activity of various organisms, mainly bacteria. These bacteria perform multiple key functions, including nutrient transformation, nitrogen compound removal, floc formation, and organic matter exchange. Starting a biofloc system requires time and can lead to ammonium and nitrite peaks in the water, but reinoculation with mature biofloc can accelerate the process, provided that an established system is available. Otherwise, preserving biofloc may offer a solution to reduce maturation time, as long as its microbial and functional diversity is maintained during storage.

## Materials and methods

Mature biofloc was collected, decanted and filtered to reduce moisture content. Afterwards, samples were subjected to three preservation treatments: refrigerated vacuum (RV), frozen (F), and dry (D). RV samples were stored in vacuum-sealed bags at 4°C. F samples were mixed with 15% glycerol and stored at -80°C. D samples were dried at 40°C. A negative control (NC) was not inoculated, while a positive control (PC) was directly inoculated with fresh, decanted, and pressed biofloc. All inoculated groups received biofloc at a concentration of 1 g/L. These preservation techniques are patented (*P202530281*). The storage period before inoculation was 7 days. Each treatment had three replicates (80 L tanks, aerated, at 28°C). *Penaeus vannamei* (76 g/tank) were stocked. Water samples were collected weekly to analyze nitrogen compounds (ammonium, nitrite, nitrate) and phosphorus (phosphate) concentrations. Microbial diversity was analyzed on days 0, 6, 21, and 41.

The full-length 16S rRNA gene was amplified using barcoded primers 27F and 1492R. PCR (27 cycles) was followed by quality control and equimolar pooling. Libraries were prepared with the SMRTbell Express Template Prep Kit 2.0 and sequenced on a PacBio Sequel II. Sequences were processed with QIIME2 using DADA2 for denoising. Taxonomy was assigned with the SILVA 138 database. Alpha diversity (Shannon, Simpson, Chao1) and beta diversity (Bray-Curtis, PCoA) were calculated. Differential abundance was analyzed with ALDEx2; Krona plots visualized taxonomic profiles.

*(Continued on next page)*

## Results and discussion

After 41 days, no Ammonium-N and Nitrite-N peaks were observed in RV, F, and PC, indicating effective nitrogen removal (Table 1). Nitrate-N levels did not differ between PC and preserved biofloc (RV, F, D), suggesting reinoculation did not increase nitrate accumulation (Table 2). Phosphate-P was significantly lower in RV than in other treatments, likely due to microbial assimilation, as no water exchanges were made and only dissolved phosphate was measured (Table 2). These results suggest that refrigeration and freezing preserve microbial activity related to nitrogen and phosphorus cycling.

*Table 1. Alpha diversity at the phylum level for each treatment on initial and final days. Values represent mean ± SE. Different letters indicate significant differences ($p < 0.05$).*

At day 0, alpha diversity at the phylum level (Shannon, Simpson, Chao1, OBS) was significantly lower in NC and D, indicating reduced microbial richness compared to RV, F, and PC. RV and PC were similar, showing that refrigeration effectively preserved phylum-level diversity, while F showed a moderate reduction. After 41 days, all diversity indices converged across treatments, suggesting that biofloc maturation stabilized microbial communities at the phylum level.

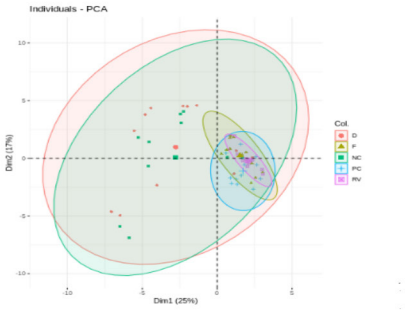

*Figure 1.Principal Component Analysis (PCoA) of microbial communities at the*

Beta diversity at the phylum level, visualized by PCA (Figure 1), showed that RV and PC communities clustered closely, indicating similar microbial structures. F samples were moderately similar, while NC and D formed separate and more dispersed clusters, reflecting higher variability due to lack of inoculation or drying. RV, F, and PC showed lower dispersion, likely due to better preservation of the initial community.

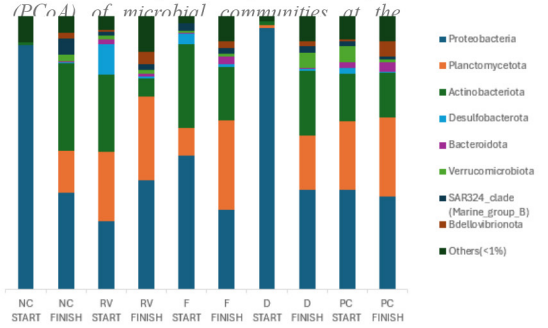

*Figure 2. Relative abundance of bacterial phyla in each treatment at the start and after 41 days of biofloc maturation.*

Respect to taxonomy compositions, Proteobacteria and Planctomycetota were the most dominant phyla across all treatments (Figure 2). Significant differences were observed between the initial communities of NC and RV, particularly in these two phyla, suggesting that refrigeration preserved a more functional microbial structure. In contrast, no significant differences were found between the initial profiles of RV and PC, indicating effective preservation of the original biofloc community in RV. For F treatment, similar patterns were observed; however, significant differences emerged between the initial F and PC communities, suggesting a partial alteration due to freezing. Notably, nitrifying bacteria, which are crucial for nitrogen cycling, belong to the Proteobacteria phylum, highlighting the importance of maintaining this group during biofloc preservation.

Introduction

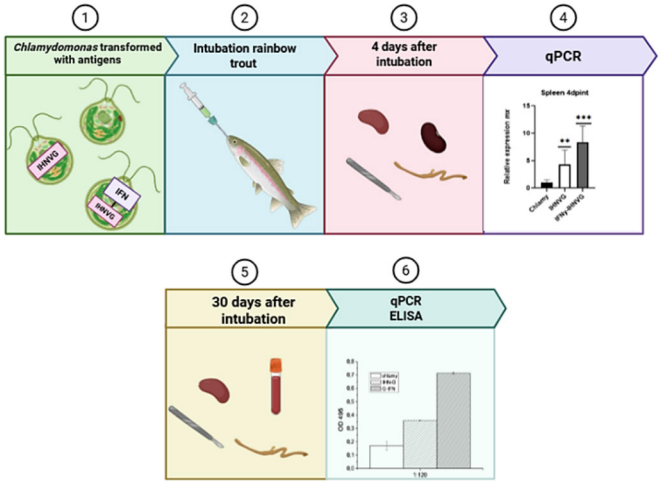
Infectious hematopoietic necrosis virus (IHNV, Salmonid novirhabdovirus) poses a major threat to salmon and trout aquaculture around the globe, with the virus nowadays present in America, Asia and Europe (1). Significant efforts have been made to develop an effective vaccine to prevent the spread of the disease. Most of the experimental anti-IHNV vaccines reported so far are inactivated virus or DNA vaccines, usually administered by injection (2). The protective efficacy of injected vaccines has been fairly good in most cases, with one licensed vaccine (Apex IHNV, Canada) available. In contrast, the development vaccines designed for oral administration to fish (a most desirable way to be implemented in aquaculture facilities) has been challenging (3).

Previous studies by our group demonstrated the efficacy of recombinant vaccines based on the expression of the main antigenic region of the rhabdoviral glycoprotein (G) in E. coli (as nanopellets) against spring viremia of carp virus (SVCV) in zebrafish and viral hemorrhagic septicemia virus (VHSV) in rainbow trout (4).

In the present work, a fragment of the IHNV glycoprotein (G) alone as well as fused to gamma interferon were expressed in the microalga *Chlamydomonas reinhardtii*. The final goal of the project is to deliver an oral vaccine to be used in rainbow trout aquaculture as a preventive method to control IHNV outbreaks.

Results

A 190-mer fragment of IHNV G protein was successfully cloned into a *Chlamydomonas reinhardtii* expression vector, as well as the IHNV-G fused to trout gamma interferon. Positive clones were selected by growing on antibody-agar plates. Next, the production of the antigens (IHNV-G, IFN-IHNG) was verified by western-blot analysis, observing the bands at the expected size (26,1kDa and 45kDa, respectively).



*(Continued on next page)*

Cultures of clones expressing IHNV-G and IFN-IHNG were concentrated and lyophilized. After reconstitution in PBS the viral antigens were delivered to rainbow trout fingerlings (three 6mg doses per fish) by intragastric gavage. At 4 and 30 days post-intubation, serum, head kidney, spleen and midgut samples were collected for analysis. When using IFN-IHNG as antigen ELISA OD values in sera were significantly higher at 30 days post intubation than in the control group (fish immunized with non-transformed microalgae). The IHNV-G group showed relatively higher OD values than controls, but the difference was not significant.

Immune-related genes expression was analyzed in the mid gut, spleen and head kidney at three time points after intubation. At early time (4 dp.int.), two interferon-inducible antiviral protein genes (*mx* and *vig*) were significantly augmented in head kidney, spleen and intestine of fish intubated with IFN-IHNG. At later times (30 days) up-regulation of *mx* and *vig* genes in spleen and intestine was observed. Immunoglobulin M (*IgM*) gene expression was not found significantly changed at any time point in immunized fish.

In a follow up experiment, the efficacy of the microalgae-based oral vaccine will be tested on rainbow trout under a diet supplemented with recombinant *Chlamydomonas* and subsequently challenged with IHNV.

Funding: This work was supported by project PID2021-126710OB-C22 funded by MIVIU/AEI (Spain) and FEDER (UE). We thank Dr. Ralph Bock (Max Planck Institute, Germany) for providing the *Chlamydomonas reinhardtti* strains.

Aquaculture is a growing productive sector that is frequently threatened by viral diseases, particularly those caused by rhabdoviruses such as the spring viremia of carp virus (SVCV). The limited availability of effective antiviral treatments has encouraged the search for natural alternatives, including the use of microalgae as sources of bioactive compounds. This study evaluates the antiviral effect of aqueous and methanolic extracts from the green microalga *Chlamydomonas reinhardtii*, against SVCV in vitro. Exposure to the extract was performed as pretreatment of the cells before infection, as well as coincubation with the extract during viral entry. The Chlamydomonas methanolic extract displayed a significant inhibitory activity on the virus cytopathic effect, reaching 89% protection in cells preincubated with the extract before SVCV infection, whereas the aqueous extract showed negligible antiviral activity. Viral RNA levels also decreased after exposure to the extract. Interestingly, incubation of the cells with the extract enhanced interferon and mx immune responses. Based on our findings the Chlamydomonas methanolic extract can be considered a promising natural therapeutic agent for mitigating SVCV pathogenicity. Additionally, this may pave the way for future research microalgae as dietary supplements for fish, aiming to prevent viral infections in a safe and sustainable manner.

## Introduction

Fish protein hydrolysates (FPH) are products from either chemical or enzymatic breakdown of fish raw material into single amino acids, peptides and oligopeptides. They are considered a suitable source of protein for animal nutrition because of their balanced amino acid composition and their low molecular weight, allowing higher gut absorption rates and functional properties. The inclusion of FPH in the range of 5-40% in diets has been reported to increase survival and growth rate, decrease malformation rate, increase enzyme activity, modify nutrient transport patterns in the intestine and induce non-specific immune responses in larvae, fry and adult fish. The positive effects of dietary FPH inclusion at the earlier stages of development are related to the fact that the gastrointestinal tract (GIT) is still under development; therefore, providing the fish with medium and small-size peptides through the diet instead of with intact proteins may help in the process of absorption through the enterocytes. Traditionally, this type of studies has been conducted by replacing certain levels of the dietary fishmeal (FM) with similar levels of FPH either as a fraction of the diet or as a fraction of the dietary protein contribution. In most cases, results have been explained based on the final dietary amino acid composition and/or the water-soluble peptides fractions distributions; however, less attention has been given to other nutrients provided by different fish products, which also vary with the dietary source exchange and may play a significant role in the evaluated responses. The present activity aimed to identify key nutrients responsible for variations in the growth rates, the development of haemal lordosis and GIT enzyme activities of E. seabass fry (0.2 – 6 g) fed with two different levels of dietary FM (53% and 65%) and FPH (0% and 13%).

## Materials and methods

Fingerlings of E. seabass (0.2 g body weight) were fed with the 4 experimental diets, in triplicate groups, for 70 days. When fish reached approximately 1.5 g body weight, they were subjected to a swimming challenge test by forcing them to swim against a water current of approximately 17-18 cm/sec for 7 days. Before and after this challenge, samples of fish were taken to document the development of haemal lordosis. At the end of the 70-d feeding trial, and following a recovery period, samples of fish were taken for analyses of growth performance, GIT enzyme activities and haemal lordosis. Data were analysed by means of 2-way ANOVA. In addition, Principal Component Analyses (PCA) were performed to identify potential correlations between the response variables and the dietary nutrients composition.

## Results and conclusions

In general, the growth of the fish was not significantly affected by dietary treatments at the end of the 70-d feeding period. However, GIT enzymes such as trypsin, pepsin, leucine aminopeptidase (LAP) and lipases did respond differently to treatments. Similarly, we found a significant interaction between dietary FM and FPH levels in the development of haemal lordosis and observed a variation in their levels before and after the swimming challenge test. As expected, the amino acid and peptides distribution profiles are key responsible for the observed parameters; however, the potential role of minerals, trace elements, lipo-soluble vitamins and phospholipids are also defined.

# BIOFOULING CONTROL, PLASTIC FOOTPRINTS AND FISH WELLFARE: EVALUATING NET MATERIALS AND CLEANING METHODS IN MARINE FARMS

Alessio Gomiero[1*] Adrián Jaén-Gil[1], Helena Hauss[1], Elisa Ravagnan[1], Renée K. Bechmann[1]

[1] Norwegian Research Centre (NORCE)
Mekjarvik 12
4072 Randaberg, Norway

* algo@norceresearch.no

Aquaculture relies extensively on polymer-based infrastructure and equipment, which likely contributes to microplastic (MP; <5 mm) release into the marine environment. Beyond feed pipes and cage collars, net pens represent a notable source of MPs. In situ net cleaning—typically performed with in situ intermittent cleaning using high pressure washers—can intensify abrasion of net fibers and coatings, thereby increasing MP emissions during cleaning operations. Consequently, both synthetic fibers and particles derived from protective coatings may be dispersed into surrounding seawater. Addressing this emerging concern, the No-Gro project sought to improve biofouling management on fish-farming nets by systematically evaluating cleaning technologies with respect to fish health, environmental sustainability, and operational costs.

In this study, the Remora Robotics AS autonomous operated cleaning vehicle equipped with brush-based cleaning interfaces, is systematically compared to conventional pressure washing methods, evaluating performance, efficiency, and the release of microplastics environmental impact across both field deployments in real scenario and controlled laboratory settings designed to isolate key variables and replicate typical cleaning scenarios. The project assessed MP emissions using a combined approach of field monitoring and controlled laboratory abrasion tests, structured within elements of a safer-and-sustainable-by-design (SSbD) framework. In the field, routine cleaning events were monitored to quantify MPs, evaluate cleaning effectiveness, and track potential implications for fish welfare. In the laboratory, abrasion experiments simulated cleaning-induced wear to quantify and compare MP release from conventional multifilament nylon nets and alternative monofilament high-density polyethylene (HDPE) nets. Tests compared automated net-cleaning vehicles (AOVs) with pressure-washing technology using aluminium-framed 80 × 80 cm net panels submerged in a 300 L tank (fig.1). Released particles were recovered by filtration (≥10 $\mu$m) and quantified and characterized by Fourier-transform infrared (FTIR) microscopy imaging.

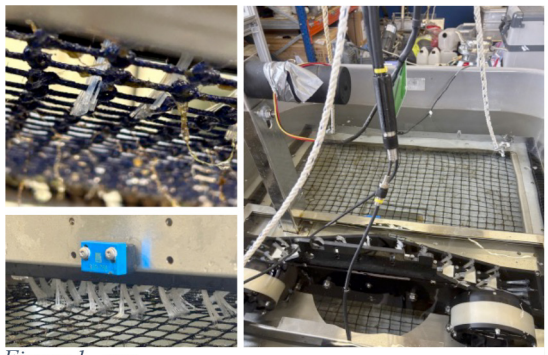

*Figure 1 - xxx*

In the filed study, areas where cleaning technologies operated showed higher levels only for polyethylene and polypropylene, reflecting the material makeup of cleaning equipment and its association with other aquaculture activities ie., HDPE pipes operated fish feed supply. The remaining detected polymer types where homogeneously distributed across all investigated sites. The results of the laboratory observations demonstrated clear material-dependent emission patterns: multifilament nylon nets released substantially more MPs than monofilament HDPE, underscoring the higher susceptibility of multifilament structures to mechanical wear. Field campaigns during routine cleaning captured sporadic and highly variable MP signals from polyethylene and polypropylene polymers, influenced by, fouling levels, and local hydrodynamic conditions. Together, these findings indicate that MP emissions are governed by polymer composition, filament architecture and the choice of cleaning technology. In laboratory-based studies, responses of material type and applied cleaning technology to microplastic emissions were observed. Independent of the cleaning technology employed, nylon nets exhibited the greatest microplastic emissions, with pressure cleaning releasing larger and more elongated fragments compared with brushing. In simulations of HDPE net cleaning, brushing technology produced a greater release of microplastic fragments than did the pressure washing solution. By adopting design-informed material selection and optimizing cleaning strategies, aquaculture operations can reduce MP releases at source while maintaining operational performance. The SSbD-oriented evidence generated by No-Gro provides actionable guidance for transitioning toward cleaner, more efficient, and environmentally responsible net-cleaning practices in marine aquaculture.

# A GUT INFLAMMATORY MODEL FOR AQUACULTURE NUTRITION

Ana Teresa Gonçalves[1,2,3]*; Daniel Jerónimo[2]; Rui Rocha[2]; Jorge Dias[1,2]

1. SPAROS, LDA., Área Industrial de Marim, Lote C, Olhão, Portugal

*anagoncalves@sparos.pt

**Introduction**

The health and functionality of gastrointestinal tract are fundamental to fish welfare, growth performance, and feed efficiency. Among the key challenges affecting gut health is inflammation—a physiological response triggered by either internal and external stressors such as the presence of anti-nutritional factors, pathogenic infections, and environmental stressors. Inflammatory conditions in the gut can disrupt nutrient absorption, impair immune responses, and increase susceptibility to pathogens, ultimately compromising productivity and sustainability in aquaculture systems. Understanding the interaction between diet and gut health has long been a major endeavor in aquaculture nutrition research. Nutritional strategies that support intestinal integrity and modulate immune responses are being actively explored. Functional feed additives—including prebiotics, probiotics, phytogenics, algae-derived compounds, and immunostimulants—are being tested for their ability to prevent or mitigate inflammation and promote a balanced gut homeostasis.

Here we introduce a standardized experimental gut inflammation model for European seabass (*Dicentrarchus labrax*), induced by dextran sodium sulphate (DSS), for evaluating the functional properties of novel ingredients under controlled conditions. This model allow researchers to study the progression of inflammation at the histological, molecular, and biochemical levels, unraveling how different dietary components influence the gut performance landscape and consequent fish thrive.

**Material and Methods**

The gut inflammatory model was developed following concept trial where increasing dosages of dextran sodium sulphate (DSS) were included in a formulated feed, complying with juvenile European seabass nutritional requirements. In triplicate tanks, fish (aprox 70g body weight) were fed DSS-spiked diets for 15 days. For this time course, feed intake was monitored to ensure a standardised ingestion of the inflammatory agent (DSS). Intestinal responses were monitored through histological assessment of the gut epithelial cell architecture and conformation (gut villi length, goblet cells' mapping, lymphocytes infiltration). More, evaluation of the relative expression of a gene's panel related with inflammatory response (e.g. *IL1-β*, *IL-8*, *TNFα*), epithelium integrity (e.g. *TJP1*, *OCL*, *CLDN15*, *iMUC*) and osmoregulation (e.g. *AQP1*, *NKCC*) was performed by RT-qPCR normalizing for *β-actin*. In addition, inflammatory markers in the faeces (e.g. calprotectin and mucins) were quantified using standardized procedures for the species. After this controlled "inflammatory" phase , fish were fed the control diet and were monitored to assess the intestinal regenerative process.

**Results and Discussion**

Fish presented a good and stable feeding behaviour throughout the feeding period, even at highest dosage. Histological score – with higher scores indicating epithelium architecture damage – presented a positive correlation with the dosage of DSS, right after the 5$^{th}$ day of feeding, indicating damage of intestinal lining. From day 10 lymphocytes' infiltration was evident with increasing severity with DSS dosage. Molecular inflammatory responses were triggered after 5 days, with higher expression of *IL-8* and *TNFα*. On the other hand, at longer periods, the expression of epithelium related markers (*OCL*, *iMUC*) was reduced, indicating epithelium damage. The correlation between DSS dosage and intestinal inflammation was established and further validated in different trials. This standardized mild-inflammatory challenge and the associated diagnostic markers allow a precise monitoring of the inflammation progress, and its recovery, allowing a reliable assessment of novel ingredients and additives with protective or regenerative potential at the intestinal level.

# EXPLORING MUCOSAL RESILIENCE IN ATLANTIC SALMON: THE IMPACT OF NOVEL ALGAE-BASED FUNCTIONAL DIETS

Ana Teresa Gonçalves[1,2,3*], Daniel Jerónimo[3], Rute Félix[2], Soraia Santos[2], Maria J. Xavier[2], Bernardo Carvalho[2], Claudia Magalhães[1,3], Luís E. Conceição[1], Rui Rocha[3], Hugo Pereira[2], Jorge Dias[1,3]

[3] RIASEARCH, Lda. Murtosa, Portugal
*anagoncalves@sparos.pt

**Introduction**

The maintenance of optimal health and resilience in aquaculture is paramount for the achievement of sustainable production. The mucosal surfaces of the gastrointestinal tract, gills, and skin serve as the principal interfaces between the fish and its external environment, functioning as the initial line of defense against pathogens and various stressors. These mucosal systems—comprising the gut-associated lymphoid tissue (GALT), gill-associated lymphoid tissue (GIALT), and skin-associated lymphoid tissue (SALT)—are indispensable for host immunity, nutrient assimilation, and osmoregulation. Despite contemporary aquaculture practices that strive to mitigate stressors, Atlantic salmon are frequently exposed to adverse conditions that may jeopardize mucosal integrity and functionality, thereby diminishing their ability to endure disease and recover from various insults. Dietary interventions that support and modulate mucosal immunity offer a promising strategy to enhance fish health and welfare. Algae, both micro- and macroalgae, are valuable sources of bioactive compounds applied by nutraceutical and cosmeceutical industries, promoting tissue healing and regenerative capacity. In this study the effects of diets supplemented with various types of algae biomasses and extracts were assessed with the objective to determine how these dietary additions can enhance mucosal resilience focusing on tissue regeneration and healing and immune response.

**Methodology**

Atlantic salmon (*Salmo salar*) smolts (body weight 99,9 ± 13,8 g) were fed functional diets supplemented with one of the algae derived ingredients: *Ascophyllum nodosum* (whole biomass) (ASCOP), *Chaetoceros muelleri* (broken cells (CHAETO-BC), and water extract (CHAETO-WE)), *Skeletonema costatum* (broken cells) (SKE-BC), *Phaeodactylum tricornutum* (water extract) (PHAEO-WE), and a blend of CHAETO-BC and PHAEO-WE, in a total of six experimental diets and a control with no functional inclusion. Fish were fed for 14 days after which a portion of the anterior intestinal mucosa, skin mucosa (bellow dorsal fin) and gill mucosa (second arch's filaments) was excised and preserved in RNALater for gene expression analysis. A comprehensive molecular marker panel was set and evaluated, including genes related with general immune response (e.g. *CATH*, *MUC2*, *TLR22*, *CD82*), antioxidant response (e.g. *SOD*, *CAT*, *GPx*), epithelium homeostasis (e.g. *iFABP*, *OCL*, *TJP1*), and with the several stages of wound healing (re-epithelization and epidermal repair, inflammation, immune cell recruitment, cell proliferation and tissue remodeling). The expression of the panel of genes was assessed by RT-qPCR for the three mucosal systems, and relative expression was calculated with the Pfaffl's method. Univariate and multivariate analysis was performed, and diets were ranked based on the expression of the genes in each process, following a predefined set of rules for categorization of fish mucosal performance.

**Results**

By the end of the functional feeding trial, the expression of several genes in the GALT (intestinal mucosa) was modulated, but not significantly. However, diets with ASCOP and PHAEO-WE promoted a differentiated response in gut, mainly due to a stronger expression of *HSP70* and *TJP1* genes. In GIALT (gills), differences were more evident, and functional feeds promoted a shift in the gills mucosa when compared with CTRL feed. This shift was mainly due to an upregulation of *TJP1*, *OCL*, *TNFa*, *AGT*, *SOCS3* and *VEGFA* genes. On the other hand, SKE-BC diet resulted in downregulation of *IL1B*, *FNA1A* and *BNC2*, indicating a possible reduction in performance. In SALT (skin), the tissue remodeling related markers were modulated by the feeds, in particular the *PDGRFA* that was upregulated in diets with PHAEO-WE and ASCOP, and downregulated with SKE-BC. Here PHAEO-WE supplemented feed promoted a differential response mainly due to an upregulation of *FNA1A*, *PDGRF1*, *AGT* and *BNC2*, all related with epithelium regeneration and healing.

*(Continued on next page)*

**Conclusion**

The analysis and further ranking of the feeds indicated the PHAEO-WE supplemented feed as the best mucosal health promoter with higher performance score in GALT and GIALT, and as a second best in SALT. In skin, the diet supplemented with ASCOP promoted the greatest impact with a healthier response mainly in immune but also regenerative and healing processes. This study brought light to the potential of the algae-derived ingredients as mucosal health promoters in Atlantic salmon, with a special focus in the tissue regeneration and healing processes. However, the effects of these ingredients should be further addressed to fully evaluate if the positive outcomes here unravelled will reflect in higher performance and resilience after an insult.

E-mail: hernanmi@uji.es

**Introduction**

Lipids are fundamental to biological systems, serving as essential components of cellular membranes, signaling molecules and energy reservoirs. The biological functions of lipids are determined by their structural diversity. Diet plays a pivotal role in shaping the lipidomic profile, resulting in either harmful or beneficial health effects (1). To better understand the relationship between diet and health, there is a growing need for biomarkers that accurately reflect the consumption of health-relevant foods. Untargeted metabolomics can provide a more comprehensive image of dietary intake by profiling lipids in biological samples. High-resolution mass spectrometry (HRMS), with its high sensitivity and selectivity, is ideally suited for such analyses.

The aim of this work was to study the lipidomic profile of *Sparus Aurata*, one of the most consumed fish in the Mediterranean Sea, in response to diets differing in their main ingredients: fish-based, plant-based, by-product-based and alternative sources such as insect-derived components.

**Materials and methods**

Lipid extracts were obtained from freeze-dried fatty tissue of the fish fillet using the Folch method (chloroform, methanol and water), followed by reconstitution in isopropanol. Extracts were analyzed by ultra-high-pressure liquid chromatography coupled to ion mobility (quadrupole)time-of-flight mass spectrometry (UHPLC-IMS-QTOF MS), in both ionisation modes (ESI+/ESI-) using data independent acquisition (DIA) mode.

**Results**

Results show lipidomic differences among diets. Fish fed the control (CTRL) diet, based primarily on fish oil, showed higher levels of long-chain phosphatidylcholines (C18, C20). In contrast, those fed the alternative (ALT) insect-based diet exhibited a shift toward shorter-chain phosphoglycerides and diacylglycerides (C12, C16). This increase in short-chain lipids in the ALT diet aligns with the fatty acid composition of insect larvae, particularly *Hermetia illucens*, which is rich in lauric acid (C12:0) content (2, 3). In contrast, diets based on plant or animal sources resulted in higher levels of longer-chain fatty acids such as palmitic (C16:0), oleic (C18:1), and linoleic (C18:2) acids (4).

## Introduction

Nutritional quality is a key concern for the food industry, encompassing producers, regulators, and consumers alike. Volatile organic compounds (VOCs) are essential contributors to food aroma, freshness and perceived quality. Their profiles may be influenced by multiple factors, such as geographical origin, storage conditions, and dietary composition, among others (1, 2), making them useful indicators for food differentiation and traceability.

This study aimed to investigate the volatolomic signatures of *Sparus Aurata*, one of the most widely consumed fish species in the Mediterranean region, associated with three distinct diets containing novel, sustainable ingredients: plant-based, by-product-based and alternative sources such as insect-derived components. Understanding how diet influences the volatile composition of *Sparus Aurata* may contribute to the development of feeding strategies that preserve or enhance product quality, while also supporting the use of sustainable ingredients in aquaculture.

## Materials and methods

Two analytical extraction methods were applied for this purpose. First, a low-temperature extraction using head-space solid-phase microextraction (HS-SPME) at 60 ºC was performed to analyse the volatile compounds present in raw fish. Additionally, a high-temperature extraction via purge and trap (P&T) was carried out, simulating cooking by including a preheating step at 120 ºC followed by thermal desorption, to mimic the aroma profile perceived by the consumer.

## Results

The low-temperature analysis revealed clear differences in the volatile profiles among dietary groups. Notably, lauric acid was significantly elevated in fish fed the alternative diet. This biomarker is particularly relevant, as lauric acid is a C12 fatty acid commonly found in insects, the main ingredient of the alternative formulation, and has been previously reported in the volatolome of other fish species, such as salmon (3). The high-temperature analysis has been completed, and statistical evaluations are currently in progress. These results will provide further insight into how diet influences consumer-perceived quality through the fish's aroma profile.

**Introduction**

Aquaculture plays a crucial role in addressing the increasing global demand for fish, requiring the development of sustainable feed formulations. Traditional diets are no longer sustainable and new nutritional strategies need to be studied (1, 2). However, incorporating alternative ingredients in feeds may introduce pollutants not commonly linked to fish farming.

This study examines the occurrence of potential pollutants across the marine food production chain—from raw ingredients to commercial feeds, and final fish fillets—using a feeding trial with gilthead sea bream.

**Materials and methods**

Eighteen raw ingredients, three different diets (each with two pellet sizes), and 48 fillet samples were analysed using advanced analytical platforms: liquid chromatography (LC) and gas chromatography (GC), both coupled to high-resolution mass spectrometry (HRMS), including ion mobility-quadrupole time of flight (IMS-QTOF) and GC-Orbitrap MS.

**Results**

A screening of different families of contaminants (pesticides, pharmaceuticals, etc.) was carried out. The results revealed the presence of typical plant-associated ingredients, such as pesticides and PAHs, in ingredients and feeds. Residues of veterinary pharmaceuticals were also detected in animal by-products ingredients, along with emerging contaminants like UV filters, musks, and phthalates. Interestingly, these contaminants did not show correlation with diet composition, suggesting contamination may originate from processing or storage. Notably, diets containing alternative ingredients showed lower contaminant loads compared to previous studies, with minimal transfer of pollutants to fish fillets. These findings highlight that alternative feed strategies can contribute to safer sustainable aquaculture practices without compromising consumer health (3).

E-mail: ismaelgonzor96@correo.ugr.es

**Introduction**

The snakelocks anemone (*Anemonia viridis*) is a highly valued species in Spain due to its popularity as a seafood delicacy. Nevertheless, global warming, high exploitation and recent rapid growth of the invasive algae (*Rugulopteryx okamurae*) has left their populations in natural environments in critical condition. In fact, in October 2023, fishing for sea anemone was legally banned in south of Spain as a measure to protect the natural populations of this species. The importance of cell culture as a research tool is well recognized to study the cellular physiology of the organism under the effect of biological or environmental factors. The object of this study is to elucidate optimal conditions for the establishment of a primary cell culture of snakelocks anemone tissue. This will allow to develop an *in vitro* model to evaluate the effect of a physiological condition such clone generation on cell metabolism to be extrapolated to more complex models.

**Materials and Methods**

*Anemonia viridis* specimens were maintained under a sea water recirculation system with controlled temperature (20 ºC) and natural photoperiod (12:12). Two experimental conditions were established: (1) control and (2) induced regenerating by longitudinal section. After one week, one specimen of each condition was collected and four tentacles were dissected from each one. Following Ventura et al. (2018), two small pieces from each tentacle (2 $mm^2$) were cut, one of them seeded directly and the second one treated with collagenase IV (0.02%) before seeding, on modified Grace Insect Medium with 29.3 g/L NaCl (GMIM) with 5% foetal bovine serum, 1% penicillin/streptomycin, 1% amphotericin B, 0.1% Tylosin and 73% sterile artificial seawater. Four types of cultures were tested: control-collagenase, control+collagenase, regeneration-collagenase, regeneration+collagenase (four replicates from each one). Culture conditions were: atmospheric $pCO_2$, Tª 20.0 ± 1 ºC and darkness. Cells were monitored until day 34 under inverted optic microscopy (Leica DMi1). Images were analysed to measure cellular homogeneity (Fiji v.2.17.0.). Mixed-design ANOVA ($p$<0.05) was performed using SPSS v.25.

**Results and discussion**

One of the most important factors on primary cell culture establishment is the growth capacity of tissue. Also, tissue treatment with collagenase IV is a key factor in the digestion of the extracellular matrix when isolating cell culture. In the present study, results revealed the presence of three types of cells in *A. viridis* tentacle tissue culture (Figure 1): epithelial cells (more abundant), cnidocytes (defence cells) y zooxanthellae (endosymbiotic cells from *Symbiodinium* genus).

The homogeneity index (percentage of epithelial cells over the total cells), evaluated from 24 hours to 34 days, displayed that at day 8 all of the groups reached values of homogeneity higher to 95 % (Figures 2). The relationship between physiological status of tentacle tissue (control or induced regeneration) and collagenase treatment, affected the evolution of the culture of epithelial cells at different time points. Control condition treated with collagenase, displayed and early cell homogenization (24 hours) compared to regeneration groups treated with collagenase, which, by other hand, reached higher values of homogeneity on later stages compared to control. This could be due to physiological condition of cells, on one hand, control under basal metabolism favoured a quick development of epithelial cells while regeneration has to deal with stressed physiological status (induced section on tissue) and enzymatic digestion, resulting in a slow beginning but steady increase in culture quality and the end of

*(Continued on next page)*

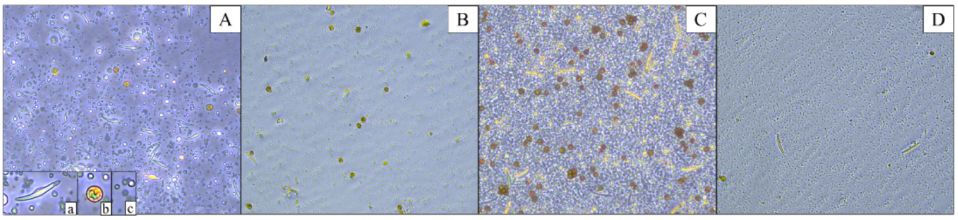

**Fig. 1** Culture cells from tentacles of *A. viridis* treated with collagenase IV. Control group (A: 24 h, B: 34 days) and regenerating induced group (C: 24 h, D: 34 days). Three types of cells can be identified (A): a: zooxanthellae, b: epithelial cells, c: cnidocytes. Observations done on inverted optic microscope with 20x.

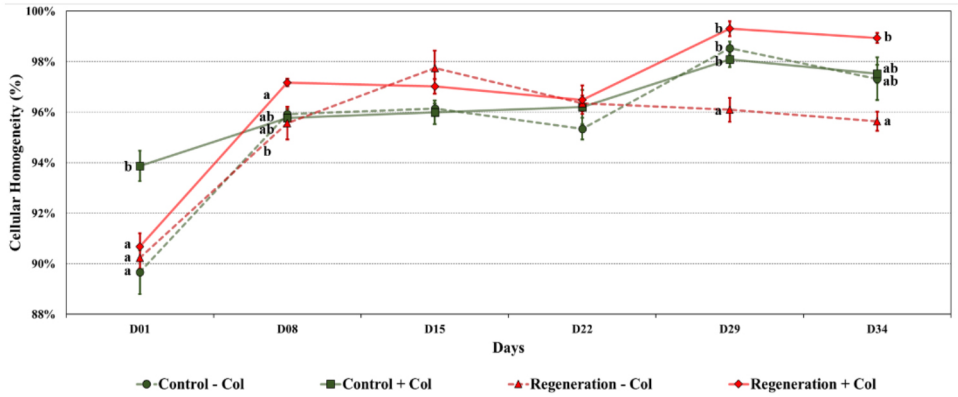

**Fig. 2** Homogeneity index of epithelial cells ((total nº of epithelial cells / total nº of cells) x 100) in primary cell cultures from *A. viridis* tentacles. Time lapse from 24 h to 34 days. control (not induced groups), regeneration (induced groups), - col (no collagenase treatment), + col (collagenase treatment). a, b, c: significant differences between experimental treatments ($p$<0.05).

the experimental time (34 days). Similarly, control and regenerating groups without collagenase treatment increased values of homogeneity over time, but in both groups, values were lower in early stages compared to collagenase treated groups. being this difference significant at the end of the experimental period in regeneration groups, which could explain an affected capacity of proliferation in cells not treated with this enzyme under an adverse condition. This study concludes that the metabolic status of source tissue can be determinant on the effect of collagenase, promoting an early or later development of the homogeneity and quality of the culture.

# ASSESSING IMPACTS OF 14° C VERSUS 17° C REARING TEMPERATURE ON COHO SALMON *Oncorhynchus kisutch* GROWTH PERFORMANCE, HEALTH, AND WELFARE IN FRESHWATER RECIRCULATION AQUACULTURE SYSTEMS

C. Good, T. May, C. Crouse, K. Fairfield, T. Horton, J. Davidson, M. Murray, A. Speck, and B. Vinci

E-mail: cgood@conservationfund.org

## Introduction

The growing land-based salmon industry, utilizing recirculation aquaculture system (RAS) technologies, has largely focused on producing Atlantic salmon *Salmo salar*. In the United States, there are presently only two such facilities raising alternative salmonid species – steelhead trout *Oncorhynchus mykiss* and coho salmon *Oncorhynchus kisutch*. While steelhead trout production benefits from decades of selective breeding efforts, an abundance of performance data, and year-round egg availability, coho salmon is a relatively unstudied species. Nonetheless, there is significant interest from RAS stakeholders in coho salmon as an alternative salmonid species with considerable market potential. Early efforts in raising coho salmon in RAS in the U.S. demonstrated disappointing growth performance well below targeted levels due to suboptimal rearing environments; however, more recent advances in rearing protocols have shown that excellent growth performance can be achievable in RAS. Nonetheless, optimized culture conditions for coho salmon production in RAS still need to be defined.

## Materials and methods

All-female diploid coho salmon eyed eggs were obtained from a U.S. commercial supplier and hatched in Heath trays within a RAS incubation system maintained at 8-10 °C. After the sac fry has absorbed the majority of their yolk sacs, they were transferred to six 0.5 $m^3$ tanks in a flow-through system (approximately 13.5 °C). Following normal industry protocols, all salmon were raised under a natural, rising photoperiod (Campbell River, BC, Canada latitude) from hatch until 30 weeks post-first feeding, in order to instigate smoltification beginning at approximately 50 g. At 30 weeks post-first feeding, the entire population was bottom-culled to eliminate fish that failed to undergo smoltification. Fish remained on natural photoperiod in the flow-through system until a mean weight of 600 g was achieved, after which they were transferred to six replicated RAS (9.5 $m^3$ total volume; 5.3 $m^3$ tanks) maintained at either 14 °C or 17 °C, with n=3 replication for high vs. low-temperature treatments. All fish were fed standard diets from a commercial supplier for the duration of the study; feed amounts provided to each study tank over the course of the experiment were based on standard industry feeding charts, but were adjusted based on feeding activity such that fish were fed to satiation. All RAS were operated at an exchange rate that facilitated 17 °C water temperature, with chillers being employed in the lower temperature group to achieve 14 °C in those specific RAS. Throughout the study period, fish performance was / will be assessed bimonthly, quantifying length, weight, dorsal and caudal fin condition, and cataract scores from a representative sample of fish per tank. The study will be completed once the best-performing treatment group attains a mean weight of 3 kg (i.e., the targeted industry harvest size). Aside from the performance outcomes listed above, maturity will be assessed via gonadosomatic index calculation from a representative sample of fish from each tank, and viscerosomatic indices will be quantified to assess coelomic adipose deposition. Mean condition factor and population coefficient of variation (weight) will be calculated at each sampling point, and specific growth rate, thermal growth coefficient, and feed conversion will also be assessed. Background water chemistry for relevant RAS parameters (alkalinity, BOD, hardness, pH, $NO_2$-N, $NO_3$-N, total phosphorus, TSS, true color, and turbidity) are being regularly assessed throughout the study period.

## Results

At the time of abstract submission, the most recent sampling event was carried out at around 1 kg mean weight, and final sampling at 3 kg is projected to be completed in June-July 2025. Presently, no clear differences in the performance, health, and welfare metrics listed above have been noted between the two treatment groups; however, all final results will be presented at Aquaculture Europe 2025.

# ENSURING OPTIMAL WATER QUALITY IN RAS ENGINEERING USING HIGH-FIDELITY MODELING

Gorle J.M.R.[1], Gorle A[1], Terjesen B.F[2].

[1] Meric Wave Computanics Oy, Nasilinnankatu 33b A 9, Tampere, Finland
Jagan.gorle@mericwave.com
[2] Cermaq Group, Dronning Eufemias gt 16, Oslo, Norway

Water quality plays a fundamental role in fish health, growth, and overall system performance in Recirculating Aquaculture Systems (RAS). Among the various water quality parameters, dissolved oxygen (DO) is one of the most critical. Fish require a stable and adequate supply of oxygen throughout the tank volume, yet maintaining this can be challenging in high-density aquaculture systems. Uneven oxygen distribution, such as too high levels around inlets, oxygen-depleted zones near the tank bottom, and the presence of biosolids can create microenvironments that stress fish, reduce feed conversion efficiency, and increase disease susceptibility.

This study highlights the role of DO distribution and water quality management in RAS. The model-visualizes and analyzes how oxygen is distributed in a commercial RAS tank under typical operating conditions, also accounting for the impact of the fish itself. The model accounts for stocking density, fish oxygen consumption and fish distribution, and shows how variations in water flow influences the oxygen availability in different parts of the tank. Figure 1 shows the model prediction of DO distribution across the central vertical plane for a salmon stocking density of 64 kg/m3. By simulating various conditions such as biomass densities, oxygenated water inlet placements, and waste accumulation patterns, it is possible to identify practical strategies to reduce oxygen gradients and promote more uniform conditions throughout the tank. These include optimizing the placement of oxygen delivery systems, improving tank flow design, and regularly removing biosolids to prevent stagnation.

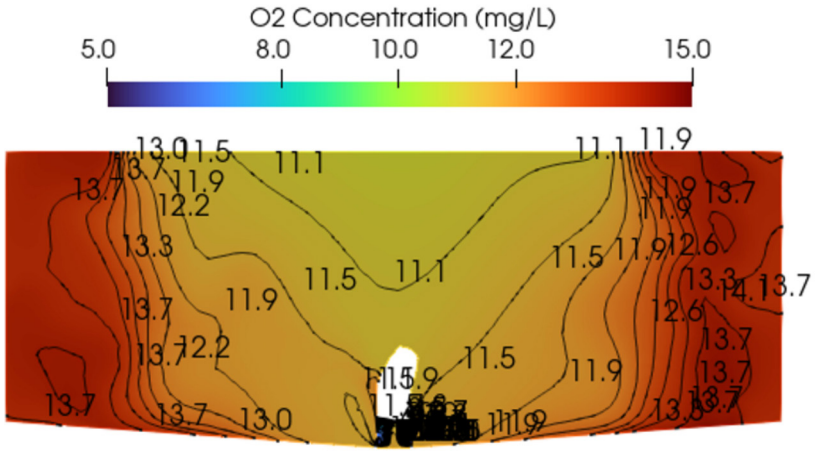

**Figure 1: CFD-prediction of oxygen distribution in a commercial RAS tank across the central vertical plane.**

# EVALUATING NUTRIENT TRANSFER AND PRODUCTIVITY IN A CLOSED-LOOP AQUAPONICS SYSTEM USING CATFISH AND ROMAINE LETTUCE

Kamal Gosh*, Tremar Ivey, Sebastian Moreno, Isis Williams, Lenoard Kibet and Ander Compere

Department of Agriculture and Natural Resources
100 Success Avenue
Langston University
Langston, OK 73050
kgosh@langston.edu

## Introduction

Aquaponics integrates fish farming with soilless plant cultivation (hydroponics) in order to establish a symbiotic system where fish waste provides nutrients for plants, with bacteria facilitating the conversion of ammonia to nitrates. In contrast, hydroponics involves plant growth using nutrient-enriched water. This study aims to compare the growth rates and production of lettuce and fish within an aquaponics system.

## Methods

Catfish (*Ictalurus punctatus*) were raised under controlled conditions, receiving a daily feed of 3% of their body weight, while Romaine lettuce (*Lactuca sativa var. longifolia*) seedlings were transplanted into a system utilizing reverse osmosis-treated water. Daily monitoring of total dissolved solids (TDS) and electrical conductivity (EC) ensured nutrient optimization. Water samples were tested for ammonia, nitrite, nitrate, pH, and dissolved oxygen using API strips.

## Results

Preliminary results from the catfish showed an average weight of 56.74 ± 15.71gm (Figure 1). Lettuce growth displayed an average weight of 17.76g ± 9.85gm. These findings suggest that the aquaponic system facilitates effective nutrient transfer from the fish tank, promoting lettuce growth. Future research will compare these results to soil-grown lettuce and pond-grown fish to evaluate which method produces higher growth and yields, providing insights into sustainable agricultural practices for both leafy greens and fish production.

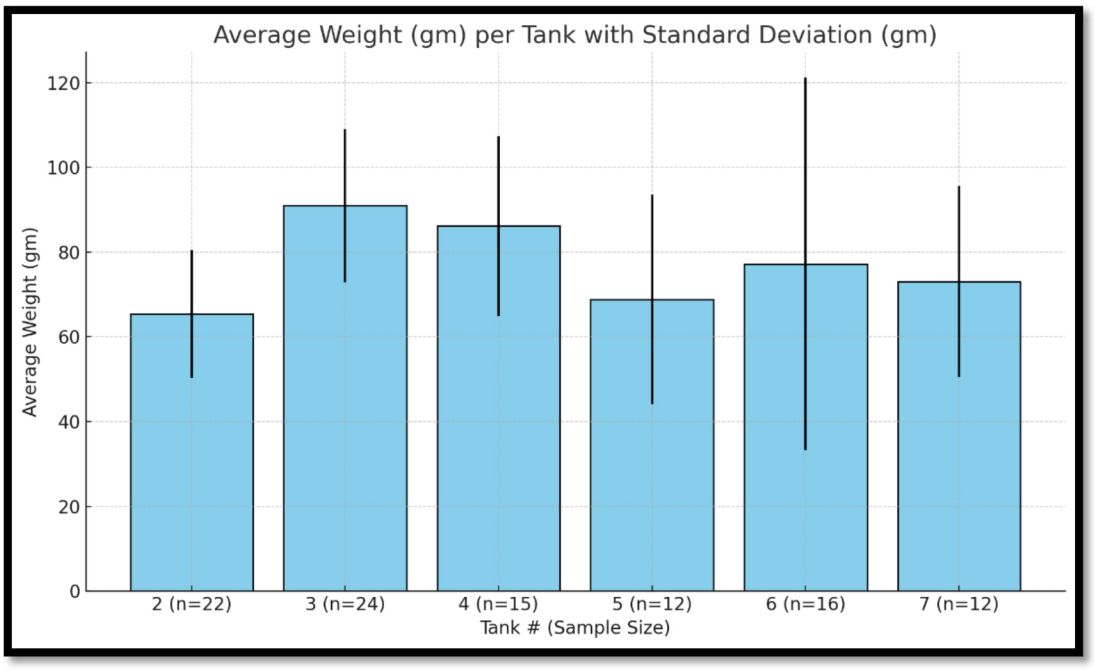

**Figure 1.** Average weight (gm) of fish per tank with standard deviation (gm). Sample size for each catfish tank is indicated in parentheses next to the tank number.

# OPTIMIZING CARBON STORAGE IN AQUACULTURE SYSTEMS: EVALUATING FISH SPECIES SELECTION AND FARMING PRACTICES

Kamal Gosh*, Malcolm McCallum, Tremar Ivey, Sebastian Moreno, Isis Williams and Ander Compere

Department of Agriculture and Natural Resources
100 Success Avenue
Langston University
Langston, OK 73050
kgosh@langston.edu

## Introduction

Aquaculture ponds, often neglected in national carbon budgets, present significant potential for carbon storage. This study investigates the carbon absorption rates of pond sediments in relation to fish species selection, pond age, and fish farming practices.

## Methods

A standardized soil sampling protocol was employed, collecting sediment samples of 200-300g from a depth of 20 cm using a hand core sampler, based on the methodology from Gilbert et al., 2021. To ensure consistency, all samples were collected by the same individual and analyzed at the Oklahoma State University Soil Testing Lab. Soils from channel catfish, koi, and bluegill ponds were sampled, with four catfish ponds, two koi ponds, and two bluegill ponds included in the study. A questionnaire gathered data on physical, chemical, and fish farming management factors.

## Results

The results showed that carbon absorption rates varied significantly between species, with bluegill ponds having the highest organic matter and total carbon content, followed by catfish and koi ponds. Carbon absorption was also analyzed in relation to pond age and management practices such as stocking rate, feed, and total production, with bluegill ponds again demonstrating the highest absorption rates. This study underscores the potential for improving carbon storage in aquaculture ponds, emphasizing the importance of fish species, pond age, and management practices in carbon sequestration strategies. These findings offer valuable insights into the role of aquaculture systems in mitigating climate change impacts.

# IMPACT OF CLIMATE-DRIVEN ENVIRONMENTAL CHANGES ON AQUATIC ECOSYSTEMS AND DISEASE OUTBREAKS

Prof. R.E. Gozlan*

ISEM, Université de Montpellier, CNRS, IRD
34095 Montpellier, France
E-Mail : rudy.gozlan@ird.fr

## Introduction

Climate change is significantly impacting aquatic ecosystems, altering species distribution and abundance, and influencing disease dynamics. Rising temperatures and environmental factors such as population density and water quality are contributing to the spread of antimicrobial resistance (AMR), with both terrestrial activities and human practices, like agriculture and urban waste, exacerbating the issue. Addressing AMR in aquaculture, a sector highly influenced by climate variability, requires a comprehensive approach that incorporates sustainable practices and proactive disease management.

## Material and Methods

We conducted a double meta-analysis of 460 scientific publications to assess the impacts of global warming and antimicrobial resistance (AMR) on aquaculture. Our analysis included 11,274 bacterial strains linked to aquaculture across 40 countries. From this, we calculated a Multi-Antibiotic Resistance (MAR) index, revealing that AMR levels are particularly high in low- and middle-income countries.

## Results

Our results show that aquaculture MAR indices are positively correlated with clinical AMR levels, environmental temperatures, and national climate vulnerability. Additionally, we found that disease-related mortalities in aquatic animals tend to increase at higher temperatures.

## Conclusion

Countries most vulnerable to climate change are likely to face the highest risks from antimicrobial resistance (AMR), with potential impacts extending beyond aquaculture to human health. This underscores the urgent need for sustainable strategies that reduce antibiotic use and enhance the resilience of aquaculture systems.

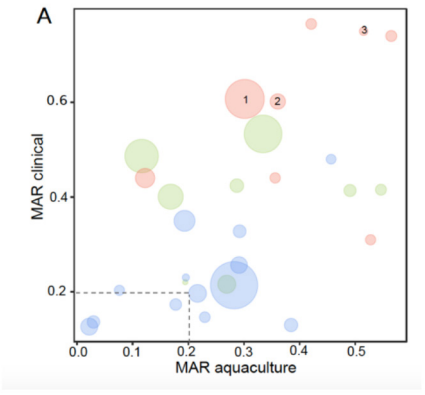

Figure 1. Correlations between MAR calculated from aquaculture-related bacteria and human clinical bacteria, temperature, and countries' climate vulnerability. Pearson correlations (two-sided test) a MAR from human clinical bacteria (n = 29, P-value < 0.001) and c temperature (n =40, P-value 0.10). Bubbles sizes are proportional to national aquaculture production standardised by the total country human population.

*(Continued on next page)*

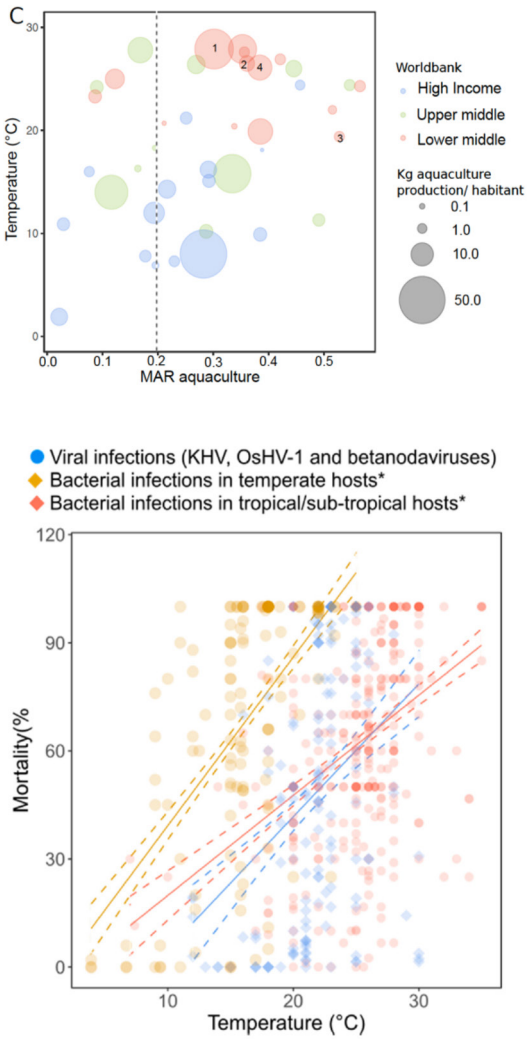

Figure 2. Predicted changes in mortality (%) of reared aquatic animals infected by bacteria (yellow and red and viral (blue, ostreid herpesvirus, koi herpesvirus and betanodaviruses) diseases in response to temperature. Solid lines represent the predicted mortalities according to selected linear and linear mixed models with dotted lines representing the 95% confidence interval for each of the models.

[4] Institute of Aquaculture, University of Stirling, Stirling, Scotland, United Kingdom

Email: p.graham@fondazioneimc.it

The BLUEBOOST project promotes the development and validation of innovative Integrated Multi-Trophic Aquaculture (IMTA) systems as a solution to improve sustainability in the aquaculture sector. By co-cultivating species from different trophic levels such as fish, bivalves, macroalgae, and other invertebrates. IMTA systems enhance nutrient recycling, reduce environmental impacts and contribute to a more circular and climate-resilient Blue Economy.

In Italy, the Sardinian case study is coordinated by the International Marine Centre (IMC) and is located in the Gulf of Oristano, a mesotrophic coastal environment in the central-western Mediterranean. The pilot system integrates an existing commercial fish farming facility rearing species such as European sea bass (*Dicentrarchus labrax*), gilthead sea bream (*Sparus aurata*) and meagre (*Argyrosomus regius*) with the cultivation of the European flat oyster (*Ostrea edulis*), a native species of high ecological and commercial value.

As part of this IMTA system, oyster farming gears, including lantern nets and Australian baskets, have been suspended at 3 m depth in close proximity (~30 m) to the fish cages. The goal is to evaluate the growth performance of *O. edulis* and to study potential trophic interactions between the fish species and oysters. Water quality and stable isotope analyses have been conducted to assess nutrient flows and the ecological functioning of the integrated system. Furthermore, local hydrodynamic conditions were evaluated to elucidate water circulation patterns and associated particle dispersion dynamics, thereby enhancing the interpretation of isotopic signatures and better assess trophic connectivity within the IMTA setup.

To complement these investigations, microbiological studies were also carried out on surface sediments, with seasonal sampling. Using next-generation sequencing (NGS), the diversity and structure of benthic bacterial communities were analyzed across multiple stations influenced to different extents by the IMTA system.

In addition to field activities, a crucial component of the Sardinian IMTA system is the production of *O. edulis* spat at IMC's experimental hatchery. The hatchery is equipped with dedicated units for phytoplankton cultivation, broodstock conditioning, larval rearing, settlement and nursery. IMC successfully completed the full hatchery cycle starting from locally harvested broodstock, gamete induction and fertilization, larval metamorphosis and juvenile growth, until producing over 5,000 spat that were transferred to sea for on-growing once they reached an average shell length of 18.7 mm.

This production process has also led to the drafting of a technical protocol for *O. edulis* seed production, with potential application in small-scale commercial aquaculture and oyster restoration initiatives. The protocol covers key aspects such as biosecurity, water quality control, feeding regimes, and grading procedures, providing a practical tool for hatcheries aiming to produce robust and healthy oyster seed.

The results of this pilot, together with those of five other case studies across Europe and South America, will feed into broader evaluations of IMTA's environmental and economic performance using Life Cycle Assessment (LCA) and other multidisciplinary tools. Through this integrated approach, BLUEBOOST aims to facilitate the adoption of IMTA systems at commercial scale and inform future policy and investment in sustainable aquaculture practices aligned with European climate and biodiversity strategies.

# TOWARDS A SUSTAINABLE AND COMPETITIVE EUROPEAN AQUACULTURE SECTOR: BREEDING AND GENETICS RESEARCH PRIORITIES FROM FABRE TP

## Introduction

Aquaculture plays a central role in the European Union's ambitions to build sustainable food systems, secure protein sources, and support economic resilience across its regions. Yet the sector faces major challenges—ranging from climate change and environmental degradation to increased global competition and evolving consumer expectations. Breeding and genetics are key tools to address these challenges while improving productivity, animal welfare, and ecological efficiency. The Farm Animal Breeding and Reproduction Technology Platform (FABRE TP) has developed a strategic framework to guide research and innovation efforts in this field, based on a shared vision for competitive, resilient and responsible aquaculture.

## Methodology

The FABRE TP Aquaculture Research Priorities were developed through a participatory process combining members' expertise, analysis of recent EU-funded projects (such as AquaFAANG, FISHBOOST, AquaExcel), and targeted stakeholder consultation like EATiP. A dedicated survey in mid-2024 gathered insights from 23 experts across 11 countries, identifying focus traits, key research gaps, and strategic directions. These inputs were synthesised into a structured roadmap aligned with the four pillars from the *Strategic Guidelines for Sustainable and Competitive EU Aquaculture (2021–2030)*, adapted to the context of breeding and genetics.

The priorities were officially presented at the SCAR FISH meeting in March 2025 and at FABRE TP's Annual Meeting in Brussels, where they were positively received by representatives from DG RTD. The entire process was guided by the principle that collaboration between private breeding organisations, academic research supported by public institutions is essential to delivering impactful, long-term change.

## Strategic Pillars and Priorities

1. **Building resilience and competitiveness**
   Aquaculture systems must adapt to environmental variability—such as temperature fluctuations, water quality shifts, and disease outbreaks—while remaining economically competitive. Priorities under this pillar include genetic adaptation to new rearing environments (e.g. RAS, IMTA), improving multi-trait disease resistance, supporting the domestication of emerging species including algae and low-trophic species, and safeguarding genetic diversity. Developing tools to monitor and limit introgression between farmed and wild populations and expanding the use of reproductive and genomic technologies are also crucial.
2. **Engaging in the green transition**
   Genetics can play a transformative role in reducing aquaculture's environmental footprint. This includes breeding for feed efficiency, resilience to climate change, and compatibility with circular systems. Innovations in feed ingredients—such as reduced fishmeal and fish oil—require genetic lines that can adapt nutritionally. Genetic co-selection strategies, sterility techniques, and genomic tools to improve traits like stress tolerance and mortality reduction are integral to supporting climate-smart aquaculture.
3. **Promoting social acceptance and consumer trust**
   Transparency, ethical considerations, and communication are central to ensuring social license for aquaculture. Responsible breeding must be paired with public understanding of its benefits for sustainability, animal welfare, and food security. Research is needed to identify and address the social, environmental, and economic dimensions that influence acceptance of breeding technologies—particularly for low-trophic and newly domesticated species. Clear policy frameworks and evidence-based regulation will help navigate innovation while maintaining trust.

*(Continued on next page)*

4. **Advancing knowledge and innovation**
   A more innovative, data-driven, and collaborative research ecosystem is needed to sustain genetic progress. Priorities include developing automation, sensors, and artificial intelligence to support phenotyping and trait monitoring; applying genomic and gene editing technologies within appropriate risk and ethical frameworks; and strengthening collaborations across public, private, and academic actors. Special attention is needed to expand capacity and infrastructure in EU Outermost Regions (ORs) and Overseas Countries and Territories (OCTs), where climate-adapted breeding programs can support local production and competitiveness.

**Conclusion**

The survival and adaptability of aquaculture species are cross-cutting challenges that touch all four pillars of this strategy. Addressing them requires long-term investment in breeding programmes and an integrated research and innovation agenda. FABRE TP calls for coordinated action at the EU level—supported by instruments such as Horizon Europe—to fund science and translate it into solutions that are socially accepted, environmentally sustainable, and economically competitive. Collaboration between the private sector, public institutions, and academia is essential to ensure that Europe reinforces its role as a global leader in breeding innovation and improves its competitiveness for sustainable aquaculture.

# FISHING FOR BRAINWAVES: HOW TO CATCH A CLEAN EEG SIGNAL WITHOUT GETTING TANGLED IN NOISE

Albin Gräns[1] Erika Sundell[1], Ulla Saarinen[1], and Jeroen Brijs[2]

[1] Department of Applied Animal Science and Welfare, Swedish University of Agricultural Sciences
[2] Institute of Zoology, University of Innsbruck

Email: albin.grans@slu.se

**Background**
The growing recognition of fish as sentient beings has led to increased attention to fish welfare in both aquaculture and wild capture contexts. A key area of concern is the period of stunning and killing, where ensuring unconsciousness prior to death is critical for securing humane treatment of animals. Humane killing is not only an ethical imperative but also a foundational principle in animal welfare legislation. In this context, the European Food Safety Authority (EFSA) highlights the use of neurological indicators obtained via electroencephalography (EEG) as the gold standard for assessing the effectiveness of stunning. Nevertheless, commercial practices often rely on operational indicators such as cessation of movement or loss of equilibrium. Emerging evidence suggests that these signs can be misleading; in many cases, fish may appear immobile while EEG recordings reveal ongoing brain activity indicative of consciousness (van de Vis et al., 2003). This discrepancy underscores the urgent need for reliable, objective tools to assess stunning efficacy.

**Material & Methods**
To address this need, we adapted EEG methodologies established in humans to develop a non-invasive technique suitable for use across several fish species. Our setup employs a silicon suction cup to attach plate electrodes securely to the head of the fish, ensuring stable contact without surgical implantation. This approach enables us to record cortical electrical activity with minimal interference to the animal (Brijs et al. 2021; Hjelmstedt et al. 2022). However, EEG recordings in fish are prone to signal contamination. External noise sources include electrical interference from surrounding equipment, variability in electrode material, and characteristics of connecting wires (e.g., shielding, length). Physiological noise, such as muscle contractions, cardiac activity, and respiratory movements, further complicates signal interpretation. These artifacts can mask or mimic genuine neural activity, increasing the risk of misinterpretation.

**Results**
Through controlled laboratory trials, we evaluated and reduced noise from external sources by optimizing equipment setup, electrode placement, and shielding. This improved baseline signal quality and reduced variability. Physiological artifacts presented more complex challenges. Our data demonstrate that muscle activity can dominate the EEG trace (Figure. 1). For example, ventilatory muscle activity can introduce low-frequency artifacts that may bias interpretations, especially in stunned but not fully unconscious fish. To improve reliability, we incorporated event-related potentials (ERPs), specifically visual evoked responses (VERs), into our assessments. Unlike spontaneous EEG, ERPs are time-locked to external stimuli, allowing for averaging over time to reduce background noise. Our findings show that VERs provide a robust method for detecting unconsciousness, as they reflect whether external stimuli are still being processed by the brain. This technique significantly enhances the interpretability of EEG data under noisy conditions.

**Conclusions**
Our work highlights the risk of misinterpretation when EEG recordings are evaluated without accounting for noise and artifacts. This is particularly critical in the context of animal welfare assessments, where the consequences of false-negative or false-positive conclusions about consciousness are ethically significant. As EFSA recommends, combining spontaneous EEG analysis with ERP-based assessments significantly enhances reliability and should become standard practice in evaluating fish stunning methods. To move this field forward and establish EEG-based methods as credible tools for welfare assessment, we must also raise the bar for methodological transparency and rigor. By ensuring this level of detail and standardization, we can promote reproducibility, facilitate cross-study comparisons, and build a stronger scientific foundation for evidence-based fish welfare policy. Ultimately, EEG-based assessments, when combined with ERP methodologies and conducted with high methodological precision, offer a powerful approach to objectively and ethically evaluate stunning efficiency in fish. These tools not only serve scientific progress but also address growing societal and regulatory demands for transparency and compassion in animal handling.

*(Continued on next page)*

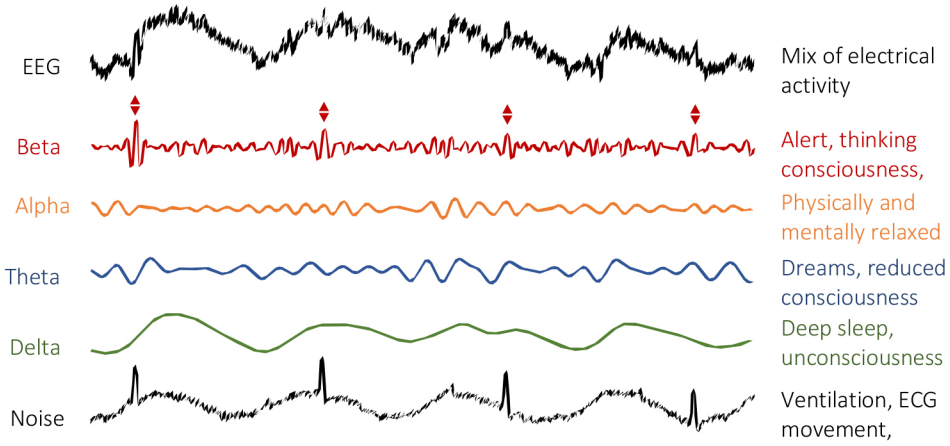

**Figure 1.** Brain waves are rhythmic patterns of electrical activity in the brain, shown here in EEG recordings from Rainbow trout (*Oncorhynchus mykiss*). These waves differ in frequency and are commonly linked to various states of consciousness and brain function. When EEG is recorded alongside the raw bioelectrical potential from the surrounding water, it becomes evident that physiological noise introduces artifacts across several frequency bands. Notably, electrical activity from ventilatory muscles strongly interferes with the lower-frequency delta range, often dominating the signal in that band.

# ASC SUSTAINABLE AQUACULTURE: CREATING SUPPORT MATERIALS FOR THE WELFARE PRINICIPLE IN THE NEW FARM STANDARD

Marianne GREEN[1*]

[1]Aquaculture Stewardship Council
Daalseplein 101
3511 SX Utrecht, The Netherlands

[*]Presenting author: marianne.green@asc-aqua.org

Aquaculture plays a critical role in the global seafood trade, contributing substantial economic value and food safety. Over the years, the industry has experienced substantial growth and is projected to continue expanding in the future. Ensuring the long term sustainability and longevity of aquaculture operations depend on the widespread adoption of responsible and sustainable farming practices that prioritize the health and welfare of aquatic species throughout their lifecycle.

In this context, the Aquaculture Stewardship Council (ASC) provides a globally recognized certification and labelling program for responsibly farmed seafood. ASC's certification program empowers farmers by enabling them to differentiate their products, expand market access, and build consumer trust through verified responsible practices

To strengthen its approach, ASC has brought together its twelve species-specific standards into one robust Farm Standard to provide greater consistency. This consolidated Farm Standard is structured according to four principles – with the new, fourth principle developed to put fish welfare front and centre of the new approach.

The welfare principle will include criteria on health and welfare related to the daily operations at the farm, handling and slaughter requirements. The welfare requirements have monitoring stipulations, however given the diversity of farmed species, production systems and current gaps in scientific data, no new set parameters for stocking density etc have been included in the standard. Instead, it introduces a novel, flexible traffic light system that is tailored to accommodate the species being farmed, their life stage and the unique farm context. Farms are required to define Acceptable, Warning Levels and Unacceptable Thresholds for the traffic light system for each requested operational welfare indicator, promoting context specific management and continuous improvement.

The presentation will focus on discussing the rationale for adding the traffic light system for specified welfare requirements to the standard as well as the tools created to support the implementation on farm.

# DEVELOPMENT OF NEW AQUAFEED FORMULATIONS WITH HIGHER NUTRITIONAL EFFICACY AND SUSTAINABILITY (PCM - 00044)

**Aim of research**

Fish aquaculture is highly dependent on the use of compound feeds, with national consumption in Spain reaching 181,000 tonnes in 2023. Fishmeal remains the predominant protein source in aquafeeds and has almost doubled its cost over the past two decades due to increasing demand combined with decline in fishery catches. This has promoted the search for alternative protein sources. Insect protein is a sustainable alternative with nutritional composition (75% w/w protein in defatted insect meal) comparable to fishmeal. Insect farming is sustainable and presents high viability due to its high feed-to-protein conversion efficiency. To date, several insect species such as soldier fly (*Hermetia illucens*), common housefly (*Musca domestica*), and yellow mealworm (*Tenebrio molitor*) have been evaluated as fishmeal replacers in aquafeed formulation. Another concern for aquafeed industry is the supplementation with functional ingredients such as peptides, fatty acids, vitamins, or probiotics. In this regard, protein hydrolysates provide low-molecular weight peptides which improve both digestibility and palatability of aquafeeds, improving feed utilization and therefore growth rate. Besides this, peptides can display specific biological activities, such as antimicrobial, anti-inflammatory or antioxidant, among others. Supplementation with bioactives (i) restrains lipid oxidation of aquafeeds, (ii) helps mitigate the oxidative stress caused by the environmental factors or (iii) avoid the extensive use of antibiotics.

The project "Development of New Aquafeed Formulations with Higher Nutritional Efficacy and Sustainability (PCM_00044)", funded by the Ciencias Marinas programme, aims at the formulation of new aquaculture diets with inclusion of partially hydrolysed insect (*Tenebrio molitor*) protein. Three functional ingredients were included in the diet formulation: (i) Arachidonic acid, which is deficient in fish oil commercial preparations, (ii) sunflower seed hydrolysates displaying *in vitro* antioxidant and anti-inflammatory activities, (iii) allium-derived extract with antimicrobial activities against fish pathogens.

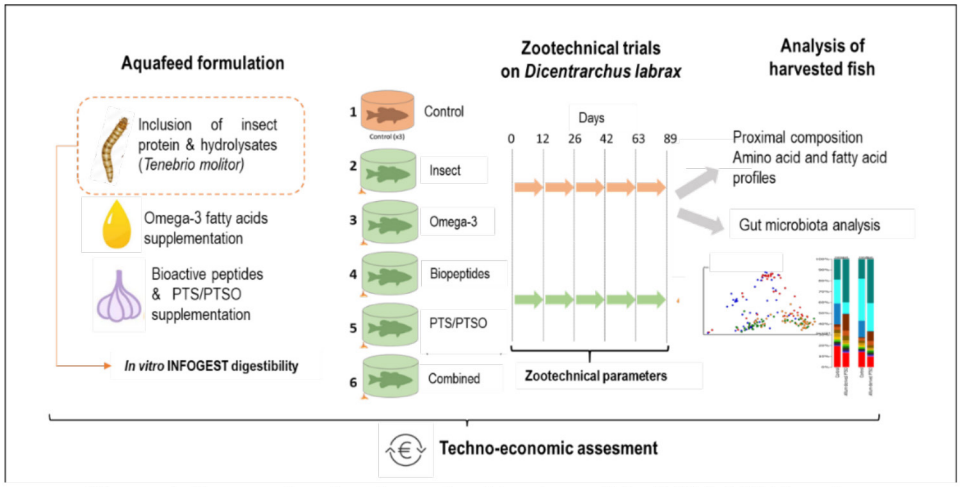

**Figure 1.** Layout showing the main objectives of the PCM_00044 project

*(Continued on next page)*

**Materials and Methods**

The project PCM_00044 engages a transdisciplinary consortium, led by the BIO-110 Research Group from the Department of Chemical Engineering at the University of Granada (UGR) with the collaboration of the BIO-160 Group from the Department of Microbiology (UGR) and the Aquaculture Technology Centre of Andalusia (CTAQUA). Two private partners are involved in the project, DMC Research Center Ltd. and TEBRIO Ltd. as suppliers of the allium-derived extracts and the defatted mealworm meal, respectively. As shown in the Figure 1, the project tasks are distributed into four main workpackages (WP), devoted to the formulation of aquafeeds and *in vitro* validation by the INFOGEST method adapted for European seabass (*Dicentrarchus labrax*). The lipid ingredient was formulated by enrichment of the standard fish oil with ARASCO® (DSM Nutritional Products, Switzerland) to meet the nutritional recommendations for larval and juvenile rearing. Sunflower (*Helianthus annuus*) seed hydrolysates (DH 10%) and a blend of extracts derived from *Allium spp.* (PTS/PTSO) were chosen as bioactives.

Six experimental diets were tested through a 12-week feeding trial in CTAQUA, involving 1,170 seabass juveniles (initial weight: 3.25 ± 0.33 g) reared in an 18-tank (100 L each) recirculating aquaculture system (RAS): (D1) a commercial control diet for pre-growing seabass, (D2) 25% w/w of the protein replaced by *T. molitor* protein partially hydrolysed (15% w/w of protein); (D3) diet supplemented with ARA; (D4) diet with sunflower seed peptides; (D5) diet containing allium-derived extract and (D6) a combined diet (insect protein, ARA and biopeptides). Growth performance was monitored throughout the trial, with immunological assessments conducted at termination. The analysis of the harvested fish after feeding trial had two goals: (i) nutritional evaluation of fish flesh and lipid content and (ii) analysis of intestinal microbiota DNA and mucus. Finally, the feasibility of the new aquafeed formulations was estimated by a techno-economic assessment.

**Results and discussion**

The experimental diets presented no significant differences against control diet in terms of survival rate (SR), specific growth rate (SGR), feed conversion ratio (FCR), Fulton's condition factor (K) and hepatosomatic index (HSI). The survival rate exceeded 95% for all the diets, with a final body weight above 40 g at the end of the feeding trial. Harvested fish flesh and oil presented no significant differences among experimental diets. The fatty acid profiles show significant levels of omega-3 fatty acids (EPA, DHA, ALA) The muscle amino acid profile stands out for the content of essential amino acids (29–31% w/w).

**Conclusion**

This study supports the feasibility of replacing fish meal by partially hydrolysed insect meal, as well as supplementation with functional ingredients such as omega-3 fatty acids, plant biopeptides and allium-based extracts in European seabass feeds. Immune response and gut microbiota profiling analysis —currently in progress— are necessary to confirm the effect of the experimental diets on reared fish.

**Acknowledgement**

This research was funded by the project PCM_00044, granted by the Consejería de Universidad, Investigación e Innovación (Junta de Andalucía), Government of Spain and NextGenerationEU-European Union. DMC Research Center Ltd. and TEBRIO Ltd. are acknowledged for their scientific advice and the provision of defatted mealworm meal and allium-derived extracts, respectively.

# FINE-TUNING SPOROVACCINES TO IMPROVE ORAL IMMUNISATION IN THE AQUACULTURE SECTOR

B. Guedes[1,2*], G. Gonçalves[1,2], R.A. Santos[2], A. Oliva-Teles[1,2], A. Couto[1,2], C. R. Serra[1,2]

Email: bguedes@ciimar.up.pt

## Introduction

The aquaculture sector has experienced remarkable growth in recent decades. In 2022, global aquaculture production of aquatic species surpassed capture fisheries for the first time, highlighting the sector's vital role in meeting global food demand (FAO, 2022). However, bacterial diseases continue to pose a significant threat to sustainable aquaculture, resulting in substantial animal losses and the overuse of antibiotics (Santos & Ramos, 2018). As antibiotic resistance increases, developing effective alternatives is important for safeguarding human, animal, and environmental health. Vaccination is the most sustainable approach for disease prevention, consequently reducing the industry's dependence on antibiotics. Among the various immunisation strategies employed in aquaculture, oral vaccination stands out for its ease of administration, and suitability for mass delivery, particularly to larvae and juvenile fish (Mondal & Thomas, 2022).

This project researches the use of *Bacillus subtilis* spores as vehicles for delivering heterologous antigens to the fish gastrointestinal tract (Gonçalves et al., 2022). We aim to utilise this spore-based vaccination system for the prevention of important aquaculture infectious diseases. Additionally, we seek to enhance spore-based vaccines or SporoVaccines immunogenicity by incorporating molecular adjuvants that target specific immune receptors, thereby amplifying mucosal and systemic immune responses. While adjuvants are well-established in injectable vaccines, their application in oral immunisations remains largely underexplored. By combining these adjuvants with our SporoVaccines, our approach has the potential to improve oral vaccination performance.

## Materials and Methods

To develop the SporoVaccines, key immunogenic proteins from two major bacterial pathogens in aquaculture *(A. salmonicida* and *S. iniae*) were fused to the spore coat protein *CotY*, allowing the antigens to be stably anchored to the spore's surface, ready to interact with the fish's immune system. To try to enhance SporoVaccines efficacy, molecular adjuvants were also fused to a different spore coat protein, *CotZ*. Currently, *in vivo* trials with zebrafish larvae (*Danio rerio*) are being conducted to evaluate vaccine efficacy by testing and comparing different vaccination strategies: (i) spores carrying only antigens; (ii) co-delivery of spores carrying antigens and spores carrying adjuvants; (iii) co-expression of antigens and adjuvants on the same spore.

## Future Perspectives

After identifying the most promising SporoVaccines candidates in the zebrafish trials, the top-performing SporoVaccines will be tested in economically important fish species. European seabass (*Dicentrarchus labrax*) and rainbow trout (*Oncorhynchus mykiss*) will be used as biological model species.

The outcomes of this research are expected to provide a novel and scalable approach to fish vaccination, contributing to disease control in various commercially important aquaculture species. By reducing the need for antibiotics, this work also supports the transition towards a more sustainable, health-conscious, and environmentally friendly aquaculture industry.

# MATERNAL TRANSCRIPTOME BIOMARKERS FOR EGG QUALITY IN LONGFIN YELLOWTAIL AND PACIFIC RED SNAPPER

Danitzia A. Guerrero-Tortolero and Rafael Campos-Ramos

Centro de Investigaciones Biológicas del Noroeste (CIBNOR)
Calle Instituto Politécnico Nacional 195
La Paz, B.C.S. 23096, Mexico

E-mail: daguet04@cibnor.mx

## Introduction

The longfin yellowtail (*Seriola rivoliana*) and the Pacific red snapper (*Lutjanus peru*) are commercially important aquaculture marine species. These species mature and spawn spontaneously in captivity, which represents an advantage in the control of reproduction. However, the egg quality among spawns is variable yet unpredictable, where poor-quality spawns may show low early larval survival and body deformities. Therefore, we investigated differential expression levels of maternal transcripts between poor and good newly fertilized eggs.

## Materials and methods

We collected spawns during 2023 and 2024. Each spawn was collected after ~ two hours of fertilization. We analyzed zootechnical and biochemical measurements and larval survival to distinguish good vs poor spawns. Then, we investigated expression levels of maternal transcripts through RNA-Seq and RT-qPCR. Transcriptome libraries were constructed using NEBNext® Ultra II™ RNA Illumina and mapped to the reference genome of *Seriola dumerili*. We analyzed differential expression, GO and KEGG enrichment analysis, and validated many maternally derived DEGs by RT-qPCR.

## Results

Body abnormalities will lead to deformed and lethargic larvae with low survival (Fig.1A). Poor-quality eggs were characterized by a disruption in Wnt signaling, Tight junction, Oxidative phosphorylation and Ribosome (Fig. 1B).

Larval survival at the onset of exogenous feeding was the only accurate criterion of egg quality. Body abnormalities can be detected from the prehatch stage, leading to deformed and lethargic larvae with low survival. Notably, in *Seriola rivoliana*, poor-quality eggs were characterized by a disruption in protein synthesis (Ribosome), energy production, and the Wnt-signaling pathway. In contrast, we found that in *Lutjanus peru*, poor-quality eggs were only characterized by a disruption in protein synthesis (Ribosome).

## Discussion

Our study agrees with recent research on zebrafish. This study revealed that poor-quality eggs contained an aberrant proteomic profile that lacked proteins involved in protein synthesis and energy and lipid metabolism, implicating a Wnt signaling in this maturation defect that prevents a proper transit through oocyte final maturation (Yilmaz et al. 2017).
Additionally, gene knockdowns of many ribosomal proteins in morphant zebrafish larvae resulted in a specific phenotype, with varying degrees of abnormality in the brain, body trunk, eyes, and ears at about 25 hours post-fertilization (Uechi et al. 2006).

Disrupted ribosome genes such as *rps3a* and *rpl35* could be involved in many body deformities (Uechi et al. 2006).

The *uqcrc2* gene is essential for the electron transport chain in energy production. The downregulation of this gene may lead to suboptimal mitochondrial functioning. In zebrafish, high oocyte ATP levels occur during the G2-M1 transition, where the insulin-like growth factor-1 (IGF1) signaling plays a crucial role in regulating mitochondrial bioenergetics (Biswas et al. 2023).

*(Continued on next page)*

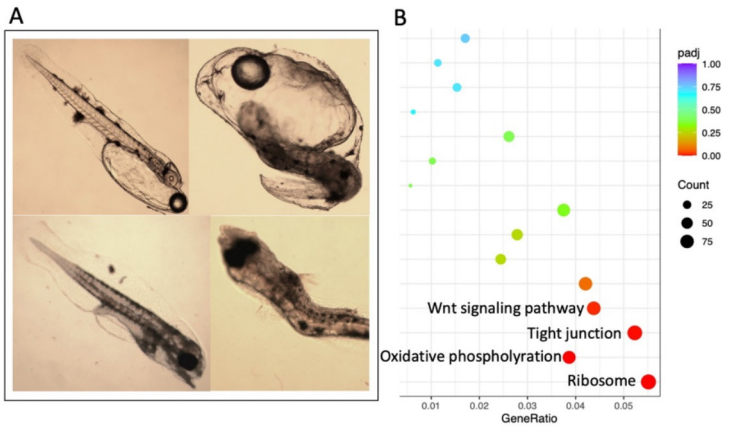

Figure 1A. Healthy hatched (Top left) and mouth opening (Bottom left) larvae. Deformed hatched (Top right) and mouth opening (Bottom right) larvae.
Figure 1B. KEEG enrichment. Red circles were significantly downregulated.

Regarding the Wnt-signaling, it targets cyclin D1(*ccnd1*), regulating the G1 to S phase transition (Röhrs et al. 2009). Frizzled receptors, such as the *fzd7* gene. In *Xenopus laevis*, embryos derived from oocytes depleted of maternal *Xfz7* RNA were deficient in dorsal-anterior structures (Sumanas et al. 2000). During embryonic development in Japanese flounder, *Paralichthys olivaceus,* it was found that *fzd7* was highly expressed during the blastula stage (Hao et al. 2021).
The dickkopf Wnt signaling pathway inhibitor (*dkk1*) gene negatively modulates the Wnt β-catenin pathway. In both *Xenopus* and zebrafish, Dkk1 interacts with the Dally-like homolog Knypek. It regulates gastrulation movements, developing the neural tube and other tissues (Caneparo et al. 2007).

Other genes not disrupted, but essential to assess egg quality, were cyclin B2 *ccnb2* regulating the G2 to M phase transition (Fernández Míguez et al. 2024). The *stk10* gene encodes a serine/threonine kinase with a critical role in oocyte maturation, by acting as a kinase that phosphorylates and activates Plk1, a polo-like kinase (Qian et al. 1998).
Therefore, we found many genes that can be used as biomarkers to assess egg quality and monitor the maternal-to-zygotic transition in this species.

# CONDITION DEPENDENT EXPRESSION OF MELANIN-BASED SKIN PIGMENTATION IN ATLANTIC SALMON (*Salmo salar*)

Gunnes M*, Green EAL, Andersen IL & Øverli Ø.

Faculty of Biosciences
Norwegian University of Life Sciences
Ås, Norway
E-mail: Mikkel.gunnes@nmbu.no

## Introduction

Access to food is a fundamental welfare requirement for farmed fish, directly influencing growth, body condition, and survival. Feed intake and appetite are shaped by environmental factors, social dynamics, and individual variation, making these traits important welfare indicators alongside growth rate and condition (Jobling et al., 2012; Noble et al., 2018). Identifying non-invasive markers of feeding history could provide valuable tools for welfare assessment. Melanin-based traits are linked to condition, stress responsiveness, immune function, and resource-holding potential across vertebrates, suggesting they may act as honest indicators of quality (Roulin & Ducrest, 2011). In Atlantic salmon, more spotted individuals show lower stress reactivity and reduced parasite load (Kittilsen et al., 2012), and in rainbow trout, pigmentation patterns have been genetically linked with faster growth (Rodríguez et al., 2019). Under controlled feeding and nutritional conditions, we test whether variation in feed intake is associated with the development and expression of melanin-based skin pigmentation in juvenile Atlantic salmon.

## Methods

Twelve juvenile Atlantic salmon (control group; 229.7 ± 49.4g, mean ± SD) from a larger experiment were transferred to isolation in 50L compartments within glass aquaria after one year of group rearing (Fig.1A). Fish were hand-fed (max. 1% BW $day^{-1}$) for three weeks to enable detailed monitoring of daily feed intake. Photographs (both sides) and biometric measurements were collected at the start and end of the isolation period to assess changes in melanin-based skin pigmentation and growth. Melanin-based skin spots within the region of interest (ROI; Fig.1B) were manually counted in ImageJ using the "cell counter" plugin, and ROI area was measured to calculate spot density (spots/$cm^2$).

## Results and discussion

All fish displayed stress-induced anorexia immediately after transfer to a novel environment, but feed intake gradually increased throughout the observation period (Fig. 2A). Despite previous studies linking pigmentation patterns to growth in rainbow trout, pre-existing variation in melanin spot density was not predictive of performance (feed intake, growth, and change in K-factor) during acclimation to a novel environment. In contrast, melanin spot pattern development was tightly linked to individual performance. Change in spot density was strongly positively correlated with growth (% BW; Spearman's $\rho = 0.87$, $p < 0.001$; Fig. 2B), total feed intake (% BW; $\rho = 0.86$, $p = 0.001$), and change in condition factor ($\rho = 0.80$, $p = 0.003$), indicating that the development of melanin-based pigmentation patterns closely reflects recent growth and feeding history. These findings highlight spot density and contrast changes as a promising welfare indicator in farmed Atlantic salmon, with potential for integration into automated image or video monitoring systems. Such monitoring could offer insight into recent feeding history and individual condition without additional handling stress, following validation under commercial farming conditions.

*(Continued on next page)*

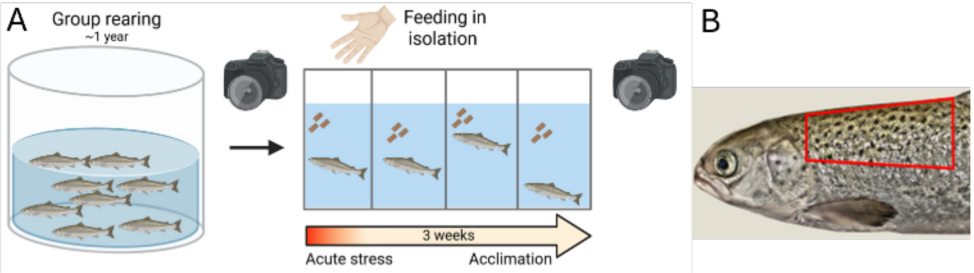

**Fig.1: A)** Overview of experimental design. **B)** Photo illustrating the region of interest (ROI) used for quantification of melanin skin spots. Landmarks of the ROI: end of the gill-lid to the base of the dorsal fin (horizontally) and from the lateral line to the top of the dorsal side (vertically).

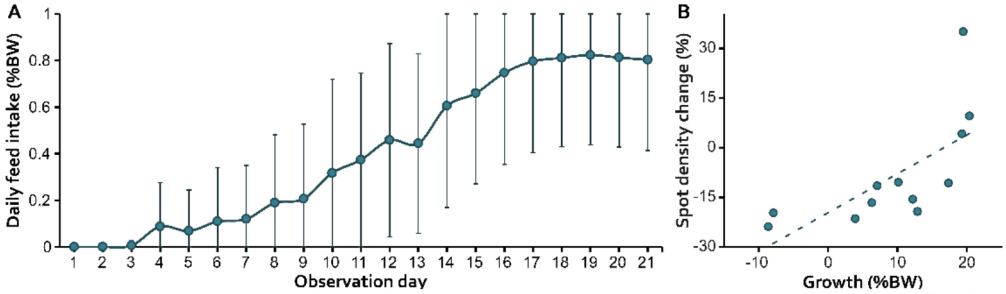

**Fig.2:** Feeding response and pigmentation dynamics in juvenile Atlantic salmon following transfer to isolation**. A)** Average ± SD daily feed intake (% body weight; limit 0-1) over a 21-day period in a novel environment. **B)** Linear relationship between growth (% body weight gain) and change in melanin-based skin spot density. Regression line shows that growth significantly predicted pigmentation change (β = 1.17, 95%CI: [0.29, 2.06], $p$ = 0.014, $R^2$ = 0.47) with higher growth associated with greater retention or development of melanin spots.

## Introduction

With the expansion of the aquaculture sector and pressure to reduce fishmeal (FM) use, there was an increase in dietary incorporation of plant-feedstuffs (PF). Although PF are a good alternative, they possess non-starch polysaccharides (NSPs) that fish are not able to digest and thus, might compromise fish intestinal integrity and diets digestibility, ultimately affecting fish performance (Sinha et al., 2011). Probiotics are living organisms that upon ingestion in certain amounts exert health benefits beyond inherent basic nutrition (Guarner and Schaafsma, 1998). Among the reported beneficial effects is the capacity to produce enzymes that hydrolyse NSPs and enhancement of host immune status and gut histomorphology (Pérez-Sánchez et al., 2014; Serra et al., 2019). The present study aimed to assess the effect of a novel sporeforming probiotic strain with NSPase (Non-Starch Polysaccharides-active hydrolases) activity incorporated in a PF-based diet, on gilthead seabream gut health and functionality through the measurement of intestinal digestive enzymes, antioxidant and immune-status, and histomorphology.

## Material and Methods

Gilthead seabream juveniles (34g) were fed two isoproteic (47% protein) and isolipidic (17% lipids) diets: one control diet mainly PF-based (blend of soybean, rapeseed and sunflower meal, wheat and corn gluten, soy protein concentrate), with 12.5% fishmeal inclusion, and a diet similar to the control but supplemented with a probiotic *Bacillus* ($2.23x10^9$ CFU $Kg^{-1}$ bacterial isolate (FI99), Serra et al., 2019). Each diet was fed to triplicate groups of fish twice daily until visual satiation, 6 days a week, during 11 weeks. At the end of the trial, 3 fish per tank were sampled 5 hours after the morning meal for collection of intestines for measurement of specific activities of digestive (total alkaline proteases, lipase, α-amylase) and antioxidant (superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPX), glutathione reductase (GR)) enzymes and oxidative damage biomarker for lipids (LPO). Intestine of 2 other fish per tank were sampled for expression analysis of immune-related (*interleukin-10* (*il-10*), *interleukin-1-β* (*il-1β*), *cyclooxygenase 2* (*cox*), *immunoglobulin M* (*igM*)) and oxidative stress-related (*heat shock protein 70* (*hsp70*), *cat*, *sod*, *gpx*) genes and for histological processing and morphological evaluation. All data were analysed by one-way ANOVA with a significant level of 0.05 used for the rejection of the null hypothesis.

## Results

Intestinal digestive enzyme activity (total alkaline proteases, lipase, α-amylase), immune-related (*il-1β*, *cox*, *igm*) and oxidative stress-related (*hsp70*, *cat*, *sod*, *gpx*) gene expression, as well as SOD and CAT activities and histomorphology, were not affected by probiotic inclusion. However, *il-10* expression was lower in fish fed the probiotic diet. GPX and GR activities, along with LPO level, are currently being determined.

## Conclusions

Dietary supplementation with the tested probiotic and supplementation level had no major effect in gilthead seabream gut health and functionality. The observed reduction in *il-10* expression suggests that probiotic inclusion modulated the anti-inflammatory response without promoting intestinal inflammation, as pro-inflammatory markers remained unchanged.

## Introduction

In an aquaculture context, feed intake (FI) assumes high importance, since growth needs to be maximized and conversion of ingested feed into growth increment must be optimized. Control of FI is crucial for proper growth and development of animals and it is under endocrine control. Plant feedstuffs (PF), which are increasingly being used in aquafeeds are rich in non-starch polysaccharides (NSP, undigestible for fish), thus compromising PF nutritional value (Sinha et a., 2011). However, gut microbiota with the capability of producing non-starch polysaccharides degrading enzymes (NSPases) are able of fermenting NSP (Serra et al., 2019). Moreover, the importance of gut bacteria in fish metabolism was already shown (Butt and Volkoff, 2019) and a connection between probiotics use and changes in appetite-related hormones was already established (Guerreiro et al., 2025). Thus, the present study aimed to assess the effect of a novel sporeforming probiotic strain with NSPase (Non-Starch Polysaccharides-active hydrolases) activity incorporated in a PF-based diet, on gilthead seabream growth, FI, feed utilization, plasmatic metabolites, and appetite-related gene expression.

## Material and Methods

Gilthead seabream (*Sparus aurata*) juveniles (34g) were fed two isoproteic (47% protein) and isolipidic (17% lipids) diets: one control diet mainly PF-based (blend of soybean, rapeseed and sunflower meal, wheat and corn gluten, soy protein concentrate), with 12.5% fishmeal inclusion, and a diet similar to the control but supplemented with a probiotic *Bacillus* ($2.23x10^9$ CFU $Kg^{-1}$ bacterial isolate (FI99) Serra et al., 2019). Each diet was fed to triplicate groups of fish twice daily until visual satiation, 6 days a week, during 11 weeks. At the end of the trial, fish in each tank were bulk-weighed after one day of fasting. After the final weighing fish continued to be fed for 3 more days to minimize manipulation stress and then 3 fish per tank were sampled 5 hours after the morning meal for collection of blood from the caudal vein, for plasma metabolites analysis, and of hypothalamus, anterior intestine, stomach and liver for expression analysis of appetite-related (*agouti-related protein* (*agrp*), *neuropeptide Y* (*npy*), *cocaine- and amphetamine-regulated transcript 2* (*cart*), *cholecystokinin* (*cck*), *peptide YY* (*ppy*), *leptin*, *ghrelin*) genes. All data were analysed by one-way ANOVA with a significant level of 0.05 used for the rejection of the null hypothesis.

## Results

Gilthead seabream final body weight, FI, feed efficiency, plasmatic glucose, cholesterol and triacylglycerides, gene expression of hypothalamus *agrp*, *npy* and *cart*, intestine *cck* and *pyy*, liver *leptin*, and stomach *ghrelin* were not affected by dietary probiotic inclusion (Table I).

## Conclusions

Dietary supplementation with the tested probiotic and supplementation level had no effect in gilthead seabream growth performance, FI, feed efficiency, plasmatic metabolites, or appetite-related gene expression. However, there was a tendency toward improved feed efficiency in fish fed the probiotic diet, while the high variability in fish final body weight among fish in the control group prevented the detection of potential growth differences.

Pharmaceutical pollution in aquatic systems increasingly threatens non-target organisms such as cladocerans. While acute effects of veterinary antibiotics are well documented, little is known about their chronic and multigenerational toxicity, particularly under realistic environmental scenarios. Conventional wastewater treatment plants remove only 32–78% of antibiotics, and even advanced treatments seldom assure complete elimination—for example, sulfamethoxazole removal in membrane bioreactor (MBR) systems was shown to be as low as 6.5%. These concerns are amplified in conflict-affected regions such as Ukraine, where war-related destruction of wastewater infrastructure has led to the discharge of untreated sewage including pharmaceutical residues into freshwater bodies, increasing ecological and public health risks.

In this study, we investigated the multigenerational toxicity of three widely used veterinary antibiotics—ciprofloxacin (CIP), sulfamethoxazole (SMX), and tetracycline (TC)—on the cladoceran *Ceriodaphnia dubia*. A semi-static exposure design was applied across three consecutive generations (F1–F3), with test concentrations ranging from 0.1 to 10 mg/L. Key life-history parameters including survival, reproductive success (offspring per surviving female), total population output, and adult body length were assessed after 21 days of exposure in each generation.

The results revealed strong generation-dependent effects. TC was the most toxic compound, reducing survival to 10–20% in F2 and F3 at 3 mg/L and causing near-complete reproductive failure. CIP significantly suppressed reproduction and population growth beginning at 0.1 mg/L, with 60% mortality observed in F3 at 10 mg/L. SMX showed a biphasic response: at 0.1 mg/L in F2, reproduction was stimulated by ~50%, whereas 5 mg/L led to consistent inhibition of reproduction and reduced body size. SMX had no significant effect on survival at any concentration.

These findings highlight the ecological relevance of low-dose, chronic antibiotic exposure and the potential for lasting impacts on zooplankton populations through multigenerational disruption. The results underscore the importance of integrating long-term biological endpoints into environmental risk assessments, particularly in light of incomplete pharmaceutical removal by wastewater treatment and increasing vulnerability of aquatic ecosystems in regions affected by war or infrastructure collapse.

# THE IMPORTANCE AND BACKGROUND OF DATA COLLECTION: CASE STUDY FROM HUNGARY

Ágnes Irma György[1*], Mónika Bojtárné Lukácsik[1], Gabriella Kiss[1], Krisztián Szabó[1], Alexandra Ferencz-Havel[1], Katalin Rácz[1], Pál Goda[1], Zoltán Bokor[1], Béla Urbányi[1,2]

1Institute of Agricultural Economics, Department of Aquaculture and Fisheries Analysis, H-1093 Budapest Zsil u. 3-5
2University of Győr, Albert Kázmér Faculty of Mosonmagyaróvár, H-9200 Mosonmagyaróvár, Hungary, Vár Square 2
E-mail: gyorgy.agnes@aki.gov.hu

Freshwater aquaculture plays a vital role in ensuring global food security, livelihood sustainability, and economic development, particularly in developing regions.

However, the sector faces significant challenges related to productivity, ecological services, and market access. A robust data collection framework is essential to address these issues effectively. By systematically gathering, managing, and analysing key data, stakeholders can make informed decisions that enhance operational efficiency and ecological balance. Moreover, standardized data facilitates research, policymaking, and resource allocation, fostering transparency and traceability throughout the aquaculture value chain.

The fisheries Data Collection Framework (DCF) was set up by the European Commission in 2000 to collect, manage and use data in the fisheries sector, to support scientific advice on the Common Fisheries Policy and to monitor and evaluate fisheries activities and resources. In Hungary, the implementation of the tasks of the DCF, as well as further relevant data collections and studies related to the fisheries sector are carried out by the Institute of Agricultural Economics under the Hungarian Fisheries Operational Programme Plus (MAHOP Plusz), co-financed by the Hungarian budget (30%) and the European Maritime, Fisheries and Aquaculture Fund (EMFAF, 70%). As part of this project, the Institute also devotes considerable resources to improving its fisheries data collection system to increase the availability and visibility of data.

The presentation will describe the developments and data collections planned under the Hungarian DCF project, the expected results, and the potential risks and ways to manage them.

These abstract underscores the critical need for implementing structured data collection systems to optimize performance, minimize risks, and support the sustainable development of freshwater aquaculture.

The work is supported by MAHOP_PLUSZ-1.2.1-24-2024-00001 project.

# ADVANCING AQUACULTURE PERFORMANCE THROUGH NANOBUBBLE TECHNOLOGY: CASE STUDY RESULTS FROM MOLEAER DEPLOYMENTS IN *Salmonid* PRODUCTION

J.E. Haagensen*

Moleaer Inc.
3232 W. El Segundo
Hawthorne, California, 90250 USA
janeric@moleaer.com

## Introduction

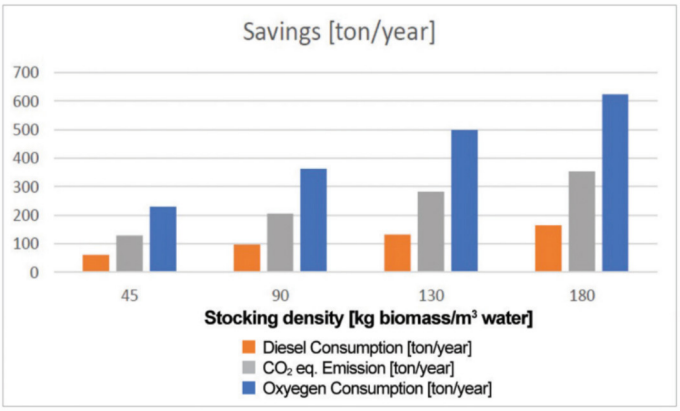
Nanobubble technology, characterized by the generation of gas-filled bubbles under 200 nanometers in diameter, is quickly gaining adoption in aquaculture due to its unique gas-transfer abilities and water-modifying properties. While interest in this technology is growing, successful outcomes depend on precise integration, tailored deployment strategies, and optimization of nanobubble concentration.

Moleaer's nanobubble generators have been tested and validated in diverse aquaculture environments to assess their impact on oxygenation efficiency, water quality, and fish welfare. This abstract synthesizes outcomes from four field case studies: SalMar InnovaNor (waiting cages, Norway), Australis Seafoods (holding tanks, Chile), Lødingen Fisk (RAS Section, Norway) and Rostein (Well boat, Norway). Moleaer's nanobubble solutions were integrated to optimize oxygenation efficiency, water quality and fish welfare.

Nanobubbles differ from conventional macro- and micro-bubbles in both behavior and impact. Their small size and near-neutral buoyancy allow them to remain suspended in water for extended durations, enabling uniform oxygenation without the rapid rise and burst of larger bubbles. Their stability enables more efficient gas dissolution, resulting in higher oxygen transfer efficiency (OTE) and more consistent dissolved oxygen (DO) levels, even in deep zones. Moreover, nanobubbles catalyze localized physical, biological, chemical effects – that support microbial suppression and improved biofilm control. When precisely integrated and optimized, these effects provide a sustainable solution for operators to reduce costs and lower emissions while enhancing fish welfare, water quality, and system performance and efficiency.

## Results

In SalMar InnovaNor's waiting cages at their Senja processing facility in Norway, Moleaer's submersible nanobubble generator was evaluated under varying oxygen demands. The system achieved OTE >85% under all flow conditions, with average DO levels rising from 46.5% to 88%. Importantly, the technology allowed SalMar to maintain optimal DO levels even during summer high-temperature events, enabling increased fish crowding capacity without compromising welfare. Operators reported more rapid and flexible response times, improved stress recovery, and more efficient bleed-out processing.



*(Continued on next page)*

At the Dumestre plant of Australis Seafoods in Chile, two nanobubble generators were installed in a 1,000 m³ holding tank. The upgrade reduced oxygen consumption by 63% compared to the previous Venturi-based system and enabled an increase in stocking density from 90 kg/m³ to 120 kg/m³ without compromising fish welfare. Notably, the fish exhibited firmer scales and less flaking, correlating with improved water quality and reduced stress indicators.

Within the first 48 hours of integrating the technology at the start-feeding system RAS section of Lødingen Fisk's in Norway. Over 50 days of continuous use, ammonia removal rates increased by 68%, water turbidity dropped by 30%, and ozone usage for disinfection decreased by 67%. Oxygen Transfer Efficiency exceeded 94%.

Rostein AS, a leading Norwegian well boat operator, integrated Moleaer's solutions to enhance oxygenation efficiency during live fish transport. The implementation resulted in 86% Oxygen Transfer Efficiency (OTE), effectively doubling the efficiency compared to the previous injector system. This translates into an estimated annual oxygen savings ranging from 230 to 360 tons, estimated annual diesel fuel reduction between 60 to 100 tons, and projected reduction in greenhouse gas emissions between 130 to 200 tons per year.

These improvements not only reduced operational costs and environmental impact but also contributed to maintaining optimal fish welfare during transportation.

Nanobubbles enabled better DO stability, reduced reliance on supplemental oxygen, and supported improved fish handling outcomes during stressful periods. These results suggest that nanobubble technology offers a scalable, adaptable solution for improving water quality, fish health, and efficiency across various production stages and system types.

**Conclusion**

The precise and optimized integration of nanobubble technology has consistently demonstrated measurable benefits across four commercial-scale aquaculture operations. These include improved oxygenation efficiency, enhanced biofiltration performance, better fish welfare, alongside reductions in resource consumption and operational costs.

Moleaer's case studies highlight the versatility of nanobubble solutions across multiple aquaculture applications including RAS, waiting cages, and wellboats. As the industry pursues scalable strategies for sustainable growth, nanobubble technology offers a scientifically backed solution to enhance production efficiency and environmental resilience. Ongoing research will continue to refine the mechanisms and expand applications across additional species and system types.

# BIO-BASED ELECTROCHEMICAL SYSTEM FOR EVALUATING ECOTOXICOLOGICAL THREATS IN THE MARINE ENVIRONMENT

salma.hafed@ua.es

The integrity of marine ecosystems is increasingly threatened by anthropogenic pollutants, particularly pesticides such as herbicides, fungicides, and insecticides that enter coastal and open ocean waters through agricultural runoff and atmospheric deposition. These substances, especially organophosphorus and carbamate insecticides, can exert toxic effects at trace levels, disrupting aquatic food chains, harming marine biodiversity, and affecting biochemical pathways in organisms.[1,2]induced by various inhibitors, leads to acetylcholine accumulation, hyperstimulation of nicotinic and muscarinic receptors, and disrupted neurotransmission. Hence, acetylcholinesterase inhibitors, interacting with the enzyme as their primary target, are applied as relevant drugs and toxins. This review presents an overview of toxicology and pharmacology of reversible and irreversible acetylcholinesterase inactivating compounds. In the case of reversible inhibitors being commonly applied in neurodegenerative disorders treatment, special attention is paid to currently approved drugs (donepezil, rivastigmine and galantamine Among the biological targets most affected is acetylcholinesterase (AChE, EC 3.1.1.7), an enzyme critical for neural function in both vertebrates and invertebrates.

Given the ecological importance of maintaining marine health and the increasing concern over pollutant accumulation, it is essential to develop monitoring tools that are both sensitive and adaptable to in-situ conditions. Traditional analytical methods, such as HPLC,[3] capillary electrophoresis (CE),[4] or colorimetry,[5]homogenates, cell suspensions, etc., has been described. The enzyme activity is measured by following the increase of yellow color produced from thiocholine when it reacts with dithiobisnitrobenzoate ion. It is based on coupling of these reactions: {A figure is presented} The latter reaction is rapid and the assay is sensitive (i.e. a 10 µ1 sample of blood is adequate though effective, are limited by the need for sophisticated instrumentation, extensive sample preparation, and operation in centralized laboratories. In contrast, biosensors offer significant advantages for environmental monitoring, including simplicity, portability, low cost, high specificity, and the potential for real-time detection.[6]there is a lack of monitoring of these contaminants. Traditional chromatographic methods - high-performance liquid chromatography, capillary electrophoresis, and mass spectrometry - are effective for the analysis of pesticides in the environment but have certain limitations such as complexity, time-consuming sample preparation, and the requirement of expensive apparatus and trained persons to operate. Over the past decades, acetylcholinesterase (AChE

In this work, we present the design and development of an electrochemical biosensor specifically tailored to detect neurotoxic pesticides in seawater via indirect monitoring of AChE activity. The strategy is based on the enzymatic hydrolysis of *p*-acetoxyphenol, a non-electroactive substrate, into hydroquinone, which is electrochemically active and easily detected using cyclic voltammetry.[7] The core of the biosensor consists of AChE immobilized within a stable sol-gel silica matrix, a material that ensures enzyme retention, biocompatibility, and optimal catalytic conditions in the marine environment.

Kinetic studies confirmed the enzymatic hydrolysis reaction, while inhibition experiments using malathion demonstrated a clear, concentration-dependent reduction in enzymatic activity. These findings support the sensor's capability to quantify pollutant levels based on the degree of AChE inhibition, offering a bio-relevant and functional measurement of ecotoxic risk.

*(Continued on next page)*

To enhance its applicability in real-world conditions, the AChE-based sensor has been integrated into a custom-designed microfluidic cell. This configuration allows precise control of small sample volumes, minimizes reagent use, and enables continuous monitoring. Moreover, the compact and modular nature of the microfluidic platform facilitates its incorporation into autonomous marine robotic systems. Our vision is to deploy this biosensor as part of a marine robot equipped for in-situ detection of neurotoxic contaminants, enabling early-warning monitoring of water quality and supporting sustainable ocean management.

This research will contribute to the development of next-generation biosensing technologies for marine environmental monitoring, aligning with global efforts to preserve ocean health and biodiversity.

## Introduction

Feed production relies on large amounts of bulk proteins, carbohydrates and oils, sometimes produced in remote areas and transported around the globe (Cottrell et al. 2020). Norway's current bioeconomy strategy emphasises the need to increase animal feed production based on domestic ingredientsto strengthen food security, increase sustainability and develop more climate friendly production. This requires a holistic system perspective that looks across multiple different potential sources of animal feed – both those available now, and those likely to become available in near future through the deployment of new raw materials and technologies. The mission of the SUSFEED project is to contribute to enhancing sustainability in Norwegian agriculture and aquaculture, business development and increased food security in Norway. The project aims to develop knowledge about how biological resources for feed production can be produced, distributed and used in a way that contributes to the development of sustainable and high-value agricultural and aquacultural sectors.

There are inadequate analyses of most new applications of novel bioresources for feed ingredients, as they are currently not included in commercial value chains. To address this challenge, we carried out four case studies, selected according to the following criteria: a) they are new applications of bioresources for feed; b) they represent different categories of bioresources (soil, wood, ocean, insect); c) they open up value chains across established sectors (agriculture, forestry, aquaculture); d) they are of interest to study at different stages in a potential value chain; and e) they are of commercial interest among companies. Grass proteins has a valuable amino acid profile comparable to soy proteins (Damborg et al., 2020), but the high fibre content need to be reduced before it can be digested properly by monogastric animals. Wood fibres can be made available in large amounts but is indigestible "as is" for most animals, however, fungal depolymerisation can be applied to improve digestibility. Microalgae provide proteins with optimal amino acid profile for fish and essential n-3-oils, but bioavailability is low. Insects are an established source of feed ingredients, but the nutritional profile of insect derived feed ingredients when reared on different substrates is poorly documented, therefore, the use of alternative feed stocks and their effects on the nutritional value of insects is important to understand. The aim of this study was to characterise these novel feed ingredients and their suitability in feed to identify opportunities and limitations in industrial upscaling and business development of new feed resource value chains.

## Materials and methods

**Case 1 – Grass:** Two different grass mixtures were harvested at different times over the season, characterised and fractionated into protein sediments, fibres and "brown juice" (GEP; Grass Protein Effluents). Grass proteins were used in a feeding trial on Atlantic salmon (*Salmo salar* L.), grass fibres were tested in feed for insects (Case 3), and the GEP was used as growth medium for microalgae cultivation (Case 4).

*(Continued on next page)*

**Case 2 – Wood:** Different wood (*Picea abies* and *Betula pubescens*) and fungal species (brown rot fungi: *Gloeophyllum trabeum, Fomitopsis pinicola, Fomotopsis rosea,* and white rot fungi: *Trametes versicolor, Phlebia centrifuga, Plaurotus ostreatus*) were subjected to different processing techniques and tested in insect feeding trials (Case 3) in combination with grass fibres (Case 1).

**Case 3 – Insects:** Grass fibres and fungal depolymerized wood chips were used in feeding trials for mealworms (*Tenebrio molitor*), house crickets (*Acheta domesticus*) and black solder fly larvae (*Hermetia illucens*). Further on, insect meal was used in two different feeding trials on Atlantic salmon and poultry. Insect frass, a co-product of insect production consisting of a mix of shed exoskeletons, droppings, and leftover feed, rich in essential nutrients and microminerals, was used as growth medium for cultivating microalgae (Case 4).

**Case 4 – Microalgae:** Non-axenic cultures of *Chlorella vulgaris, Chlorella sorokinana, Phaeodactylum tricornutum* and *Tetraselmis suecica* were cultivated to test the suitability of insect frass extract (IFE) and grass processing effluent (GPE) as microalgae growth mediums.

**Results and discussion**

Wood particles should be finely ground, significantly depolymerised by fungi and mixed with a feedstock that keeps the moisture in the feed to be used as insect feed. Similarly, grass fibres should also be processed into smaller particles and mixed with some other nutritional feed stock to be attractive as feed for different insects and maintain its moisture. Moreover, it appears that black soldier fly larvae and mealworms are more positive to the incorporation of depolymerised wood and grass fibres compared to house crickets. The chemical composition of GPE and IFE revealed that both solutions should be able to support microalgae growth, if certain microelements are added in bioavailable forms. However, we observed inhibitory growth effects of the GPE extract causing low yields and/or prolonged lag phases which warrants further investigation. Results from the feeding trials on Atlantic salmon and poultry are pending and will be presented.

**Introduction**

The general concept of sustainability and the components of sustainable development has now been well defined (FAO 1989). Sustainability is also one of the most important horizontal aspects of the European Green Deal's priorities. It means such transition in farm systems that is better adapted to environmental conditions, minimises environmental footprints, and preserves natural values. Beyond the formulation of the sustainability goals, to determine the environmental performance of the production systems developing sustainability metrics became more and more urgent. The evaluation of the environmental interactions of aquaculture technologies is also a key component in enhancing sustainability, a principle that is well reflected in the EU aquaculture policies such as Aquaculture Strategic Guideline and Aquaculture Assistance Mechanism.

Filling this knowledge gap wide range of indicator-based evaluations were developed in the latest year (FEAP 2022, Garlock et al. 2024, EC 2024, Nielsen et al. 2025). The aim of these assessments to measure performance of aquaculture production systems in the three key dimensions of sustainability: environmental, economic, community dimensions and comparing aquaculture management systems as well as evaluating the effectiveness of investment and reforms (Garlock et al. 2024).

Our analysis of the current indicators revealed that these methods basically focus for one-way industrial processes and not fully appropriate for evaluating circular production systems. Furthermore, when such circular systems are characterised using these indicators, the results are typically false and significantly lower than those obtained using a natural science-based approach (Knösche et al. 2004, Koushik et al 2020).

**Conceptual framework**

Pond farming in the EU concentrated in the Central Eastern European (CEE) region giving the vast majority of aquaculture production in these countries and being an important part of European agricultural heritage. The pond aquaculture sector produces yearly 80,000 tonnes of carp that is 26 percent of the total EU freshwater aquaculture production in volume and 260 million euros in value (EUMOFA, 2021). Pond farming applying circular approach is operated in a traditional, extensive production system. It is based on natural nutrient cycle and operates as an open ecological system, where natural and technological processes support each other (Halasi-Kovács 2022). It is a well-documented fact that extensive pond aquaculture provides a wide range of ecosystem services in addition to primary fish production (Willot et al. 2019, Palásti et al 2020, Sharma et al. 2024).

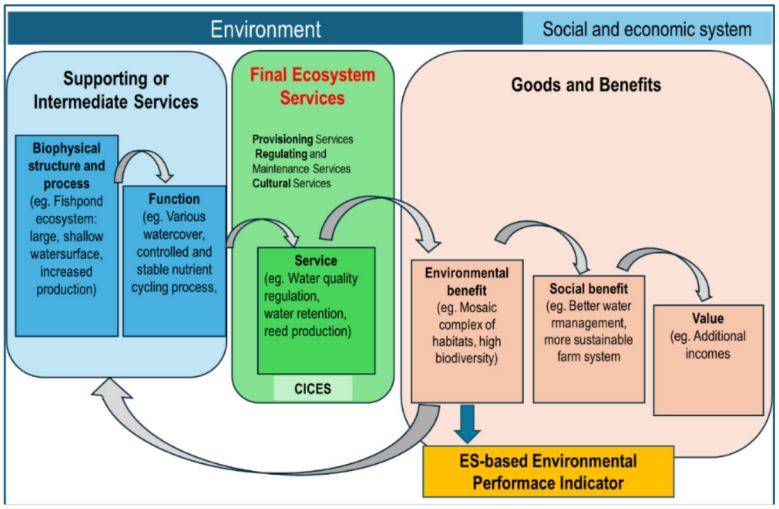
A comprehensive assessment of these services has not been conducted yet, and there is an absence of specific environmental performance indicator based on the evaluation of these systems. As a first step in formulating our evaluation system, the concept of ecosystem services (Haines-Young 2023) can provide a natural theoretical framework. However, being developed an indicator, we were facing different long-standing problem: (1) the difficulty of the quantification of ecosystem services; (2) confusion of terms. So, we modified the conceptual framework of ES by adding a new benefit category, the 'environmental benefits' that can well reflect the clear difference between the term of ecosystem service and environmental benefit. Furthermore, it provides an operational solution for developing ecosystem service-based environmental performance indicator that can be integrated in Environmental Impact Assessment (EIA) and Life Cycle Assessment (LCA) studies of fishponds.

**Next steps and results**

In the next step, the ecosystem services provided by fishponds will be assessed. Subsequently, the environmental benefits resulting from these services will be determined and evaluated. Ecosystem service-based environmental performance indicator will be developed and scaled based on the environmental benefits of pond aquaculture.

*(Continued on next page)*

**Figure 1.** Conceptual framework of the ecosystem-based environmental performance indicator



after Haines-Young and Potschin (2023)

The results of this research provide a clear concept and definitions of the ecosystem service-based environmental performance indicator and can provide tools for the evidence-based environmental evaluation of different circular approached extensive, low-trophic aquaculture systems.

## Introduction

Microalgae offer a sustainable alternative to conventional, chemical-intensive wastewater treatment by harnessing solar energy and converting excess nitrogen and phosphorus from wastewater into bioactive compounds that can be developed into valuable bioproducts (e.g. aquaculture feed). Among various microalgae, *Nannochloropsis oceanica* is particularly appealing due to its robust growth and high lipid content, especially omega-3 polyunsaturated fatty acids (e.g. C20:5n3 or Eicosapentaenoic acid EPA), a critical ingredient for the promotion of growth and immune development in farmed fish. However, scaling up microalgae-based wastewater treatment from laboratory to industrial scale remains a key challenge due to difficulty in maintaining tightly controlled environmental conditions at large scale. This study investigated how different nutrient supply modes (Single-Batch where nutrients are supplied at once at the beginning of cultivation cycle and Fed-Batch where nutrients are periodically replenished throughout cultivation cycle) affect microalgal performance in treating brewery wastewater and how feeding regime can be optimised when upscaling lab production to pilot-scale. The resultant microalgal biomass obtained from brewery-wastewater cultivation was then incorporated into feed formulations for seabream trials. The effect of *Nannochloropsis* biomass inclusion on fish growth and tissue health was assessed. Overall, our study demonstrates the potential of using *Nannochloropsis* to upcycle brewery waste into aquaculture feed, creating a circular food system which contributes to waste management sustainability in the brewing sector and alleviating dependence of farm fishing on wild-caught fish.

## Materials and methods

Raw brewery wastewater was collected onsite from a local brewer in Dublin, Ireland. A total of 4200 L of brewery wastewater were collected from February 2023 to October 2023. The microalgae *Nannochloropsis oceanica* (CCAP 849/10), obtained from Culture Collection of Algae and Protozoa (CCAP, SAMS Ltd., Oban, Scotland), were cultivated on the brewery wastewater. Two different cultivation regimes (Single-Batch and Fed-Batch) were implemented to evaluate the growth sensitivity of microalgae against scaling up the cultivation system, from bench scale (2L flasks and 10L carboys) to pilot scale (900 L PBR). Key nutrients in the wastewater (e.g. nitrate, phosphate) were continuously tracked to assess bioremediation efficiency The harvested biomass in PBR was also analysed in terms of lipid content, fatty acids profile, amino acids, and protein.

For seabream feeding trials, the harvested microalgal biomass from pilot-scale cultivation was then used to partially replace conventional protein and lipid sources in four isoproteic (48%) and isolipidic (18%) experimental diets, formulated to compare against commercial fishmeal-based feeds. A total of 840 fish with an average body weight of 11 g in 12 x 500 L tanks were fed with one of the four experimental diets for 96 days from April to July 2024 (70 fish per tank; 3 tanks per diet). Fish were weighed during the feeding period. At the end of the trial, the fish were randomly selected, anesthetized, and euthanized for biometric and organ index analyses, including liver and viscera weights to calculate hepatosomatic (HSI) and viscerosomatic (VSI).

*(Continued on next page)*

**Conclusions**

*Nannochloropsis* was successfully cultivated on brewery wastewater and systematically scaled up from bench to pilot scale. Under bench scale conditions, both cultivation modes achieved a maximum biomass concentration exceeding 1.2 g/L. However, in pilot scale, the early depletion of the nitrogen source under Single-Batch feeding regime resulted in algal growth stagnation and eventually bacterial takeover. In contrast, the Fed-Batch mode enabled continuous and stable biomass production up to 22 days, attaining a maximum biomass concentration of 1.31 g/L. Additionally, the mode of nutrient supply also affecteed microalgae composition and associated features relevant to their potential use as aquaculture feed. The Fed-Batch harvested biomass contained more protein (29.4% vs. 15.1% in biomass) and lipid (44.0% vs. 30.6% in biomass) compared to the Single-batch. In terms of fatty acid composition, Fed-Batch biomass is also enriched in monounsaturated fatty acids (39.6% vs. 29.5% in total fatty acids) and polyunsaturated fatty acids (13.7% vs. 11.7% in total fatty acids) relative to the Single-Batch biomass.

During the seabream trials, feeding *Nannochloropsis* biomass obtained from brewery waste cultivation as a protein and lipid replacement resulted in growth performance similar to a commercial fishmeal-based diets. Additionally, the histopathology of the liver and intestine cells in the fish highlighted that a high replacement of fishmeal and fish oil with *Nannochloropsis* did not trigger any apparent tissue damage and/or malfunction. These results are the first to demonstrate the potential of *Nannochloropsis* biomass cultivated on waste as a viable alternative source of lipids and protein in aquafeeds.

# PHOSPHORUS NUTRITION IN WHITELEG SHRIMP *Litopenaeus vannamei*: CURRENT KNOWLEDGE AND RESEARCH GAPS

Ali Hamidoghli* and Felipe Nobre Façanha

Skretting Aquaculture Innovation (AI)
Sjøhagen 6
4016 Stavanger, Norway
Email: ali.hamidoghli@skretting.com

Over the past two decades, the aquaculture production of whiteleg shrimp (*Litopenaeus vannamei*) has increased by 623%, reflecting the species' growing importance in global aquaculture. FAO reports indicate that global production of whiteleg shrimp has surpassed seven million tons per year, with China and Ecuador emerging as the primary producing countries. As market demand continues to rise, shrimp production is projected to exceed current margins, prompting the feed industry to place greater emphasis on refining nutritional strategies for this economically important species. Phosphorus (P) is an essential mineral in aquafeeds, playing a critical role in energy metabolism, nucleic acid synthesis, skeletal development, and exoskeleton in crustaceans. In whiteleg shrimp, efficient phosphorus nutrition is particularly important due to their fast growth rates, low tolerance to P deficiency, and the ecological implications of P leaching in intensive/extensive farming systems. Over the past two decades, considerable progress has been made in defining dietary phosphorus requirements, identifying available phosphorus sources, and improving assessment methodologies—including apparent digestibility studies and predictive modeling. However, major gaps remain, particularly in understanding phosphorus bioavailability from alternative and plant-based ingredients, the interaction of dietary P with other minerals, and the implications of high dietary P levels on shrimp health and water quality. Moreover, standardization of digestibility methods, especially under varying salinity and environmental conditions, remains a key challenge. This review synthesizes current knowledge on phosphorus nutrition in *L. vannamei*, identifies critical research gaps, and highlights opportunities for advancing precision nutrition and sustainability in shrimp aquaculture.

# OFFSHORE AQUACULTURE – TECHNICAL DEVELOPMENT OF A COMBINED AQUACULTURE PROCESS WITH FISH AND MUSSELS FOR THE COASTEL WATERS OF MECKLENBURG – VORPOMMERN

B. Damm, L. Hannawald, M. Zentner

Mecklenburg-Vorpommern Research Centre for Agriculture and Fisheries
Institute of Fisheries
Aquaculture Department
Fischerweg 408
18069 Rostock, Germany
b.damm@lfa.mvnet.de

The purpose of the project is to test various methods of fish and mussel aquaculture and to evaluate their economic viability and environmental compatibility in order to enable the most sustainable, environmentally friendly and local aquaculture production possible in the western Baltic Sea of Mecklenburg-Vorpommern. The fish aquaculture project aims to build and test net-carrier systems for fish farming (*Oncorhynchus mykiss*) that are adapted to the conditions of the shallow and dynamic coastal waters of Mecklenburg-Vorpommern. Two different farming systems with the type names "The Cage" and "Bjørn" are to be built:

"The Cage" is an experimental tiny enclosure for scientific works with a small number of fish (up to 2000). The net is fixed in a static pipe structure which is octagonal cylindric and has a volume of approx. 100 $m^3$. The tubular structure is braced over 4 corners centrally in a plastic pen and sits on a buoyancy frame. This is used for stabilization as well as lifting and lowering. Primarily, it is a test system whose focus is on evaluating the fattening of smolts weighing approx. 100 g to approx. 400 g in approx. 3 months. The goal is to continuously produce portion fish for catering or sale over the masting season of approximately 9 months (April - December).

"Bjørn", on the other hand, is an innovative aquaculture design that is to be evaluated for the practical and fundamental commercial applicability of small-scale systems. For this purpose, a small-sized business (SMB), preferably a regional fishing company, will take over the management. The Institute of Fisheries (IfF) will provide the enclosure, feed, trout and advice. The SMB decides on the stocking density and masting phases in agreement with the IfF.

In addition to the technical and economic issues, accompanying environmental monitoring is being considered, in order to draw conclusions about operational emissions and potential environmental impact. These are of particular importance with regard to the permissibility of such facilities. Due to various requirements of the Water Framework Directive, compensatory measures must be taken to counteract the deterioration of water quality around the cage. The extraction of mussels can be seen as a removal of the nutrients (especially nitrogen and phosphorus) released through fish aquaculture. In parallel to compensating for the fish aquaculture, this can also generate an additional source of income.

Three different mussel culture systems are set up. Surface double longline, surface close single longline and submerged single longline are equipped with data loggers placed at different depths to monitor the movement of the collectors in x, y and z direction. These data loggers are used to test in which system less movement is detected in order to minimize the loss of mussels. In parallel to hydrodynamics, it should also include the possible minimization of predation pressure by birds. In addition, an Acoustic Doppler Current Profiler (ADCP) is installed on the seabed to monitor the currents around the aquaculture facilities and an Automatic Profiling Buoy (APB), which is designed for automatic Conductivity Temperature and Depth (CTD) profiling. The CTD is an instrument with multi parameter functionality with sensors like Oxygen, Turbidity, fluorescence and photosynthetic light sensor. This means that a profile of the water quality can be obtained throughout the year. In addition to the annual profiles, mussels and fish are sampled and analysed for pollutants in the laboratory.

# SHIFTING PRODUCTION CYCLE FROM SEA TO RAS – WHAT DOES THE FISH SAY?

**Introduction**

In combined RAS (recirculating aquaculture system) and sea cage farming, fish are first farmed in RAS and then transferred to sea cages for the rest of their lives. By increasing the size of fish in RAS, the production cycle of farming can be accelerated, and the sea cage period can be shortened (Bjørndal and Tusvik, 2017). A shorter sea cage period provides means to capture nutrients more efficiently and reduces biological risks (Bjørndal and Tusvik, 2017). Shorter sea cage period would also make it possible to avoid risks associated with overwintering of fish (Donaldson et al., 2008). However, RAS and sea cage farming are very different production methods and the effects of combining them on fish growth and welfare are not well understood. In this study, we investigated 1) Does growth of rainbow trout (*Oncorhynchus mykiss*) farmed in RAS and PRAS (partial RAS) differ after transfer to freshwater and brackish water conditions? 2) Does the size of rainbow trout and/or the timing of transfers affect the growth of rainbow trout? and 3) Does the water quality of initial farming influences the success of transfers?

**Materials and methods**

Rainbow trout were first farmed in RAS and PRAS. In summer, some fish were transferred to fresh and brackish water, while the rest remained in the original RAS and PRAS tanks. The fish were farmed in the fresh and brackish water for five weeks (the summer period). In autumn, another transfer took place, and the fish were again transferred to the fresh and brackish water. The autumn period took also five weeks. The fish were sampled after the summer and autumn periods. The sample fish were killed by an overdose of anaesthetic. The total length, weight and gutted weight were measured. Based on the fish growth data, feed conversion ratio, condition factor, specific growth rate, and thermal-unit growth rate were calculated. A blood samples were taken for haematocrit, plasma osmolality, plasma chloride content, and plasma cortisol content determination.

**Results**

During the summer period, the RAS-farmed fish grew better in the freshwater than in the RAS environment (SGR 34%, TGC 37%, $p < 0.001$) or in the brackish water (SGR 27%, $p < 0.001$). The RAS-farmed fish grew better in the RAS environment than in the brackish water (TGC 30%, $p < 0.001$). The PRAS-farmed fish grew better in the freshwater than in the PRAS environment (SGR 8%, $p < 0.05$) or in the brackish water (SGR 8%, TGC 35%, $p < 0.001$). The PRAS-farmed fish grew better in the PRAS environment than in the brackish water (TGC 33%, $p < 0.001$). In the RAS environments, the PRAS-farmed fish grew better than the RAS-farmed fish (SGR 22%, TGC 37%, $p < 0.001$). In the freshwater, there was no significant difference between the RAS- and PRAS-farmed fish. In the brackish water, the RAS-farmed fish grew better than the PRAS-farmed fish (9%, $p<0.05$).

During the autumn period, the RAS-farmed fish grew better in the RAS environment (SGR 295%, TGC 283%, $p < 0.001$) and in the freshwater (SGR 270%, TGC 333%, $p < 0.001$) than in the brackish water. There was no difference in the RAS-farmed fish between the RAS environment and the freshwater. The PRAS-farmed fish grew better in the PRAS environment than in the freshwater (32%, $p < 0.01$). The PRAS-farmed fish grew better in the PRAS environment than in the brackish water. In the PRAS environment the fish continued to grow normally (SGR 1.39, TGC 0.23), while in brackish water fish did not eat and lost weight (SGR -0.07, TGC -0.01). PRAS-farmed fish grew also better in the fresh than in the brackish water. In the freshwater, the fish continued to grow (SGR 1.05, TGC 0.23), while in the brackish water the fish did not eat and lost weight (SGR -0.07, TGC -0.01). In the RAS environments, there were no difference between the RAS- and PRAS-farmed fish. In the freshwater, the RAS-farmed fish grew better than the PRAS-farmed fish (29%, $p < 0.01$). In the brackish water, the RAS-farmed fish grew better than the PRAS-farmed fish. The RAS-farmed fish continued to grow (SGR 0.37, TGC 0.06), while the PRAS-farmed fish did not eat and lost weight (SGR -0.07, TGC -0.01).

*(Continued on next page)*

**Discussion**

Seawater transfer plays an important role in salmonid production, where juveniles are produced on land in freshwater and then transferred to the sea for further farming (Thorstad et al., 2012; van Rijn et al., 2021). This study investigated the transfer of two different sizes of rainbow trout from two different RAS environments to fresh and brackish water. We observed differences in the growth of RAS- and PRAS-farmed fish after transfers to the fresh and brackish water. The most striking exception was the results for the PRAS-farmed fish in the brackish water during the autumn period. The fish did not eat despite continuous offering of the feed and therefore lost weight. Stress does not seem to explain the differences in appetite and growth of fish, as we did not observe significant differences with a clear pattern in the physiological parameters. Our results also show that the size of fish and the timing of transfer affect growth of fish. In this study, the smaller fish transferred in the summer grew better than the larger fish transferred in the autumn. Based on our study, the environment and water quality in the initial farming did not seem to affect growth of fish after transfer in themselves. Continuous lighting and feeding, as well as the fish growth in the RAS and PRAS environments, may influence the growth success in the further farming. Ultimate reasons for these phenomena remain unclear and need clarification to develop the farming method for wider use in salmonid aquaculture.

# EFFICACY OF NOVEL SETTLEMENT SUBSTRATES FOR STANDARDISING SETTLEMENT FOR COMMERCIAL PRODUCTION OF ABALONE AND SEA URCHINS

Colin Hannon, Devin Ayres

Marine & Freshwater Research Centre
Atlantic Technological University
Galway, Ireland

Aqunion (PTY) LTD
Hermanus, South Africa

## Introduction

Inconsistent settlement rates for commercially important species remain a bottleneck at the beginning of the production value chain. The commercially important species such as sea urchin *Paracentrotus lividus,* and abalone *Hailotitos discus hannai* & *H. midae* are increasing in commercial interest for aquaculture in Europe and South Africa.

However suitable larval settlement substrates (e.g. *Ulvella lens*) remain untested and in many commercial settings. Inconsistent low settlement rates are currently achieved at the nursery stage by commercial hatcheries and efforts to establish other commercial hatcheries around Europe, have been hampered by inconsistencies in production, which remain a key bottleneck (Hannon et. al., 2013, Lawrence and Lawrence, 2014).

Development of settlement cues and production methods by the Hannon et. al., (2014) have been transferred from Ireland to Spain (2015) and South Africa (2017) to support hatchery production of sea urchins and abalone under commercial conditions. This presentation is evaluating the efficacy and implementation of the use of novel settlement cues and how they can be used to standardise settlement with a guaranteed average settlement range of 50-70% inside 24-hours from transfer to settlement tanks or systems.

Under commercial conditions postlarval survival increases significantly once an effective settlement cue is utilised with an overall increase of 30-40% hatchery output for the same time period.

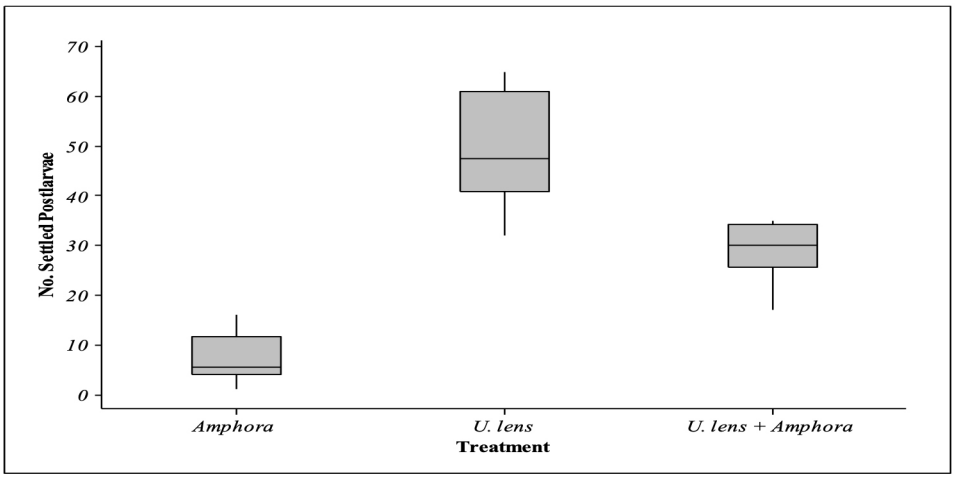

Figure 1. Box-Plot comparing the settlement achieved on the different treated settlement substrates. There is a significant statistical difference between the settlement rates of each treatment with the *U. lens* treatment achieving the highest number of settled post larvae ($P < 0.05$)

*(Continued on next page)*

**Materials & Methods**

Overcoming the production barriers for the culture of *Ulvella lens* required the streamlining of the production method to aid the tech transferability to commercial production. This required the removal of the trial and error approach. All cultures were establish under commercial conditions at commercial facilities in Ireland, Spain and South Africa.

Cultures of *U. lens* were isolated and scaled up in culture to increase available adult sporophyte biomass for mass sporulation which can be repeated every 14-days once the sporulation cycle is initiated. This has halved the current time from the original method developed in the 1980s'. Post larval settlement and survival was assessed along with their feeding transitions and weaning

**Results**

Significant differences were observed when the cues were assessed at commercial scale when compared to the benthic diatoms (e.g. *Amphora* Spp.). Using monospecific diatoms have been shown to increase settlement rates than relaying on natural assemblages of wild benthic diatoms available to hatcheries. When *U. lens* is used in commercial production we have seen an average settlement rate of 50-70% inside the first 24-hours after the competent larvae are introduced to the settlement cue (Figure 1).

**Discussion**

*U.* lens can be used as a settlement cue for sea urchins, abalone and sea cucumbers and is ready for transfer into commercial production of low trophic aquaculture species in the hatchery.

knowledge transfer resulted in a fully scaled *U. lens* hatchery directly improved spat production by 30% to 40% for abalone hatcheries and resulted in a on average settlement of 50-70% for sea urchins under commercial conditions.

Hatcheries are very complex and the *U. lens* used in the settlement phase gave the species produced a head start in life; and not only did settlement production improve, but so did weaning survival as the macroalgae phase of the mollusc was already achieved in settlement, and sea urchins are able to graze as postlarvae with no feeding transition period or loss in growth rates.

# NEW ROTIFER ENRICHMENT IMPROVES GROWTH IN LARVAL ATLANTIC COD (*Gadus morhua*)

Øyvind J. Hansen*, Velmurugu Puvanendran, Jens Petter Jøstensen

Norwegian Institute of Food, Fisheries and Aquaculture Research (NOFIMA), Muninbakken 9-13, Breivika, 9019 Tromsø, Norway
Tromsø Fiskeindustri AS, Roald Amundsens plass 1, 9008 Tromsø
*Email – oyvind.j.hansen@nofima.no*

## Introduction

Early growth and nutrition in cod larval farming significantly affect weight development during later stages, impacting the overall performance of farmed fish (Hansen et al., 2018). Renewed interest in cod farming has emerged due to advancements in selective breeding and declining wild stocks (Puvanendran et al., 2022). To further develop the industry, new enrichment products for rotifers have been tested in cod production.

## Materials and Methods

Eggs and sperm were stripped from broodstock and fertilized using the standard protocol at the CMA. Five families were created, and fertilized eggs from each family were incubated in 25L conical silo incubators with a flow-through of ambient water at 4-5°C. After 100% hatch, 3,000 larvae from each family were transferred to one of four replicates first feeding tanks (190L) per treatment (15,000 larvae per tank), with water temperature gradually increased from 4-5°C to 10°C over 5-10 days (~1°C per day).

## Feeding Protocol

Rotifers were enriched with three different enrichments:

1. Control group – Rotifers enriched with Multigain®, PhosphoNorse®, Pavlova, Chlorella.
2. Treatment 1 – Rotifers enriched with new enrichment formula I.
3. Treatment 2 – Rotifers enriched with new enrichment formula II.

**Table 1: Details of the feeding protocol used in this experiment.**

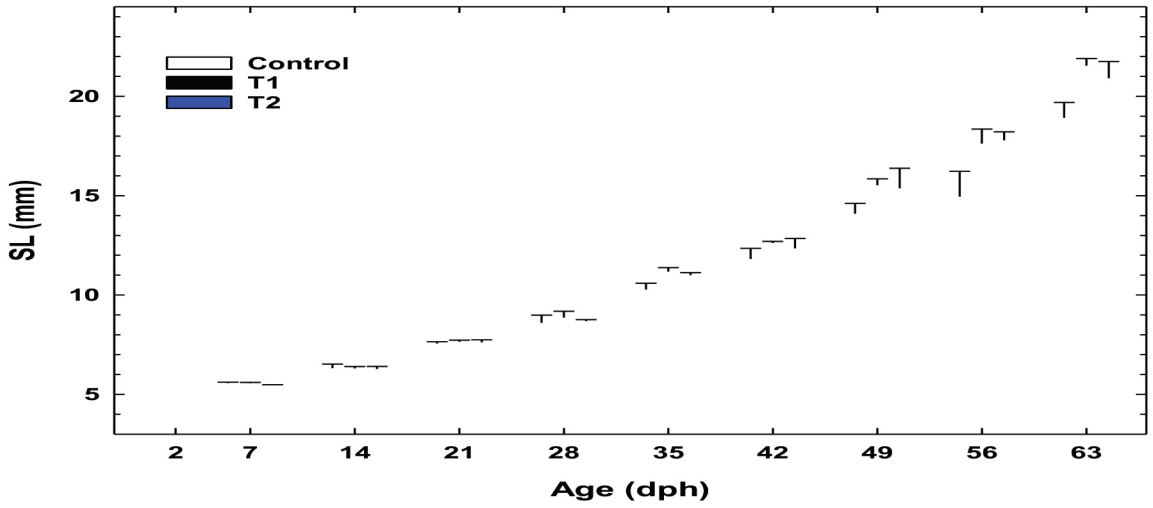
**Figure 1: Differences in standard length at different ages between treatments.**



**Results**

Growth rate, survival, and deformities were measured across treatments. Deformities in juveniles were analyzed using x-ray. Protein, fat, and mineral content in juveniles and live feed were also analyzed. The new enrichments (T1 and T2) resulted in increased growth rates compared to the control group, with no significant differences in deformities or survival between groups.

# DEVELOPMENT OF AN EFFICACIOUS AND SAFE VACCINE AGAINST VIRAL NERVOUS NECROSIS (VNN) IN EUROPEAN SEA BASS *(Dicentrarchus labrax)*

Tove Hansen*, Trygve Eliassen, Inge Tom Solbakk, Stian Brekke and Terje Tingbø

Pharmaq part of Zoetis
Harbitzalléen 2A
0275 Oslo, Norway
E-mail: tove.hansen@zoetis.com

## Introduction

Viral Nervous Necrosis (VNN), also known as Viral Encephalopathy and Retinopathy (VER), is caused by a virus belonging to the genus Betanodavirus of the Nodaviridae family. The disease has been described in more than 50 fish species and is still considered a serious threat to aquaculture. Farmed European sea bass is severely affected, the virus is causing animal suffering and significant losses to the industry. Because of the need for preventive measures, Pharmaq developed a vaccine against VNN and the demand for vaccines is growing.

## Methods and Results

Development of the monovalent injection vaccine targeting Viral Nervous Necrosis Virus (VNNV) was initiated in 2012 and extensive research and documentation continued up to 2017 when the first Marketing Authorization was granted. Developing a robust and reproducible challenge model is key to be able to test and document vaccine efficacy. Protection was assessed clinically* through dose-response studies, evaluation of onset- and duration of immunity, and cross protection testing using challenge isolates of various origin. The safety of the vaccine, including local reactions such as abdominal adhesions and pigmentation, was investigated after vaccination. Extensive clinical testing under controlled laboratory conditions showed that the vaccine is safe to use and provides high levels of protection, which has been further supported by experience from the field. Data have also been gathered after large scale commercial use of the vaccine, and feedback from farmers has been vital to monitor efficacy and safety.

This presentation will review the highlights of the development process, with a special focus on clinical studies. Current field situation will also be addressed.

*The pre-clinical studies were conducted in line with the “License to Carry out Research on Animals” granted to AquaBioTech Group by the Ministry for Agriculture, Fisheries, Food and animal rights, Animal welfare Department in Malta and in accordance with procedures approved by the Zoetis Animal Ethics Committee.

# FROM SOIL TO SEA: OMEGA-3 BIOSYNTHESIS IN *Enchytraeus albidus* AND ITS POTENTIAL FOR AQUACULTURE

J.G. Haro[1*], S. Gerlich[2], J.C. Navarro[1], S. Slotsbo[2], M. Holmstrup[2], Ó. Monroig[1]

E-mail: juan.haro@csic.es

**Introduction**

Methyl-end desaturases (or "ωx des") play a significant role in the biosynthesis of omega-3 long-chain polyunsaturated fatty acids (ω3 LC-PUFA), biologically essential nutrients for vertebrates including fish. These enzymes are present in multiple aquatic invertebrates, including molluscs, cnidarians, crustaceans and annelids. Within the latter group is the terrestrial oligochaete *Enchytraeus albidus*, an organism often used as live feed in flatfish larviculture. While indirect evidence from lipid composition and transcriptomic analyses suggested that *E. albidus* is capable of synthesizing ω3 LC-PUFA, the responsible enzymes have not been characterized yet. This study aims to identify and characterize the repertoire of ωx des from *E. albidus*.

**Materials & Methods**

To identify the ωx des, tblastn searches were conducted against publicly available Transcriptome Shotgun Assembly (TSA) from *E. albidus*, using as a query known ωx des sequences from marine annelids. The putative ωx des sequences retrieved from *E. albidus* were used as a reference to design primers enabling the amplification of the complete open reading frames (ORF) by PCR. The PCR template was cDNA prepared from total RNA from fresh worms (pools of 3 ind). The PCR product corresponding to the ORF of the putative ωx des from *E. albidus* was digested and cloned into pYES2 for functional assays in yeast (see below). Correctness of the ORF inserts in pYES2 was confirmed by sequencing. For the molecular characterization of the ωx des, we compared the deduced protein sequences with other annelid desaturases, identified ωx des-like conserved domains, and performed a Maximum likelihood phylogenetic tree along with desaturase sequences from multiple invertebrates. For functional characterization, transgenic yeast transformed with the pYES2 constructs containing the *E. albidus* ωx des ORF, were used in two different assays. First, yeast expressing each ωx des gene were grown in the absence of exogenously added substrates, and their fatty acid profiles were then compared with those of yeast transformed with empty pYES2 (control) and grown under the same conditions (n=3). This assay informed about the ability of the *E. albidus* ωx des to desaturate yeast endogenous fatty acids. In a second assay, the transgenic yeast expressing each ωx des gene were supplemented with potential ω6 PUFA substrates (18:2ω6, 18:3ω6, 20:2ω6, 20:3ω6, 20:4ω6, 22:4ω6 and 22:5ω6). For both assays, yeast were harvested after 48h incubation, and total lipids were extracted for further derivatization into fatty acid methyl esters (FAME). FAME were analyzed through Gas Chromatography (GC-MS).

**Results**

We identified two distinct *E. albidus* ωx des, termed hereafter "ωx1" and "ωx2". Both *E. albidus* ωx des possess the three histidine boxes characteristic of methyl-end desaturases. The phylogenetic analysis successfully locates these proteins within one of the Annelida clades, and near other oligochaetes such as *Eisenia fetida* and *Glossoscolex paulistus* (Fig. 1). Despite their close phylogenetic relationship, the *E. albidus* ωx1 and ωx2 exhibited very different functions. The functional assays showed that yeast expressing ωx1, but not ωx2, were able to convert 18:1ω9 into 18:2ω6, confirming this enzyme is a Δ12 desaturase. However, the ωx2 showed Δ15, Δ17 and Δ19 activities, converting a variety of ω6 substrates into ω3 LC-PUFA such as EPA and DHA (Table 1)..

**Conclusions**

We have successfully identified and functionally characterized two ωx des from *E. albidus*. Both ωx des have conserved domains and are phylogenetically related. The functional assays demonstrated that ωx1 des is a Δ12 desaturase, whereas ωx2 can be categorized as an ω3 desaturase. While ongoing investigations are aiming at the characterization of front-end desaturases and fatty acid elongases with potential roles in the LC-PUFA biosynthesis in *E. albidus*, the present results confirm that this terrestrial annelid possess key enzymatic capacity required for *de novo* synthesis of LC-PUFA.

*(Continued on next page)*

**Table 1**. Substrate conversion of the ωx2 methyl-end desaturase from *E. albidus*. Results are presented as percentage (%) of the exogenously supplemented fatty acid (FA) substrates converted into the corresponding products.

| FA substrate | FA product | Conversion (%) | Activity |
|---|---|---|---|
| 18:2ω6 | 18:3ω3 | 16.13 | Δ15 |
| 18:3ω6 | 18:4ω3 | 48.89 | Δ15 |
| 20:2ω6 | 20:3ω3 | 20.52 | Δ17 |
| 20:3ω6 | 20:4ω3 | 19.24 | Δ17 |
| 20:4ω6 | 20:5ω3 | 18.29 | Δ17 |
| 22:4ω6 | 22:5ω3 | 2.02 | Δ19 |
| 22:5ω6 | 22:6ω3 | 11.93 | Δ19 |

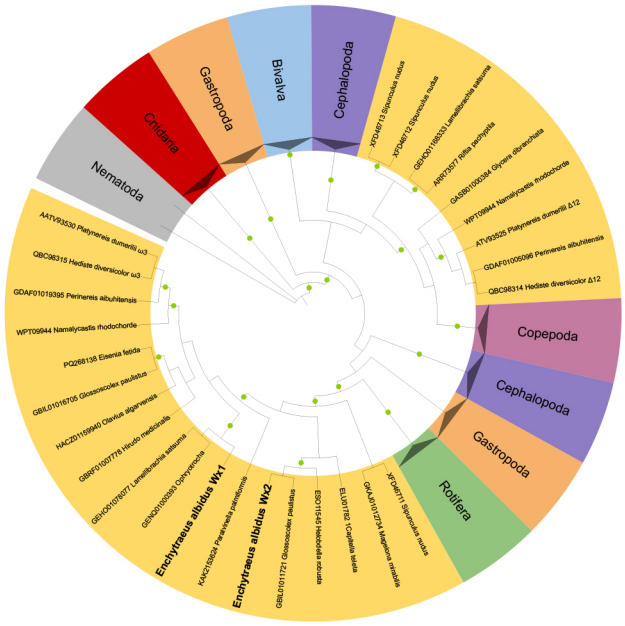

**Fig.1** Maximum likelihood phylogenetic tree of invertebrate ωx des. *E. albidus* ωx des are marked in bold. Bootstrap values (1000 iterations) with a support value of 90% or higher are highlighted in green. NCBI accession numbers are given for each sequence.

**Funding**

The POLYPUFA grant PID2022-136234OB-C21 was funded by MICIU/AEI /10.13039/501100011033 and by FEDER, UE. Additional funding was received from Independent Research Fund Denmark for the NOVOPUFA project to MH (grant no. 3164-00138B).

# A RAPID RISK ASSESSMENT TOOL TO ENHANCE AND STANDARDISE AQUATIC ANIMAL HEALTH RISK MANAGEMENT UNDER FAST CHANGING AQUATIC ENVIRONMENTS

Jacob Harper*, Mark Thrush, Ed Peeler, Debbie Murphy, Sophie Armitage, Mickael Teixeira Alves

Centre for Environment Fisheries and Aquaculture
The Nothe, Barrack Road
Weymouth, DT4 8UB, United Kingdom
Email: jacob.harper@cefas.gov.uk

## Introduction

Aquaculture has experienced significant growth since the 1980s, yet its expansion is increasingly constrained by disease outbreaks, which account for approximately 20% of production losses annually (Brummett and Hargreaves, 2019; Peeler et al., 2023). Risk assessments are integral to the development of adaptive and timely disease management strategies to counterbalance these losses, notably by evaluating disease risks, impact and mitigation measures (WOAH, 2024). Conducting risk analysis for aquatic animal health, however, presents several challenges, including the need for rapid response to sudden epidemiological events, limited knowledge of emerging novel threats, shifting ecological and socio-economic drivers and transparent communication of risks and uncertainties across diverse stakeholder groups. To address these, a Rapid Risk Assessment (RRA) tool was specifically developed to support strategic decision-making and effective aquatic animal health management, particularly under rapidly evolving environmental conditions.

## Materials and Methods

The RRA tool was developed using Microsoft® Excel® (Microsoft Corporation 2024) and is structured according to the World Organisation for Animal Health (WOAH) risk analysis framework (WOAH, 2024). The RRA begins with general assessment information that includes the pathogen name, a colour-coded risk summary, the assessor's name, versioning, completion date and scope. The second section of the RRA tool covers pathogen characterisation: pathogen description, disease pattern, host species (including their native status) and routes of disease introduction and spread. This informs the subsequent section of the RRA tool where standard terminology is used to provide qualitative likelihood estimates for each of the 3 core components of the risk assessment: introduction, establishment and consequence of establishment. The likelihood estimates are aggregated using risk matrices and result in qualitative risk estimates assigned with numerical scores. The RRA utilises internationally recognised terminology and standards for descriptors of likelihood and risk estimates, ensuring consistency and comparability across assessments (Horigan et al., 2023). The amount of uncertainty associated with each estimate is also incorporated to document gaps in knowledge (EFSA, 2018).

## Results

Rapid risk assessments are mainly conducted following the first occurrence of an event of public or animal health concern to facilitate the rapid collection of information and provision of advice to risk managers within a short period of time (de Vos et al., 2022). Yet, the RRA tool also provides a flexible framework to capture risk under future environmental conditions, specifically climate change. In this latter context, the RRA tool was applied to assess disease risks under current, 2°C (RCP4.5) and 4°C (RCP8.5) increased temperature scenarios (CCC, 2021). Rapid risk assessments were completed by reviewing the literature for minimum, maximum and optimal temperature ranges associated with disease viability, clinical expression and persistence of non-native host species under each climate scenario. The systematic, consistent approach provided a comprehensive ranking of diseases per risk and advice on prioritisation for future adaptation of aquatic animal health management.

## Discussion

The RRA tool has been developed for enhancing aquatic animal health management. It provides a structured, transparent and objective framework to rapidly support evidence-based decision-making and facilitate risk communication. As RRAs are completed, a library of RRAs is built which grows preparedness for emergency response and identifies knowledge gaps for further research and development.

This adaptable framework also facilitates direct comparison of existing, new or emerging aquatic disease threats in a systematic manner, allowing decision makers to plan disease management strategies under fast changing aquatic environments and ensure aquaculture resilience to future threats.

## Introduction

The increasing global demand for fish and seafood has led to significant growth in the aquafeed industry. However, this expansion has raised sustainability concerns due to the limited availability of marine-derived ingredients, such as fishmeal (FM) and fish oil (FO), which are essential in conventional aquafeeds. As the global production of these ingredients nears its maximum capacity, it is crucial to find sustainable alternatives to ensure the continued growth of the aquaculture sector. Over the past few decades, terrestrial plant-based ingredients such as soy, rapeseed, and maize have been used to partially replace FM and FO. While these ingredients show promise, they have limitations, such as an unbalanced amino acid and fatty acid profile, which can impact fish growth and health (Cardinaletti et. al., 2022). In recent years, protein alternatives from terrestrial animal by-products, such as poultry by-product meal (PBM), have gained attention as viable substitutes for FM (Psofakis et. al., 2020). PBM contains a balanced amino acid profile but may require supplementation with other protein sources like feather meal hydrolysate (FMH) to address deficiencies in lysine and methionine. In addition, alternative oils such as algae oil have been proposed as substitutes for FO, providing essential omega-3 fatty acids. This study aims to investigate the effects of a diet completely replacing FM with PBM and FMH, alongside the complete substitution of FO with algae oil and rapeseed oil, on the growth performance, gut health, and liver morphology of rainbow trout (*Oncorhynchus mykiss*). The results from the experiment were compared with the nutrient-based model FEEDNETICS™ (FEEDNETICS Software, SPAROS). The model was used to do a follow-up of the trial and assess whether the observed fish performance aligned with theoretical expectations.

## Materials and methods

Two experimental diets were formulated to evaluate the effects of poultry by-product meal (PBM) and fish oil (FO) replacement in rainbow trout (*Oncorhynchus mykiss*) diets. The control diet (FM) contained 15% fishmeal, 5% poultry meal (PM), and FO, while the PBM diet fully replaced FM with 15% PM and 5% feather meal hydrolysate (FMH). FO was substituted with 5.35% VeraMaris® algae oil and rapeseed oil. The diets were extruded at SPAROS facilities, Portugal. The 90-day feeding trial was conducted at "Fattoria del Pesce" in Cerano, Italy. Juvenile rainbow trout (n = 2,908; initial weight = 27.5 ± 0.3 g) were randomly distributed in four 10 m³ outdoor tanks (727 fish/tank, initial density: 20 kg/m³). Following a one-week acclimation, fish were fed once daily at 1.5–2.0% biomass. Water quality parameters were monitored regularly. Growth performance was assessed by monthly weighing, and daily mortality was recorded. The data were entered into FEEDNETICS™ to model fish growth based on dietary inputs.

At the end of the trial, 32 fish per diet were sampled for histological evaluation (liver and intestinal morphology), short-chain fatty acid (SCFA) analysis, and fillet fatty acid composition. Histological samples were stained with hematoxylin-eosin and analyzed using microscopy. SCFAs were quantified using HPLC, while fatty acid profiles were determined via gas chromatography. Statistical analyses were conducted at the individual fish level using Student's t-test or Mann-Whitney test ($p < 0.05$).

## Results and Discussion

### Growth Performance and Feed Utilization

Rainbow trout readily accepted both diets, and the 90-day feeding trial showed no significant differences in survival rates (>97%), final body weight (FM: 170.80 ± 7.61 g, PBM: 166.91 ± 6.62 g), or feed conversion ratio (FCR: FM = 1.33 ± 0.05, PBM = 1.35 ± 0.04) between dietary groups. The specific growth rate (SGR) was similar ($p > 0.05$) between fish fed FM (2.03 ± 0.04 % day$^{-1}$) and PBM (2.00 ± 0.08 % day$^{-1}$). No external or internal lesions were observed in either group.

*(Continued on next page)*

**Intestinal and Liver Histomorphology**

Histological examination revealed well-organized intestinal tissue in both groups, with significantly longer intestinal folds ($p < 0.05$) in the anterior intestine of PBM-fed fish. However, the PBM group exhibited a significant increase in submucosa thickness in the posterior intestine ($p < 0.05$), possibly indicating a mild inflammatory response. Liver histology showed normal parenchymal structure in both feeding groups, with PBM-fed fish exhibiting reduced hepatic lipid accumulation compared to FM-fed fish.

**Fecal Short-Chain Fatty Acids (SCFAs) and Fillet Fatty Acid Composition**

SCFA analysis indicated significantly higher acetate (18.73 mmol/L) and butyrate (0.91 mmol/L) levels in PBM-fed fish. Fatty acid composition analysis revealed lower saturated fatty acids (SFAs) and significantly higher polyunsaturated fatty acids (PUFAs), including EPA+DHA, in PBM-fed fish, with improved nutritional indices (atherogenic and thrombogenic indices).

**Benchmarking of the trial results with FEEDNETICS ™**

The FEEDNETICS™ application model, served as a reference point and supported the conclusion of this study, in terms of the performance of fish fed diets with PBM and natural algal oil.

**Conclusions**

Replacing 20% of fishmeal with PBM and FMH, along with fully substituting FO with VeraMaris® algae oil, sustained growth performance, gut morphology, and liver health in rainbow trout. Although fillet PUFA levels decreased, improved nutritional indices suggest potential human health benefits. Additionally, the FEEDNETICS™ model provided valuable validation, reinforcing the observed performance of fish fed PBM- and algal oil-based diets. These findings underscore the potential of PBM and algal oil as sustainable, nutritionally balanced alternatives for environmentally friendly trout diets.

**Introduction:**
*Aeromonas veronii* is a bacterial pathogen infecting both freshwater and marine aquaculture species. *A. veronii* infection results in *hemorrhagic septicemia* and epizootic ulcerative syndrome leading to severe pathology, mortalities and economic losses particularly in European seabass (*Dicentrarchus labrax*) and Nile tilapia (*Oreochromis niloticus*). Like other Gram-negative bacteria, *A. veronii* the outer membrane (OM) is essential for bacterial survival, virulence, and adaptation, particularly under iron-limited conditions. Since iron availability is restricted in host environments, *A. veronii* has evolved specialised iron uptake systems and iron-regulated outer membrane proteins (OMPs) to enhance survival. Understanding these adaptations is crucial for developing targeted antimicrobial strategies and identifying protective antigens. This study compares the OMP expression profiles of three commercially relevant *A. veronii* isolates grown under iron limitation and standard laboratory conditions, aiming to identify OMPs associated with the adaptation to iron-limited environments.

**Method:**
Three *A. veronii* strains (NK01 (tilapia), NS and PDB (seabass)) were cultured in TSB medium with/without 100 μM 2,2'-dipyridyl. OMP fractions were obtained using a sarcosine-insoluble isolation method (Huang et al., 2006). Proteins were digested with trypsin using single-pot solid-phase enhanced sample preparation (SP3) and analysed by Orbitrap Exploris mass spectrometry in data-independent mode (DIA). Differential expression of OMPs was analysed using the R package prolfqua (Witold et al., 2023)

**Result:**
Iron limitation resulted in significant changes in the OM proteome of *Aeromonas veronii* strains NK01, NS, and PDB. OMPs associated with iron uptake, membrane transport, and virulence were upregulated in all three strains including TonB-dependent siderophore receptors (CF123_19915 and CF123_11360), a lipocalin (CF123_10435), a ligand-gated channel protein (CF123_06935), the Type IV pilus biogenesis protein PilW, and several autotransporters and general transporters (Figure 1). In addition, proteins of key iron acquisition systems, including ABC transporters, ferrous iron transporters, and heme utilisation proteins were significantly upregulated. These results suggest a coordinated adaptation to iron stress particularly the upregulation of TonB-dependent siderophore receptors which play a crucial role in transporting iron-chelating compounds from the outer membrane to the periplasm, enabling the bacterium to extract iron from the environment and contributing to iron homeostasis (Wang et al., 2017). In contrast, several OMPs involved in export or non-essential transport, such as the TonB-dependent copper receptor (CF123_17620), PilQ (CF123_07595), the Type II secretion system protein GspD, and porins, (OmpA, LamB, OprD family porin, OmpW, maltoporin and OmpA (CF123_10155)) were significantly downregulated. Components of the electron transport chain and other iron-dependent metabolic enzymes were also downregulated. Our findings are consistent with previous data, which suggests that under iron-limited conditions, bacteria suppress the expression of OMPs associated with non-critical permeability or export functions (Zhang et al., 2020). This dual response indicates a strategic metabolic adaptation to conserve energy and enhance iron uptake under iron-limited conditions.

*(Continued on next page)*

**Conclusion:**

Our findings show that *A. veronii* undergoes a co-ordinated regulatory response under iron limiting conditions. We observed a significant increase in key iron acquisition proteins, including TonB-dependent siderophore receptors, ABC transporters, ferrous iron transporters, and heme utilisation proteins, which enhance iron transport and maintain cellular iron homeostasis. Conversely, expression of non-essential OMPs in the response to iron limitation such as components of the electron transport chain, iron-dependent metabolic enzymes, and several other OMPs were significantly downregulated to alleviate the stress caused by iron limitation. Overall, this mechanism is vital for the adaptive regulation of *A. veronii* under metal ion-limited conditions. A comprehensive understanding of how bacteria acquire iron in metal ion-deficient conditions supports the invasion mechanism of *A. veronii* disease.

# AQUASTAR: AUTONOMOUS UNDERWATER SYSTEM FOR TARGETED ASSESSMENT & REPAIR

Bent Haugaløkken*, Oscar Nissen

SINTEF Ocean, Department of Aquaculture
Brattørkaia 17C, 7010 Trondheim
Email: bent.haugalokken@sintef.no

## Introduction

The AQUASTAR project targets combined autonomous inspection and repair of holes in sea-based aquaculture net pens. Holes in the net represent the main reason for fish escape and is a challenge in aquaculture fish farming in traditional net pens.

## Motivation

Net inspections are currently carried out manually and include a remotely operated vehicle (ROV) and an ROV pilot. However, inspecting net patterns for hours on end is tedious and can increase the risk of overlooking holes. Divers are usually employed for repair; however, they are exposed to risks that may lead to injuries and even death. This strongly advocates for both enhanced hole detection systems and alternative net repair solutions.

The AQUASTAR project will develop solutions for ROVs with manipulators enabling automatic hole localization, automatic vehicle positioning and hole repair. This will serve as a tool for ROV pilots to achieve enhanced net inspections and the opportunity to immediately repair holes in the net.

## Project status and project results

AQUASTR has developed and tested a net-relative navigation system that allows for horizontal and vertical movement and station keeping relative to the net. The project has also developed a fully operational automatic hole detection system, which, to the best of the project consortium's knowledge, marks the first time hole detection is being used commercially. There is an on-going process of gathering images of holes in the net that will be published as open-source datasets. The datasets will include several varying conditions present in aquaculture, (e.g., different illumination, turbidity and biofouling conditions. Moving further, the project aims to develop hole-relative station keeping and control strategies for combined vehicle-manipulator systems for hole repair.

## Acknowledgments

The AQUASTAR project is an industrial research and collaboration project between Njord Aqua, Måsøval, Sintef Ocean, and NTNU, and is supported by the Research Council of Norway.

# PACIFIC WHITE SHRIMP (*Litopenaeus vannamei*) CULTURED IN RECIRCULATING AQUACULTURE SYSTEMS (RAS). EFFECTS OF DENSITY ON GROWTH, MORTALITY, AND WELFARE

Kristina Haugland[1]*, Dr. Atle Foss[1] & Dr. Albert Kjartan Dagbjartarson Imsland[1,2]

Akvaplan-niva[1]
Department of Biological Sciences – University of Bergen[2]

kha@akvaplan.niva.no

**Background**
Aquaculture is a rapidly growing industry and one of the most vital pillars in addressing the increasing global demand for food. Different farming systems and strategies have been developed to achieve more modern and innovative ways of farming, involving automated and more accurate technologies, such as recirculating aquaculture systems (RAS). The Pacific white shrimp, *Litopenaeus vannamei*, is one of the most common species in shrimp farming. *L. vannamei* are usually cultured in industrial monoculture systems, hence, few studies have investigated the effect of using RAS technology to cultivate *L. vannamei*. This study aimed to investigate the impact of two stocking densities (Low Stocking Density, LSD, initial density 165 individuals/m2 and High Stocking Density, HSD, initial density 264 individuals/m2) on the growth, mortality, and welfare of *L. vannamei* cultured in a clear-water RAS.

**Experimental setup & data collection**
There were two independent clear-water RAS, and each system had two tanks. The experiment had four tanks in total. The two tanks connected to system 1 had a stocking density of 165 individuals/m2 (defined here as low density, LSD). The two tanks connected to system 2 had a stocking density of 264 individuals/m2 (defined here as high density, HSD). The mean weight was 0.35 g when the grow-out phase was initiated. Water quality parameters such as temperature, salinity, oxygen, and pH were measured daily. Water quality analysis was performed weekly to monitor ammonia, nitrite, and nitrate concentrations. Length, weight and welfare parameters were measured every fifteen days throughout the experiment. For each sampling, 10 shrimp was retrieved from each tank to be inspected and measured.

**Results**
The overall mean salinity was significantly different between the two treatments. The salinity fluctuated in both treatments, but the HSD experienced more frequent fluctuations than the LSD. The oxygen saturation fluctuated throughout the experiment and was significantly different between the LSD and HSD systems. The HSD system was the only system that experienced an oxygen saturation level below the optimal range. There was no significant difference in the specific growth rate (SGR) between treatments. The LSD and HSD systems had an overall SGR of 4.84 %/day and 4.71 %/day. During the last sampling, the mean weight varied significantly between treatments, where the mean weight was significantly higher for the LSD system. The mean length showed a tendency towards differences at the two final sampling points. Mortalities were observed throughout the experiment. An incident of high mortality (5 % of total biomass was lost) occurred on day 1 of the experiment following handling and distribution at start-up. Approximately 21–28 days into the grow-out phase the HSD system experienced a brief period of high mortality (8.6 % of total biomass was lost in one week) due to a disease called white muscle necrosis. The overall welfare of the shrimp was estimated by combining the results from indirect welfare indicators, individual welfare indicators, and daily observations that were made. There was a significant difference in animal welfare between treatments of LSD and HSD. Specifically, there was a significant difference between antennae damage between the treatments, where HSD scored significantly lower than LSD. There was no significant difference for the other individual welfare indicators. Overall, there was a significant difference in survival between treatments. There was a significant difference in animal welfare between treatments of LSD and HSD.

*(Continued on next page)*

**Conclusions**

The overall growth of *L. vannamei* was satisfactory although similar between treatments. Survival was poor for both treatments, but significantly lower in the HSD group, most likely due to the occurrence of muscle necrosis and unforeseen events that caused mortality. The welfare assessment technique was sufficient, but a significantly poorer welfare in the HSD system was observed. This study found that stocking density do affect the mortality and welfare, but not growth of *L. vannamei* cultured in RAS.

**Future research**

It has been well documented for biofloc systems and ponds that density does affect the growth of *L. vannamei*, and in the current study a significant difference in mean weight was observed during the last sampling. It is therefore suggested that more research on the cultivation of *L. vannamei* in RAS is needed.

# ACUTE EFFECTS OF INORGANIC MERCURY ON RAINBOW TROUT (*Oncorhynchus mykiss*) HEART EXCITABILITY

Jaakko Haverinen[1]*, Ahmed Badr[12], Anita Kervinen[1], Matti Vornanen[1]

[1]Department of Environmental and Biological Sciences, University of Eastern Finland, Finland
[2]Zoology Department, Faculty of Science, Sohag University, Egypt
Email: jaakko.haverinen@uef.fi

## Introduction

Mercury contamination in aquatic environments poses a potential risk to aquaculture species, as it can impair fish health, growth, and survival. Cardiotoxic effects of mercury may compromise performance and stress tolerance in farmed fish, especially under intensive rearing conditions. Mercury ($Hg^{2+}$) is a potent environmental toxin and a persistent environmental problem, with inorganic mercury ($Hg^{2+}$) being a significant pollutant in aquatic ecosystems. Fish cardiovascular physiology is particularly sensitive to chemical stressors, and disturbances in heart excitability can impair survival. While organic mercury forms have been widely studied, the acute cardiotoxicity of inorganic mercury in fish remains less understood. This study aimed to investigate the acute effects of $HgCl_2$ on rainbow trout (*Oncorhynchus mykiss*) heart excitability at whole-heart, cellular, and molecular levels. We hypothesized that $Hg^{2+}$ disrupts cardiac ion channel function, leading to arrhythmias and altered electrophysiological parameters.

## Methods

We used ex vivo perfused hearts, isolated ventricular myocytes, and patch-clamp techniques to assess responses to 0.1–10 μM $HgCl_2$. ECGs were recorded to measure heart rate, PR, QRS, and QTc intervals, as well as T-wave amplitude. Action potentials were recorded in current-clamp mode, analysing $APD_{50}$, $APD_{90}$, and $APD_{10}$, resting membrane potential, and upstroke/repolarization rates. Voltage-clamp experiments quantified effects on $I_{Na}$, $I_{CaL}$, $I_{Kr}$, and $I_{K1}$. Statistical analyses included ANOVA and Hill equation fitting for $IC_{50}$ values.

## Results

$Hg^{2+}$ induced concentration-dependent arrhythmias, including bradycardia (50–57% HR reduction at 6–10 μM), atrioventricular block, and QTc prolongation. Action potentials showed prolonged $APD_{50}$ and $APD_{90}$, shortened $APD_{10}$, and early and delayed afterdepolarizations. $I_{Na}$ ($IC_{50}$: 0.2 μM), $I_{CaL}$ ($IC_{50}$: 0.7 μM), and $I_{Kr}$ ($IC_{50}$: 1.0 μM) were dose-dependently inhibited, whereas $I_{K1}$ was unaffected.

## Conclusions

Inorganic mercury is acutely cardiotoxic to rainbow trout, disrupting ion channels and causing arrhythmias that may impair cardiac output. These findings highlight the ecotoxicological risk of $Hg^{2+}$ in fish, particularly in polluted aquatic environments, with implications for aquaculture operations facing multiple stressors, such as elevated temperature and intensive farming conditions.

# DIFFERENTIAL IMPACT OF TWO JELLYFISH SPECIES ON RTGILL-W1 CELLS

S. H. Helland-Riise[1]*, V. Voldvik[1], E. Ytteborg[1], C. C. Lazado[1]

[1]Nofima, 9019 Tromsø, Norway
*E-mail: siri.helland-riise@nofima.no

## Introduction

Gills are a multifunctional organ which is responsible for gas-exchange, ion-regulation and osmoregulation, amongst others. It is therefore of upmost importance for fish well being and health to have functional gills. Unlike lungs of terrestrial animals, gills are constantly exposed to the environment and as a result more prone to adverse effects. It is well established that jellyfish can damage – and cause mortalities in fish. Fish can either die as a direct result from the jellyfish venom, or as a result of secondary infections. Jellyfish can also damage the gills, which will negatively affect the overall health of the fish.

## Materials and methods

In vitro studies were carried out to determine the effects of two types of jellyfish, *Aurelia aurita* and *Apolemia uvaria*, on a rainbow trout gill cell line (RTgill W1, from ATCC). In order to obtain the optimal concentration and exposure time of macerated jellyfish, we performed a dose response study. We utilized measurements of cell proliferation, ATP and cytotoxity in order to determine which exposure time and concentration to use in further experiments.

After finding the optimal concentration and exposure time, we performed a pre-exposure to a compound stressor experiment where we first exposed the cells to either $H_20_2$ or LPS before exposing them to *A. aurita* and *A. uvaria*. Thereby we examined genes of interest by utilizing qPCR.

## Results

We discovered that after the longest exposure time and the highest concentration of *A. uvaria*, almost all of the RTgill W1 cells had died. We found that after 24 hours of exposure to *A. aurita* and *A. uvaria* proliferation decreased in a concentration dependent matter. Regarding ATP-levels, we observed an increase in cells exposed to *A. uvaria* for 4 hours, and a decrease in cells subjected to *A. aurita*. For cells exposed to jellyfish for 24 hours, there was a concentration dependent decrease. We observed an increase in cytotoxicity after both 4 and 24 hours of jellyfish exposure with increasing concentrations.

Regarding the experiment with pre-exposure to a compound stressor we discovered different results on apoptosis related genes. For instance, in cells treated with *A. uvaria* had an increase in caspase 8, caspase 7 and caspase 3a2 compared to the control group. For CK11, a gene involved in immune regulation, we also observed an increase in cells treated with *A. uvaria* compared to the control group.

## Conclusion

We discovered that the optimal concentration and exposure time, that achieved a response in the cells but still had good survival, was 2 % macerated jellyfish for 4 hours. Furthermore, we discovered that *A. uvaria* increases the relative expression of apoptosis related genes and an immune regulatory gene. These results indicate that A. uvaria damages the cells in such a way that the cells induces apoptosis. This suggests that A. *uvaria* has the ability to harm the gills directly, not only because of secondary infections.

# FROM FIELDS TO FJORDS; A FRAMEWORK FOR ENHANCING FISH PERFORMANCE AND RESILIENCE ACROSS GLOBAL AQUACULTURE ENVIRONMENTS

D. Henderson[1]*, S. Tsairidou[2], D. Waters[1], D. Tolhurst[1]

[1]Roslin Institute, Royal (Dick) School of Veterinary Studies, University of Edinburgh, EH25 9RG, UK

## Introduction

Selective breeding in Atlantic salmon (*Salmo salar*) has delivered substantial gains in productivity, disease resistance and other key traits. However, these gains are often not realised consistently across the heterogeneous environments in which salmon are farmed worldwide. This inconsistency is explained by genotype-byenvironment (GxE) interaction, where genotype performance and rankings can change between environments, reducing selection accuracy and slowing genetic progress (Gonzalez et al., 2022; Sae-Lim et al., 2016; Tollervey et al., 2024).

In aquaculture, GxE interaction is particularly pronounced due to the high sensitivity of fish to stressors, such as temperature, parasites, and handling (Sae-Lim et al., 2014). Environmental variability, both within and between locations (Fig.1), reduces resilience of Atlantic salmon for complex traits like growth and stress tolerance. This generally manifests as unpredictable shifts in performance across environments, meaning that genotypes bred for "optimal" conditions may underperform in commercial production systems subject to environmental challenges.

## Objectives

This project introduces a novel framework for integrating GxE interaction, into aquaculture breeding strategies, to improve environmental resilience across global aquaculture environments, which is being accelerated by climate change.

The specific aims are to (1) quantify changes in genetic gain and environmental resilience over time, (2) assess the extent of genotype reranking across production en ironments, and (3) identify index weights that optimise performance and resilience.

## Methods

Using AlphaSimR (Gaynor et al. 2021), genotypes for 5 founder populations of Atlantic salmon were simulated and mated randomly, subsequently being selected for growth to create a 'domesticated' base population. Environmental structure was then introduced using real-world climate data from four global regions: Scotland, Norway, Tasmania, and Chile to reflect realistic variation in production environments. These environments differ greatly in their timing, frequency and magnitude of heat stress events (Fig. 1).

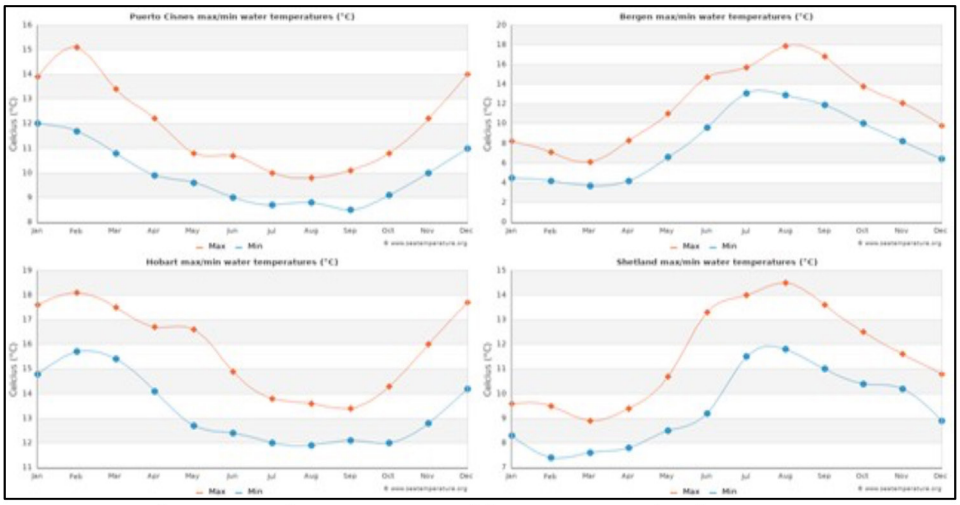
The simulation had three key traits: *Baseline growth* - performance under optimal conditions, *Environmental sensitivity* - performance under stress conditions, *Stress recovery* - performance following exposure to stress. These traits were used to (i) calculate novel 'resilience' traits as deviations from normal growth when under stress, (ii) construct weighted selection indices that combine productivity and resilience, and (iii) quantify the value added of including resilience into breeding objectives.

## Results

The three growth traits were initially explored in a model environment with equal time under optimal, stress and recovery conditions (Fig. 2) to assess the decay of the correlation between expected growth and realised growth due to the stress (Fig. 3). The parameters of the stresses experienced were varied to show the change in decay when the start and duration of stress is unpredictable (Fig. 4).

The simulations in this project demonstrate how selecting for resilience traits, alongside traditional performance metrics, can improve the stability of genotype performance across diverse environmental conditions. The framework can be used to balance selecting for performance in "optimal" environments and selecting for resilience in variable ones. This trade off can be navigated by incorporating informed selection indices to find the optimal balance of productivity and environmental resilience, helping identify and breed for genotypes with more predictable and stable performance in the face of a changing environment.

*(Continued on next page)*



(2) assess the extent of genotype reranking across production

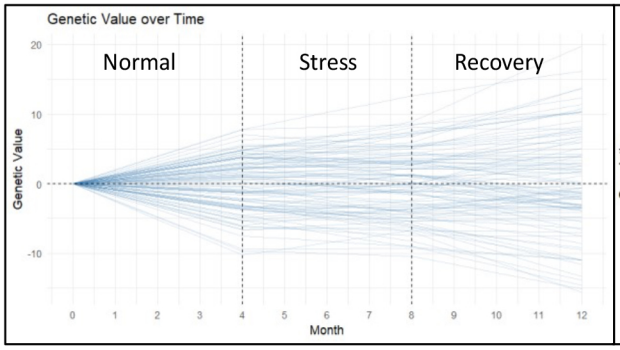

*Figure 2: Growth for 100 genotypes as deviations from the population mean, as the environment changes from optimal realised conditions (0-4 months), under stress (4-8) and recovery (8-12).*

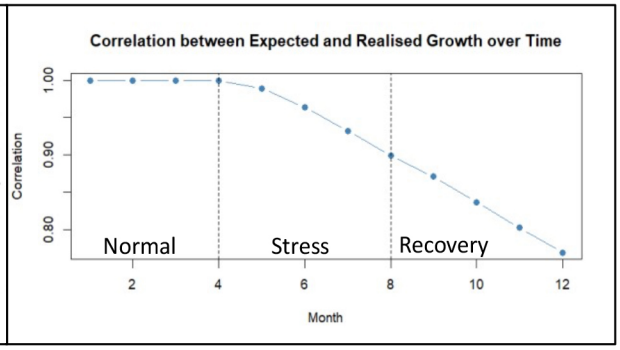

*Figure 3: Plot showing the decay of the corelation between expected growth rate under optimal conditions and the growth rate due to stress.*

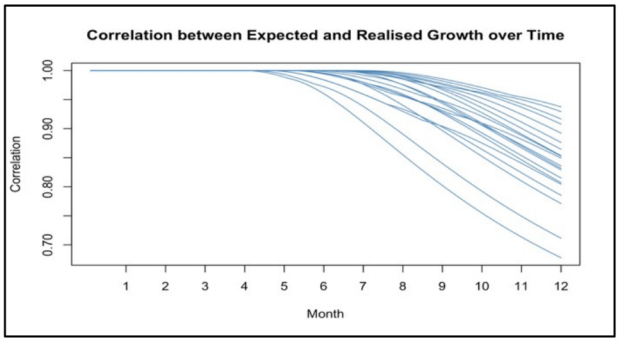

*Figure 4: Plot showing the decay of the corelation between expected growth rate under optimal conditions and the realised*

*(Continued on next page)*

## Conclusions

The new framework enables aquaculture breeding programmes to effectively leverage GxE interaction, contributing to the development of salmon stocks that are resilient to environmental change. This framework can be extended to numerous other commercially important traits and production systems, to improve long-term productivity and sustainability under the emerging pressures of climate change.

# BUSINESS MODELS FOR EUROPEAN ALGAE ENTREPRENEURS; A REVIEW OF FINDINGS FROM THE ALGAEPROBANOS PROJECT

Josien Hendricksen*[1], Ngoc T. A. Pham[1], Sander W.K. Van den Burg[1]

[1] Wageningen Social and Economic Research
Wageningen University & Research
Atlas (building no. 104)
Postbus 88
6700 AB Wageningen (Netherlands)
E-mail: josien.hendricksen@wur.nl

## Introduction

AlgaeProBANOS is a Horizon Europe project that aims innovation and market access pipelines for accelerating 6 highly relevant algae value chains, namely food, feed, textiles, nutraceuticals, biostimulants and cosmetics, covering both microalgae (two value chains) and seaweeds (macroalgae, four value chains). To help the products developed within the project reaching the global market (see Selnes et al., 2021), sustainable and circular business models are developed and financial analyses of the algae products are conducted. These business models help the sector identify its strengths, and relevant upgrading strategies (van den Burg et al., 2021). This contributes to communicating the commercial value of algae products and companies to potential investors and stakeholders. The economic insights from these six value chains can pave the way for future developments in the wider algae sector.

## Materials and methods

The project uses a collaborative co-creation process to identify the business models currently in place in the European algae sector, using the Business Model Canvas as framework. The companies are actively involved in developing and discussing the business model, with the research team analysing the information provided. Business models will be informed by strategic financial analysis which will quantify the revenue generating potential, capex and operating costs, the margins and operating profit, and payback period and break-even volumes of proposals. Additional insights about developments in the business (e.g. changes in technical processes or partners, trading market and the motivation behind them) are collected throughout the project. The project then zooms out to the wider European algae sector by incorporating lessons learned via a survey and interviews with other companies, which are external to the project.

## Results

The first results indicate that, contrary to observations made a few years ago (Selnes et al., 2021), many companies are moving away from cultivating seaweed. Compared to harvested from the wild, cultivated seaweed can currently not compete in costs. For companies in the macroalgae business, the focus is often on the processing of wild harvest. However, another barrier is that European prices cannot compete with Asian prices. This means that growing a business based on wild harvested macroalgae is challenging as well. Instead, companies focus on the end of the value chain and try to increase the value of their products by using seaweed extracts and processing it into high-value products for the nutraceutical and cosmetic market. This switch in the focus of companies aligns with the observation that algae as food gets less attention in the debate. Obstacles like the Novel Food regulation, a lack of certification and standards, concerns about iodine and heavy metal levels, and low consumer acceptance have stagnated the sector. There is a reliance on few and bigger companies now to make a success of new algae products in different value chains.

## Discussion & Conclusion

The European algae sector is in development and strong support from the EU and national governments pushes development and innovation. Numerous business venture into the processing and development of products from seaweed, supported by investors. The review of business models however also shows the difficulties that companies experience to develop commercially viable products. Recognizing the potential of the algae sector to contribute to the provision of sustainable natural resources from Europe, it is pivotal to further support development of the sector. Future support is also justified given the positive impacts of seaweed cultivation and use, for nature restoration, climate mitigation and adaptation.

# THE SINGLE-CELL ATLAS OF EARLY DEVELOPMENT IN ATLANTIC SALMON

Christiaan Henkel*, Tomasz Podgorniak, Junsoung Kwak, Juan Fu, Romain Fontaine, Torvald Blikra Egeland & Erik Burgerhout

Faculty of Biosciences
Norwegian University of Life Sciences (NMBU)
Ås, Norway
christiaan.henkel@nmbu.no

As they develop in eggs exposed to the environment, fishes are especially susceptible to external influences during embryogenesis. These include temperature and light, which have been shown to have long-term fitness effects. In the SALMOCODE project, we use single-cell transcriptomics to investigate these vulnerabilities in the Atlantic salmon embryo.

In the first phase of this project, we have sampled eggs of farmed salmon between 124 and 238 day-degrees of development, corresponding to the interval between early organogenesis and the 'eyed' stage. By sampling every day, we have created a time lapse consisting of 23 developmental stages, which we have used for single-cell library preparation using the Parse Biosciences Evercode WT Mega kit. After sequencing, the current atlas contains data on 50000 cells, which belong to the approximately 50 broad cell types that emerge during early development.

In our main time lapse experiment, conducted at 4 °C, survival was high; however, in concurrent experiments at elevated temperatures, mortality was very high, and concentrated around specific developmental time points. We are currently profiling survivors of these bottlenecks using single-cell transcriptomics, under the hypothesis that they might show temperature-induced deviations from healthy organ development. These deviations could, in turn, have a negative impact on resilience later in life.

For the second phase of the project, we have sampled eggs more broadly between gastrulation and hatching, and under both controlled (4 °C, no light, commercial domesticated genetic background) and natural conditions (changing environmental conditions during the Norwegian winter, wild Atlantic salmon). After processing using single-cell transcriptomics, these will be combined with the phase one atlas to form a comprehensive, reuseable reference for early development.

# IMPACT OF NOVEL FEEDING PROTOCOLS ON ORGAN DEVELOPMENT AND SKELETAL ANOMALIES IN ATLANTIC COD LARVAE (*Gadus morhua*)

[5]Planktonic AS, Trondheim, Norway.

## Introduction

Aquaculture of Atlantic cod (*Gadus morhua*) continues to face some bottlenecks, particularly during larval rearing. Optimizing rearing protocols and customizing nutrition is essential not only for promoting larval growth and survival, but also for supporting organ ontogeny and skeletogenesis during the critical early life stages. During early ontogeny, the digestive and musculoskeletal systems undergo rapid morphological changes, and tailored nutrients play a critical role in supporting maturation, enhancing digestive capacity, and promoting proper skeletal formation. Although enriched rotifers and Artemia remain the benchmark live feeds in cod larviculture, inclusion of natural zooplankton such as barnacle nauplii has yielded improved growth, survival, and larval quality in several species, particularly in cod larvae (Øie et al., 2017). Despite comprehensive research into cod larval development and feeding protocols, knowledge on species-specific nutritional needs remains scarce. Given that the composition of weaning microdiets can influence appetite, gut development and bone formation, there is a pressing need to evaluate customized feeding regimes that combine novel live-feeds with tailored microdiet formulations. Therefore, the present study tested feeding protocols incorporating plankton eggs (Cryo-µ) and barnacle nauplii (Cryo-S, Cryo-L), alongside with customized microdiets, to assess effects on growth performance, skeletal anomalies, and organ ontogeny in Atlantic cod larvae.

## Material and methods

Two independent trials were conducted to evaluate the effects of different feeding protocols and novel microdiets on the growth performance, incidence of skeletal anomalies, and organ ontogeny of Atlantic cod (*Gadus morhua*) larvae. In both trials, larvae were obtained from ODE AS (Norway) and randomly distributed at 2 days after-hatch (DAH) into triplicate 400 L tanks. Rearing conditions were identical in both trials, with 24h light and water temperatures ranging from 8.8 to 10.8 ± 0.2°C. Trial 1 was conducted from 3 to 66 DAH and consisted of three treatments: CONTROL, D1, and D2. The CONTROL group was fed rotifers, large barnacle nauplii (Cryo-L), and a commercial microdiet. Treatments D1 and D2 received a diversified live feed protocol composed of rotifers, plankton eggs (Cryo-µ), small barnacle nauplii (Cryo-S), Cryo-L, in addition to experimental microdiets Diet 1 and Diet 2, respectively. Trial two, lasting from 3 to 67 DAH, also included three treatments: CONTROL, D3, and D4. In this trial, all groups were fed the same live feed protocol (rotifers, Cryo-µ, Cryo-S, and Cryo-L). The CONTROL group received the commercial microdiet, while D3 and D4 were fed experimental microdiets Diet 3 and Diet 4, respectively. Sampling was conducted at day 3, 30, 50, and at the end of the trial (66 and 67 DAH). Growth parameters, skeletal anomalies and organ development were assessed.

## Results

Experimental groups D1 and D2 showed earlier signs of gill development at 15 DAH and improved ontogeny of gut, liver and eye at 30 DAH, when compared to the control group (Figure 1A). At the end of the trial, both experimental groups showed lower incidence of skeletal anomalies. Particularly D1 (Figure 1B) and D4 (trial 2, results not shown) presented lower incidence of skeletal anomalies ($P<0.05$) than the control group (SK).

B

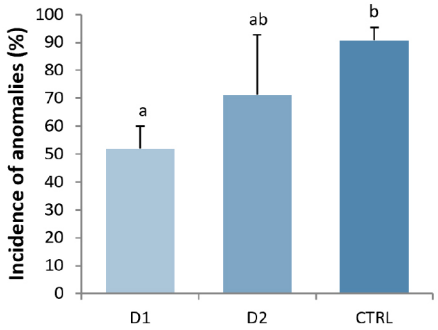

**Figure 1.** (A) Histology score for each organ of cod larvae at 15 DAH and at 30 DAH, according to the scoring system of Pacoring et al, 2022. The scale is from 1 (very poor organ development) to 5 (very good organ development). (B) Incidence of skeletal anomalies in Atlantic cod (66 DAH) fed two experimental (D1 and D2) and one commercial (SK) microdiets, in trial 1. Results are expressed as means + standard deviation. Different lowercase letters indicate significant differences between the dietary treatments ($P<0.05$).

## Discussion and Conclusion

The impact of the feeding regime on growth, organ ontogeny and skeletal anomalies of Atlantic cod larvae was evaluated in the present study. In both trials, there was no relevant effect of the experimental feeding regimes on growth performance, with RGR ranging from 10-10.7% (results now shown) and standard length within the same range or above values previously reported in studies using live feed protocols supplemented with natural zooplankton (Folkvord et al., 2017). Nevertheless, in trial one, experimental groups D1 and D2 showed earlier signs of organ development at 15 and 30 DAH when compared to the control group (Fig.1A), indicating that that the live feeding regime combining Cryo-µ, Cryo-S and Cryo-L has a positive effect on organ ontogeny, potentiating earlier cell development and differentiation. Such effect was also observed in trial two – cod larvae organs showed early development across all treatments at 35 DAH (results not shown). Remarkably, from 46-67 DAH cod larvae fed Diet 4 experienced a higher degree of cell differentiation when compared to the control group, hence demonstrating the potential synergistic effects of early feeding protocols with Cryoplankton and customized microdiets. Regarding skeletal development, both trials showed that experimental groups had a significantly lower incidence of skeletal anomalies (Fig. 1B), including fewer severe deformities (data not shown). This strongly suggests that the nature of Phospholipid (PL) sources in the experimental diets promote proper bone formation and larval tissue maturation. In marine fish larvae, dietary phospholipids have been shown to enhance not only vertebral ossification and reduce deformities but also support digestive enzyme activity and histological development. In Atlantic cod specifically, limitations in endogenous PL synthesis during early development mean that dietary PL is critical for both lipid transport and membrane formation, indirectly influencing organ differentiation and ontogenetic maturation of the intestine and liver. Overall, these findings support the hypothesis that the enhanced skeletal and organ development observed in the experimental treatments is closely associated with the synergistic effects of combining cryoplankton with tailored microdiets. In particular, the nature of phospholipid sources included in the microdiets appears to play a pivotal role in promoting the physiological maturation and skeletal development of cod larvae, ultimately contributing to improve juvenile quality.

Over 35% of global fishery stocks are overexploited (FAO, 2022), partly driven by the demand for small pelagic fish to feed carnivorous farmed species. To address this, the aquaculture sector has significantly reduced fishmeal (FM) in feeds, from 50% in 1997 to 14% in 2017 (Naylor et al., 2021). Yet, overall FM use continues to rise due to rapid aquaculture growth. While plant proteins like soy have helped lower FM content, they bring nutritional and economic challenges. Alternative proteins and fats are being developed but remain limited by cost and availability, whereas aquaculture by-products are abundant, inexpensive, and, through enzymatic hydrolysis, offer promising nutritional and functional benefits.

We undertook a study to assess the feasibility of halving the FM content (low fish meal -LFM- vs high fish meal -HFM-) in the pre-grower diet of red sea bream (*Pagrus major*), with or without supplementing with protein hydrolysates derived from aquaculture by-products (shrimp hydrolysate -SH- or tilapia hydrolysate -TH-). We also included stress situations (daily net chasing for 1 minute) to study the interactions between farming stress and diet. After 15 weeks of rearing and the final weighing, the fish were subjected to physiological sampling and a bacterial challenge to better understand the underlying physiological mechanisms.

Although the diet with low FM content yielded very satisfactory zootechnical performance, close to that of the control diet, the addition of hydrolysates accelerated growth while reducing the feed conversion ratio, and FM use (Fig. 1). Stress similarly impacted all diets, reducing feed intake, growth, and health indicators. All these results are supported by variations in intestinal structure, cortisol levels, and the expression of growth factors in the liver. Hydrolysates also reduced sensitivity to bacterial infection in fish fed the LFM diet. These effects appeared to be linked to improvements in several markers of the non-specific immune system.

Overall, this study highlights the great potential of hydrolysates to further reduce aquaculture's dependency towards wild fish and pave the way for future research on feed optimization.

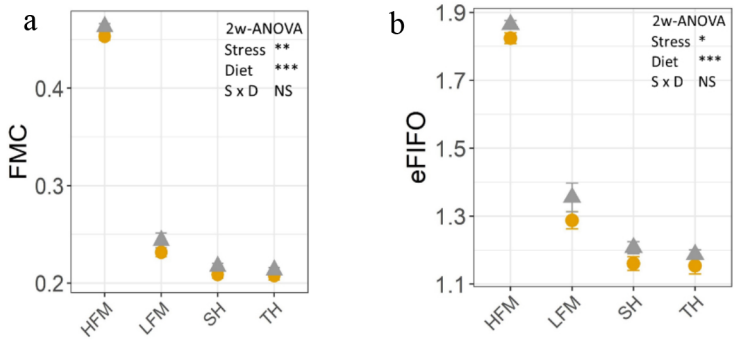

Figure 1. (a) Fish meal consumption (FMC, in kg/kg of produced fish) and (b) economic Fish In Fish Out ratio (eFIFO) of red seabream fed experimental diets for 15 weeks. HFM: High Fish Meal, LFM: Low Fish Meal, SH and TH: LFM supplemented with Shrimp Hydrolysates or Tilapia Hydrolysates respectively.

# ENHANCING AQUACULTURE PRODUCT QUALITY: THE ROLE OF SENSORY EVALUATION IN ASSESSING NUTRITIONAL AND FEEDING STRATEGIES

A.J. Hernández[1,3*]& J.B. Calanche[2,3*]

[1]Laboratorio de Nutrición y Fisiología de Peces, Departamento de Ciencias Agropecuarias y Acuícolas, Facultad de Recursos Naturales, Universidad Católica de Temuco, Casilla 15-D, Temuco, Chile.

Email: ajhernandez@uct.cl/calanche@unizar.es

Aquaculture plays an important role in global food security and economic development, providing a growing supply of high-quality animal protein. Nowadays, it supplies most of the fish consumed worldwide (FAO, 2024). Among the factors influencing aquaculture production efficiency and product quality, nutrition and feeding strategies stand out for their potential to enhance animal health, to improve sustainability of activity through the reduction of unfavorable environmental impacts and meet consumer expectations. Changes in feed formulation, particularly the incorporation of alternative protein and lipid sources, can significantly alter the sensory quality of aquaculture products, basically with respect to appearance, texture, flavor, taste and odor, which are key drivers of consumer acceptance (Calanche *et al.*, 2019).

Sensometrics found in sensory evaluation and mathematics tools provide effective methods to evaluate the impact of dietary formulations and to guide the development of products that align with market demands. However, many aquaculture nutrition studies are limited by experimental designs that focus on isolated variables, restricting a more comprehensive understanding of how feed formulation influences the overall quality of the final product. The lack of scientific rigor in the application and use of sensory science in the field of aquaculture is a persistent problem today, despite the recognized importance of the sensory quality of fishery and/or aquaculture products in commercial terms. This presentation aims to highlight the role of sensory analysis in nutrition research, emphasizing their value as integrated tools to assess the effects of feed composition and to tailor the sensory quality of aquaculture products.

Sensory evaluation in aquaculture has evolved across four main application areas: nutrition and feeding, production systems, product quality, and marketing. Properly designed sensory studies can be employed to generate objective data or apply hedonic and affective testing to capture consumer perceptions. Sensometrics offers valuable tools to quantify and interpret these responses, allowing researchers to relate to organoleptic properties with nutritional and biochemical parameters. In the agrifood field many researchers often default to using complex statistical methods simply because modern software makes them easily accessible, leading to unnecessarily sophisticated analyses (Qannari, 2017). However, true progress in sensometrics requires grounding research in psychological, behavioral, and motivational concepts that genuinely reflect the phenomena under study. Sensometrics is inherently interdisciplinary, and advancements should be informed by developments in psychology, behavioral and social sciences, neuroscience, and machine learning. With the advent of new data collection techniques, powerful computing, and advanced analytical tools like meta-analysis and interactive databases, sensometrics is well-equipped to address new challenges in understanding perceptions and preferences. Ultimately, there is a strong reason to believe that sensometrics has a bright future, especially in the era of big data.

**Introduction**

The exponential growth of aquaculture in recent years has led to an increase in diseases caused by opportunistic pathogens (viruses, bacteria, and fungi), resulting in significant economic losses. Among viral pathogens, one of the most relevant in the Mediterranean area is Betanodavirus (NNV), the causative agent of viral encephalopathy and retinopathy (VER) in fish. NNV can cause up to 100% mortality in juvenile stages of susceptible species, including the commercially important European sea bass (*Dicentrarchus labrax*) (Kibenge, 2019). Antimicrobial peptides (AMPs) are key components of the innate immune system and are found across a wide range of organisms. These small molecules regulate inflammation, promote leukocyte recruitment, and bridge the innate and adaptive immune responses. In addition, AMPs exhibit broad-spectrum activity, acting directly against bacteria, viruses, fungi, and parasites by disrupting their membranes. Due to their low likelihood of inducing resistance, AMPs are considered a promising alternative for enhancing disease resistance and improving overall fish health. Among them, beta-defensins (Bdef) have attracted attention for their antibacterial, antiviral, immunomodulatory, and anti-inflammatory properties. The use of AMPs as a preventive measure against NNV is increasingly supported by recent scientific evidence (Valero et al., 2020; Cervera et al., 2024). However, the *in vivo* role of orally administered Bdef in European sea bass has not yet been explored. Therefore, the aim of this study was to evaluate the involvement of European sea bass Bdef1 in NNV infection and its potential as an immunomodulatory agent in functional diets designed for sea bass prior to infection.

**Material and methods**

The synthetic mature peptide Bdef1 derived from European sea bass was encapsulated at 1 mg/mL in alginate-chitosan nanoparticles (NP) using a method that was previously described (Collado-González et al., 2020)we report the synthesis of nanocomposites for the oral delivery of insulin composed of alginate, dextran sulfate, poly-(ethylene glycol. Then, juvenile European sea bass were fed for 5 days with: Control (commercial diet), NP (diet with empty nanoparticles a), and NP+BD (nanoparticles with Bdef1) diets. After sampling for immune analysis, the NP and NP+BD groups were infected with a sublethal dose performed by intramuscular injection of 50 µL of the containing $10^4$ TCID50 of NNV/fish. The control group was injected intramuscularly with 50 µL of PBS alone. At 2 and 24 days post-infection (dpi), samples of brain, head-kidney and hindgut of each fish were collected and processed for immune gene expression analysis by qPCR. Moreover, serum samples were collected to detect NNV specific antibodies using a ELISA assay and as well to evaluate the antibacterial activity agains *Vibrio harveyi* and *Vibrio anguillarum* using a method previously described (Oriol Sunyer & Tort, 1995). Data were expressed as the % of bacterial growth inhibition.

**Results**

Our results showed that sea bass fed with encapsulated Bdef1 during 5 days had not changed their immune parameters. In addition, the antiviral response elicited against NNV was again not altered. In fact, the results obtained from the ELISA assay performed on serum samples have shown that the production of specific antibodies was reduced by the intake of Bdef1.

**Discussion and conclusions**

This study suggests that 5 days dietary administration of encapsulated Bdef1 exerts a limited effect on the immune response of European sea bass as well as little response during NNV infection. Bdef1 appeared to modulate the immune response without inducing excessive activation. Additionally, a significant increase in antibacterial activity was observed against *Vibrio harveyi*,

while no effect was detected for *V. anguillarum*. ELISA results showed lower virus-specific antibody levels in treated fish, indicating a potential modulation of the adaptive immune response. Overall, the promised benefits of Bdef1 as an immune-modulating agent are controversial, supporting further research to optimize its delivery and application in aquaculture.

# CIRCULAR BIOECONOMY IN AQUACULTURE: INNOVATION FOR SUSTAINABILITY IN ARID ZONES

Ruth Elena Hernández Benítez*, Luisa Marcela Villamil Díaz, Ender David Egurrola Pedraza, Ever Rojas Díaz, Edson Villamizar Otero

SENA Regional Guajira
Calle 21 Av. Aeropuerto
Riohacha – Colombia
Email: rhernandezb@sena.edu.co

The adoption of circular bioeconomy principles in aquaculture represents a key strategy for achieving sustainable development in resource-constrained regions such as La Guajira (Colombia). Based on recent research on intensive tilapia farming (*Oreochromis niloticus*) and low-impact aquaculture production models (Zimmerman et al., 2023; FAO, 2024), this study evaluates the viability of Recirculating Aquaculture Systems (RAS) as an innovative solution to enhance productivity and reduce environmental impacts. Through case studies in Riohacha and Fonseca, RAS proved to reduce water footprints, improve food security, and generate stable income for rural communities. The proposed model aligns with Sustainable Development Goals (SDGs 2, 6, 12, and 14), offering a replicable framework for arid areas in Latin America.

## Introduction

La Guajira faces severe environmental constraints for aquaculture, characterized by annual rainfall below 500 mm, high evaporation rates, and aquifer salinization (IDEAM, 2023). Conventional aquaculture systems generate between 15 and 20 $m^3$ of effluent per ton of fish, negatively affecting freshwater bodies.

Circular bioeconomy seeks to close water and nutrient cycles through sustainable practices such as RAS and multitrophic systems (Chopin, 2022). This approach integrates technology, environmental management, and resilient food production in water-scarce settings. Table 1 summarizes the main circular bioeconomy strategies applied in aquaculture:**Methodology**

Two RAS pilots were evaluated, integrating:

- **Biofloc technology:** Conversion of nitrogenous waste into microbial biomass
- **Aquaponics:** Use of effluents to cultivate *Oreochromis niloticus*
- **IoT sensors:** Real-time monitoring of pH, oxygen, and temperature

**Table 1. Main circular bioeconomy strategies applied in aquaculture**

| Strategy | Description | Reference |
|---|---|---|
| Water use optimization | RAS with ≥90% recirculation, reducing dependence on external sources | Dauda et al. (2020) |
| Functional feeds | Use of diets with probiotics and prebiotics to improve feed conversion | Hai (2020) |
| Waste valorization | Integration of biofloc and bio-RAS to convert sludge into secondary biomass | Emerenciano et al. (2021) |
| Renewable energy | Incorporation of solar energy to reduce carbon footprint | Nhan et al. (2023) |

*(Continued on next page)*

## Results

The case studies in Riohacha and Fonseca showed that implementing RAS under circular bioeconomy principles reduced water consumption by 40% compared to traditional systems, significantly contributing to water sustainability in arid zones. Furthermore, consistent production of 8 tons per hectare per year of tilapia was achieved during drought seasons, enhancing local food security. Economically, rural incomes increased by 35% through direct sales in regional markets.

## Discussion

The integration of RAS and circular bioeconomy technologies reduces pressure on aquifers and surface water bodies—crucial in arid regions. Additionally, the use of functional feeds improves feed conversion, lowering production costs (Hai, 2020). However, the main barrier identified was the high implementation cost (USD 15,000/ha), which can be mitigated through state incentives and public-private partnerships. The use of renewable energy represents a complementary strategy to further reduce operational costs.

## Conclusions

Implementing RAS under a circular bioeconomy approach in La Guajira can:

- Generate 1,200 direct jobs over the next five years.
- Produce more than 1,500 tons per year of sustainable animal and plant protein.
- Reduce pressure on local aquatic ecosystems by 75%.
- Increase the socio-economic resilience of rural communities.

This model has strong replicability potential in other arid regions of Latin America, contributing to SDG achievement and promoting innovation in sustainable aquaculture.

## Acknowledgments

Project funded by the Ministry of Science, Universidad de La Sabana, and SENA Colombia.

## Introduction

Biochar is a carbon-rich material produced through the pyrolysis of biomass under low-oxygen conditions. It is a highly product with a wide range of applications, among which its use as a dietary additive in aquaculture has shown promising potential. Its porous structure and high retention capacity have been linked to enhanced nutrient absorption, thereby improving feed efficiency and overall fish health (Amjad et al., 2024). Additionally, these retention characteristics may contribute to trapping nitrogenous compounds, diminishing its presence in water (Khalid et al., 2024). Beyond its functional benefits, the use of biochar derived from wood waste aligns with circular economy principles, supporting sustainable production while potentially reducing the need for other feed ingredients such as fishmeal and fish oil. In this context, the objective of this study was to evaluate the metabolic effects of dietary biochar supplementation in turbot (*Scophthalmus maximus*), with a particular focus on determining an optimal inclusion level without impairing fish growth or health.

## Material and methods

The biochar was produced on an industrial scale through the carbonization of plum (*Prunus domestica*) residues at around 450 °C. A total of 315 turbot juvenile (initial mean body weight of ~34 g) were randomly distributed into 9 tanks (35 fish per tank in triplicate). They were fed manually *ad libitum* twice daily with three different diets: i) control diet (CT), ii) diet supplemented with 0.25 % biochar (B0.25) and iii) diet supplemented with 0.50 % biochar (B0.5). Fish were fed experimental diets for 65 days at the Marine Aquaculture Facility "El Bocal" of the Spanish Institute of Oceanography in Santander. An intermediate biometric sampling was conducted to monitor growth progression. At the end of the feeding trial, final biometric measurements were recorded, and plasma, liver, and muscle samples were obtained. Somatic indexes were calculated, and cortisol along with metabolic parameters were analysed in each tissue.

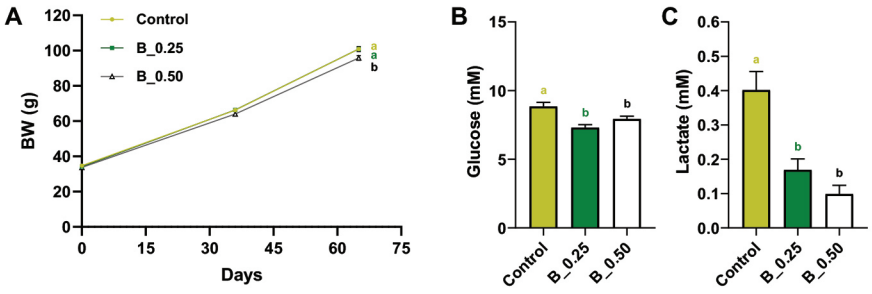

**Fig.1: A)** body weight (BW) evolution during the experiment; plasma glucose **B)** and lactate **C)** levels at the end of the experiment.

*(Continued on next page)*

**Results and discussion**

The inclusion of 0.25 % biochar in the diet did not impair growth compared to the control group; however, the 0.50 % inclusion negatively affected performance, resulting in significant lower final body weight and body length. Viscerosomatic index (VSI) was significantly reduced in fish fed the B0.5 diet. Since no differences were found in the hepatosomatic (HSI) or intestinal length (ILI) index, this reduction in VSI may indicate lower visceral fat accumulation, possibly reflecting increased energy expenditure. This energy could be used to compensate some physiological stress generated by an excessive inclusion level of biochar.

Fish fed with biochar reduced plasma energy metabolites (proteins, glucose, TAG, cholesterol and lactate) compared to the control, although all levels were within normal physiological range. In B0.25 fish group, these results together with the maintained growth and non-significant trends found in liver and muscle, suggested a better metabolic efficiency, probably due to more effective nutrient utilization and reduced basal energy mobilization requirements. In contrast, in fish fed B0.5 diet, these reduction of circulating metabolites accompanied by impaired growth and the tendencies followed in the tissues, could be indicative of an energy metabolic resources redirected toward maintenance or detoxification, rather than growth. This suggests a mild adaptive response, perhaps due to an overdose of biochar inclusion in the aquafeed.

The significant decrease in plasma lactate observed in specimens fed with biochar diets reflected a reduced dependence on anaerobic glycolysis or better tolerance to acute stress. The tendency towards an elevation of cortisol with biochar, without exceeding low physiological levels, suggested that the additive may cause mild endocrine adaptations, but without inducing a chronic or harmful state of stress (at least in fish fed with an intermediate level of biochar).

These results indicate that dietary biochar, particularly at 0.25 % inclusion level, may contribute to more efficient metabolism and energy utilization without compromising growth performance or fish health. Combined with its potential for reducing environmental impact, biochar represents a promising and sustainable additive for aquafeeds.

## Introduction

The widespread use of copper as a biocide in French vineyards has led to the accumulation of heavy metals in coastal environments, raising concerns about its ecological impacts. Oysters (*Magallana gigas*), known to be among the strongest marine bioaccumulators of copper, can accumulate concentrations ranging from 719 to 14,000 µg/g of dry weight. While copper is an essential micronutrient required for enzymatic functions, elevated levels can exert strong selective pressure on microbial populations, promoting the evolution of metal-resistance mechanisms.

*Vibrio aestuarianus* subsp. *francensis* is an emergent marine pathogen first described in France in 2001, with a re-emergence observed in 2011–2012. It is now widely distributed along French and some other European coasts[1-2]. This pathogen is responsible for mass mortality events in market-size oysters, causing real and growing economic losses in aquaculture. *V. aestuarianus* subsp. *francensis* strains are clonal and characterized by oyster-specific pathogenicity and a notable copper-resistant phenotype compared to the environmental non-virulent strains of the species[3]. Copper resistance is also observed in other oyster pathogens such as *V. tasmaniensis* and *V. crassostreae*, suggesting a broader evolutionary trend linked to host adaptation[4-5].

In oysters, copper homeostasis is closely tied to immune function. Mechanisms such as the regulation of metallothioneins and metal transporter genes (e.g., Ctr1, ATP7A, ZIP1, Znt2) contribute to resistance against other vibrio species infections[4;6]. These findings underscore the complex interplay between environmental metal exposure, pathogen evolution, and host immune responses in marine ecosystems. However, the immune response of adult oysters during *V. aestuarianus* pathogenesis and the role of environmental factors such as copper levels remains poorly understood. This study aims to investigate whether accumulated copper influences the outcome of the host–pathogen interaction, by deciphering copper-induced immune modulations in oysters and their impact on disease progression.

## Materials and methods

Adult *M. gigas* oysters were exposed to copper ($CuSO_4$ 0, 30, 60 and 120 µg/L; 3 groups of 40 animals per condition) via immersion for 1 month. 15 oyster per copper condition were collected at 0, 14 and 28 days to quantify copper content and determine microbiota composition in order to evaluate correlations with disease progression. Subsequently, the osyters were bath-challenged with *V. aestuarianus* strain 12/016 or in the absence of bacteria (control group) (3 replicates of 10 animals per condition) to assess the impact of copper pre-exposure on infection outcomes. Mortality was monitored daily during 14 d. Hemolymph was collected before and after infection for downstream analyses (hemocytary titre, ROS production, and bacterial multiplication). Finally, gills were collected for transcriptomic analysis by RNAseq. To assess immune modulation and copper-mediated protection to the infection, gills (n=5) from infected and non-infected animals were dissected pre- and post-infection before mortality peak started. Samples were used to extract RNA and sequencing. Differential expression analysis was performed.

*(Continued on next page)*

**Results**

Copper pre-exposure conferred a moderate yet reproducible protective effect against *V. aestuarianus* infection in vivo, with reduced mortality observed across independent exposure and infection protocols. Copper dosage data suggest a potential correlation between individual copper content and mortality timing. Our results also revealed that copper pre-exposure did not impact *V. aestuarianus* growth in plasma either in vitro or in vivo, nor did it affect baseline hemocyte populations. However, transcriptomic (RNA-seq) and targeted qPCR analyses are ongoing to evaluate whether copper modulates the expression of immune-related genes in gill tissues and hemocytes. Notably, preliminary observations suggest that copper pre-exposure may reduce intracellular survival of *V. aestuarianus* in oysters' hemocytes. This potential enhancement of cellular immunity remains to be validated through further experiments. In parallel, to further investigate the physiological consequences of copper exposure, microbiota analyses are currently underway to determine whether copper alters oyster microbial communities.

**Discussion and conclusion**

Our findings suggest that copper accumulation in oysters may contribute to modulating the host–pathogen dynamic during *V. aestuarianus* infection. The observed moderate protection conferred by copper pre-exposure supports the hypothesis that metal-induced immune priming plays a role in disease outcome. While copper did not affect pathogen growth (neither in vitro nor in vivo) or baseline immune cell populations, reduced intracellular bacterial survival in hemocytes of copper-expossed oysters' points toward copper-mediated enhanced cellular immune defenses. These results align with previous reports linking heavy metal homeostasis to antimicrobial activity in oysters. Ongoing microbiota analyses and localization studies will help clarify whether copper's impact is mediated by host immunity alone or also involves shifts in microbial communities. Taken together, this work highlights the complex interplay between environmental metal exposure, immune modulation, and pathogen success—emphasizing the need to consider abiotic stressors in the management of oyster health in aquaculture settings.

## Introduction

*Vibrio harveyi* is one of the major agents of vibriosis in marine aquaculture, causing considerable economic losses globally (Austin & Zhang, 2006). Moreover, global warming is causing a shift in its epidemiological role. In the last decade, *V. harveyi* has been increasingly associated with outbreaks in farmed European sea bass (*Dicentrarchus labrax*) along the Mediterranean Sea, posing a serious threat to the industry. The pathogenic strains are not serologically homogeneous and there appear to be three dominant serotypes among the Mediterranean ones (Amaro et al., 2020). However, scarce research comparing their characteristics exists. That is why, despite vaccination efforts targeting *V. harveyi*, outbreaks continue to occur, suggesting that vaccine efficacy may depend on the specific serotype used in its formulation. Thus, *V. harveyi* represents an evolving threat in Mediterranean aquaculture systems and underscores the need for updated surveillance and control strategies. In this study, we aimed to study the serological variability and their potential immunogenicity (based on outer membrane proteins (OMPs) and lipopolysaccharide (LPS) and O-antigen characteristics).

## Materials and methods

Bacterial strains: a collection of strains isolated from diseased seabass in farms located in the Iberian Peninsula was identified using PCR targeting the *V. harveyi toxR* gene (Pang et al., 2006). All strains were routinely grown on Tryticasein Soy Agar or Broth supplemented with 1 % NaCl (TSA-1 or TSB-1) at 28 ºC.

Serology: rabbit polyclonal antisera were raised against formalin-killed whole cells of strains representative of the three putative dominant serotypes (ser): 972 (ser A), 203 (ser B) and C2 (ser C). Then, slide agglutination with whole cell suspensions ($10^8$ colony forming units (CFU)/mL) and O-antigens in PBS was performed (Fouz et al., 1992). Preparation of LPS and OMPs: representative strains of each serotype (see above) were selected for cellular envelope characterization. Crude fractions of LPS were obtained from $10^8$ CFU/mL from overnight TSB-1 cultures and OMPs were extracted as previously described (Fouz et al., 1992).

Electrophoretic analysis and immunoblot: LPS and OMPs were separated by SDS-PAGE with a 10% acrylamide separation gel. In the case of OMPs protein bands were stained with Coomassie brilliant blue. For immunoblotting, fractioned LPS or OMPs were transferred to a PVDF membranes (100V/1 h) that were probed with polyclonal sera anti ser A, B or C diluted 1:750 and, subsequently with anti-rabbit IgG-AP-conjugated (Sigma) diluted at 1:3000. Bands were visualized using NBT and BCIP.

## Results and discussion

Isolates from diseased seabass were confirmed as *V. harveyi* by using specific PCR. Agglutination tests showed that they mostly belonged to ser A and C and to a lesser extent to ser B, previously reported in Croatia (Pavlinec et al., 2022). Moreover, no crossed reactions were observed among serotypes.

LPS patterns differed among serotypes, with ser B and ser C harboring more medium molecular weight O-antigen bands and lipid A (signal below 35 kDa) than ser A (Figure 1). As occurred in agglutination assays, no crossed reactions among serotypes were observed.

*(Continued on next page)*

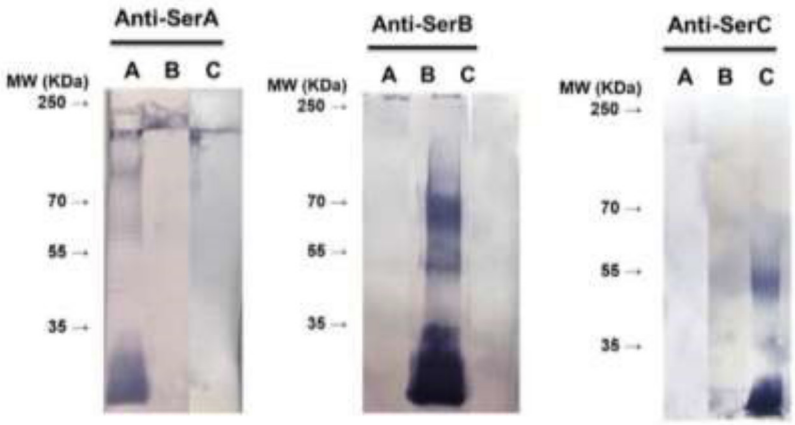

Figure 1. Immunoblot analysis of lipopolysaccharide (LPS) of *Vibrio harveyi* using polyclonal antibodies raised against serotypes (Ser) A, B and C. Lanes: LPS from SerA strain (972) (A), SerB strain 203 (B) and SerC strain C2 (C). Immunostaining was performed with primary antibodies anti-*V. harveyi* SerA, SerB or SerC (1:750), and anti-rabbit IgG-AP-conjugated (1:3000), and visualized with NBT and BCIP.

Regarding the OMPs patterns, all strains exhibited common protein bands, with few serotype-specific ones (data not shown). OMPs immunoblots reinforced these observations, since strains of the three serotypes reacted with antibodies raised against different serological groups. In fact, low molecular weight bands (30-40 kDa) were common in strains of the three serotypes (data not shown). If these common immunogenic OMPs were protective, vaccines developed with strains belonging to any serotype could confer some protection against others.

Our results are especially relevant for the future development of broadly protective and effective vaccines against this new concerning pathogen. Moreover, the emergence of new serotypes highlights the potential lack of cross-protection and immunogenic overlap between circulating and vaccine strains.

Conclusion

This study highlights the serological diversity of *V. harveyi* strains responsible for vibriosis in European sea bass. For this reason, current vaccination strategies may not provide broad protection, reinforcing the importance of continued monitoring and the development of more comprehensive vaccines.

Email: l.hernandezrodriguez@um.es

**Introduction**
Dredging involves the relocation of marine sediments for different purposes such as bioremediation or maintenance of ports and navigation channels (Beljin et al., 2023; Eke et al., 2023). Although it is currently an essential activity, dredged sediments are classified as hazardous waste due to the amount of contaminants, such as Potentially Toxic Elements (PTEs) including As and Pb (DCMD, 2021; Martínez-López et al., 2021; Beljin et al., 2023; Yi et al., 2023). Consequently, recent research focuses on reducing pollutant concentrations to enable the reuse of dredged sediments in different areas such as construction and agriculture (Rozas et al., 2018; Loudini et al., 2020; Beljin et al., 2023).

The main objective of this work was to characterize dredged sediments from Los Nietos, a highly environmental impacted area in the Mar Menor coastal lagoon. Subsequently, the study analysed the risks associated with As and Pb to public health and ecosystems for the subsequent use of the dredged material in beach regeneration and the creation of construction materials.

**Materials and methods**
Properties and mineralogical composition of 20 marine sediment samples were analyzed according to the current Spanish regulation guideline, "Directrices 2021"(DCDM, 2021). Then, bioaccessibility of PTEs was determined by *in vitro* digestion to determine human health risk associated with As and Pb according to current standardized regulations (USEPA, 1989). Finally, an ecotoxicological study was made to evaluate As and Pb transference from dredged sediments to the aquatic ecosystem.

**Results and discussion**
The results showed that the highest total and bioaccessible concentrations of As and Pb were found in the closest areas to ports and watercourses, which were considered sources of pollution related to anthropogenic activities such as maritime transportation, agriculture and urban development (Ardila et al., 2023). These samples were classified as hazardous sediment according to DCDM (2021) and were associated with unacceptable risk to human health according to USEPA (1989) as well as with evidence of transference of As and Pb to aquatic ecosystem. Therefore, these dredged materials cannot be used in beach regeneration or creating construction materials.

**Conclusions**
This work highlights the importance of marine sediments geochemistry in assessing human and environmental health risks associated with PTEs, particularly when considering new productive uses of marine sediments.

**Acknowledgements**
This work is part of GEOSEM project. This study forms part of the ThinkInAzul programme and was supported by MCIU with funding from European Union NextGenerationEU (PRTR-C17.I1) and by CARM-Fundación Séneca.

## Introduction

Restorative aquaculture pretends to address the growing demand of food production while delivering net ecological benefit to ecosystems along with social and economic advantages (Alleway et al. 2023). This approach prioritizes the cultivation of low-trophic-level aquatic organisms whose biological functions enhance ecosystem processes such as nutrient cycling, water filtration, and habitat provision. This statement is the cornerstone of the Mar Menor Oyster Initiative (MMOI), an initiative which aims to use bivalves as Nature Base Solutions (NbS) to improve the Mar Menor lagoon (MM) condition. The MM is the largest hyperhaline lagoon in the Mediterranean basin and since the 1970s has been increasingly threatened by a eutrophication process. The lagoon ecosystem collapsed in 2016 as a result of a phytoplankton bloom which caused biodiversity loss, hypoxia and the collapse of the ecological structure (Ruiz et al. 2020). The MMOI has focused on the recovery of the European native oyster (*Ostrea edulis*) to establish a restorative aquaculture program to leverage the ecosystem services provided by the species (Albentosa et al. 2023). This species established a large population in the lagoon of over 100 million individuals in the 1980s and 1990s that has been disappearing, partly due to ecosystem degradation (Rosique 2006). As a first step in the initiative, an oyster culture is taking place in a saltpan located in the north of the MM. In the present work we present two years of growth and survival of the oyster culture in the saltpan.

## Material and methods

*O. edulis* individuals were obtained by breeding lagoon's broodstock at the hatchery (Hernandis et al. 2023). In March 2023, a total of ≈5800 seed were translocated and maintained during 24 months in the entrance canal of the saltpans from San Pedro del Pinatar, located in the north basin of the MM. Initially, oyster height size was 22.24 ± 0.70 mm and live weight was 1.51 ± 0.10 g. The oysters were distributed in circular oyster's baskets stacked in groups of 5. A total of 3 – 6 groups (15 – 30 baskets) were hold, depending on the number and size of the oysters throughout the experiment, in order to maintain a suitable density. Temperature was constantly monitored in the canal throughout experiment.

Once a month approximately, the total live weight of all the oysters was measured and three subsamples of 50 individuals were collected to check for the percentage of mortality and measure size. Besides, a complete biometry with dissections was done in 40 individuals, measuring height, length, width, live weight and dry weight.

## Results and discussion

The maximum temperature recorded in the canal was 34ºC. During the first summer (2023), a high mortality of 38% of the individuals was observed. During the second summer the mortality increased up to 50%. Shell growth followed a seasonal pattern, with higher increases from spring to late summer and lower during the colder months, except for the summer, when shell growth continued while meat weight decreased. Meanwhile, oysters' meat weight followed a similar pattern, but showing a decrease in weight during the warmer months. Condition index followed a similar pattern, probably affected also but the higher temperatures but also the reproductive season, which usually occurs in spring-summer for the MM.

In aquaculture, maintaining optimal fish health and welfare is one of the main challenges, primarily due to multiple stressors including high stocking densities, temperature fluctuations, jellyfish blooms, or pathogenic diseases. Among these, infectious diseases notably impact fish survival and overall welfare, leading to significant economic losses. An innovative approach to mitigate these effects and enhance aquaculture sustainability involves incorporating functional feed additives into fish diets.

In recent years, numerous functional feed additives such as probiotics, prebiotics, nucleotides, single-cell proteins, and phytochemicals have been integrated into aquaculture feeds to enhance fish robustness under stressful conditions. Notably, whole plant materials, owing to their phytochemical complexity, have emerged as promising ingredients with potential health benefits.

In this context, we evaluated the immunomodulatory effects of a specific plant material in fish, using both *in vitro* and *in vivo* approaches. Initially, we performed a series of *in vitro* experiments employing rainbow trout cell lines (RTS11 and RT-gut) and primary head kidney leukocyte cultures. Here, we examined the expression of inflammatory biomarkers following stimulation with *Aeromonas salmonicida* in the presence of the plant extract. The results indicated a significant reduction in the expression of pro-inflammatory genes, including *il1□*, *tnf-□*, and *saa5*. Additionally, flow cytometry analyses revealed a decrease in phagocytic capacity of RTS11 cells, and reduced IgM secretion by B cells in primary cultures. These outcomes suggest differential immunomodulatory effects depending on cell type and the concentration of plant material.

Encouraged by these findings, we subsequently formulated an experimental diet incorporating the tested plant material combined with other functional ingredients, aiming to evaluate potential synergistic effects. Two *in vivo* challenge trials were conducted, involving bacterial (*Yersinia ruckeri*) and viral (viral hemorrhagic septicemia virus) pathogens. Remarkably, fish fed with the experimental health-promoting diet showed significantly increased survival rates compared to those fed a control diet or a similar diet without the plant additive.

Collectively, these findings demonstrate that this novel plant additive exhibits promising anti-inflammatory properties and potential synergy with other functional ingredients, making it a valuable addition to functional diets aimed at improving fish health and resilience in aquaculture systems.

# SMALL PARTICLES, BIG IMPACTS: ANOREXIGENIC AND ANXIOGENIC EFFECTS OF MICROPLASTICS IN GOLDFISH

## Introduction

Microplastics, defined as plastic particles ranging from 1 µm to 5 mm, originate from the fragmentation of larger plastics or from industrial sources such as cosmetics and synthetic textiles. These pollutants pose a serious threat to aquatic organisms, potentially affecting their growth, health, and welfare by causing physiological and behavioural disturbances (Santos *et al*., 2022). This study aims to evaluate the impact of microplastic exposure on energy balance, stress-related behaviours, and overall performance in a freshwater species.

## Materials and methods

Twenty-four goldfish (*Carassius auratus*) were divided into two experimental groups (n=12/group): control group (no exposure to microplastics) and microplastics-exposed group (15 µm polystyrene microspheres, 0.5 mg/L). To maintain microplastic concentration, they were renewed every 24 hours, with a 50% water change over a 14-day period. Food intake, locomotor activity, body weight, and length were daily recorded. After one week of treatment, black-white and open-field preference tests were performed to assess anxiety-like behaviours. At the end of the 14-day exposure, oxygen consumption ($MO_2$) was measured through 24 h. Lastly, fish were euthanized (MS222, 400 mg/L), and liver, intestine, gonads, perivisceral fat, and hypothalamus were collected. The expression of genes related to feeding regulation was analysed in gastrointestinal tissues and hypothalamus.

## Results and discussion

Exposure to microplastics for 14 days significantly reduced both feed intake (Fig. 1a) and food anticipatory activity (FAA), measured during the 2 h preceding feeding time (Fig. 1b). These results suggest a potent anorexigenic effect of microplastics, consistent with previous studies in the same species following 28 days of exposure (Zhang *et al*., 2024). Our results demonstrate that such effects become noticeable after only 14 days of exposure and might be mediated by upregulation of anorexigenic-related genes alongside a downregulation of orexigenic neuropeptides in hypothalamus. Regarding energy expenditure, an increase in metabolic rate was observed (Fig. 1c), aligning with previous findings in black rockfish (*Sebastes schlegelii*; Yin *et al*., 2019).

Together, these findings may explain the observed decrease in both body weight gain and standard growth rate in the microplastics-exposed group (Figs. 2a–b), consistent with previous results in other fish species (Salerno *et al*., 2021). A significant decrease in the hepatosomatic index and a trend towards reduced perivisceral fat index were also observed (Figs. 2c–d); both organs play essential roles in goldfish energy storage.

Moreover, fish exposed to microplastics spent less time and made fewer entries into the aversive zones in the behavioural anxiety tests: i.e. open area in the open field test, (Figs. 3a-b), and the white area in the black-white preference test (Figs. 3c-d). This suggests that microplastics may contribute to heightened anxiety-like behaviour, which may be related to the elevated cortisol levels observed after microplastic exposure (Zhang *et al*., 2024).

In conclusion, short-term exposure to microplastics negatively affected feeding, growth performance, metabolic rate and emotional reactivity in goldfish. These findings highlight the detrimental physiological and behavioural effects of microplastics, compromising energy regulation and overall welfare in this species.

## Introduction

Oxytocin is a key neuropeptide involved in the regulation of social behaviours and the attribution of emotional valence to social stimuli across vertebrates (Dölen *et al*., 2013; Matthews & Tye, 2019). Its signalling is essential not only for social recognition, but also for the formation of social bonds and reinforcement learning based on conspecific interactions (Johnson & Young, 2017). Although the teleost homolog of oxytocin is isotocin, we use the term "oxytocin" here for consistency with the broader vertebrate literature and to emphasize its functional equivalence. Conditioned Place Preference (CPP) assesses whether a stimulus is sufficiently rewarding or aversive to shift preference toward a previously neutral cue (Dölen *et al*., 2013). By comparing pre- and post-conditioning choices, CPP quantifies both the valence and salience of the associated stimulus. This study aimed to evaluate the role of oxytocin in social conditioning and affective processing in zebrafish (*Danio rerio*).

## Materials and methods

We used 36 adult zebrafish (6–8 months) of Tüpfel Long-fin background: 16 oxytocin receptor (*oxtr*) mutants and 16 wildtypes (balanced sexes), plus 4 heterozygotes as social stimuli. Fish were bred and housed under standardized conditions at 27–28 °C with enriched environments and a 14:10 L:D cycle. The *oxtr* line carries a frameshift mutation from a 1-bp TALEN-induced deletion (ZFIN ID: ZDB-ALT-190830–1), confirmed by PCR and sequencing. CPP was conducted in a 4.5 L tank with red and green compartments (visually distinct), and a central grey acclimation zone. Fish were tested individually, with balanced circadian timing and fasted pre-trial. The experiment had three phases: pre-test (5 min acclimation + 10 min preference), conditioning (20 min with a visible, sex-matched, familiar heterozygous stimulus in the non-preferred side), and post-test (same as pre). Time spent in each zone, latency to enter, and number of entries were analysed using BORIS 8.27.10 software All animals were siblings to minimize genetic background effects; tank orientation and water were changed between trials. No significant differences were found between males and females, so data were pooled for analysis. Statistical comparisons between groups were performed using the *Mann–Whitney U test*.

## Results and discussion

Both wild-type zebrafish and oxytocin receptor (*oxtr*) mutants initially showed a strong preference for the green cue, allowing conditioning to be reliably applied in the red compartment. After social conditioning with a visible, familiar conspecific, wild-type individuals exhibited a clear increase in time spent in the previously non-preferred (conditioned) compartment (Figure 1). This shift in preference was absent in *oxtr* mutants, indicating that oxytocin signaling is necessary for associating social stimuli with positive affective value.
Additionally, wild types approached the conditioned zone more quickly after conditioning (Figure 2), reflecting a greater motivational drive towards the socially reinforced cue. In contrast, *oxtr* mutants displayed no consistent directional change in preference, suggesting that while they perceived the social interaction, they failed to assign it a rewarding valence.

These findings support the hypothesis that oxytocin is critical for encoding the rewarding nature of social interactions, through the oxytocin receptor, similar to results from mammals (Dölen *et al*., 2013). Thus, understanding oxytocin's role in social reward can inform strategies to enhance welfare and social cohesion in aquaculture species.

# INNOVATIVE BIOMASS RESOURCES FOR SUSTAINABLE FRESHWATER AQUACULTURE FEEDS: INSIGHTS FROM THE SAFE PROJECT

S. Hilali *, E. Stierlin, J. Tchoumtchoua, M. Hamzaoui

Celabor SRL
Av. du Parc 38
4650 Herve
E-mail: shil@celabor.be

## Introduction

The growing demand for sustainable aquaculture feeds calls for novel protein, lipid, and bioactive sources to reduce reliance on fishmeal and fish oil. The Horizon Europe SmartAqua4FuturE (SAFE) project explores diverse biomass resources including insects, microalgae, aquatic plants, and mushrooms produced via circular economic approaches. This work presents the compositional, functional, and safety characterization of these biomasses for integration into freshwater aquaculture diets.

## Material and Methods

Biomasses evaluated included mealworms (*Tenebrio molitor*), redworms (*Eisenia fetida*), microalgae (*Phaeodactylum tricornutum*, *Scenedesmus*), duckweed, watercress, and mushrooms (*Pleurotus ostreatus*). Analytical methods comprised proximate composition (Kjeldahl protein, Soxhlet lipid), β-glucan and chitin quantification, fatty acid profiling (GC-FID), amino acid profiling (UPLC-DAD-MS), elemental and heavy metal analysis (ICP-MS), and bioactive compound quantification (polyphenols, flavonoids, carotenoids via HPLC-UV and colorimetry). Production parameters such as insect diet composition, nitrogen limitation and light exposure for microalgae, and seasonal plant harvesting were adjusted to enhance nutritional traits.

## Results

All biomass types demonstrated favorable nutritional properties and the presence of health-promoting bioactives. Insects provided high-quality proteins and beneficial lipid profiles; microalgae offered valuable long-chain omega-3 fatty acids and carotenoids; aquatic plants contributed minerals, antioxidants, and fiber; and mushrooms grown on alternative substrates retained rich nutrient content. Across all categories, contaminant levels remained within safe regulatory limits, and several cultivation approaches enhanced targeted traits, supporting their suitability for aquafeed inclusion.

## Conclusion

The SAFE project confirms the potential of diverse, sustainably produced biomasses as functional, safe, and nutritionally balanced components of freshwater aquaculture feeds. Their integration could strengthen circular production models, lower environmental impact, and improve the resilience and self-sufficiency of the aquaculture sector.

# GROWTH, SURVIVAL AND HISTOLOGICAL STATUS OF ANTERIOR INTESTINE EURASIAN PERCH *Perca fluviatilis* L. FRY IN DIFFERENT LIGTH CONDITIONS

**Introduction**

The varying light conditions can significantly affect the efficiency of rearing perch fry in RAS systems by determining fish growth, survival and/or cannibalism. In order to ensure high productivity and reduce production costs, the rearing conditions need to be optimized. Moreover, at an early stage of ontogenetic development, the digestive structures and activities can be affected by the different light conditions (Hamza et al. 2015). In this study, an assessment of the effect of different light regimes on basic growth parameters and selected histological parameters of the middle part of the intestine of Eurasian perch fry was examined.

**Material and methods**

The six-week experiment was conducted with a 42-day-old Eurasian perch (average body weight of 0.055 ± 0.023 g and average body length of 1.78 ± 0.28 cm), where four variants of different photoperiod (L:D – light:dark) i.e. 24L:0D; 20L:4D; 16L:8D and 12L:12D were tested. Throughout the entire rearing period, the intensity of light, measured at the water surface was 800-900 lux, mean temperature of water 21.5±0.5ºC, pH 7.9±0.3, oxygen concentration 8.2±0.6 mg $L^{-1}$. At the end of the experiment 30 perch fry from each group were euthanized, individually weighed, measured and relevant growth parameters were assessed: coefficients of body length variation [CVL(%)]; coefficients of body weight variation [CVM(%)]; Fulton's condition factor [K]. Moreover, cumulative mortality was calculated including the victims of cannibals. For histological examination, the samples of proximal intestine from 30 fish of each experimental group were collected. The tissues were fixed in Bouin's fluid, dehydrated in ethanol, cleared in xylene and embedded in paraffin blocks. Slices 4–5 μm thick were cut using a LEICA RM 2165 rotational microtome (LEICA Microsystems, Wetzlar, Germany) and stained with HE (hematoxylin-eosin) (Zawistowski, 1986). Tthe number of mucous cells within a surface area of 2500 $\mu m^2$ (50 × 50 $\mu$m) and the length of the mucosa folds of the anterior intestine was determined with a LEICA DM3000 transmission light microscope and micro image computer analysis software LEICA QWin Pro (LEICA Microsystems AG, Heerbrugg, Switzerland). The normality of data distribution was tested by the Shapiro- Wilk test and, to confirm for homogeneity of variance, Levene's test was used. The data expressed in percentages were *arcsin* transformed before the statistical analysis. Data were compared using one-way ANOVA. The significance of differences was estimated using a post hoc LSD Fisher test ($p<0.05$). Analyses were performed using Statistica software (TIBCO Software Inc.).

**Results**

At the end of experimental rearing no significant differences ($p<0.05$) between experimental groups for final length and weight of fry as well as for Fulton's condition factor were noted (Table 1). However, significant differences in the values of CVL but not of CVM between perch juveniles reared in different photoperiod regimes were found. Significant differences were also noted in relation to histological parameters, i.e. the number of mucous cells (24L:0D group) and the length of intestinal mucosa folds (24L:0D and 20L:4D groups). The highest survival was observed in the 20L:4D group, while highest intensity of cannibalism was noted in the group reared in 12L:12D (Table 1).

**Discussion**

The lack of significant differences in perch fry growth parameters reared under different photoperiod conditions suggests the limited influence of this factor on rearing efficiency. According to Kestemont et al. (2015) data, at the post-larval stage, the length of the light day did not significantly influence the survival of Eurasian perch. However, the proportion of mortality due to cannibalism was significantly reduced when the day length was increased from LD 8:16 to 24:0, similarly to our results. The higher number of mucous cells and length of intestinal mucosa folds observed in the 24L:0D group may suggest a positive effect of length light day on digestive efficiency in the next stages of perch rearing.

*(Continued on next page)*

Table 1. Initial (n=30) and final parameters (n=3 replicates) of Eurasian perch fry according to experimental groups. All data are expressed as mean ± SD. Data in rows marked with different letter subscripts indicate statistically significant differences between groups ($p<0.05$).

# REDUCING RISK FOR PERSONELL IN NORWEGIAN SALMON FARMING – INTERORGANISATIONAL WORK

S. Holen*, H.T Slette, K. Størkersen, T. Thorvaldsen

SINTEF Ocean
7465 Trondheim, Norway
Email: siri.holen@sintef.no

Introduction

Norwegian salmon fish farming companies rely on contractors and suppliers in their production, including crew on specialized vessels such as well boats, slaughter vessels and service vessels. Research indicates that conditions related to interorganizational interaction, such as work pressure and efficiency demands related to economic considerations, can impact personnel safety negatively (Kongsvik et al. 2025), but more knowledge is needed. The interview study presented therefore explores the topic of cooperation and personnel safety further.

The study is part of the ongoing project "Knowledge and measures to reduce risk for personnel in the fish farming industry", financed by the Norwegian Seafood Research Fund (project 902016).

Material and methods

An interview study is being conducted in the period February – august 2025. It includes 15 employees (OHS-personnel at salmon farming companies and contractors, fish farm workers and vessel crew members) who work in companies of different sizes and geographical locations along the Norwegian coast.

An interview guide, which targets risk factors, challenges related to cooperation and collaboration among different actors and possible improvements that can reduce risk for personnel is used.

Results

Results from the interview study will be presented. Key topics include the different types of collaboration agreements between contractors and fish farming companies and how they may impact safety (long term agreements, spot market etc.), prominent risk factors for personnel in operations, how procedures are designed and harmonized between companies, how new types of technologies influence work task and operations (e.g. submerged fish farms), how cooperation operations are planned, performed and evaluated. Furthermore, regulations that influence safety as well as training employees and crew members will be discussed. Based on these results, some suggestions for measures and improvements are given.

**Conclusion**

The study provides knowledge about challenges related to interorganizational interaction in salmon farming and suggestions that can improve risk management and cooperation between organizations moving forward. Results are discussed and communicated to the industry as part of the project.

# A STUDY OF TWO ADIPOSE TISSUE DEPOTS IN ATLANTIC SALMON (*Salmo salar)*

Ingrid Holmlund*[1], Yi Yuan[2], Bente Ruyter[2], Esmail Lutfi[2], Tor Gjøen[1], Marta Bou[2]

Department of Pharmacy, University of Oslo, Norway
Nofima, Ås, Norway
E-mail: ingrid.holmlund@farmasi.uio.no

**Introduction**
A growing prevalence of obesity in humans has led to an increased global interest in white adipose tissue biology over recent years. In the aquaculture industry, commercial diets have shifted towards higher lipid content; modern pelleted diets for Atlantic salmon now commonly contain 35 – 38% lipids, compared to early formulations that had lower lipid levels (8 – 22%). The development of these high-energy diets has allowed the aquaculture industry to reduce production time by increasing growth rates and feed efficiency. This change has resulted in higher lipid levels in farmed fish, including larger visceral and myoseptal fat depots, which can cause lower quality filets and physiological changes such as oxidative stress. New insights into the development and function of these adipose tissue depots could aid in preventing excessive fat accumulation in farmed fish.

**Materials and Methods**
This study aimed to compare the morphological and functional differences between visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) in farmed Atlantic salmon using both in vivo and in vitro approaches. A combination of cellular characterization techniques was performed, including histology, microarray analyses, and total RNA sequencing, to gain a comprehensive understanding of the unique properties of each adipose depot.

**Results**
The findings revealed significant differences between VAT and SAT. The histological examination showed that VAT was characterized by larger adipocytes, while SAT contained a higher number of smaller adipocytes per area studied. This difference indicates a hypertrophic versus hyperplastic trait in these tissues. VAT adipocytes displayed an enhanced capacity for lipid droplet accumulation and mobilization, highlighting their substantial role in lipid storage.

Gene expression analyses demonstrated distinct profiles between VAT and SAT, affecting insulin resistance, immune activity, energy provision, and lipid metabolism. Notably, VAT had a higher expression of immune-related genes, suggesting increased immune activity and inflammation. Furthermore, SAT predominantly functioned as a direct energy provider, while VAT exhibited greater lipolytic activity, underscoring its dual role as both a lipid storage site and a potential facilitator of free fatty acid mobilization for oxidation in other organs.

In vitro studies reinforced these observations. Primary adipocytes were isolated from VAT and SAT and cultured. Differences in cell morphology were observed, with VAT cells exhibiting a round shape from day 1 of culture, while SAT cells displayed a characteristic fibroblastic appearance and grew in clusters. After inducing differentiation with a hormone cocktail, both cell types changed their morphology and began accumulating lipids. At day 15, the lipid storage capacity of both cell types was evaluated using oil red O and LipidTox staining techniques, demonstrating that adipocytes isolated from VAT had a higher capacity to accumulate lipids than those isolated from SAT.

**Conclusions**
This study provides insights into the distinct morphological and functional characteristics of VAT and SAT in farmed Atlantic salmon. These findings could be crucial in future strategies to reduce excessive fat accumulation and improve fish health and quality in aquaculture.

**Introduction**
Modern aquaculture is the fastest-growing animal food sector, yet rearing juvenile fish remains constrained by the lack of suitable live feed. Current feeds such as *Artemia* and rotifers are nutritionally suboptimal, expensive to enrich, and poorly digested by young fish, leading to high mortality, poor growth, deformities, and premature transition to dry feed. There is an urgent need for sustainable, high-quality, immune-boosting live feeds that support antibiotic-free and environmentally friendly aquaculture.

**Methods**
Through the DELIFEED and LiveFishHealth projects, we are developing next-generation live feeds based on Enchytraeids and nematodes. Research activities include:

1. Enhancing essential fatty acid content in novel live feed organisms.
2. Developing industrial-scale cryopreservation methods to ensure long-term storage and global distribution.
3. Evaluating performance in juvenile Atlantic salmon, Atlantic halibut, ballan wrasse, pike perch, turbot, European flounder, and rainbow trout.
4. Investigating live feed potential as vectors for probiotics and oral vaccines, including early vaccination against Rainbow Trout Fry Syndrome (RTFS).

**Results and Discussion**
Preliminary trials show that Enchytraeids and nematodes provide high nutritional value without enrichment, enhance juvenile fish growth by up to 200%, and reduce mortality. They can be mass-produced on organic waste, aligning with circular bioeconomy principles. Potential cryopreservation and anhydrobiosis of live feeds may enable stable supply chains. Early results also indicate promise as oral vaccine carriers, offering a route to reduce or eliminate antibiotics in aquaculture.

**Conclusion**
The integration of novel live feeds into aquaculture has the potential to improve fish survival, growth, and welfare, support sustainable and organic production, and expand the range of species that can be farmed. The DELIFEED and LiveFishHealth projects demonstrate a pathway from innovation to industry adoption, addressing critical bottlenecks in fish larval rearing.

*(Continued on next page)*

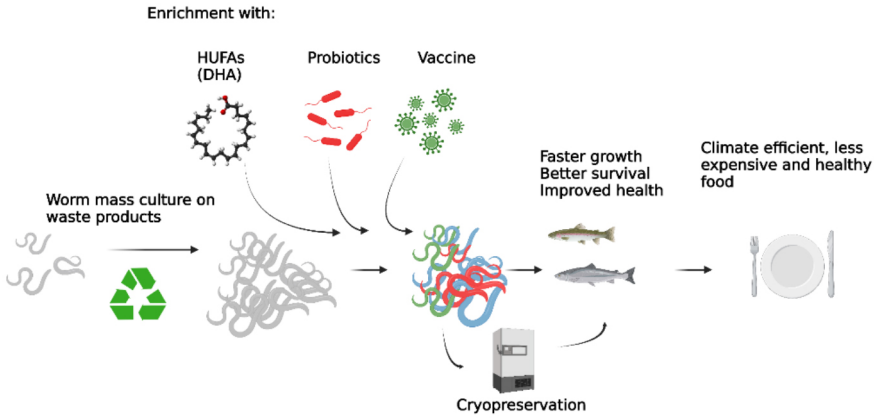

*Figure 1. Conceptual workflow for developing sustainable live feed for aquaculture. Enchytraeids and nematodes are mass-cultured on organic waste products and can be enriched with health-promoting additives, including essential highly unsaturated fatty acids (HUFAs, e.g., DHA), probiotics, and vaccines. These enriched worms are fed to juvenile fish to promote faster growth, improved survival, and better health. Cryopreservation enables long-term storage and stable year-round supply. The approach contributes to climate-efficient, cost-effective, and nutritious seafood production.*

# 1227
# TINY WORMS, BIG POTENTIAL *Enchytraeus albidus* AS STARTER FEED FOR RAINBOW TROUT

The aquaculture industry is increasingly seeking sustainable feed alternatives to address ecological concerns associated with traditional feed ingredients and enhance the health and growth of farmed fish during their early life stages. Live feed, such as the annelid worm *Enchytraeus albidus,* has been shown to increase growth in marine fish species. In this study, we evaluate *E. albidus* as a potential starter live feed for rainbow trout fry (*Oncorhynchus mykiss*), focusing on growth, health, and fatty acid composition. Fry were fed one of three diets: standard dry feed (DF), live *E. albidus* (EF), or a combination of both (DF/EF) for 21 days, followed by a transition to DF for the following 22 days. Fry initially fed with EF exhibited significantly higher growth rates compared to those on DF, and they maintained superior size even three weeks after being transitioned to dry feed. At the end of the experiment the fish fed EF had a 10% higher mass than fish fed DF. No significant differences were found in health or welfare indicators across the treatment groups, which all demonstrated good health and low mortality. The fatty acid profiles differed between treatments, with lower essential fatty acid DHA (docosahexaenoic acid) levels in fish fed EF. However, despite the lower body levels, critical DHA levels seemed to be preserved in the neural tissues of the fry. These findings highlight the potential of *E. albidus* as a sustainable and effective starter feed for rainbow trout fry. Furthermore, they provide a compelling basis for further investigating the feasibility of *E. albidus* as a bio-carrier for oral vaccines.

# FIT-FOR-PURPOSE ENVIRONMENTAL AND ECONOMIC SUSTAINABILITY ASSESSMENT OF INTEGRATED MULTITROPHIC AQUACULTURE

## Introduction

Integrated multitrophic aquaculture (IMTA), i.e. co-farming of species from different trophic levels, combines aquatic species into one farming system to provide benefits for: *i)* one or several of the farmed species, e.g. seaweed can grow faster in the nutrient rich waters from fish farming, and/or *ii)* ecosystems, i.e. nutrient uptake from fish farming, and *iii*) aquaculture producers, e.g. better productivity and new revenue streams – combined allowing for production efficiencies as more biomass is produced from the system. This is aligned with societal ambitions on resource-efficiency, circularity and mitigation of drivers for biodiversity loss. Despite the potential benefits, IMTA remains uncommon in Europe, where its application has been mainly limited to pilot-scale trials within the framework of research projects.

In the BLUEBOOST project (https://www.blueboost.eu/), suitable design of IMTA systems will be investigated. Case study experiments are undertaken in Italy, Spain, Portugal, Poland and Brazil and evaluated as to their environmental and economic sustainability. One area of focus is the specific methodological choices needed to assess environmental impacts and benefits of the multi- and circular output nature of IMTA systems. Although some insights have been gained using Life Cycle Assessment (LCA) – feed, effluents and energy use are impact hotspots – a standardized LCA methodology of IMTAs is called for (Hala et al 2024). Further, reduced externalities have so far been underexplored in cost-benefit analysis (CBA) of aquaculture (Knowler et al. 2020).

## Method

An initial LCA literature screening in March 2024, resulted in four studies applying LCA on IMTA (Chary et al. 2020; Mendoza Beltran et al. 2018; Prescott 2017; Wilfart et al. 2020), from which key methodological decisions were extracted, compared and discussed to derive a suitable approach for harmonized evaluation of IMTA systems for BLUEBOOST (Ziegler et al. 2024). Further, we explored the general CBA literature, economic assessments of IMTA and literature on the valuation of environmental externalities relevant in the aquaculture context. Insights gained are important to share and discuss with IMTA experts and LCA practitioners beyond the project for good practice sustainability assessments of IMTAs beyond BLUEBOOST. We have therefore undertaken a more structured systematic literature review in Scopus, identifying additional documents of interest. These are currently in the process of being analyzed to see if and how they add to the findings from the screening and inform on a more comprehensive overview to provide overall good practices when applying LCA to IMTA.

**Table 1** Key LCA decisions and the suggested BLUEBOOST approach.

| Methodological aspect | BLUEBOOST approach |
|---|---|
| **Modelling approach** | Attributional |
| **Functional unit** | 1 kg biomass of economic value |
| **Allocation** | Mass-balanced |
| **System boundary** | Hatchery to farmgate |
| **Impact Assessment** | ReCiPe H + Cumulative Energy Demand |
| **Background data** | Ecoinvent 3.9.1 + Agrifootprint 6.0 |
| **Circularity assessment** | According to ISO 59020 |
| **Nutrient retention** | Bioremediation (N/P/C retained) |

*(Continued on next page)*

Here we present the results from the initial screening and the methodology suggested for sustainability assessment in BlueBoost, which is work in progress as additional publications will be analyzed and discussed during spring 2025 for a more generic decision-support framework.

**Results**

The four IMTA LCA studies all focus on different systems and, most importantly, use different LCA method decisions. Functional units varied considerably, i.e. the output of the system which environmental pressures are related to – and which has a strong effect on results. Further, how to allocate environmental burdens between main product and co-products and choice of impact assessment method (and environmental impact categories included) also matter for results on IMTA system performance. Comparability of results between studies is therefore limited without harmonization. The key method choices suggested for BLUEBOOST are found in Table 1.

Drawing on general CBA practices and extant economic assessments of IMTA systems (e.g. da Silva et al. 2022), an applied cash flow calculator is being formulated. In case studies with important environmental externalities, we attempt to identify feasible monetary valuations to be used in the social CBA.

**Discussion**

Robust and comparative LCAs are vital to understand differences between aquaculture production systems and how they can be optimized. A decision-support tool will assist LCA practitioners in future assessments. Alongside, a suitable economic assessment is required to ensure that the proposed solutions are economically viable.

# MANUAL VS. MACHINE LOADING OF STRAWS FOR THE CRYOPRESERVATION OF COMMON CARP (*Cyprinus carpio*) SPERM

Á. Horváth[1*], Z. Vorrath[2], N. Kitanović[1], K.K. Lefler[1]

1. Department of Aquaculture, Institute of Aquaculture and Environmental Safety, Hungarian University of Agriculture and Life Sciences, 2000 Páter Károly u. 1., Gödöllő, Hungary

E-mail: Horvath.Akos@uni-mate.hu

**Introduction**

Cryopreservation is a useful assisted reproductive technology for the conservation of genetic resources as frozen live cells and tissues can be stored for an infinite period of time. In case of common carp (*Cyprinus carpio*) several frozen gene banks have been created in order to maintain the genetic resources of valuable or disease resistant strains. Commercialization of cryopreservation requires standardization and upscaling of existing techniques. These can include standardization of the sperm-egg ratio used for fertilization of eggs (Nynca et al., 2017; Pataki et al., 2022) and advanced sperm quality assessment methods. In this study we have tested if the use of a commercially available semi-automatic straw loader results in higher post-thaw sperm quality than traditional manual loading of straws. Additionally, we have also investigated if the position of straws during storage (top or bottom goblet on the cane) has an effect on post-thaw quality.

**Materials and methods**

Sperm from 3 common carp males was used in the experiments. Sperm was diluted at a 1:9 ratio in an extender composed of 200 mM glucose, 40 mM KCl, 30 mM Tris (pH 8.0) to which 10% methanol (v/v final concentration) was added as a cryoprotectant. Diluted sperm was loaded into 0.5-ml straws either manually or with an semi-automatic straw loader (SFS, Minitube, Germany). Loaded straws were placed onto dedicated metal frames with 36 positions and frozen in the vapor of liquid nitrogen in a polystyrene box at the height of 3 cm above the level of liquid nitrogen for 3 minutes. Straws were stored in 13-mm goblets attached to aluminum canes immersed in liquid nitrogen. Following thawing in a 40 °C water bath for 13 seconds, sperm quality was determined using a computer-assisted sperm analysis (CASA) system (AndroVision, Minitube, Germany). Altogether, 281 straws were filled with the machine (120 in top and161 in bottom position) and 290 manually (160 in top and 130 in bottom position). Two-way ANOVA was used to investigate the main effects of straw loading methods as well as goblet position on post-thaw motility parameters.

**Results**

Neither the straw loading method ($P = 0.215$), nor the goblet position ($P = 0.116$) had a significant effect on the post-thaw motility of carp sperm (Fig. 1). On the other hand, the loading method had a significant effect on all post-thaw sperm velocity parameters (VCL: $P = 0.006$, VSL: $P = 0.004$, VAP: $P = 0.005$) with machine loading producing higher values than manual filling. Goblet position did not affect post-thaw sperm velocity with the exception of VSL ($P = 0.038$).

**Discussion**

In the current study, we have demonstrated that machine loading of straws for the cryopreservation of common carp sperm results in higher post-thaw sperm velocity values than manual filling. The use of a straw filling machine represents an improvement over manual loading due to increased consistency and faster processing of sperm prior to freezing, leading thus to standardization of existing methodologies.

# ENHANCED RESILIENCE TO MUCOSAL DISEASES IN ATLANTIC SALMON (*Salmo salar*) SUPPLEMENTED WITH A NOVEL YEAST-BASED INGREDIENT

C. Houdelet[1*], M. Rawling[2], E. Leclercq[1]

[1] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac, France
[2] School of Biological, Plymouth University, PL4 8AA Plymouth, UK
*choudelet@lallemand.com

## Introduction

Farmed Atlantic salmon frequently encounter harmful infectious and non-infectious factors as well as necessary management practices causing serious mucosal health issues across the industry. Functional feeds are commonly used as preventive measures to enhance fish health and well-fare among which yeast cell wall (YCW) products are well-established. Two independent trials were conducted to evaluate the potential benefits of in-feed supplementation with specific YCW product on two mucosal-associated diseases; Tenacibaculosis (*T. maritimum* challenge) and Amoebic Gill Disease (AGD; *N. perurans* challenge).

## Materials and Methods

Both trials used a baseline recipe reflecting current commercial practices in the European Atlantic salmon industry. Each trial tested 3 diets in quadruplicate as follow. A non-supplemented diet (Control); and two diet supplemented with two novel YCW products (Proto and Y+ respectively; Lallemand, France). Feed were fed to apparent satiation over the trial's duration.

The first trial lasted 15 weeks with fish exposed to *T. maritimum* by immersion at week 5. The second trial lasted 10 weeks with fish exposed to a first AGD challenge at week 5 using upstream shedders; followed by freshwater (FW) treatment and a second AGD challenge. In both trial, growth, feed performance and survival were monitored; visual scoring of the gross pathology (skin lesions and gill score respectively) were performed at interval and mucosal tissue were collected for analysis.

## Results

In the first trial (*T. maritimum* challenge) and compared to the Control; supplementation with Y+ resulted in a significant improvement in survival (+22%; Fig 1A) which was associated with a significant decrease in the proportion of moderate and severe skin lesions (-30% at the end of the trial; Fig 1B). In the second trial (AGD-challenge); diet Y+ was associated with improve specific growth rate and feed conversion ratio (+ 20% and -32% compared to the Control, respectively; Fig 2A) over the trial's duration. Gill scoring over time documented the propagation of the pathology and the positive impact of the intermediary FW-treatment. At the end of the trial, gill-scoring was significantly improved in dietary group Y+ with a marked decrease in the proportion of heavy and advanced scores and, inversely, a higher proportion of fish showing a light AGD-score.

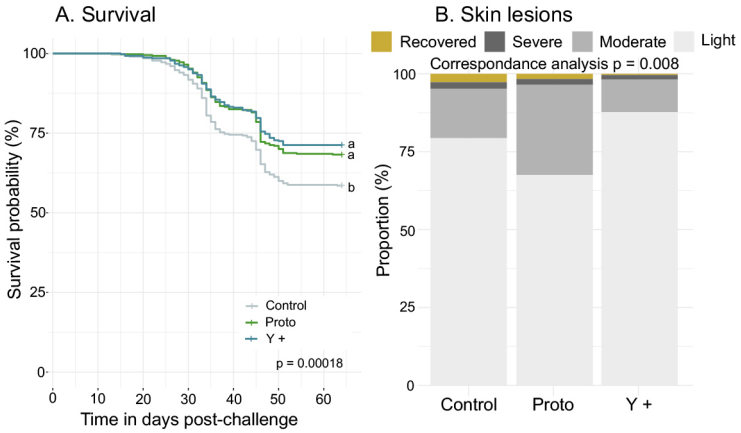

**Figure 1:** A) Survival probability and B) skin score lesions at the end of the first trial (*T. maritimum* challenge). Different letters refers to significant differences.

*(Continued on next page)*

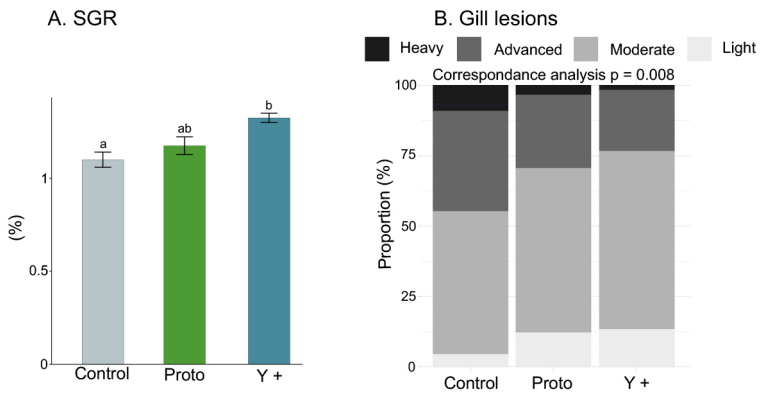

**Figure 2:** A) Specific growth rate (SGR) and B) proportion of gill score lesion's category at the end of the trial (AGD-challenge). Different letters refers to significant differences.

Analyses of histology, gene expression and mucus qualities will be presented to decipher the beneficial effects of the YCW product on mucosal robustness and disease resilience.

**Conclusion**

This novel-YCW product as the potential to contribute to the preventive management of gill and skin health in seawater Atlantic salmon. Further trial's under commercial-like conditions should be performed.

# BEHAVIOURAL AND CARDIAC RESPONSES OF EUROPEAN SEABASS REARED IN SEA-CAGES: INSIGHTS FOR WELFARE STATES ASSESSMENT

**Introduction**

Aquaculture has grown significantly in recent years, necessitating the development of advanced monitoring techniques to ensure fish welfare and optimize management practices. Understanding how fish respond to environmental and anthropogenic factors is key to improving welfare standards. Surgically implanted biologgers, capable of measuring heart rate (HR) and external acceleration (ACC), are increasingly used to monitor fish behaviour and physiological states, providing valuable insights into activity patterns.

As the aquaculture industry shifts toward more sustainable and ethical practices, welfare monitoring is becoming increasingly important. Within the context of Precision Fish Farming, these technologies facilitate informed decision-making and enhance farm management (Morgenroth et al., 2024; Brijs et al., 2021). Among them, biologgers stand out for their ability to measure HR and ACC, offering insights into fish physiology and behaviour under farming conditions. However, despite extensive research on northern species such as Atlantic salmon (e.g. Brijs et al., 2018), few studies have focused on Mediterranean species such as the European seabass (*Dicentrarchus labrax*).

This study assesses the behavioural and physiological responses of seabass reared in open-sea cages using data from implanted biologgers, applying machine learning techniques to classify welfare-related behavioural states and highlighting the potential of integrating sensor technology and data analysis to support welfare monitoring in aquaculture.

**Materials and Methods**

The study was conducted at the LIMIA-IRFAP aquaculture facilities (Balearic Islands, Spain), using 1000 adult seabass reared in four open-sea cages. Sixteen fish were implanted with biologgers (DST milli HRT-ACT, Star-Oddi®) to monitor HR and ACC over two 15-day periods in March and July. Surgical implantation followed the protocols described by Cabrera-Álvarez et al. (2024), ensuring minimal impact on fish recovery and behaviour. Data were recorded every five minutes and retrieved post-mortem. To classify behavioural states, a Random Forest (RF) model was developed with data obtained from swimming and crowding stress challenges, enabling the definition of four key states: Resting, Regular Activity, Reactive Stress Response, and Proactive Stress Response. The RF model was trained using 540 labelled observations, with independent testing to ensure its robustness. During the swim challenge, fish were exposed to incremental swimming speeds (0.2 to 1.0 m/s), while the stress challenge included progressive stressors such as reduced water levels and net chasing. Behavioural states were labelled as follows: nighttime observations were categorized as Resting, swimming speeds between 0.2-0.6 m/s as Regular Activity, stress-induced peaks as Proactive Stress Response, and post-stress periods as Reactive Stress Response. Following validation, the RF model was used to classify the data in the present study.

All procedures involving fish were approved by the Ethical Committee of Animal Experimentation (CEEA-UIB, Spain; Ref. 206/12/22), the Dutch Central Committee for Animal Experiments (CCD; project AVD40100202115078, 15 November 2021), and the Animal Experiments Committee (DEC) and Authority for Animal Welfare (IvD) of Wageningen University and Research (experiment 2021.D-0005.004). They were performed by trained personnel in accordance with the European Directive 2010/63/UE and Spanish Royal Decree RD53/2013, ensuring optimal animal care, health, and welfare.

*(Continued on next page)*

**Results and Discussion**

The biologger data revealed distinct behavioural patterns in seabass under farm conditions. The RF model successfully classified behavioural states with an overall accuracy of 67.38% on the test dataset and over 73% during cross-validation. The model performed particularly well in detecting stress-related behaviours, correctly identifying Proactive and Reactive Stress Responses in over 80% of cases. These stress states were characterized primarily by elevated ACC values, with HR also contributing in reactive contexts.

When applying the RF model to the biologgers data obtained from the seabass reared in open-sea cages, circadian behavioural rhythms that aligned with operational routines were detected. Resting states predominated at night and on weekends when human activity around the cages was minimal. Conversely, stress-related behaviours were more frequent during daylight hours, particularly in July, when water temperatures and maritime traffic were higher. These findings indicate that both environmental and anthropogenic factors significantly influence seabass behaviour and welfare.

Overall, by combining sensor-based monitoring with behavioural classification, this study presents a practical approach to real-time welfare assessment in open-sea aquaculture. The method not only helps identifying stressing events but also provides insights into baseline activity and seasonal activity patterns. These findings underscore the value of integrating behavioural data into farm management strategies and support the development of PFF technologies tailored to open-sea aquaculture systems.

# CARDIAC RESPONSES, ACTIVITY, AND OXYGEN CONSUMPTION OF EUROPEAN SEABASS SUBJECTED TO STRESS CHALLENGES

Esther Hoyo-Alvarez[1*], Joaquim Tomàs-Ferrer[2], Wout Abbink[3], Martin J. Lankheet[4], Pablo Arechavala-Lopez[1], Arjan P. Palstra[3]

e-mail: ehoyo@imedea.uib-csic.es

**Introduction**

The use of biologgers as tools to monitor behaviour and welfare in cultivated fish is becoming increasingly widespread. These biosensors enable the measurement of physiological parameters such as heart rate and external acceleration, which are related to oxygen consumption during stressful events. In such situations, increased oxygen demand triggers cardiovascular adjustments to maintain metabolic function (Morgenroth et al., 2024).

Assessing swimming ability and both aerobic and anaerobic metabolism is essential for evaluating the physiological state of fish and their ability to cope with stress. Swimming tests and exposure to standardized stressors (e.g., confinement, water level reduction, or net chasing) allow for the determination of the aerobic and anaerobic components of metabolism, which can be quantified through oxygen consumption, heart rate, and external acceleration of the fish. Several studies have linked physiological parameters such as heart rate or acceleration to oxygen consumption during stressful events in aquaculture species of interest, such as amberjack and sea bream (Arechavala-Lopez et al., 2021; Palstra et al., 2024). However, no studies have addressed the relationship between metabolic and cardiac responses to stressful events in European seabass (*Dicentrarchus labrax*), one of the most important species in Mediterranean aquaculture.

The main objective of this study is to characterize the metabolic and physiological activity of sea bass by analysing the relationship between cardiac response, activity, and oxygen consumption in individuals subjected to swimming tests and stress events.

**Materials and Methods**

For this study, 18 adult European bass (WW = 421.1 ± 51.46 g) were housed in a 600L circular tank at a controlled temperature of 22.5 ± 0.45 ºC and fed daily with commercial feed at Wageningen University (WUR). Of these, 12 individuals were implanted with heart rate and acceleration biologgers (DST milli-HRT ACT; Star-Oddi, Garðabær, Iceland). Implantation was carried out under anaesthesia with an aqueous solution of 2-phenoxyethanol (0.3 ml/L), followed by a 10-day recovery period in a quarantine tank.

Swimming tests were conducted in three 127L tunnels, with the water flow speed gradually increasing from 0 to 1 m/s in 0.2 m/s intervals per hour. Heart rate and external acceleration were measured at 10-minute intervals.

For the stress test, the fish were transferred to a 600L tank and subjected to four stressful events, which consisted of lowering the water level in the tank until the dorsal fin emerged, followed by refilling the tank. The events varied in the duration of the time with a low water level and included a net chasing procedure in the fourth event. Recovery periods of 40 minutes were included between events, and heart rate and acceleration were monitored for up to 3 hours after the test.

All experimental procedures were approved by the Dutch Central Committee for Animal Experimentation (CCD), project number AVD40100202115078, as well as by the Animal Experimentation Committee (DEC) and the Animal Welfare Authority (IvD) of Wageningen University.

*(Continued on next page)*

**Results and Discussion**

During the swimming test, no significant differences were found in the optimal swimming speed ($U_{opt}$) between the control group and the tagged individuals ($U_{opt}$ Control = 0.737 m/s, $U_{op}$t Logged = 0.740 m/s; p-value > 0.05). Oxygen consumption (MO2) increased exponentially with varying swimming speeds ($R^2$ = 0.461). Additionally, a positive linear correlation was found between oxygen consumption and heart rate, as well as between oxygen consumption and external acceleration as swimming speed increased ($R^2$ = 0.45 and $R^2$ = 0.48, respectively).

In the stress test, an increase in heart rate and external acceleration was detected during the application of the stressors, followed by a decrease in these parameters during the recovery period between events. Heart rate during the first three stressful events showed an increasing trend, although not significant (p-value > 0.05), whereas in the fourth event, there was a significant increase compared to the other stress events, reaching average values of 110 bpm (p-value < 0.01). Regarding the recovery periods between stressful events, heart rate decreased but did not return to baseline values ($HR_{recovery}$ = 82-95 bpm; $HR_{baseline}$ = 63 bpm). Three hours after the test, heart rate still did not reach baseline values, showing values similar to those recorded during the first stress event ($HR_{final}$ = 78 bpm). During stressful moments, a significant increase in external acceleration was detected compared to the recovery periods (p-value < 0.001 in all cases).

These results demonstrate that heart rate and acceleration sensors are a key tool for monitoring welfare in aquaculture fish (Hvas et al., 2020; Palstra et al., 2024). During stressful situations, heart rate and acceleration increase, indicating that there is a higher oxygen demand associated with cardiovascular adjustments to maintain metabolism (Morgenroth et al., 2024). For this reason, it is essential to monitor oxygen concentration during typical stressful procedures in aquaculture.

*email: albaaoa4@gmail.com

**Introduction**

Fish individuality is an understudied yet critical factor in aquaculture animal welfare, encompassing the consistent physiological and behavioural responses of individual fish to stressors. This individuality is typically classified into two distinct coping styles: proactive individuals, characterized by active, exploratory and bold behaviours, and reactive individuals, who are more docile, shy and evaluative in their responses. These coping styles have been associated to the regulation of gene expression, particularly involving genes related to cognitive processes and decision-making influencing, which may influence whether an individual adopts a reactive or proactive profile. This relationship between phenotype and genotype plays a key role in shaping how fish interact with their environment. Risk-taking behaviours, whether bold (proactive) or shy (reactive), is shaped by evolutionary pressures, as animals maximize fitness through behavioural plasticity and selection. Gene expression not only regulates these coping styles but also influences survival and reproductive success, especially under changing environments or stressing conditions, highlighting its importance for aquaculture. This study aims to investigate individual behavioural responses and cognitive abilities in European sea bass exposed to different challenges, identifying coping style patterns, explore the genetic basis of individuality, and discuss its implications for animal welfare management in aquaculture systems.

**Materials and Methods**

The experiment was conducted at the Marine Research and Aquaculture Laboratory (LIMIA-IRFAP) in Port Andratx (Mallorca). A total of 21 juvenile sea bass (7.81 ± 0.29 cm SL and 8.63 ± 0.43 g WW) were individually subjected to the *Cylinder task* test, a standardized protocol designed to assess inhibitory control functions in fish in response to an associated stimulus, by training individuals to obtain food from a plate placed inside a transparent cylinder. Following a 14-day acclimatization period, fish were individually transferred to aquaria (RAS system) comprising a "resting zone" with an enrichment element (artificial plant), and a "test zone". The experimental procedure spanned 7 test days per individual, structured into 4 phases: 1) Days 1 and 2: plate training. 2) Days 3 and 4: Cylinder familiarization. 3) Day 5: Forced door test using a cylinder. 4) Days 6 and 7: Cylinder + plate test. Video images of the different tests were recorded (5 minutes each test in phases 1, 3 and 4) and a range of behavioral parameters were quantified and analyzed with BORIS software. The behaviours recorded included swimming activity, exploratory behaviour, cylinder interaction, visual cue recognition, interaction with food or objects, surface activity, and stress-related behaviours such as immobility, thigmotaxis, and stereotypies. Upon completion of phase 4, fish were euthanized using anaesthetic overdose (5-10 ml/L) of 2-phenoxyethanol, followed by surgical removal of the telencephalon, which was used to quantify the expression levels of ten genes related to stress response, neuroplasticity, and behaviour (*mr, crf, crhbp, bdnf, npas4, dlg4, jph3, cfos, egr1, edrf1*) via qPCR, using *ef1a* and *β-actin* as reference genes for normalization.

**Results and Discussion**

Only 29% of individuals (n = 6) completed at least one phase of the experiment, and just one fish completed all stages. This low success rate likely reflects both the cognitive demands of the task and the species' sensitivity to acute stress. Nonetheless, PCA and heat map analyses based on behavioural metrics validated the Cylinder task as an effective tool for identifying coping styles in juvenile sea bass. Distinct behavioural profiles emerged, enabling classification into proactive and reactive types, with some individuals exhibiting intermediate or flexible traits. Notably, certain reactive fish displayed increased proactive behaviours over time, indicating adaptive flexibility. Gene expression patterns supported these behavioural trends (Fig. 1): reactive individuals overexpressed genes linked to stress regulation and neural plasticity (*npas4, crf, mr, edrf1, crhpb*), while proactive fish showed elevated expression of genes involved in exploration, neurogenesis, and memory (*bdnf, jph3, dlg4, egr1, cfos*). These results underscore the interplay between coping styles, gene expression, and behavioural individuality in sea bass.

*(Continued on next page)*

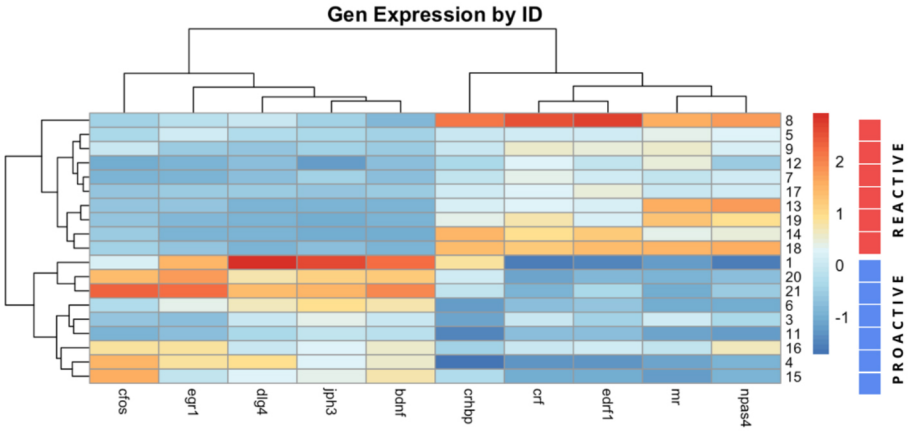

**Fig.1.** Scaled gene expression heat map (Z-score) of the 10 genes studied in *Dicentrarchus labrax*. Individuals were hierarchically grouped according to their gene expression profiles, revealing two main clusters associated with proactive and reactive coping styles. The genes represent key functions in stress regulation, synaptic plasticity, memory and exploratory behaviour.

# EFFECTS OF FISH PEROXIDE TREATMENTS IN AQUAPONICS

M. Huertas*, E. Wheat, and C. Shultz

Texas State University
601 University Drive
San Marcos, TX 78666
mhuertas@txstate.edu

**Introduction**

Aquaponics integrates hydroponics (growing plants in a soilless medium) and fish culture in a controlled environment. However, culturing livestock and plants together presents ample opportunities for pests and diseases to invade the system, leading to crop yield reductions and monetary losses. Hydrogen Peroxide($H_2O_2$) has been used as an antibacterial and antiparasitic preventive treatment in aquaculture. However, it is unknown how fish peroxide treatments in aquaponics will affect the hydroponic culture, the biofilter, or the system.

**Material and methods**

Our goal in our experiment was to describe the effects of $H_2O_2$ treatments on aquaponics systems, specifically focusing on fish welfare, nitrogen balance, plant and root production, and water microbiome communities. To test this, we conducted 1-hour 200 ppm H2O2 treatments in a tilapia-basil aquaponic co-culture in a mid-size farm. After that, we measured the effect of the treatment on fish stress (cortisol excretion) and bacterial nitrification (health of the microbiome) over 21 days. Daily nitrification processes were tracked by measuring $NO_2$, $NO_3$, and $NH_4$ using a Hannah photometer. Fish welfare was monitored weekly by measuring water-borne cortisol at different points of the aquaponic system, as well as individual fish excretions of ammonia (NH4) and cortisol. We repeated this experiment three times over 3 months. At the end of each experimental period, we harvested the basil and recorded plant weight, height, leaf width, and root length. Moreover, we took water, root, and leaf samples for nutrient analysis.

**Results and discussion**

Our preliminary data showed peroxide treatments had a fast (48 hours) and long-term (21 days) effect. In the first two days after treatment, we found an increased concentration of ammonium by 2-3-fold. Additionally, the concentration of cortisol increased. These concentrations returned to normal values after a week. The increase of ammonia can be related to an increase in excretion of ammonium by fish after treatment, combined with peroxide damage to the biofilter denitrifying bacteria. At the end of the culture, we found that peroxide treatments significantly affected plant growth. However, this effect was not detectable to the naked eye, and the plants appeared healthy in both the control and treatment groups.

The results of our experiments indicate that, although it doesn't seem to affect plant production dramatically, the use of peroxide as a prophylactic or post-infection treatment must be monitored for possible nitrogen imbalances and damage to the microbiome in the biofilter.

# MODELLING LOW-TROPHIC AQUACULTURE CO-LOCATED WITHIN OFFSHORE WIND FARMS IN THE NORTH SEA UNDER CLIMATE CHANGE

Emma Huijben*, Loreta Cornacchia, Lauriane Vilmin, Luca van Duren, Alex Ziemba, Ghada El Serafy

Deltares, Data Science and Water Quality Department
Boussinesqweg 1, 2629 HV Delft
Email: emma.huijben@deltares.nl

In line with the European Green Deal, the European Commission has adopted strategies and guidelines with ambitious visions for the offshore renewable energy sector and aquaculture sector. Aligned with this vision, the EU-funded ULTFARMS project aims to advance low trophic aquaculture systems, supporting their integration within offshore wind farms, while safeguarding the environment, minimising carbon footprint and addressing commercial viability. As part of the project, we modelled large-scale cultivation of sugar kelp and/or blue mussels, co-located within offshore wind farms in the North Sea, under climate change.

We used a 3D coupled hydrodynamic, water quality and ecological model of the Northwest European Shelf: the Dutch Continental Shelf model – Flexible Mesh (DCSM-FM). The DCSM-FM contains modules that simulate the growth dynamics of sugar kelp and blue mussels, including their interaction with the environment. The model also simulates the interaction of the wind turbines on ambient flow.

The DCSM-FM was nested in outputs from the global CMCC Earth System Model (CMCC-ESM2) for the SSP5-8.5 climate scenario. Aligning with the 2050 horizon of the European Green deal, we ran the simulations under the projected climate conditions around 2050. The climate change scenario, SSP5-8.5, is a scenario that was described by the IPCC. It is the scenario that arises from socio-economic trends described in the Shared Socio-economic Pathway 5, that lead to a radiative forcing of 8.5 $Wm^{-2}$ in 2100. Of the five SSP-based scenarios, SSP5-8.5 is the scenario with the highest amount of greenhouse gases.

The model provides insight into the effect of large-scale cultivation on the environment, such as changes in ambient nutrient availability and primary production. In addition, the model shows effects of wind turbines on current patterns, stratification regimes, fine sediment dynamics and any consequential changes in the growth dynamics of sugar kelp and blue mussels. Our findings help to identify the potential future impacts of large-scale seaweed and shellfish production on the North Sea ecosystem, and how climate change might alter the suitability of offshore wind farms for multi-use.

# CAN WE PREDICT NUTRIENT AND MINERAL DIGESTIBILITY OF PELLETED AQUAFEED DIETS BY *in-vitro* MODEL OF CULTIVATED SHRIMP GUT (*Litopenaeus vannamei*)?

Joseph L Humble*[1], Nicola Pontefract[2], Nidhi Dalal[3], Martin Llewellyn[1]

[1]School of Biodiversity, One Health and Veterinary Medicine, University of Glasgow, UK
[3]Department of Agricultural Sciences, University of Naples, Italy
[2]Pontus Research Ltd, UK
Email: joseph.humble@glasgow.ac.uk

**Background**
Farming *L. vannamei* produced 11.96% of total aquaculture output in 2020. While easing pressure on wild stocks, sustainability depends on balanced, cost-effective feeds. Fish meal use has fallen from >25% in the 1990s to ≤12% in the past decade[1], replaced by plant, animal, fungal and bacterial ingredients. Plant sources offer cost and availability benefits but often contain indigestible carbohydrates, fibres and anti-nutritional factors[2]. Animal ingredients can also lack digestible nutrients. High saturated fat in animal-derived diets can impair growth, while PUFAs (EPA, DHA) are essential as shrimp cannot synthesise them efficiently; 0.86% dry weight is optimal. Fat requirements vary with salinity (6% at 40 ppt; 8% at 2 ppt). Meat/bone meal can replace 80% of dietary fish meal; blood/feather meals are limited to 30% without affecting growth[3]. Defatted insect meals can replace 60% of fish meal, but full-fat forms (high in saturated fats) are limited to 25%[4].

Phosphorus is vital for growth, but its digestibility varies. Liu et al. found phosphate digestibility of 52.1–79.9% and lipid digestibility of 2.1–92.5%[5]. Phosphorus-rich shrimp waste can trigger bacterial blooms and ammonia spikes, harming welfare and yield.

The *in vitro* salmon gut model "SalmoSim" has been used to evaluate novel feed ingredients. However, consultants in the aquaculture industry have been requesting a method to assess shrimp feeds, as feeding trials of cultivated shrimp are particularly arduous due to their small quantities of faecal matter. Here, we apply "ShrimpSim", an *in-vitro L. vannamei* gut model, alongside Pontus Research feeding trials to assess the digestibility of minerals and fatty acids in UK-produced feeds. Nutritional che

**Objective/ aim**
We aim to test ShrimpSim's ability to predict the in vivo digestibility of lipids, fatty acids and key minerals (Ca, P, Mg, Se, I, Zn, Fe) by measuring feed content before and after ShrimpSim assays on six diets.

**Methods**
Six InSuRAFeed pelleted diets (produced by Pontus Research with locally sourced Northern European ingredients) are being tested with ShrimpSim. Pellets are ground (mandible and gastric mill simulation), enzymatically digested and subjected to selective absorption (hepatopancreas simulation).

Nutritional chemical analysis will be conducted at University of Naples Federico II, thanks to the AQUASERV Transnational Access Programme. Absorbed and residual fractions will be lyophilised, homogenised and analysed via TQ-ICP-MS, Soxhlet and GC-MS for fatty acids and minerals. Digestibility coefficients will be calculated by comparing digesta with diets. Parallel *in vivo* trials at Pontus Research (Wales) will determine coefficients for crude protein, amino acids, lipids, fatty acids, Ca, P and energy.

**Expected Outcomes**
ShrimpSim is expected to screen ingredients for desirable mineral and fatty acid profiles. Regression analysis will compare ShrimpSim and *in vivo* results, with slope and intercept used to calibrate ShrimpSim predictions.

*(Continued on next page)*

**Significance**

Validating ShrimpSim for lipid fatty acid and mineral digestibility could provide the shrimp farming industry with a rapid, cost-effective tool to enable faster formulation of sustainable feeds. ShrimpSim has a rapid turnaround (1 week to generate digestates for up to four diets) compared to *in-vivo* trials (often 2-3 months). ShrimpSim supports fishmeal/ fish oil replacement, thus reducing the pressure on forage fish populations.

**Acknowledgments**

Sample analysis will be funded by the European Commission under grant agreement No 101131121, AQUASERV project.

# SHRIMP FARMING IN VIETNAM: NEW MODEL FOR EFFICIENCY, SUSTAINABILITY AND TECHNOLOGY TRANSFER

Loc Tran

Founder & CEO of EcoSeafood Group and ShrimpVet Laboratory
Vietnam

Email: loctran@shrimpvet.com

Vietnam's shrimp industry is undergoing a period of profound stress, driven by persistently low farmgate prices, escalating input costs, and increasing scrutiny over environmental sustainability. These structural challenges are further intensified by global competition, particularly from cost-efficient producers such as Ecuador and India, resulting in a prolonged price crisis and declining profit margins for Vietnamese farmers.

In response, EcoSeafood Group (E.S.G) - a newly established enterprise building upon the technological foundation and field experience of ShrimpVet - has introduced a novel, systems-based shrimp farming model. This model integrates modular farm design, advanced production technologies, and mangrove agroecological integration to enhance productivity while minimizing environmental impact. With a current pilot site of 30 hectares, the system is engineered to optimize resource efficiency, reduce labor dependency, and lower carbon footprint through automation and scale.

E.S.G aims to expand this model to 50 modules by 2030, accounting for just 1% of Vietnam's total shrimp farming area, yet potentially matching national production levels through intensified yield. Beyond economic efficiency, the model addresses a broader socio-structural issue: attracting a new generation of farmers by offering a high-tech, profitable, and sustainable alternative to conventional shrimp aquaculture.

This presentation outlines the conceptual framework, preliminary outcomes, and long-term vision of this transformative approach to sustainable shrimp production in Vietnam.

# THE EFFECT OF SUPPLEMENTING DIET OF EUROPEAN SEA BASS (*Dicentrarchus labrax*) WITH FISH MEAL AND CHEMICALLY PROTECTED SODIUM BUTYRATE ADDITIVE ON GROWTH AND RESISTANCE TO VIBRIOSIS

E-mail: esther@iats.csic.es

**Introduction**

Feed efficiency and disease resistance represent the main economic challenges in aquaculture. For this reason, development of feeds, which improve growth but also reinforce the health fish status, is a priority for the sector. Different strategies can be implemented for this purpose, for instance a) inclusion of fish meal (FM) as source of protein to achieve better performance and b) supplementation with additives for the gut health benefits in livestock animals (Piazzon *et al*., 2017). European sea bass (*Dicentrarchus labrax*) (ESB) is one of the main farmed species in Mediterranean Basin and *Vibrio harveyi* one of the most concerning pathogens for this species, whose impact is also growing due to global warming (Amaro *et al*., 2020). This study investigates the effects of dietary incorporation of FM as well as supplementation with a chemically protected sodium butyrate (CpSB) additive on growth performance and vibriosis resistance in ESB.

**Materials and methods**

Functional feeds. Functional feeds were prepared by Spin-Off Life Bioencapsulation S.L. and the CpSB additive was provided by Novation 2000 SL. Diets contained 15 % (T15) or 30 % (T30) of fish meal (FM) and were supplemented with 0.2 or 0.4 % of the additive (T15 0.2, T15 0.4, T30 0.2 and T30 0.4).

Growth trial. Fish (Aquicultura Balear S.A.U, Palma de Mallorca, Spain) with 4.5g of average weight were kept in 250-liter tanks. with a 12-hour light/dark photoperiod, and fed *ad libitum* with a commercial diet along the acclimation period (1 month). Subsequently, a total of 960 fish were distributed in six experimental groups (n = 160 per group, with 4 replicates) and fed daily diets indicated above for 45 days. The control group received the commercial diet during the same period. Trial was performed in IATS fish facilities (ES1200330001055). Fish were weighed and measured before administering the different experimental diets and at the end of the feeding trial. Prior to handling, fish were anaesthetised with tricaine and euthanised with an overdose of the same anaesthetic.

Bacterial challenge. After the feeding period, an infection challenge with *V. harveyi* strain C2 was conducted by prolonged immersion (1 h) in seawater at 24± 2ºC, using the previously estimated lethal dose 50%. Within each group, 4 replicates of 20 fish were infected. After immersion, animals were transferred to 90-liter tanks. Moribund fishes were euthanized with tricaine, and internal organs were sampled on Trypticase Soy Agar with 1% of NaCl (TSA-1) to confirm *V. harveyi* as the cause of death (if the inoculated bacterium is recovered as a pure culture). Challenge ended when no mortality was recorded during, at least, 2 days, and survival rates were calculated.

Statistical analysis. Biometrical data were subjected to a one-way ANOVA. Survival rates were analysed using Kaplan-Meier method and Cox method to test for significant differences among diets, using R (version 4.5.1).

**Results and discussion**

All developed diets significantly improved fish weight and length, their impact on growth performance was therefore positive. Diets containing 30% FM yielded greater growth (11.5 g and 9.9 cm) than those with 15% (10.2 g and 9.6 cm), while additive supplementation alone had no clear effects (Fig. 1). However, in groups fed T30 diets supplemented with additive, a significant and dose-dependent increase in biometric parameters was observed (Fig. 1). This suggests that combining a higher level of FM with a high dose of the CpSB additive could enhance growth and be beneficial for sea bass farming.

*(Continued on next page)*

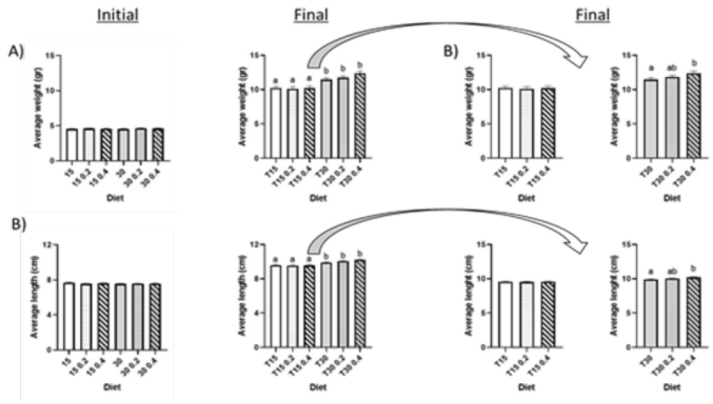

**Fig.1 Fish biometrical parameters. A)** Average weight and length of the fish (n=160) at the beginning and end of experiment. **B)** The average weight and length of the fish (n= 160) depending on the content of the fish meal diet (15 or 30%) at the end of the experiment. Data are expressed as means ± standard error of the mean (SEM). Different letters denote significant differences after one-way ANOVA (p<

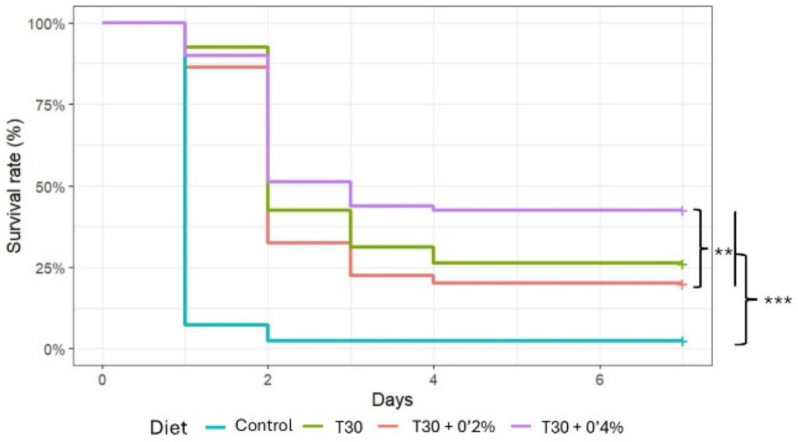

**Fig 2. Survival rates of sea bass groups fed different diets and challenged by immersion with *Vibrio harveyi***. Groups fed control diet, diet with 30% of fish meal (T30), diet T30 plus 0.2% or 0.4% of additive. Significant codes: p-value < 0.01 (**), p-value < 0.001 (***).

Fish fed T30 diets, the most promising ones in terms of growth performance, showed a significant increase in the survival rate after challenging with a high *V. harveyi* infection pressure (dose around $1x10^6$ cfu/mL), comparing with the control group (Fig. 2). Survival rate was significantly higher when T30 diet was supplemented with the greater dose (0.4%) of CpSB additive (Fig. 2).

## Conclusions

- Feeding with diets containing 30% of fish meal (*versus* 15%) over 45 days significantly enhances growth performance and survival of European sea bass (ESB) challenged with *Vibrio harveyi*.

- The inclusion of a chemically protected sodium butyrate additive at 0.4% in the diet leads to a notable increase in growth of ESB and improves their survival after *V. harveyi* challenge.

# NORTH SEA SEAWEED EXTRACTS AS FUNCTIONAL AQUAFEED TO COMBAT AHPND IN *Litopenaeus vannamei* SHRIMP POST-LARVAE

Felina Pranata Irawan[1*], Vincent Vermeylen[1], Jessica Knoop[2], Annelies Declercq[1]

[1] Laboratory of Aquaculture and Artemia Reference Center, Ghent University, Coupure Links 653, 9000, Ghent, Belgium
[2] Royal Netherlands Institute for Sea Research NIOZ, PO Box 140, 4400 AC, Yerseke, The Netherlands
[*] Felina.PranataIrawan@UGent.be

## Introduction

Despite their ecological impact, invasive seaweeds may offer a promising opportunity for sustainable aquafeed development. Along the North Sea coastline, the non-endemic green and brown seaweeds such as *Ulva australis* (southern sea lettuce) and *Sargassum muticum* (Japanese wireweed) are now widespread. Their inclusion in shrimp and fish diets could reduce reliance on costly and less sustainable ingredients like fish meal and fish oil. Additionally, many studies demonstrated the antimicrobial properties of seaweed extracts and components. This is particularly relevant in Pacific white-leg shrimp (*Litopenaeus vannamei*) hatcheries, where *Vibrio parahaemolyticus* infections cause acute hepatopancreatic necrosis disease (AHPND) and result in high mortality and economic losses. Vaccination is ineffective due to the shrimp's lack of adaptive immunity, and antibiotic use is strictly regulated to prevent the development of antibiotic resistance in the pathogen. Incorporating bioactive-rich seaweed extracts into pelletized feed may provide a functional immunostimulant solution that supports growth, disease resistance, and environmental sustainability. However, key questions remain about the specific bioactive compounds involved, optimal inclusion rates, and the cost-benefit analysis of the practical application in shrimp farming. This study aims to explore the potential of *U. australis* and *S. muticum* as alternative shrimp feed ingredients by evaluating their impact on shrimp growth performance and resistance to AHPND.

## Materials and Methods

Seaweed extracts from two *U. australis* strains and one *S. muticum* strain collected along the North Sea coastline were prepared using 70% ethanol and lyophilized. Bioactive compounds were analyzed via high-performance liquid chromatography (HPLC) and total phenolic content (TPC) assays. The minimum inhibitory concentration (MIC) against *V. parahaemolyticus* (AHPND strain M0904) was determined using microbroth dilution. A four-week feeding trial tested 1% and 3% inclusion rates of one of the seaweed extracts in shrimp post-larvae (PL) diets, assessing survival rate (SR), weight gain (WG), feed conversion ratio (FCR), and specific growth rate (SGR). The control group was made of shrimp fed the standard diet without seaweed extracts. A pathogenic challenge evaluated the anti-*Vibrio* effects of these seaweed-supplemented feeds.

## Results

The MIC of both *U. australis* strains was 12.5 mg/mL, and that of *S. muticum* was 25 mg/mL. Classified as a phenolic acid and a flavonoid, respectively, gallic acid and quercetin were identified in all extracts and have been extensively studied previously as antimicrobial and antioxidant agents. The estimated TPC in *U. australis* strain NL, *U. australis* strain FR, and *S. muticum* extract was 269 ± 7.86, 69 ± 6.50, and 89 ± 8.65 µg gallic acid equivalent (GAE) per gram dried extract (Table 1).

Table 1. Phytochemical properties and antibacterial activity of seaweed extracts.

| Seaweed | Total Phenolic Content (µg GAE/g) | Minimum Inhibitory Concentration (MIC) (mg/mL) |
|---|---|---|
| *U. australis* strain NL | 269 ± 7.86 | 12.50 |
| *U. australis* strain FR | 69 ± 6.50 | 12.50 |
| *S. muticum* | 89 ± 8.65 | 25 |

*(Continued on next page)*

Preliminary results of the TPC and MIC values suggest that even low inclusion levels of seaweed extract in shrimp diets may confer protective effects against *V. parahaemolyticus*. A lower MIC combined with a higher TPC indicates stronger antimicrobial activity. Notably, experimental diets containing 3% of the *U. australis* strain NL showed promising trends in SR, WG, and SGR, with values of 97.78 ± 3.85%, 97.77 ± 26.16%, and 9.65 ± 1.97%/day, respectively, compared to 93.33 ± 5.77%, 92.70 ± 3.48%, and 9.37 ± 0.26%/day in the control group by week one. The FCR was considered relatively high concerning the digestive capacity in the adaptation phase in the first week of the experiment. Based on the SGR comparison, the treated PLs underwent efficient nutrient absorption from feed intake into their body mass. Key water qualities remained favorable and within the limits. These findings imply that seaweed supplementation has not had adverse effects and may contribute to enhanced immune function and growth performance in shrimp.

**Conclusion**

Selecting seaweed extracts with prospective antimicrobial and antioxidant potentials would reduce reliance on antibiotics or synthetic additives and aligning with sustainable aquaculture goals. Additionally, seaweed extracts may function as growth promoters to improve nutrient utilization. This study provides valuable insights for countries facing widespread macroalgae invasions and intensive aquaculture activities, where the challenges of managing foreign seaweed biomass, ensuring feed sustainability, and improving disease control must be simultaneously addressed. Understanding the relationship between the antimicrobial properties of invasive seaweeds as a dietary supplement and their therapeutic advantage on shrimp PL could be an ecologically and economically friendly prophylactic strategy to support stewardship in global aquaculture practices.

# AQUACULTURE AT EXPOSED SITES: CHALLENGES IN A NORTH SEA WIND FARM (EU-PROJECT OLAMUR)

Wolf Isbert*, Jochen Horstmann, Bela H. Buck

Alfred Wegener Institute
Helmholtz Centre for Polar and Marine Research (AWI)
Am Handelshafen 12
27570 Bremerhaven, Germany
Email: wolf.isbert@awi.de

Many EU countries aim to be less dependent on global markets and create new income opportunities for coastal communities in a climate changing world. In addition to the already overused coastal areas of Germany, the site development plan for offshore wind farms in the German Bight will increase significantly over the next 25 years. Multi-Use (MU, Schupp et al. 2019) is intended to offer the possibility of joint use of the marine realm by different users without exerting additional ecological impact on the marine environment. Consequently, MU could pave the way for new stakeholders, such as offshore aquaculture enterprises, which will be conducted in synergy with offshore wind farms.

The OLAMUR-Project aims to assess the viability of MU aquaculture in three case studies representing differently exposed areas in the North and Baltic Sea. 70 km off the coast in Germany (case study A) low-trophic aquaculture experiments are located in the wind farm MeerWind Süd/Ost. After two years of planning, designing, testing of various system-designs, mooring concepts and farming strategies, farming of some of these selected taxa such as blue mussels (*Mytilus edulis*), European Oysters (*Ostrea edulis*), sea lettuce (*Ulva* sp.) and sugar kelp (*Saccharina latissima*) started in spring and early summer 2025.

Here, we present preliminary results (abiotic/biotic data, technology, moorings) of all farming trials. Results of this case study may provide a first insight whether aquaculture in very exposed offshore areas could be a potential new sector in the North Sea to achieve the above-mentioned aims.

# ON-DEVICE AI-ENHANCED REAL-TIME FISH COUNTING SYSTEM IN AQUACULTURE

Yuko Ishiwaka*, Yen-chi Xu, Yuchen Xu, Weier Wan

SoftBank Corp., 1-7-1, Kaigan, Minato-KU, Tokyo (Japan)
Aizip Inc, 20370 Town Center Lane, Suite 252, Cupertino, CA 95014, (United States)
E-mail: yuko.ishiwaka@g.softbank.co.jp
yenchi, yuchen, weier@aizip.ai

**Introduction**
Aquaculture is a crucial industry in global food production, facing numerous challenges in efficiency, cost management, and environmental impact. Traditional methods of monitoring aquaculture rely on manual labor and primitive technologies, leading to inefficiencies and high operational costs. To address these challenges, this research focuses on developing an AI-empowered system capable of real-time fish counting underwater using on-device technology. By deploying advanced neural network models on edge devices, we aim to revolutionize aquaculture monitoring.

**Methods**
Accurate fish counting is essential for optimizing feeding strategies, which not only benefits fish farmers economically but also helps prevent marine pollution from excess feed. Key fish counting events include transferring juveniles into cages, monitoring growth phases in the cages, and during harvest. We have adopted different counting methodologies for each scenario: 1.Object Detection: Fish are often moved through specific checkpoints, making object detection suitable for counting during transfers. Correct camera positioning is crucial for this method. 2. Heat Map: In densely populated environments like entire cages, occlusion presents challenges for object detection; thus, a heat map approach is more appropriate.

We utilized a large-scale dataset consisting of videos collected on-site and synthetic videos generated via 3D CG simulations for training. The 3D CG generated data is especially valuable as it can be treated as ground truth. These datasets cover diverse environmental conditions, including varying lighting, water quality, and fish species. For the model training, we employed advanced deep learning techniques, we trained neural networks to achieve high precision and efficiency. For the edge deployment, the model is deployed onto chipsets near underwater cameras, enabling real-time processing and eliminating the need to transmit large volumes of video data.

**Implementation**
The system is designed to maximize efficiency and adaptability.Utilizing high-performance embedded chipsets like the Snapdragon 8 Gen 3 processor enables real-time video processing in embedded systems.Underwater cameras collect video data, which is processed locally on the embedded system. This reduces latency and communication overhead. Our application includes specialized neural network models for fish countings, and these models are all optimized for edge computing. Only essential metadata and summaries are sent to the central monitoring system, ensuring bandwidth efficiency.

**Results and Discussion**
We conducted fish counts during transfers and within entire cages. The deep learning models achieved 90%-95% accuracy in real-time underwater environments. However, for entire cage counts, visibility of the whole cage is crucial. Counting during transfers proved faster and less stressful for the fish compared to current mechanical systems. The on-device processing capabilities eliminated the need for extensive data transmission infrastructure, increasing system reliability and reducing overall costs.
These findings contribute to the following expectations. Real-time measurement of fish numbers and appetite indicators reduces feed waste and lowers production costs, enhancing feeding efficiency. Automated fish counting and size estimation during transfers increase process efficiency and operational productivity.

Future research will focus on several key areas. Enhancements to neural network models will continue to accommodate a broader range of environmental conditions and fish species. The system's scalability will be ensured for deployment in large, diverse aquaculture environments. Predictive analytics will be integrated to provide early warnings for potential issues like disease outbreaks and environmental risks. Intuitive user interfaces will be developed for easier adoption and operation by aquaculture farm operators.

*(Continued on next page)*

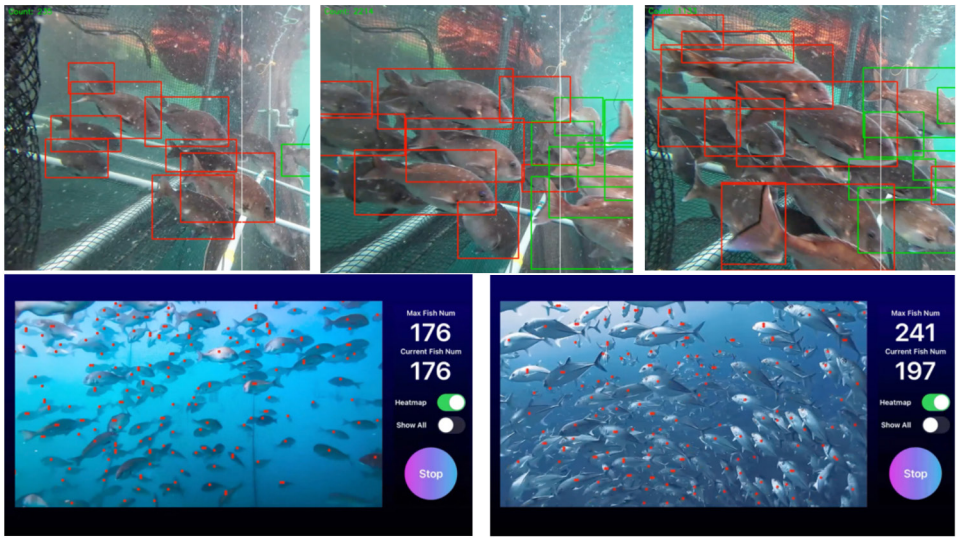

Fig. 1 Fish counting results: Above: by object detection (red seabreams); Bottom: a heat map method (left: red seabreams, right: tuna)

**Conclusion**

This research signifies a substantial advancement in aquaculture technology, providing a robust and efficient solution for farm monitoring. By leveraging advanced AI and edge computing, the study enhances operational efficiency, reduces costs, and improves the overall quality and safety of aquaculture practices. Anticipated future enhancements and expansions will further solidify this system as an indispensable tool in modern aquaculture.

# REAL-TIME FRESHNESS EVALUATION OF FISH USING AI-DRIVEN NEAR-INFRARED SPECTROSCOPY: APPLICATION FOR POST-HARVEST VALUE ENHANCEMENT

Yuko Ishiwaka*, Marta Casar, Lluís Formiga, Jordi Adell, Jaume Padrell

SoftBank Corp., 1-7-1, Kaigan, Minato-KU, Tokyo (Japan)

E-mail: yuko.ishiwaka@g.softbank.co.jp
mcasar, lformiga, jadell, jpadrell@verbio.com

**Introduction**

Post-harvest quality management is a critical issue in the global aquaculture industry. Fish prices are determined by species and weight, and the quality itself is often branded by origin by a few experts known as connoisseurs rather than by individual quality. By quantifying quality, it becomes possible to accurately reflect the value of fish in the market. Furthermore, in the supply chain of Japanese sea bream (Pagrus major), up to 15% of processed fillets are discarded annually due to uncertainty in freshness and subjective grading. This leads to a decrease in added value, increased food waste, and constraints on the predictability of shelf life. The K-value is a standard for evaluating the freshness of fish as per JAS (Japanes Agricultural Standards) regulations. Traditional K-value evaluation requires destructive, costly, and time-consuming laboratory HPLC analysis. To address emerging regulatory requirements and sustainability challenges (UN SDGs 12 and 14), we developed and validated a real-time, non-destructive freshness evaluation platform integrating handheld near-infrared spectroscopy (NIR) with advanced AI.

**Materials and Methods**

Sampling and Workflow: We sampled 1,178 skin-on fillets of [Pagrus major] farmed in the Sea of Japan over 0-7 days post-mortem, reflecting distinctive post-harvest conditions in Japan. The fillets were scanned at three standardized positions using two InnoSpectra MEMS NIR devices (900–1700 nm and 1350–2500 nm, 3 mm spot, 2-second acquisition). The scanning was implemented by workers using mobile or tablet interfaces during the packaging process.

Reference Method: The K-value ([HxR+Hx]/[ATP+ADP+AMP+IMP+HxR+Hx]×100) was measured by two inspection agencies, which measured samples on the day of slaughter and three days later. The two agencies measured the same samples simultaneously to confirm consistency in results.

Spectral Processing and Modeling: Each spectrum was processed using a triangular filter bank and differential feature extraction, then normalized (mean 0/variance 1, training set). Model Pipeline: RandomForestRegressor (scikit-learn), hyperparameters optimized with nested CV. An 80/20 split was used for training/testing sets (n=942/236), with 10-fold cross-validation conducted. Outliers (≤2%) were detected using Mahalanobis distance and excluded from model training. Cloud integration supported immediate result transfer and batch traceability.

**Results**

The NIR-AI platform achieved an MAE=1.62, RMSE=2.46, and $R^2$=0.74 for K-value estimation in the test set, attaining a 91% category accuracy (Sashimi: K<20%, Cook: 20-40%, Reject: >40%), outperforming both baseline statistics and subjective evaluations. The shelf-life prediction curve using the NIR system matched observed spoilage and sensory cut-off points (average $\Delta t$ <1 day). The real-time analysis results from the NIR sensor showed a high accuracy, with the Lab test K-value at 15 compared to our model's analysis of 15.1.

**Discussion and Impact**

Comparison with State-of-the-Art: Unlike traditional linear regression or lab-supported NIR solutions, our deep learning and SaaS-connected approach enables real-time, operator-independent automation. Each test costs less than €0.002 (compared to €250 for HPLC) and can handle TEU-level processing capacity with five handsets per line.

Traceability and Scalability: The cloud-integrated results enable dynamic FIFO stacks, price optimization, and regulatory audit trails, essential for achieving EU Green Deal/"Farm to Fork" goals.

*(Continued on next page)*

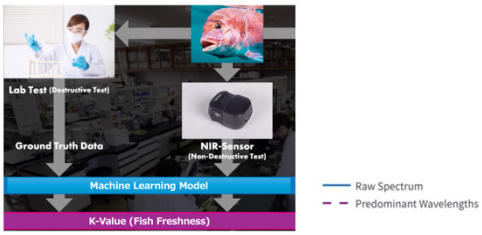

Fig. 1 Overview of our system

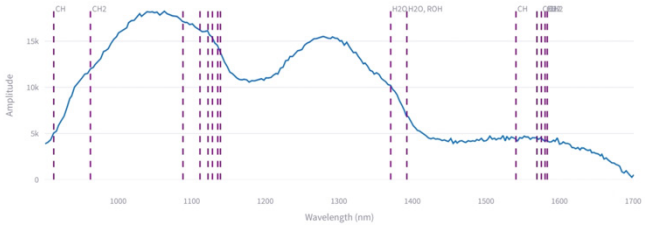

Fig.2 An example of NIR sensor data of a red seabream. It shows the explainability.

**Deployment and Future Work**

The current model is developed for sea bream, with plans to expand to other fish species. Pilot installations are scheduled for Mediterranean mackerel and bluefin tuna lines. Future upgrades will include outputs for microbial spoilage and nutritional components, as well as blockchain or digital twin features for farm-to-fork traceability. We are actively seeking collaboration with additional processing plants in the EU, NGOs, and retailers.

**Conclusion**

This study validated a real-time AI/NIR platform for fillet grading that directly addresses post-harvest value, waste, labor efficiency, and Green Deal SDG goals. This system establishes a new digital standard for aquaculture quality management in the EU and Japan.

**Introduction:**
The application of probiotics in the aquaculture industry of Bangladesh has been gradually increasing in recent years; however, the probiotic industry of the country, worth $410 million, is solely dependent on imported products. Country of origin, transportation and storage conditions of these imported probiotics vastly affect the performance compared to the price (Wardad, 2024). Spore-forming bacteria, mostly of the genus *Bacillus,* exhibit probiotic properties (Elshaghabee et al., 2017). Several *in vitro* and *in vivo* models revealed that members of this genus comply with the standards for being probiotic candidates, have tolerance to acidic substances and are competent to thermal stability during processing and storage conditions (Bader et al., 2012). To reduce dependency on imported probiotics, this study aimed to isolate probiotic candidates from the indigenous sources, i.e., river and canal water. Bacterial identification was done by whole-genome analysis, and probiotic properties were evaluated by several *in vitro* and *in vivo* assays.

**Material and methods:**

Bacteria were collected from the Bishna River and Talbuniya Lake in Bagerhat, southern Bangladesh, and plated onto HiChrome Bacillus Agar for genomic DNA extraction. Library preparation was performed using the Rapid Barcoding Kit 96 V14 (Oxford Nanopore Technologies, Oxford, UK). Long read DNA sequencing was conducted using PromethION R9.4.1 flow cell chemistry. Assembly and annotation were performed using Flye (2.9.6) and the Bacterial and Viral Bioinformatics Resource Centre (BV-BRC), respectively. Type Genome Server (TYGS) was used to construct the phylogenetic tree. The endurance test of the bacteria was performed following the method previously described by (Gao et al., 2024) with a slight modification. Efficacy of the locally isolated strains Bacillus subtropicus_W1 sp. Nov. (W1), Rummeliibacillus bengalensis_S3 sp. Nov. (S3), B. pacificus_S5 (S5) and Priestia bengalensis_S6 sp. Nov. (S6) were evaluated both individual and in combination, in parallel with a commercial probiotic in a feeding trial with a control (commercial fed with no probiotic added) in triplicate. In the feeding trial, commercial feed coated with bacterial culture (~103 cfu/ml) was fed twice (5% of body weight) daily for 5 weeks. Average weight, total haemocyte count (THC), pro-phenoloxidase (Pro-PO) and digestive enzyme activity (amylase, lipase and protease) were evaluated to justify the probiotic potential.

**Results:**
The assembled genome of the novel isolate *Bacillus subtropicus*_W1 possessed 2 contigs, with a total length of 5,572,840 bp (Contig1:236880bp, Contig 2: 5335960bp) and an average G+C content of 35.38%. This genome consisted of 5,728 protein-coding sequences (CDS), 106 transfer RNA (tRNA) genes, 14 complete operons and an extra 5S gene. The annotation included 1,442 hypothetical proteins and 4,286 proteins with functional assignments (Figure 1A). The phylogenetic tree placed the isolate next to *Bacillus tropicus* with dDDH value < 70% (Figure 1B). The isolate showed survival potential at extremely high temperatures (60°-100°C), acidic (pH 2) and basic (pH 10) conditions. Prawns fed the *B. subtropicus*_W1 coated diet resulted in higher ($p<0.05$) average weight, total haemocyte count, Pro-PO, amylase, lipase and protease enzyme activity than those fed the control diet and commercial probiotic supplementation. In contrast, haemocyte clotting time was significantly lower in the group fed *B. subtropicus*_W1-coated diet, indicating better health condition (Figure 2).

**Conclusion:**
Findings of the study showed that locally isolated *Bacillus subtropicus*_W1 sp. Nov. possesses great potential as a probiotic candidate for the aquaculture industry of Bangladesh along with the countries experiencing temperature rise due to global warming.

*(Continued on next page)*

# FISH FARM PRODUCTIVITY AND THE VALUE OF "SUPER-SITES" IN SALMON FARMING IN NORWAY

Audun Iversen*, Silje Steinsbø, Katrine Eriksen, Eirik Mikkelsen

Nofima
Muninbakken 9-11
9294 Tromsø.
*Audun.iversen@nofima.no

**The value of "Super-sites"**

Salmon farmers in Norway talk about "super-sites", for sites that are especially suited for grow-out of salmon, and which have especially high productivity. High productivity can however be measured in different ways, and there may be different types of qualities and effects that can make an area a "super-site". The productivity can e.g. be measured in terms of the total average volume produced to slaughter per year, the effective economic feed factor, or in pecuniary terms (low production costs or high profitability).

Factors that describe and explain competitiveness between salmon producing nations include growth rates, feed conversion ratio, harvest weight, smolt yield and mortality for the farmed fish (Iversen, Asche, Hermansen, & Nystøyl, 2020). The same factors may explain what makes a site a super-site. In addition, the prevalence of lice, disease and external shocks like algae blooms and string jellyfish may strongly affect productivity and profitability.

While some literature find that biophysical factors does not explain profitability (Zhang, Sogn-Grundvåg, He, Tveteras, & Xu, 2025), this is probably because they fail to recognize the great variation among sites. Measuring productivity at firm level (some firms holding up to 300 sites) you effectively cancel out the variation between sites in terms of temperature, growth, lice prevalence, mortality et.c. Analyzing productivity at the site-level (using data on pen level to improve data on growth and feed conversion ratios) will give a significant contribution to the literature on biophysical factors and productivity.

Under the newly proposed production regulation regime in Norway, the productivity of aquaculture sites will be of increased importance, as the productivity of the site will be a strong determinant of company value.

**This presentation**

We will present an analysis that identify actual super-sites in Norwegian grow-out salmon farming. These will be based on different criteria and criteria-sets for what defines a super-site. The simplest measure is its revealed capacity to produce over time.

The production capacity of the site as defined by the aquaculture license (which is in terms of the maximum biomass in tonnes that can be held at the site at any given time), but real production capacity varies much more than licensed capacity, dependent on depth, currents, how long fallowing periods are needed between generations to restore sea bottom conditions, average lice numbers on the salmon in the farm and the need for lice treatments to stay within the mandatory limits, disease outbreakset.c. Revealed capacity is illustrated in figure 1 (each site on the x-axis). This shows the combined production for each site over the last ten years. Production ranges from close to 45.000 tonnes, or 9000 tonnes over each two-year production cycle. Only 1/3 of the sites have shown a production of more than 10.000 tonnes for these ten years.

The analysis will describe the distribution of growth rates, mortality, feed conversion ratio, smolt yield et.c., and analyze how these parameters are explained by temperature, lice prevalence et.c. Even for these factors variation is huge, as exemplified by mortality in figure 2. Mortality ranges from over 50 % down to 1-2 % for the best sites.

The analysis will also include how different operational characteristics and parameters for individual farms as well as groups of adjacent farms may help explain the variation in performance and what makes a site a super-locality. The analysis is based on a dataset with production data from all individual pens in Norway for the period 2005-2024. This is combined with data on lice prevalence, lice treatments and disease. The huge range of productivity between sites will be translated into economic effect by a techno-economic model as used in (Holan et al., 2017; Iversen, Hermansen, Nystøyl, & Hess, 2017).

# EXPLORING *Punica granatum* LEAF-DERIVED POLYPHENOLS AS INNOVATIVE PREBIOTICS FOR SYNBIOTIC FORMULATIONS IN SUSTAINABLE AQUACULTURE

Abdul Jabbar [a*], Daniela Sateriale [a], Giuseppina Forgione [a,b], Nicoletta Fidanza [a], Andrea D'Anna [b], Paola Salvatore [c,d] Marina Paolucci [a] and Caterina Pagliarulo [a]

[a] Department of Science and Technology, University of Sannio, Benevento, Italy
[b] Department of Chemical Engineering, Materials and Industrial Production, University of Naples Federico II, Naples, Italy
[c] Department of Molecular Medicine and Medical Biotechnologies, University of Naples Federico II, Naples, Italy
[d] CEINGE-Biotecnologie Avanzate Franco Salvatore s.c.ar.l, Naples, Italy
[*] a.jabbar@studenti.unisannio.it

**Objectives:**
Pomegranate (*Punica granatum* L.) leaves, rich in bioactive polyphenols, are promising agri-food byproducts for sustainable health applications. Despite their known antioxidant and antimicrobial properties, their use in synbiotic systems with probiotic yeasts remains underexplored. This study evaluates the prebiotic effects of pomegranate leaf extracts on *Saccharomyces boulardii* and their antimicrobial activity against fish pathogens, highlighting their synbiotic potential for sustainable aquaculture.

**Methods:**
Pomegranate leaf extracts were obtained via microwave-assisted hydroethanolic extraction and analyzed for chemical composition, antioxidant capacity, and antimicrobial activity against aquaculture pathogens. Their prebiotic effects on *S. boulardii* were assessed through a fitness assay at varying concentrations. Extracellular and intracellular postbiotic fractions were isolated and evaluated for polyphenol content, antioxidant activity, soluble protein levels, and antimicrobial properties. Extracellular postbiotics were recovered from the cell-free supernatants, while intracellular compounds were extracted via cell lysis and subjected to the same analytical assessments.

**Results:**
The hydroethanolic extract of pomegranate leaves exhibited high total polyphenol content, strong antioxidant capacity, and notable antimicrobial activity against aquaculture pathogens. Additionally, it significantly enhanced the growth of *S. boulardii* in glucose-free medium over a 7-day incubation, demonstrating strong prebiotic potential. Pomegranate leaf extract enhanced extracellular and intracellular postbiotic fractions, increasing polyphenols, antioxidant activity, and proteins, with extracellular postbiotics showing the highest bioactivity. Antimicrobial assays demonstrated that pomegranate leaf extract and postbiotic compounds of *S. boulardii* exerted inhibitory activity against *Aeromonas veronii* and *Aeromonas hydrophila*, two significant pathogens associated with infectious diseases in aquaculture systems.

**Conclusions:**
Pomegranate leaf extract enhances *S. boulardii* growth and postbiotic activity while showing antimicrobial effects against aquaculture pathogens. This highlights the combined potential of both *S. boulardii* and pomegranate leaf extract as sustainable synbiotic ingredients to improve fish health and reduce antibiotic use in aquaculture.

# BACTERIAL CONTAMINATION IN SHELLFISH – ENDOTOXIN PROVIDES A RAPID TESTING SOLUTION

Christian Good[1], Alistair White[1], Joao Brandao[2,3], Craig Baker-Austin[4], Simon K. Jackson*[1,5]

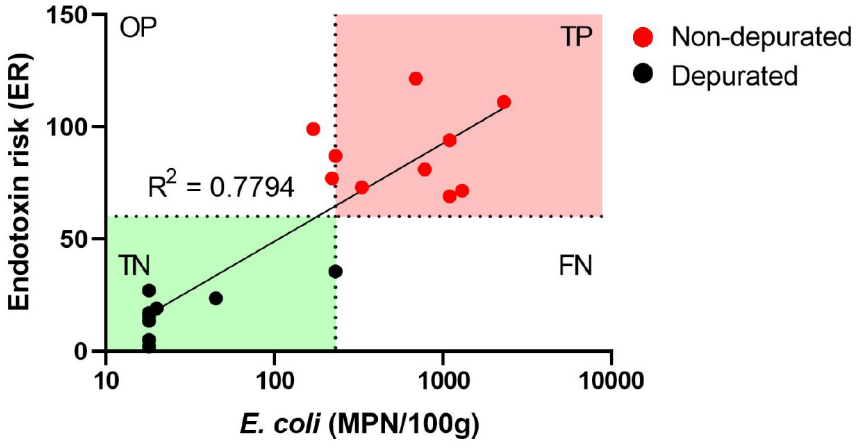
Corresponding author: simon.jackson@molendotech.com

**Background**

Shellfish are filter feeders that can accumulate harmful pathogens, including bacteria (e.g., *Vibrio* spp, *Salmonella* spp, *Shigella* spp, *Campylobacter* spp and pathogenic *Escherichia coli*). Culture of *E. coli* in shellfish still represents the primary way of assessing the microbiological quality of shellfish. The reference methods (EN/ISO 6888-1 and 2 of 1999) require incubation periods ranging from 24 to 48 hours (or longer), to allow bacterial colonies to grow, which delay results and potential public health protection actions. This presents several problems including the long time to results and focus on *E. coli*. Moreover, culturing bacteria requires trained personnel, specialized lab facilities, and expensive reagents. These factors make it less practical for high-throughput or field-based testing, especially in resource-limited settings.

Shellfish classification categories are based on permitted levels of E. coli/100g flesh and intravalvular liquid. The disadvantages of culture-based testing for bacterial contamination highlights the need for new rapid, sensitive, field-based tests to detect bacterial contamination of shellfish to allow proactive measures to protect public health.We have previously described a validated method to rapidly assess bacterial contamination in recreational water (Good et al., 2024; Sattar et al., 2022). This is based on the detection of a bacterial molecule (endotoxin). In this study, we describe an adaptation of this method to rapidly detect Gram-negative bacterial contamination of shellfish that can be used in the field by non-technical staff. This study has established the feasibility of a novel method to rapidly detect bacterial contamination in oyster flesh and has shown that the Endotoxin Risk (ER) value significantly correlates with *E. coli* content in oysters.



*(Continued on next page)*

**Methods**

Two hundred pacific oysters (Crassostrea Gigas) were sourced locally in Devon; 100 of the oysters had been depurated and 100 had not been depurated. The oysters were stored at 4°C ± 2°C and were examined within 48 hours. The amount of *Escherichia coli* in the oysters was enumerated by the Most Probable Number (MPN) method, following the ISO 16649-1. Endotoxin was measured using the Bacterisk assay (Molendotech Ltd., Brixham, UK; www.molendotech.com) and was performed following the manufacturer's instructions. The Bacterisk device was pre-calibrated using known endotoxin standards (0.1-10 EU/mL) and against known reference concentrations of E. coli (10-5000CFU/100mL) Output from the Bacterisk device is given in Endotoxin Risk units (ERU) which are calibrated from known endotoxin standards. The ERU values can be equated with known concentrations of *E. coli* (CFU/100mL) to give threshold and cut-off values (Good et al., 2024)

**Results**

By using the threshold for class A shellfish of 230 *E. coli*/100g and setting a proposed equivalent threshold of 60 ERU it was possible to split the data into quadrants (see Figure 1) to show off-target positives (i.e. detection of other Gram-negative bacteria) (n=3), true positives (n=7), true negatives (n=10) and false negatives (n=0). From this the following was calculated: Sensitivity: 100%, Specificity: 77%, False negative rate: 0% and Off-target[1] positive rate: 30% The specificity and off-target rate reflect that this test will also respond to bacteria other than *E. coli* including pathogens such as Salmonella spp and Vibrio spp and can thus alert to the contamination of shellfish with pathogens not detected by current methods.

**Conclusion**

This study has established the feasibility of a novel method to rapidly detect bacterial contamination in oyster flesh and has shown that the Endotoxin Risk (ERU) value significantly correlates with *E. coli* content in oysters. As microbial threats evolve, continued investment in rapid detection technologies and regulatory oversight will be essential for maintaining public health standards.

# EFFECT OF FISHMEAL QUALITY ON DIGESTIBILITY, GROWTH PERFORMANCE AND FEED UTILIZATION IN ATLANTIC SALMON (*Salmo salar*)

M.Jaidene, G.Lamborelle, S.Meiske, D.Sutter, W. Koppe

MARS (Matís Aquaculture Research Station)
Vinlandsleid 12
Reykjavik, 113, Iceland
E-mail: mohamed.jaidene@gmail.com

## Introduction

Fishmeal represent a major component of aquafeeds due to its high protein quality, balanced essential amino acid profile, high digestibility and palatability, essential traits for feed efficiency and optimal growth of farmed fish, such as Atlantic salmon (*Salmo salar*) (Hasan et al., 2023). However, variability in fishmeal quality, different species of fish, raw material freshness, processing conditions, and chemical composition, can influence the nutritional value of fishmeal (Mundheim et al., 2004). The purpose of this study was to assess the effect of fishmeal quality on digestibility and growth performance in Atlantic salmon (*Salmo salar*) raised in RAS, as part of a larger effort to profile and benchmark the majority of commercially available fishmeal products in the Icelandic market; with an ultimate goal to assist with a calibration predictive model using near-infrared (NIR), which allows rapide and accurate determination of fishmeal quality and its nutrient potential.

## Materiel and methods

Atlantic salmon (initial mean weights of 121g) were fed experimental diets formulated based on the protocol developed by Cho et al., (1982) where a reference diet of high palatability will be formulated with a known digestibility and a test diet in a ratio of 70:30 (70% reference diet and 30% of test ingredient), where only the fishmeal source is different. Seven fish meals (Sandeel (*Ammodytes* sp) 73%, Sandeel (*Ammodytes* sp) 55%, European anchovy (*Engraulis encrasicolus*) 40%, Gulf menhaden (*Brevoortia patronus*), Blue herring (*Clupea harengus*), Mackerel (*Scomber* sp) trimmings 1, Mackerel (*Scomber* sp) trimmings 2) and one reference commercial fish meal were tested (in triplicate tanks = 24 tanks). All fish were kept under stable water conditions and overfed over six weeks. Daily, uneaten feed was removed to calculate feed intake. At the end of the trial, all fish were weighed individually, and feces were collected by stripping to determine the Apparent Digestibility Coefficients (ADC) of crude protein and amino acids using yttrium oxide as an inert marker.

## Results

Growth performance indicators were positively correlated with crude protein and essential amino acid digestibility. Strong negative correlations were observed between ash and NaCl, and digestibility. Crude protein digestibility and methionine digestibility were identified as primary drivers for variation among fishmeal for growth rate and feed conversion ratio (FCR). Predictive models indicated that digestibility values could explain up to 83% of the variability in Specific Growth Rate (SGR). Quality indicators (TVBN and biogenic amines; histamine, putrescine, and tyramine) had negative associations with nutrient digestibility indicating an indirect effect on growth due to reduced bioavailability. Notably, putrescine concentration, a major spoilage marker, was linked with lower digestibility and poorer growth. Among the products tested, a fishmeal produced from mackerel trimmings showed the best performance in growth and feed efficiency, while a European anchovy meal had the lowest performance.

## Conclusion

Fishmeal quality plays a significant role in nutrient digestibility and growth performance of Atlantic salmon. Poor digestibility and growth efficiency were associated with high levels of spoilage indicators, like total volatile basic nitrogen (TVBN), histamine, putrescine, and cadaverine. The current data highlight the importance of raw material freshness and processing quality in determining fishmeal nutritional value. For optimized feed utilization, improved growth performance, and enhanced sustainability in aquaculture, high crude protein digestibility and low spoilage is required in fishmeal.

# ENHANCED FISH WEIGHT ESTIMATION THROUGH YOLO AND ELECTRODE DATA INTEGRATION

Jamal, A.*, Cohen, L., Hadar, O.

Institute of Agricultural and Biosystems Engineering
Agricultural Research Organization – Volcani Institute
Rishon LeZion 7505101, Israel
alaa@volcani.agri.gov.il

## Introduction

Accurate fish weight estimation is critical to efficient aquaculture management, impacting feeding optimization, health monitoring, and harvest scheduling. Non-intrusive methods have gained significant attention for their ability to streamline this process without inducing stress in fish populations (Li et al., 2020). Among these methods, the You Only Look Once (YOLO) object detection framework has emerged as one of the most widely used approaches for non-intrusive fish weight estimation due to its high accuracy in detecting and analyzing fish morphology from images. However, YOLO's performance can be limited when dealing with fish sizes and conditions not represented in its training data, particularly in extrapolation scenarios (Tengtrairat et al., 2022).

## Method

To address these limitations, we propose an enhanced method integrating electrode-based voltage measurements with YOLO-driven image processing, leveraging machine learning (ML) regression models for fish weight estimation. While electrode measurements have traditionally been utilized for applications such as fish counting, their integration with visual data for weight estimation remains underexplored (Sheppard & Bednarski 2015). By combining these two complementary data sources, our approach aims to improve predictive accuracy, especially in challenging conditions where image-only models struggle, with affordable component prices.

Our model was evaluated under two distinct conditions: interpolation, where YOLO performed well due to familiar weight ranges in the training data, and extrapolation, where YOLO's detection accuracy was reduced due to unfamiliar fish sizes. The integrated model consistently outperformed image-only models in both case studies, with statistical significance. This outcome demonstrates the robustness of the combined approach, as electrode measurements provide additional physiological insights that compensate for the limitations of image-based models.

## Results

The results underscore the potential of integrating multi-modal data sources to enhance non-intrusive fish weight estimation, offering cheap and a more resilient and accurate solution for aquaculture operations.

| Method | YOLO MSE [$gr^2$] | Model MSE [$gr^2$] |
|---|---|---|
| Interpolation | 2.82 | 1.74 |
| Extrapolation | 6 | 4.3 |

# CO CULTURE OF *Palmaria palmata* WITH FINFISH ON LAND, OPPORTUNITIES IN NORWAY

Philip James

philip.james@nofima.no

*Palmaria palmata*, commonly known as ‘dulse’ or ‘søl’ in Norwegian is a well know red seaweed that has relatively high value as a human food product. There is considerable interest in growing the species throughout Norway, Europe and other countries worldwide, and Nofima has been investigating the specific opportunities in the north of Norway.

Research at Nofima has focused initially on protocols for maximizing the spore release and utilization from seaweed collected in the north of Norway. Optimal protocols have now been defined for P. palmata in the north of Norway and work is continuing to develop techniques for commercial seeding onto ropes.

Novel techniques and growing systems for growing *P. palmata* have also been explored. These have focused on growing *P. palmata* in discharge water from land-based finfish facilities in the north of Norway. Seawater was monitored and collected from a large land-based RAS salmon smolt facility on the island of Kvaløya in northern Norway. A series of trials were conducted to test the capacity of *P. palmata* to grow in discharged water from these facilities. These included trials at various inclusion rates of discharge water to find the optimal growing conditions. The results showed that approximately 50% inclusion of discharged seawater was optimal. Further trials showed the influence of varying salinities on the growth of *P. palmata*. The water analysis during these trials also allowed the calculation of production capacity figures for *P. palmata* based on discharge rates from land-based RAS facilities. This presentation presents the results of these trials and discusses the potential to commercialize such activities in the north or elsewhere in Norway.

# GROWTH PERFORMANCE, FILLET YIELD AND SOMATIC INDICES OF EUROPEAN PERCH (*Perca fluviatilis*) FED DIETS CONTAINING VARYING LEVELS OF *Ganoderma spp*. COMPOSITE MYCELIUM MEAL

T. Janssens*; P. Pawlak; F. Weirauch; J.B. Luce; V. Stejskal

School of Agricultural, Forest and Food Sciences (HAFL)
Bern University of Applied Sciences (BFH)
Zollikofen, 3052, Switzerland
E-mail: thomas.janssens@bfh.ch

**Introduction**

In aquaculture, maximizing growth performance and fillet yield while maintaining good fish health is crucial for sustainable and economically viable production. With increasing pressure to replace conventional feed ingredients such as fishmeal and soybean, novel and functional alternatives are gaining traction. Composite mycelium meal (CMM), derived from *Ganoderma spp*. through solid-state fermentation (SSF) of agrifood side-streams, offers promising nutritional and bioactive properties. While the potential of *Ganoderma*-based ingredients has been explored in various species, evidence for its effects in European perch (*Perca fluviatilis*) is lacking. This study investigates how different inclusion levels of CMM affect growth, fillet yield, and somatic indices in European perch.

**Materials and methods**

Juvenile European perch were fed one of four diets for 12 weeks: CTRL (0% CMM), CMM-5 (5% CMM), CMM-7.5 (7.5% CMM), CMM-10 (10% CMM).

The CMM was co-developed by KIDEMIS and BFH-HAFL using *Ganoderma spp*. through SSF. At the end of the trial, fish were measured and dissected to evaluate final weight, fillet yield, hepatosomatic and visceral fat index.

Data were analyzed using linear models in R (lm function), with estimated marginal means calculated using the emmeans package.

**Results**

Growth performance:
Fish in the CMM-10 group had significantly higher final body weight compared to the CTRL and CMM-5 groups ($p < 0.05$).

Fillet yield:
Despite differences in body weight, fillet yield did not significantly differ between dietary groups.

Somatic indices:
Hepatosomatic index showed a progressive but non-significant increase with higher CMM levels. However, visceral fat index was significantly higher in the CMM-10 group compared to CMM-7.5.

**Conclusion**

Composite mycelium meal derived from *Ganoderma spp*. supported enhanced growth in European perch, particularly at the 10% inclusion level. However, the increase in visceral fat and organ weight without a corresponding rise in fillet yield highlights potential shifts in energy partitioning. These metabolic effects require further investigation to determine long-term implications and optimal inclusion levels. The results indicate that while CMM is a promising sustainable ingredient, moderate inclusion rates may offer a more balanced outcome for performance and product quality.

# ARTIFICIAL INTELLIGENCE (AI) TOOLS USED IN AQUACULTURE FACILITIES IN THE EUROPEAN UNION, WITH RESPECTIVE COUNTRIES

Javid, J.*[1], Mohamed Dahlan, M.F.[2], Reji, S.[3]

Faculty of Science and Technology, Nantes University, France[1]
Centre Algatech, Institutes of Microbiology, Czech Academy of Sciences, Czech Republic[2]
University of Pau and Adour Countries, France[3]
Email: *joeljavid98@gmail.com

Aquaculture has become a vital component of the European Union's food production system, contributing significantly to the economy and food security. Due to the increased demand for fish, a quest for novel and efficient techniques in aquaculture production, systems to alleviate the burdens of fish disease management, environmental degradation, and high production costs have become imperative. The integration of Artificial Intelligence (AI) tools in aquaculture facilities across the European Union (EU) has emerged as a promising solution for rapidly transforming and enhancing productivity, sustainability, operational efficiency, and competitiveness. Prominent corporations and academic institutions have created innovative artificial intelligence (AI) solutions, including autonomous underwater vehicles (AUVs) for monitoring and maintenance in offshore environments, real-time behavioral monitoring systems for accurate feed dispensing, and AI-powered cameras for fish size and growth analysis.

AI-enabled sensors, as demonstrated in EU-funded projects like ASTRAL, provide continuous, automated water quality monitoring, utilizing machine learning algorithms to detect anomalies and environmental risks, thereby promoting sustainable and high-quality production. Across the EU, AI tools are being integrated into aquaculture to address key operational challenges. Countries like Norway and France use smart cameras and feeding systems for biomass estimation and waste reduction, while Denmark and Italy apply AI for real-time water quality and disease monitoring. Spain, Greece, and the Netherlands leverage AI for health grading, production forecasting, and biofouling control, showcasing a shift toward precision and efficiency in aquaculture. Table 1 shows the AI tools currently used in aquaculture facilities across the European Union.

By harnessing AI, EU aquaculture is transitioning toward data-driven, resilient, and eco-efficient production systems. These innovations reduce labor costs and environmental impact and improve productivity and animal welfare. The integration of AI in European aquaculture aligns with policy objectives such as the European Green Deal, and the Farm to Fork Strategy by providing a path to overcoming the economic, environmental, and social burdens that have long challenged the sector.

**Table 1.** Key AI Tools in EU Aquaculture

| Tool/Project Name | Country/Region | Main Applications |
|---|---|---|
| AquaREAL | France, EU-wide | Predicting water quality, optimizing fish welfare |
| EdgeSpot Sensor | EU-wide (ASTRAL) | water quality monitoring, anomaly detection |
| iFarm | Norway, EU | Individual fish identification, health monitoring |
| Aquaculture 4.0 | Spain | Biomass analysis, fish welfare monitoring, and decision support |
| Fish-AI | Italy, Belgium, Portugal | Artificial intestine for predictive feed assessment |

# IMPROVING THE NURSERY CULTURE OF THE GREENSHELL™ MUSSEL IN NEW ZEALAND

A. Jeffs*, B. Skelton, M. Mugica, A. Jordan, M. Packer, L. Sampollo, K. Himiona, E. Ram

Institute of Marine Science
University of Auckland
New Zealand
E-mail: a.jeffs@auckland.ac.nz

## Introduction

The annual total production of Greenshell™ mussels in New Zealand has remained at around 100,000 tonnes for the past ten years. This industry continues to struggle with improving the efficiency of utilisation of early juvenile mussels or spat, that are used for seeding long-line mussel farms in coastal waters. The losses of mussels between seeding farms with spat and harvesting adult mussels is estimated to exceed 99% for a variety of reasons that have proven difficult to solve with on-farm husbandry. As a result, attention has moved toward using research to develop contained nursery culture of mussel spat to raise them to a larger and more resilient sizes, prior to seeding out onto coastal mussel farms for on-growing to harvest size. However, the nursery culture of mussel spat in containment does not have an international precedent that can be followed, either for mussels or other aquacultured shellfish species. This has led to a multi-pronged research programme aiming to overcome some of the many challenges associated with contained nursery culture of mussel spat, including sourcing spat, feeding, contained nursery culture systems, handling and husbandry. This presentation will outline the problems faced by the Greenshell™ mussels in New Zealand, the breadth of research activity that has resulted, and the progress of the research toward resolving the challenge of developing an effective nursery culture system to improve aquaculture production of this species.

# POTENTIAL OF THE AMPHIPOD *Elasmopus rapax* FOR USE IN AQUACULTURE SYSTEMS

## Introduction

The use of biological agents to control parasitic diseases in aquaculture is becoming increasingly popular, as it is considered a safe, effective, and economically beneficial strategy for sustainable aquaculture practices (Shirakashi & Takagi, 2021). Monogeneans are among the most problematic parasites in fish farms. Among them, *Neobenedenia* spp. severely affects *Seriola dumerili*, largely due to the accumulation of eggs in farming structures. The elimination of these eggs using biological agents, such as the gammarid *Elasmopus rapax* may be a novel solution for controlling outbreaks. Previous results obtained at our facilities have shown high consumption of *Neobenedenia*'s eggs by *E. rapax*, indicating that it may be a useful biological agent for removing monogenean eggs from culture facilities (Marrero et al., 2024).

On the other hand, *E. rapax* shows great potential as an alternative live feed for the larvae of species of aquaculture interest, due to its size and nutritional composition, especially its high content of essential fatty acids. However, the culture of amphipods, and specifically of *E. rapax*, has been poorly studied, so it is necessary to improve its mass culture to benefit the aquaculture industry (Suhaimi et al., 2024). Therefore, it is important to obtain information on both the culture parameters that may influence growth, development, and survival of juveniles, as well as the reproductive biology of *E. rapax*. So, it is important to provide information on *E. rapax* culture parameters such as density, culture method and feeding strategy. Among these parameters, the use of different food combinations and photoperiod regimes may provide valuable information on *E. rapax* growth and survival, and are relevant for mass culture protocols.

## Material and methods

Specimens of *E. rapax*, abundant on the walls of outdoor culture tanks at the facilities of the Oceanographic Center of the Canary Islands (COC-IEO), CSIC (Canary Islands, Spain), were collected from the surface of the tanks and kept in plastic containers with biofouling and sessile organisms. As *E. rapax* is commonly found among algae in the shady areas of the tanks, we tested three food sources: (1) eggs of *N. melleni* (Eggs), (2) algae that occur naturally in COC tanks (Algae), and (3) a mix of both diets (*N. melleni* eggs + algae) (Mix), combined with two photoperiod regimens (12L:12D and 4L:20D). To this end, 8 females at a similar stage of maturation were selected and kept individually, being monitored daily. When juveniles were observed, 6 offspring of *E. rapax* newly released from the females' brood chambers, were selected, and placed in each Petri dish (9 cm in diameter, 1.5 cm deep) with 40 ml of seawater (by triplicate). The Petri dishes were kept at 25°C, and monitored for 34 days in order to determine survival and growth.

To determine the optimal culture density of *E. rapax*, a second experiment was conducted, consisting of four treatments with different initial densities in Petri dishes (50 cm²): 1, 5, 8, and 15 ind/dish (by triplicate). The plates contained nylon mesh discs as a substrate, and *N. melleni* eggs as a food source, and 40 ml of seawater. The survival was monitored daily for 5 days. In both experiments the water and food (eggs, algae and mix) were replaced daily. The *E. rapax* were counted, photographed and measured using ImageJ software (NIH). The eggs of the parasite *N. melleni* used for the experiments were collected daily (every 24 h) from the *S. dumerili* rearing tanks, washed thoroughly, and used immediately for the experiments, after estimating their number under a stereomicroscope.

## Results

Survival and growth of *E. rapax* was affected significantly by food source and photoperiod regimen (Fig. 1). In all treatments, mortality began at 20 days, except for amphipods fed algae under 12L:12D, which began at 15 days. Regardless of the photoperiod, the highest final survival occurred when amphipods fed eggs, and the worst in those fed algae.

*(Continued on next page)*

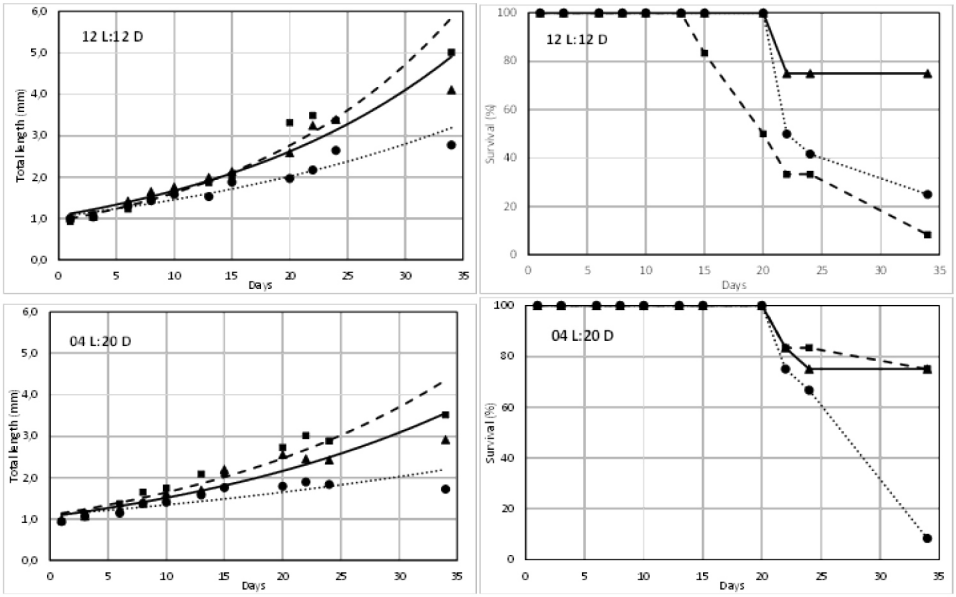

**Figure 1.** Total length (mm) and survival (%) of *E. rapax* under the experimental treatments of food (Eggs (–▲–), Algae (▪●▪), Mix (–■–). and photoperiod (12L:12D and 4L:20D).

The size of *E. rapax* kept under 12L:12D was greater than under 4L:20D. However, this difference was only significant ($p<0.05$) in those fed with algae. Regardless of the photoperiod, gammarids fed the algae-based diet were significantly smaller than those fed the egg-based or mixed diets, which showed similar growth.

On the other hand, the second experiment showed that the survival rate of treatments with initially 5, 8, and 15 ind/plate was similar after 5 days (73, 71, and 60%, respectively). Furthermore, regardless of the initial density, 25% of mortality occurred at 24 h.

**Discussion and conclusions**

Although *E. rapax* is commonly found among algae in low-light areas, where it protects itself and feeds, the present results show that it is possible to keep them with monogenean parasite eggs without special lighting conditions. However, adequate culture density would minimize mortality in mass cultures.

Integrated Multi-Trophic Aquaculture (IMTA) offers a sustainable strategy for modern aquaculture by combining species from different trophic levels to optimize nutrient recycling and reduce environmental impacts. This study evaluated the integration of the polychaete *Hediste diversicolor* in a Recirculating Aquaculture System (RAS) producing corvina (meagre - *Argyrosomus regius*), using as input a sludge effluent originally intended for discharge. Three polychaete stocking densities (250, 500, and 1000 ind/m$^2$) were tested over 35 days, with stable environmental parameters monitored throughout the trial.

*H. diversicolor* exhibited high survival (>93%) in all treatments, with no significant differences in growth performance, suggesting that higher densities increase biomass yield without compromising individuals. Proximate composition showed stable protein and lipid content, while carbohydrate levels increased with density, indicating the feasibility of dense cultivation for valuable biomass production. Fatty acid analysis highlighted the species' biosynthetic capacity: despite being fed nutritionally poor sludge (EPA: 0.04%, DHA: 0.23%, n-3/n-6: 0.5), enriched levels of essential fatty acids were recorded (EPA: 13.4–14.5%, DHA: 2.2–2.5%, n-3/n-6 ~1.8). This demonstrates the ability of *H. diversicolor* to convert organic waste into nutritionally valuable biomass.

Beyond its use as fishing bait, *H. diversicolor* shows potential for aquafeeds and broodstock nutrition (particularly for *Solea senegalensis*, where its nutritional profile and natural odorants may stimulate feeding and enhance reproductive performance). This innovative system provides a promising model for integrating high-value species into corvina RAS production, reinforcing IMTA as a tool for effluent remediation and circular resource valorization in sustainable aquaculture.

# RETHINKING AQUACULTURE FEEDS: SENSORY IMPACT OF ALTERNATIVE PROTEINS IN GILTHEAD SEA BREAM (*Sparus aurata*)

## Introduction

The growing demand for sustainable aquaculture practices, driven by the rapid expansion of global aquaculture production, has highlighted the need to reduce reliance on fishmeal and fish oil as primary ingredients in aquafeeds. This has prompted the exploration of alternative protein sources that can support both fish growth and product quality. Traditionally, plant-based ingredients of terrestrial origin have been used as substitutes in grow-out feeds for marine species. Moreover, current formulations with high levels of plant-derived meals and oils have proven suitable for the present genetic variability of gilthead sea bream populations selected for different growth potentials. However, the limited availability of these raw materials and increasing competition from other industries underscore the urgency of developing and testing new, more sustainable feed formulations. These include insect proteins, processed animal proteins, microbial proteins, micro- and macroalgae extracts, and by-products or discards from aquaculture and other animal and plant production systems.

Sensory analysis plays a crucial role in evaluating food quality, particularly in fish products, where sensory attributes directly influence consumer acceptance and market value. Attributes such as appearance, odor, flavor, and texture are especially important, as they are strongly affected by various factors, including species and especially diet composition. Changes in feed formulation—such as replacing traditional marine-based ingredients with alternative protein sources—may alter the organoleptic characteristics of the final product. Therefore, combining descriptive sensory analysis by trained panels with consumer studies is essential to understand both the objective sensory differences among fish fed different diets and their subjective acceptance by end consumers.

Considering the above, the aim of this study was to explore the effect of feeding gilthead sea bream (*Sparus aurata*), sampled at a final weight of 800 grams, with alternative protein sources, compared to a fishmeal-based diet, on its sensory profile and consumer acceptance.

## Materials and methods

The gilthead sea bream were fed the control (CTRL: fish meal-based diet) and two experimental diets (PAP: processed animal protein-based diet, and ALT: alternative protein-based diet) at the IATS aquaculture facilities, from an initial weight of 10–15 grams until they reached market size (800 grams), without any changes in growth rates or feed conversion efficiency. A trained panel from the research group Food Quality and Safety Group (Universidad Miguel Hernández de Elche, UMH Orihuela, Alicante, Spain) conducted the descriptive sensory analysis in one session. A sample group of 80 consumers was recruited at UMH (Spain). The consumer study was conducted at the UMH facilities in Orihuela. A penalty analysis was conducted on the affective data to identify which sensory attributes had the greatest negative impact on overall liking scores.

## Results

The trained panel detected significant differences ($p < 0.05$) for the attribute 'color', with fish fed the ALT diet being evaluated as darker compared to the CTRL and PAP treatments. Differences were also observed for 'firmness', where the muscle of fish fed the CTRL diet was less firm, while no significant differences were found between fish fed the two alternative diets. In the consumer study, significant differences were found in the attributes 'fatty flavor', 'fat perception', and 'aftertaste'. Considering the first two attributes, consumers preferred, and therefore rated more highly, fish fed the PAP diet, whereas CTRL fish received the lowest scores. Regarding aftertaste, that of the CTRL group was the least liked by consumers compared to fish fed the alternative diets (PAP and ALT). Penalty analysis revealed that low intensity of attributes such as fat perception, fish flavor, and

*(Continued on next page)*

aftertaste negatively impacted the overall liking scores—by up to two points—in fish from the ALT and CTRL groups. In the case of PAP, the only penalizing attribute was juiciness, also due to low intensity. Overall, consumer preference favored fish fed the PAP diet, with 42.5% of participants selecting it as their most liked sample, compared to 27.5% and 30% for fish fed CTRL and ALT diets, respectively.

**Conclusions**

The results suggest that alternative protein sources can be used in gilthead sea bream diets without negatively affecting sensory quality. However, fish fed the PAP diet showed the most favorable sensory attributes and the highest consumer acceptance. These findings highlight the potential of processed animal proteins as a promising alternative to fishmeal in aquafeeds, combining sustainability with product quality.

# SUSPENDED CULTURE OF COCKLES (*Cerastoderma edule*) IN EARTHEN PONDS UNDER IMTA CONDITIONS

E-mail: sandra@ipma.pt

## Introduction

Bivalve production plays an increasingly important role in European aquaculture, not only for its economic and social value but also for the ecosystem services these organisms provide, such as nutrient recycling and water quality improvement. The cockle (*Cerastoderma edule*) is particularly relevant in regions such as the Ria Formosa, Portugal, where it supports both traditional fisheries and aquaculture initiatives. However, conventional intertidal culture practices often present limitations, including high mortality and exposure to environmental variability. In recent years, suspended culture systems within earthen ponds have gained attention as a potential alternative, especially when integrated into Integrated Multi-Trophic Aquaculture (IMTA) frameworks. In such systems, bivalves benefit from continuous immersion and the constant supply of organic matter derived from fish feeding, which can enhance growth performance compared to intertidal plots. Moreover, IMTA approaches contribute to the circular use of resources, promoting both environmental sustainability and economic efficiency.

This study aimed to evaluate the feasibility of suspended cockle culture in earthen ponds under IMTA conditions by comparing two container types (rigid mesh bags and perforated circular trays), two culture depths, and different stocking densities. Beyond assessing growth and condition index, particular attention was given to how suspended cockle rearing within polyculture ponds can complement fish farming, improve resource efficiency, and provide insights into the balance between productivity and product quality.

## Material and methods

Two types of containers for suspended cockle culture were tested: rigid mesh bags and circular perforated trays with a 1-cm mesh size. Each tray contained four perforated containers (5-mm mesh) arranged as pie-shaped sections within the tray. The trays (40 cm in diameter and 10 cm in height) were stacked in groups of four. Only the second tray from the top and the bottom tray in each stack were stocked with cockles, allowing a comparison of culture at two depths (20 and 40 cm). Two stocking densities were tested for each container type: 2 kg $m^{-2}$ and 3 kg $m^{-2}$. The culture system consisted of six rigid mesh bags and six stacks of trays suspended from a long-line with floaters, arranged side by side with alternating densities. At both ends of the line, two supplementary rigid mesh bags and two tray stacks with the same density treatments were installed to replace sampled individuals.

The structures were cleaned once or twice per month, depending on the degree of fouling by macroalgae and other organisms. Cleaning of rigid mesh bags only required turning them over to maintain water circulation. In contrast, circular trays had to be replaced and washed with freshwater or dried in the sun before removing fouling organisms. Every month, five cockles from each replicate, density, and container type (rigid mesh bag and circular tray) were sampled for biometric measurements (length, width, thickness, and weight) and for condition index determination.

## Results and Discussion

Over the same experimental period (3.8 autumn/winter months), cockles reared in circular trays at 3 kg $m^{-2}$ reached a growth rate of up to 85 µm $day^{-1}$, attaining 27.83 ± 1.69 mm in length and 6.92 ± 1.30 g in weight at the end of the trial. Growth in rigid mesh bags was slower, with cockles reaching 25.22 ± 1.91 mm in length and 5.29 ± 1.05 g in weight at the same density (Figure 1). Biomass yield ranged between 1300 g $m^{-2}$ and 1900 g $m^{-2}$ for both circular trays and mesh bags, with no substantial effects of density or rearing depth.

**Introduction**

Fish and shrimp hatcheries world-wide use a variety of methods to monitor the growth of their animals and live feed. This is often a labor-intensive process which relies on subjective judgements of field operators to produce accurate results. The ability of artificial intelligence (AI) models to recognize specified objects in digital images is an established trait that could prove useful when applied to counting animals and live feed in hatcheries in addition to tracking the growth of their developmental stages. The aim of this study is to create an AI model, trained on images labeled by experts, along with digital support systems that can recognize and track Artemia developmental stages, rotifers, rotifer eggs, early shrimp developmental stages, fish eggs, and fish egg quality for use in hatcheries around the world.

**Materials and Methods**

Samples containing examples of the target animals and animal life stages were prepared in 3x4 cell culture well plates. Images of these wells were taken using a digital camera and lens system that uploaded the files into a computer vision annotation tool (CVAT). The labels used in this image library include Artemia embryos, Artemia umbrellas, Artemia nauplii instar I, Artemia nauplii instar II, live rotifer, dead rotifer, rotifer eggs, shrimp nauplii, zoea, mysis and PL stages, live and dead seabass and seabream eggs. The labels were applied manually by experts and the AI model was trained using this dataset. A separate labeled dataset was used to verify the training of the model. The model is derived from a You Only Look Once (YOLO) object recognition base. This was chosen due to its speed and accuracy in tandem with a proper microscope-optics setup. The model was trained recursively via comparison to the known result of the separate set until a maximum accuracy asymptote was reached. This trained model was then installed with proper optics on a custom device named the SnappArt 360 to be tested in the field by technicians. The technicians reported feedback, and the model was trained several more times based on this cycle of labeling, training, technician testing, and feedback until the technicians reported satisfaction with the model accuracy. A user-friendly data management system for the SnappArt 360 machine was also created to let technicians track trends in animal growth patterns from past measurements.

**Results and Discussion**

Raw counts per sampled well (250µL sample volume) of Artemia nauplii, umbrella, and embryos were used to compare accuracy of the SnappArt AI model to the technician results for Artemia stage objects. Figure 1 shows the distribution of the differences between the technician and SnappArt measured values of these counts respectively. The average differences are 0.02, -0.03, and 0.03 with standard deviations of 1.00, 0.53, and 0.41 with no statistically significant difference in results between technicians and the SnappArt AI model according to p-Values of 0.728, 0.355, and 0.238 for nauplii, umbrella, and embryo counts respectively.

Results on other objects reflect the accuracy found in Artemia measurement with 95% of seabass and seabream eggs and over 95% of rotifers and rotifer eggs being identified with the SnappArt AI model under the correct annotation of live or dead. Figure 2 shows the accuracy of rotifer animal and egg counting.

Furthermore, results for shrimp show an accuracy of 99% with no statistically significant difference between technician and SnappArt AI counts for all larval stages of shrimp.

These results indicate that AI modeling could be a promising option for future automation of counting and monitoring the health of animals in hatcheries for a wide variety of species.

# EFFECTS OF ENVIRONMENTAL ENRICHMENT ON BEHAVIOR AND GROWTH OF JUVENILE RAINBOW TROUT (*Oncorhynchus mykiss*) – RELEVANCE FOR FISH WELARE AND AQUACULTURE PRODUCTION

Jonassen AK*, Gunnes M, Andersen IL, Green EAL, Wedaa LO, Selvik P, Øverli Ø.

Norwegian University of Life Sciences
Ås, Norway
E- mail: ane.kjelle.jonassen@nmbu.no

## Introduction

Intensive aquaculture production challenges fish health and welfare, impacting both economic and ethical sustainability (Ashley, 2007). Increasing the complexity of the holding environment (environmental enrichment, EE) has been shown to have a range of positive effects on fish physiology and welfare, and is assumed to encourage the expression of adaptive behaviors (Gerber, 2015). How these advantages translate into an actual impact on central production parameters such as growth remains insufficiently documented, and EE is not yet broadly adopted in current aquaculture practices. This study investigates how early exposure to environmental complexity affects growth and welfare- related behavioral responses in juvenile rainbow trout.

## Material and methods

After 90 days of rearing in EE or BE, fish were transferred to individual isolation for two weeks, allowing for observations of differences in stress coping ability (Øverli, 2005).

## Results

Despite the fact that fish from EE vs B environments regained feed intake at a similar rate after transfer to a novel environment (figure 2 & 3A), mass gain was more than twice as high in fish transferred from EE compared to B rearing (figure 3B). Additionally, EE led to significantly lower frequencies of stereotypic vertical swimming following transfer to the novel environment (figure 4).

## Discussion

Findings from this study suggest that EE fish developed greater behavioral flexibility and resilience, based on the significantly lower frequencies of stereotypic vertical swimming following transfer to the novel environment (Mason, 1991; Prentice, 2025). The increased stereotypic behavior in BE fish after exposure to the novel environment suggests that growth differences are closely linked to stress coping behaviors in EE- and BE-reared fish.

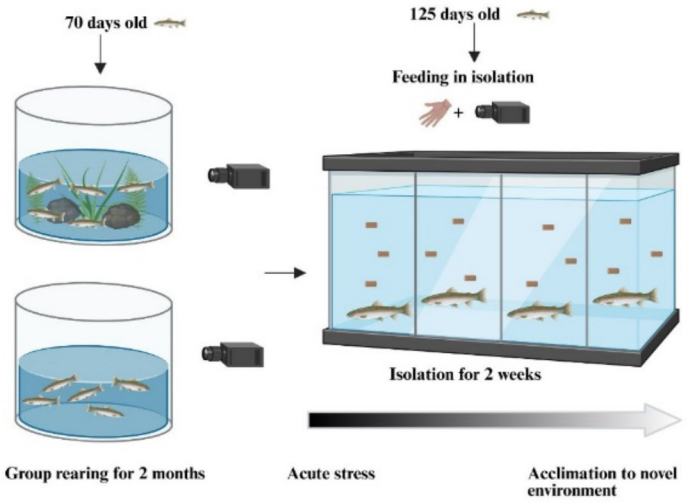

**Fig.1:** Overview of the experimental design. After 90 days of rearing in EE vs BE, juvenile rainbow trout (85.4 ± 3.54 g) were sedated, weighed and measured, transferred to isolation and handfed (limit 2% BW/ day) for two weeks.

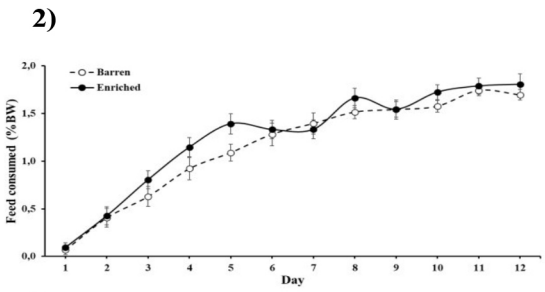
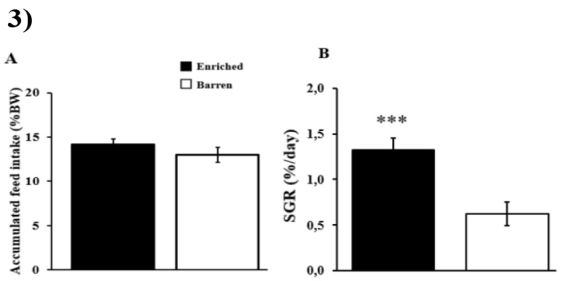
*(Continued on next page)*





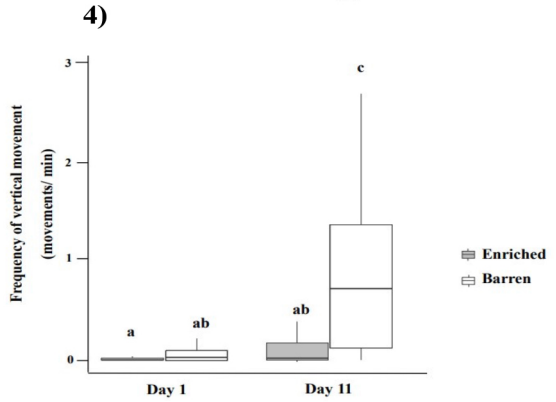


**Fig. 2:** Accumulated feed intake (%BW) over 12 days in juvenile rainbow trout after transfer to a novel environment showed no significant effect of EE.

**Fig 3:** Feed efficiency during acclimation to a novel environment in juvenile rainbow trout reared in EE and BE tanks. **A)** Feed intake (%BW) unaffected by rearing environment. **B)** SGR (%/day, mean ± S.E.M) significantly higher in EE fish.

**Fig 4:** Stereotypic vertical movement in juvenile rainbow trout reared in EE and BE tanks on day 1 and 11 after transfer to isolation; significant interaction effects indicated by lowercase letters.

## Conclusions

These results point to the value of broadening behavioral indicators used in aquaculture, as behavioral outcomes of welfare translate, to some degree, directly to growth performance following environmental change. This observation should serve as a strong motivation to maintain a clear focus on welfare status in aquaculture production.

**Introduction**

Freshwater is becoming increasingly scarce and valuable, and agriculture and agro-processing sectors remain among the world's largest users of this resource. This program has integrated various nature-based technologies and processes, e.g., algal ponding, constructed wetlands, hydroponics, aquaponics, vermiculture and permaculture to recover water and nutrients from effluent produced by agro-processing and to do so using a circular economy to generate agriculture and aquaculture products. The proof-of-concept was established within the first few years of the program. Algal ponding and wetland technologies were integrated with hydroponics and aquaponics with a focus on optimising the anaerobic digestion phase of the treatment process; effluent was successfully cleaned, crops were produced, and this was all done using an integrated effluent treatment/aquatic food production system. The next decade was designed to obtain societal support to scale up the project, while also further developing and optimising the process.

**Recent research progress**

The presentation will delve briefly into the progress that has been made in the following areas of research, all of which have supported the development of this alternative effluent treatment and food production system in an aquatic environment:

- A sustainable, nature-based method of "harvesting" microalgae from treated effluent using filter-feeding fish;
- Comparison of different kinds of constructed wetlands and their effect on effluent treatment and vegetable production;
- The addition of nanobubble and ebb-and-flow wetlands to increase treatment capacity of the constructed wetland;
- Optimising wetland filter media type, size and hydraulic retention time;
- Developing measures to mitigate the buildup of salts to optimise crop production, as effluent is recycled;
- Preliminary look at the inclusion of fish production in the system; and finally
- Obtaining societal support to demonstrate the process on a commercial scale.

**Culmination of this work**

This alternative wetland-based system has been successfully integrated with hydroponics, vermiculture, permaculture and aquaponics, and has been tested on a commercial-pilot scale for the last three years. Approximately 350 $m^3$ of brewery effluent is treated daily and about 250 $m^3$ of cleaned water is returned to the brewery. Post anaerobically digested brewery effluent enters the system with a chemical oxygen demand (COD) of 400-600 mg/L and leaves at 60-80 mg/L. Total ammonia enters at 40-50 mg/L and is discharged at < 1 mg/L. This integrated effluent treatment process produces over 2-tons of fresh vegetables per month, supporting seven farm workers, and this fresh-produce is used to support local feeding schemes and is sold to supermarkets.

**Way forward**

The next steps will be to develop partnerships so that we can demonstrate this approach using different effluent streams, in different geographical regions, using alternative crops and optimising the process for a more universal application. Future work will also look at including a finfish loop in the system to add nitrogen and additional, valuable protein-rich products because the primary effluent source can be nitrogen limited. The addition of aquaculture effluent might reduce the need for the addition of inorganic fertilizers needed to optimise plant production, but this remains to be tested.

# EFFECT OF FEEDING SYSTEM USING TIMER OR ACOUSTIC FEEDERS, AND TRANSFER WEIGHT ON PERFORMANCE AND ECONOMIC PROFITABILITY OF WHITE SHRIMP (*Penaeus vannamei*)

J.C. Valle*, R. Ulloa and M. Jover

Institute of Animal Science and Technology
Universitat Politècnica de Valencia
Spain
jcvalleec@yahoo.com

## Introduction

White shrimp is the most important species from an economic point of view of world aquaculture, which is produced in semi-intensive ponds, with two production phases, pre-growing and growing until commercial size. Recently, the use of automatic feeders, timed and acoustic, has increased in commercial farms (Valle et al., 2023; 2025), with a positive effect on performance, but the recent trend for increasing transfer weight of shrimp from pre-growing to growing ponds requires an evaluation of performance and profitability performance for optimizing shrimp production.

## Material and Methods

Data from 240 production cycles from four different shrimp farms of Guayas region (Ecuador) were studied. Size of ponds ranged between 1.7 and 22.7 has. Initial density varied between 7 and 18 shrimp per square meter. Two automatic feeding systems were analyzed, time feeding during 12 hours a day, from 12.00 to 24.00 hours, and demand feeding with acoustic feeders. Shrimp transfer weight to growing pond ranged from 0.3 g to 11.2 g, but they were grouped for analyzing in five intervales, ≤ 1g, ≤ 2g, ≤ 4 g, ≤ 8 g and ≤ 12 g. ANOVA of one way and two ways were used for statistical analysis data of final weigh, survival, production (kg/ha), food conversion ratio (FCR), days of cycle, growth (g/week), and economic profit (US$/ha, and US$/ha/day), using LSD test for comparing the means.

## Results and discussion

Shrimp farms and size of ponds do not have a significant effect on performance or profit. Results of shrimp fed with timer feeder and acoustic feeder are presented in Tables 1 and 2 respectively. Final weight and survival were not present statistical differences, with mean values of 31.6 g and 30.9 g, and 78.5 % and 30.9 %, respectively. Production (kg/ha) was positively related to density, but $R^2$ was very low, 20%.

The low transfer weight (≤ 1g and ≤ 2g) originated a longer production cycle, lower weekly growth, and lower economic profit in both feeding systems, and a worse FCR but only with time feeder. Production was higher with a transfer weight ≤ 8 g with time feeders, but similar for all transfer weight with acoustic feeders.

Global profit of shrimp production with acoustic feeders was statistically higher than with timer feeders, 1906 vs 927 US$/ha and 32.3 vs 14.7 US$/ha/day (data not shown), but the effect for several transfer weight was different. Feeding systems did not present statistical differences on economic profit when transfer weight was ≤ 1 g, ≤ 4 g and ≤ 8 g, but when transfer weight was ≤ 2g, acoustic feeding origin a higher profit than timer feeding (Table 3). Likewise, some differences appeared for transfer weight ≤ 12 g.

Results are not definitive, because data with high transfer weight are scarce for comparing, and more data for evaluating technical performance and economic profit should be needed, but as preliminary conclusion, a transfer weight between 4 and 8 g with timer feeders and between 2 and 4 g with acoustic feeders, could be adequate.

## Introduction

White shrimp is a very important species in world aquaculture, because it means the most economic value. Nutrition is the key to production and in recent years the use of functional additives has been considered in diets, particularly *Bdellovibrio bacteriovorus* and other additives as bacterial biocontrol (Cao et al., 2019; Williams and Piñeiro, 2006; Harpeni et al., 2024; Wena et al., 2014; Hany et al., 2022; Hossain et al, 2024) and weight promoter (Li et al., 2014). The objective of this study was to determine the effect of diets enriched with some biocomponents and nano-encapsulated additives on white shrimp performance.

## Material and Methods

Four experimental diets supplemented with *B. bacteriovorus* (10 g/kg), Bacteriophage (10 g/kg), Bovine plasma (5 g/kg) and a Mixture of amino acids (0.07 g/kg methionine, 0.04 g/kg arginine, 0.05 g/kg tryptophan, 0.22 lysine, 2 g/kg glutamine, 0.5 g/kg taurine, 0.054 g/kg syli-grenade and 0.04 g/kg nano-grenade), and one commercial control diet were studied. Experimental diets were prepared from a commercial diet (22 % protein) by ground, water addition, drying and granulation (1 mm diameter). All diets were given twice with an initial feeding rate of 10 %, which was adapted based on daily consumption determining daily non-consuming feed.

Sixteen semi-conical 800 L fiber tanks (3 replicates for experimental diets and 4 for control diet) were used. Water operational volume was 400 L/tk and water exchange was 400% a day, using saline water with 33 ppt. The water temperature was 29-30 ºC, dissolved oxygen 6.1 ppm, ammonia 0.14 ppm and nitrite 0.03 ppm.

Fifteen shrimp weighting 1,01±0,12 g were installed in each tank, and they were fed during eight weeks.

Weight gain and survival results were analyzed by one way ANOVA, using Student-Newman-Keuls test for mean differences.

***Table 1. Performance of white shrimp fed with experimental diets.***

| Diet | Weight gain (g) | Survival (%) | Biomass gain (%) | Feed consumption (g) | FCR |
|---|---|---|---|---|---|
| Control | 4.3 bc | 96.7 | 431 ab | 242 a | 3.8 a |
| *B. bacteriovorus* | 6.0 a | 91.1 | 487 a | 306 d | 3.6 a |
| Bacteriophague | 5.4 ab | 86.7 | 358 b | 289 c | 3.9 a |
| Bovine plasma | 3.0 c | 82.2 | 207 c | 257 b | 6.2 c |
| AA mixture | 4.0 bc | 80.0 | 259 c | 265 b | 5.0 b |
| Signif. Level | 0.0021 | 0.3349 | 0.0001 | 0.0000 | 0.0002 |

Means with different letters are statistically different (S-N-K test) ($P$<0.05).

*(Continued on next page)*

## Results and discussion

Results of weight gain, survival, feed consumption, biomass gain, and food conversion ratio (FCR) are presented in Table 1.

Highest weight gain was obtained with *B. bacteriovorus* diet (6.0 g) and Bacteriophague diet (5.4 g), and lowest with Bovine plasma diet (3.0 g). Growth was low in all diets, less than 0.75 g/week, probably due to low dietary protein and space limitations in the tanks.

No differences in survival were obtained at the end of trial, but Control diet presented a high value, whereas Plasma and AA Mix had low value.

In general, FCR were very high, because the objective was sure the maximum ingestion of experimental diets instead of minimizing feed conversion ratio. Feed consumption was highest for *B. bacteriovorus* diet, and lowest for Control diet. No differences in FCR were observed for Control, *B. bacteriovorus* and Bacteriophague diets, but Plasma and Mix diet presented the highest value.

Results suggest that Bovine plasma and AA mixture diets had a negative effect in growth and survival, but *B. bacteriovorus* diet improved growth and biomass gain, which agrees with results obtained by Li et al. (2014) in *P. monodon* shrimp, although these authors used the additive in water instead of into the feed.

In conclusion, shrimp diet supplementation with *B. bacteriovorus* could be interesting for improving performance in clear water trials, but new studies are necessary in commercial farming conditions.

## Introduction

Despite intensive research and operational innovation for over the past 30 years, "aquaponic" systems that combines fish culture and hydroponic plant production are still considered "experimental" by most authors. The effluent from a recirculating aquaculture system (RAS) includes ammonia, nitrate, nitrite, phosphorus, potassium, and other secondary micronutrients that are necessary to sustain hydroponic plants production (Rakocy et al. 2006; Kloas et al., 2015). There are basically two types of hydroponic systems. A "coupled" aquaponics system, uses the hydroponic biomass (specifically the submerged roots) as a large biofilter that extracts the nutrients from the wastewater, purifying it and returning it to the fish tanks for sustaining this secondary biomass. To be effective, coupled aquaponics systems must be sized exactly to balance the nutrient production from the fish culture with the potential for nutrient uptake by the plants. This balance can be precarious to achieve and maintain. For example, the nitrification process necessary for water quality maintenance is efficient at a pH of 7.0 or higher but practically ceases at less than 6.0. The optimum for nutrient solubility is 6.5. If pH is too high, nutrients precipitate out of solution and plants display nutrient deficiencies. There is minimal acceptable overlap of even this simple water quality parameter. In an "uncoupled" aquaponics system, the fish production and hydroponics systems are separate, and are designed independently. The recirculating aquaculture operation treats the water using biofiltration and solids removal technologies, resulting in elevated nitrate levels and the accumulation of solid wastes in the waste stream. These effluents can be processed in different ways to the benefit of a hydroponics operation. However, the wastewater leaving the fish culture operation is not returned to the fish tanks. There are various designs of each type of aquaponics system, some successful but often not, due to inadequate understanding and respect for either of the two basic activities: fish farming or hydroponic farming. This article describes the design and efficiency of a decoupled aquaponic system consisting of a closed recirculating aquaculture system, waste stabilization tanks, a constructed wetland, and a hydroponic greenhouse.

## Materials and Methods

The recirculating fish production system design includes concrete tanks, with a total volume of 120 $m^3$ of water. Hybrid striped bass were raised at the maximum stocking density of 45 $kg/m^3$. Each e tank was integrated with a water recirculation unit (Jug-Dujaković et al., 2010). Solids were removed from the aquaculture system by a micro-screen filter. The screen was backwashed at periodic intervals to discharge solids to a swirl separator, discharging between 5% and 8% of the fish culture system volume daily. The swirl-separator was used to separate settleable solids. Cleared supernatant was transferred directly to the hydroponic greenhouse. The concentrated solids were transferred to aerobic stabilization tanks where heterotrophic bacteria aerobically degraded and mineralized the solids for 3-4 weeks. These were then applied to the surface of a constructed wetland. Constructed wetlands are fabricated inside a concrete basin, with layers of coarse and fine gravel, topped with a reed bed of Phragmites. The periodic discharge from aerobic stabilization tanks was filtered through the constructed wetlands and the clear nutrient-rich water was transferred to the hydroponic greenhouse, the elevated nutrient levels available to a variety of hydroponically cultured vegetables. Maximal planting density was 30 plants per $m^2$. During the hydroponic growth cycle, the plants purified the water by utilizing the dissolved nutrients for their growth. The greenhouse area was scaled to efficiently extract the nutrients from water discharged from the recirculating aquaculture system. The clear treated water could then be sterilized with ozone and reused within the fish culture facility or discharged. After years of accumulation, the solids on the surface of the reed beds are removed and used as fertilizer.

*(Continued on next page)*

**Results and Discussion**

The aquaculture process continuously generates both solid and liquid organic waste. Liquid waste includes nitrates a by-product of the biofiltration process) and other dissolved nutrients within the culture water. Approximately 25% of the feed given to fish is excreted as solid waste. If not stabilized the organic waste has a characteristic unpleasant smell, and since it is not mineralized and dissolved in water, it is mostly unusable for growing plants. Also, if solids are not properly removed, they will adhere to plant roots, decrease oxygen levels as they decompose and have an adverse effect on nitrifying bacteria (Jug-Dujaković et al., 2010). A substantial quantity and variety of organic vegetables can be cultured using the dissolved waste from a RAS, creating a secondary profit center. Those plant varieties studied and confirmed as appropriate for this process include various types of lettuce, water crest, tomatoes, cucumbers and herbs. The measured average levels of macronutrients in the waste stream from the mechanical drum filters and from the hydroponic greenhouse effluent demonstrates reduction of N-NO3 from 165 to 8.4, N-NO2 from 0.84 to 0.56, and P-PO4 from 8.2 to 0.7 ppm. Waste mineralization and water quality of the system was maintained at a feeding rate of 90 g of striped bass feed/$m^2$/day for mixed vegetable production, which is in agreement with data from Rakocy et al. (2006). Gloger et al. (1995) reported that the raft hydroponic tanks removed an average of 0.56 g of total ammonia-nitrogen, 0.62 g of nitrite-nitrogen, 30.29 g of chemical oxygen demand, 0.83 g of total nitrogen and 0.17 g of total phosphorous per m2 of plant growing area per day using romaine lettuce.

In conclusion, a decoupled aquaponic system designed with appropriate pretreatment of wastewater before sending it to the hydroponic greenhouse was successful in producing fish and plants creating two profit centers, while effectively reducing aquaculture wastewater.

.

# ELUCIDATING THE IMMUNOREGULATORY ROLE OF NLRC5 IN VIRAL INFECTION

Sumi Jung[1,2], K.A.S.N. Shanaka[1,2], K.P. Madushani[1,2] and Jehee Lee[1,2]

## Introduction

The growth of the aquaculture industry is being hindered by increasing mortality caused by infectious diseases and environmental stressors. In particular, viral infections cause significant damage in aquaculture fish due to the lack of effective treatments. Therefore, understanding and studying the antiviral immune system of fish is essential to deal with viral diseases.

NLRC5 (NOD-like receptor family CARD domain containing 5) belongs to the NOD-like receptor family and is known to be involved in immune responses by regulating histocompatibility complex (MHC) I gene expression and type 1 interferon in mammals, but its role in teleost remain unclear. In this study, we established an Nlrc5 knockout (KO) zebrafish model to investigate the role of NLRC5 in the antiviral immune response of teleost, and demonstrated its importance through viral hemorrhagic septicemia virus (VHSV) infection experiments.

## Materials and methods

Nlrc5 KO zebrafish were generated using the CRISPR/Cas9 system. VHSV infection was induced in both wild-type (WT) and Nlrc5 KO zebrafish via intraperitoneal (IP) injection ($1\times10^6$ and $5\times10^6$ $TCID_{50}$/fish), and mortality rates, viral replication, and downstream gene (cytokines, class-I MHC pathway components, neutrophil markers) expression were subsequently compared.

## Results and discussion

CRISPR/Cas9-mediated Nlrc5 knockout zebrafish were identified to have a 10 bp deletion sequence at the sgRNA target site, resulting in a frameshift mutation that produced a truncated 206-amino acid peptide. The mutated protein contained only the CARD domain, while other functional domains, including the NACHT domain, were completely absent.

In the VHSV infection experiment using WT and Nlrc5 KO zebrafish, the Nlrc5-deficient fish exhibited higher mortality, increased virus replication, and severe pathological symptoms (including hemorrhage, and eye extrusion). Gene expression analysis following VHSV infection revealed that ifnϕ1 was significantly upregulated, while expression of cytokines involved in neutrophil migration and MHC-I genes was significantly downregulated in Nlrc5 KO zebrafish compared to WT zebrafish. In addition, neutrophil migration analysis confirmed reduced neutrophil recruitment to the caudal fin injury site in Nlrc5 knockout zebrafish. These results demonstrate that Nlrc5 is essential for the antiviral immune response to VHSV infection in zebrafish, primarily through regulation of the MHC class I pathway.

Collectively, this study provides evidence for the role of Nlrc5 in antiviral immunity in teleost, enhancing our understanding of innate immune regulation and highlighting its significance in antiviral immune system.

# EMBRYOTOXIC EFFECTS OF CONTAMINATED WATERS FROM WAR ZONES ON *Danio rerio* in EARLY DEVELOPMENT

The ongoing military conflict in Ukraine has led to substantial ecological degradation, including the contamination of freshwater systems. To evaluate the potential developmental toxicity associated with aquatic pollution in conflict zones, six surface water samples were collected from four affected regions: Kyiv, Chernihiv, Kharkiv, and Odessa. The present study assessed the impact of these water samples on early developmental stages of *Danio rerio*, a widely accepted vertebrate model in ecotoxicological research. Embryonic spontaneous tail coiling at 24 hours post-fertilization (hpf) showed no significant differences among treatment groups, suggesting the absence of acute neurodevelopmental toxicity. Heart rate (HR) analysis at 48 hpf indicated a physiological response to waterborne exposure; however, HR values did not significantly differ from those of the control group ($p > 0.05$). No statistically significant changes in HR were observed at 96 hpf. In contrast, a significant reduction in hatching rates was observed at 72 hpf among treatment groups ($p < 0.05$), although this effect was no longer apparent at 96 hpf ($p > 0.05$). These findings suggest that exposure to water from war-impacted regions may induce transient developmental delays, particularly in cardiophysiological function and hatching. The results underscore the need for further investigation into the long-term ecotoxicological consequences of armed conflict on aquatic organisms and freshwater biodiversity.

## Introduction

Tetrodotoxin (TTX) is a potent neurotoxin that blocks voltage-gated sodium channels, disrupting nerve conduction and causing muscle paralysis, respiratory failure, and potentially fatal outcomes in humans at doses as low as 1–2 mg. Initially isolated from pufferfish (genus *Takifugu*), TTX has since been detected in various marine organisms, including gastropods (mud snails, trumpet shells), cephalopods (blue-ringed octopus), and crustaceans (xanthid crabs). Recent detections of TTX in European bivalves—species historically considered free of this toxin—have raised significant food safety concerns and underscored the importance of continuous monitoring. The occurrence of TTX in bivalves is attributed to bioaccumulation through filter feeding on TTX-producing microorganisms, with environmental changes potentially facilitating the spread or migration of these microorganisms into new habitats. Despite these developments, data on TTX occurrence in bivalves from Korean waters remain scarce. To address this gap, this study conducted a preliminary screening to investigate the presence and spatial distribution of TTX in both wild and farmed bivalves from Korean waters.

## Materials and Methods

Bivalve samples were collected from 10 coastal regions of Korea, encompassing the west, south, and east coasts, and comprising 11 species, including ark cockles (*Anadara kagoshimensis*), oysters (*Crassostrea gigas* and *Saccostrea kegaki*), mussels (*Mytilus galloprovincialis*, *M. coruscus*, and *Arcuatula senhousia*), clams (*Ruditapes philippinarum*), and scallops (*Mizuhopecten yessoensis*, *Argopecten irradians*, *Chlamys farreri*, and *Chlamys* sp.). At each site, one to three individuals per species were measured for shell length and whole-body wet weight, after which 1 g of homogenized whole-body tissue was analyzed for TTX using a EuroProxima competitive ELISA kit (R-Biopharm Nederland B.V.) with a mouse monoclonal anti-TTX antibody. The assay, validated for TTX screening (limit of detection: 9.4 μg/kg; detection capability: 20 μg/kg), followed the manufacturer's protocol, which involved tissue homogenization, buffer extraction, centrifugation, and competitive binding with TTX-precoated microplates. Colorimetric detection was performed at 450 nm after substrate development, and TTX concentrations were determined from standard curves generated using RIDASOFT Win software (R-Biopharm, Darmstadt, Germany).

## Results

TTX was detected at two sites on the west coast in wild farrer's scallop (*C. farreri*) from Incheon and Sinan. The TTX level in farrer's scallop from Incheon was below the safety limit recommended by the European Food Safety Authority (44 μg/kg), whereas scallops from Sinan contained 51.6–125.5 μg/kg, exceeding the limit. On the south coast, TTX was detected in wild Mediterranean mussels (*M. galloprovincialis*) and wild scallops (*Chlamys* sp.) from Wando, with only one scallop specimen exceeding the limit. In Jeju, TTX was detected in *S. kegaki* and *R. philippinarum*, with *S. kegaki* below the limit but two *R. philippinarum* specimens exceeding it (48.2 and 63.7 μg/kg). On the east coast, TTX was detected only at Gangneung, where wild *M. galloprovincialis* contained up to 166.5 μg/kg.

## Discussion

Consistent with numerous previous reports, TTX is not restricted to traditionally recognized TTX-bearing taxa, but has also been identified in bivalve species. To our knowledge, the present study provides the first evidence of TTX occurrence in bivalves from Korean waters. The potential influence of marine environmental shifts, including elevated seawater temperatures, on toxin bioaccumulation in these organisms remains unclear. Consequently, continued seasonal and long-term surveillance are warranted to safeguard seafood safety and to enhance understanding of the spatial distribution of the toxin within Korean coastal ecosystems.

# IMPACT OF FEEDS CONTAINING ALGAE OIL ON INTESTINAL MICROBIOTA AND FILLET QUALITY OF GILTHEAD SEABREAM (*Sparus aurata*)

Violeta Kalemi[1]*, Simona Rimoldi[1], Luca Chiodaroli[1], Genciana Terova[1]

**Introduction**

This study is part of a larger project to improve the nutritional properties of freshwater and marine fish. The aim is to ensure the effective transfer of high-quality nutrient molecules from the processing of the raw material to the final product through the use of innovative, fortified feeds. The final aim is to deliver fish products with optimal nutritional value that fully meet consumer expectations.

Within this framework, the present study experimentally investigated the effects of enriching feed with algal oil on the physiology and health of a marine fish: Gilthead sea bream (*Sparus aurata*). Key evaluation parameters included growth performance, fatty acid profiles in the fillets, gut microbiota composition and intestinal short-chain fatty acid (SCFA) profile.

**Materials and methods**

The experiment was carried out with 360 gilthead sea bream, distributed over nine tanks (three tanks per feeding group), over a period of 15 weeks. The fish were fed a commercial control diet and two experimental diets containing algal oil in two different quantities. At the end of the feeding trial, samples were collected to analyze the composition and functionality of the gut microbiota using high-throughput sequencing techniques previously described in publications by our group (Terova et al., 2021; Hasan et al., 2024; Rimoldi et al., 2025). In addition, gas chromatography was used in conjunction with mass spectrometry to quantify short-chain fatty acids (SCFAs) in the intestinal lumen and to evaluate the fatty acid profile of the fillets.

**Results**

The inclusion of algal oil in the experimental diet led to an enrichment of omega-3 fatty acids, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in the fillets of sea bream. Consistent with this increase, the ratio of omega-3 to omega-6 PUFAs was higher in the sea bream fillets fed the experimental diets. Overall, the fatty acid profile in the fillets matched that of the diets, which we have previously observed in a similar study (Terova et al., 2021). While the lipid composition differed, the lipid content of the fillets remained similar in the different feeding groups.

The composition of the gut microbiota remained largely unchanged in the feeding groups, suggesting that the addition of algal oil had no dysbiosis effects on the autochthonous microbiota. A higher proportion of algal oil in the diet led to a decrease in a few families comprising potentially pathogenic species. Interestingly, the concentration of butyric acid in the intestinal lumen of the fish belonging to the experimental feeding groups was lower than in the fish of the control group. This could indicate that either the addition of algal oil influences the production of butyric acid or improves the absorption of butyric acid, resulting in a lower accumulation in the lumen.

**Conclusions**

This study demonstrates the importance of the feed used in fish farming beyond the growth performance and health of the fish. In particular, it emphasizes the role of feed formulations in shaping the nutritional quality of farmed fish for human consumption. We have found that the addition of algal oil to gilthead sea bream feed increases the content of omega-3 PUFAs, important nutrients for human nutrition, in the filet without any negative effect on the health of the fish, particularly on the status of the microbiota. Most importantly, these results provide a basis for the next phases of the I-FISH project, where different additives will be included in fish feed to improve the nutritional value of the final product, i.e., the fish filet. Understanding how different nutritional strategies affect gut microbiota, metabolic outcomes and filet composition is essential for the development of more sustainable and nutritionally valuable aquaculture products.

**Introduction**

Sustainable development of aquaculture requires industrial aquafeeds that make a rational use of fishmeal and an increasing use of ingredients that are produced with a low environmental impact. Insect meals can serve as high quality proteins and sustainable ingredients towards sustainable aquafeeds (Gasco et al. 2022; Karapanagiotidis et al. 2023). The Mediterranean fruit fly (MFF, *Ceratitis capitata*) is a highly damaging crop insect pest for the management of which sterile insect technique (SIT) mass rearing programs are widely implemented worldwide (Colacci et al. 2025). From a nutritional point of view, it is a species with high protein and essential amino acid contents but so far has not been evaluated in fish diets. Thus, the aim of this study was to evaluate the dietary fishmeal replacement by graded levels of a *C. capitata* meal on the growth performance and fatty acid profiles of an important Mediterranean farmed fish species, the gilthead seabream (*Sparus aurata*).

**Materials and Methods**

A total number of 480 *S. aurata* juveniles of 6.5 g initial mean weight were obtained from a commercial fish hatchery, transferred to the aquaculture facilities of University of Thessaly and stocked at 16 tanks (125 L) in a closed seawater recirculation system. MFF with 56.6% of crude protein and 7.5% of crude lipid was supplied by Flying Spark (Israel). Fish in quadruplicate groups (30 fish/tank, 4 tanks/dietary group) were fed to satiety, twice a day, four isonitrogenous (49%), isoenergetic (21 MJ/Kg) and isolipidic (15%) diets. The control diet (CTRL) contained 25% of fishmeal, and in the rest three diets graded levels of MFF were included, viz. 7% (MMF7 diet), 14% (MMF14 diet) and 21% (MMF21 diet) corresponding to fishmeal protein replacement of the control diet at 20%, 40% and 60%, respectively. Water quality parameters were maintained at 21.0 ± 1.0 °C, pH at 8.0 ± 0.4, salinity at 33.0 ± 0.5 g/L, dissolved oxygen >6.5 mg/L, total ammonia nitrogen <0.2 mg/L and photoperiod was at 12:12h (light:darkness). After 12 weeks of feeding, fish were weighted to measure growth and feed utilization parameters. Four fish per tank (12 fish/group) were randomly selected for muscle fatty acid analysis and another 12 fish /group were selected for whole body proximate composition. Analyses were those described by Asimaki et al. (2025). Data were analysed using one-way ANOVA and differences between means were determined by Tukey's multiple-range test (P=0.05).

**Results and Discussion**

Results showed that survival, growth performance and feed utilization parameters of *S. aurata* fed the experimental diets were similar (P>0.05) among the fish groups (Table 1). This denotes that the dietary inclusion of *C. capitata* meal up to 210 g/Kg, replacing 60% of fishmeal protein, did not impair growth performance of *S. aurata* and feed utilization. The whole-body proximate composition of fish was unaffected by the diets (results are not shown) denoting that *C. capitata* meal was utilized/catabolized at a similar extent to fishmeal resulting in similar body nutrient deposition. The increased dietary inclusion of MFF meal significantly increased the muscle tissue levels of 18:2n-6 and total n-6 PUFA but did not exert an influence on the levels of DHA, EPA, n-3 PUFA and n-3/n-6 PUFA ratios. These encouraging findings recommend a deeper look on the use of *C. capitata* meal in fish diets as up to date no relative literature exists.

*(Continued on next page)*

**Table 1.** Growth performance, feed utilization and selected fatty acids (% of total) of *S. aurata* fed the experimental diets.

| Parameters / dietary groups | CTRL | MFF-7 | MFF-14 | MFF-21 |
|---|---|---|---|---|
| Growth & feed utilization | | | | |
| Survival (%) | 97.5 ± 1.7 | 99.2 ± 1.7 | 95.0 ± 3.3 | 96.7 ± 2.7 |
| FR (% BW/day) | 1.89 ± 0.05 | 1.95 ± 0.02 | 1.97 ± 0.04 | 1.96 ± 0.07 |
| FBW (g/fish) | 34.6 ± 1.6 | 34.4 ± 1.8 | 35.0 ± 1.8 | 34.2 ± 1.8 |
| TL (cm) | 12.5 ± 0.3 | 12.4 ± 0.2 | 12.5 ± 0.2 | 12.5 ± 0.3 |
| SGR (%/day) | 1.99 ± 0.06 | 1.98 ± 0.06 | 2.00 ± 0.06 | 1.98 ± 0.07 |
| FCR | 1.16 ± 0.03 | 1.20 ± 0.03 | 1.21 ± 0.05 | 1.21 ± 0.07 |
| PER | 1.75 ± 0.05 | 1.70 ± 0.04 | 1.68 ± 0.07 | 1.67 ± 0.09 |
| LER | 5.56 ± 0.15 | 5.38 ± 0.12 | 5.32 ± 0.21 | 5.44 ± 0.31 |
| HSI (%) | 1.26 ± 0.23 | 1.27 ± 0.12 | 1.29 ± 0.12 | 1.28 ± 0.26 |
| Selected fatty acids (%) | | | | |
| 18:2n-6 | 10.6 [a] | 10.7 [ab] | 10.9 [bc] | 11.1 [c] |
| 18:3n-3 | 2.5 | 2.5 | 2.4 | 2.4 |
| 20:5n-3 (EPA) | 4.4 | 4.2 | 4.2 | 4.2 |
| 22:6n-3 (DHA) | 11.2 | 10.7 | 11.3 | 11.6 |
| SFA | 27.0 | 27.1 | 26.2 | 25.9 |
| MUFA | 40.5 | 41.0 | 41.7 | 41.4 |
| Total n-6 PUFA | 12.5 [a] | 12.6 [ab] | 12.8 [ab] | 13.0 [b] |
| Total n-3 PUFA | 20.4 | 19.7 | 20.3 | 20.7 |
| n-3 / n-6 | 1.59 | 1.53 | 1.50 | 1.52 |

# PARTICIPATORY ASSESSMENT OF RESILIENT AQUACULTURE SYSTEMS IN NEPAL: HEALTH, WELFARE & SOCIOECOLOGICAL POTENTIAL

Manjurul Karim[1*], Catherine Phiri[2], Tek Bahadur Gurung[1]

1 Lutheran World Relief (LWR), Kathmandu, Nepal
2 Corus International, Washington D.C., USA
E-mail: manjurul7@gmail.com

**Background & Objectives:**
Smallholder aquaculture in Nepal supports thousands of livelihoods, but systemic barriers—such as inadequate inputs, improved genetic species, disease, and unreliable profitability margins—curtail its potential. This study examines aquaculture resilience, productivity, and welfare across 16 districts along the terai regions of Nepal, blending quantitative analysis from the National Development Research Institute baseline evaluation with farmerand market actor-led insights from 190 LWR-facilitated Participatory Rural Appraisal (PRA) sessions involving 4,023 farmers between January and June 2025.

**Methods:**
A mixed-method, non-experimental design was used to assess aquaculture systems across 16 districts. Data were collected from 1,003 fish farmers and 160 value chain actors using structured surveys, KIIs, and PRA tools (resource mapping, seasonal calendars, pair ranking). Carp yield (t/ha) was calculated using a farm-specific pond profile approach. A multistage stratified sampling strategy and Proportional to Population Size (PPS) estimates ensured representativeness. Data collection used Kobo Toolbox; analysis involved Stata and SPSS. Quantitative and qualitative findings were triangulated to evaluate ecological resilience, equity, and economic outcomes.

**Results:**
Productivity ranged from ~5.2 t/ha in nonfish zones to ~7.4 t/ha in fish superzones, aligning with national pond yield averages (~5.0–5.6 t/ha in 2022/23). Benefit–Cost ratios ranged from 1.3 to 1.7, with the highest returns on farms exceeding 0.5 ha in size, using integrated fishcroppoultry systems, and with access to credit. PRA groups consistently prioritized challenges such as seed quality, disease, feeding practices, credit access, technical knowledge gaps, and local market inefficiencies. Both PRA and survey data underscore that profitability correlates strongly with farm scale, credit access, integrated system usage, and feed-use efficiency.

**Conclusion & Significance:**
Feed comprises 40–50% of production costs, but nutrient recycling through integrated systems significantly reduces input dependence. Smallholders consume over 30% of their harvest, limiting the surplus for market sales and reducing income. Farmers with >10 years' experience and ponds larger than 0.5 ha achieved significantly higher returns. This study demonstrates that combining precision productivity measurement with participatory farmer diagnostics enables regenerative aquaculture pathways featuring integrated farming models, equitable input financing, and tailored extension services—offering replicable models for sustainable aquaculture and food-system resilience in Nepal and similar Global South contexts.

**Introduction**

Skin ulceration is a persistent issue in Norwegian salmon farming, adversely affecting fish welfare, increasing mortality rates, and diminishing product quality. The primary causes of skin ulcer formation are mechanical handling and bacterial infections, with winter ulcer disease caused by *Moritella viscosa* being particularly problematic in Northern Norway. The skin, composed of layers such as mucus, epidermis, dermis, and hypodermis, acts as the first line of defense against environmental changes, physical damage, and infections. Understanding the responses triggered in these skin layers is crucial for developing effective strategies to enhance fish health and resilience against environmental stressors and infections.

**Materials and methods**

Direct exposure of scale explants (SE) from Atlantic salmon of various sizes to marine commensal bacteria of the skin, as well as the skin pathogens *M. viscosa* and *Tenacibaculum finnmarkense*, has been utilized to investigate initial bacterial-skin interaction responses. Additionally, a full commercial-scale Atlantic salmon feeding trial was conducted under Arctic conditions, testing different levels and sources of dietary lipids. The fish were fed one of three diets: 7.5% or 10% of the fatty acids (FA) as EPA and DHA from fish oil, or 10% of the FA as EPA and DHA from a combination of 5% fish oil and 5% algae oil, each in triplicate net-pens. All three diets were designed to meet the known nutritional requirements of Atlantic salmon. Data from the end of the production cycle at slaughter will be presented to demonstrate dietary effects on skin, including SE to examine lipid impacts on *M. viscosa* responses. Gene expression analysis was performed using microarray, cell morphology, stress and migration capacity was assessed using imaging and immunocytochemical detection, and skin health and characteristics evaluated for a more comprehensive understanding of the initial bacterial-skin interaction responses.

**Results and conclusion**

The SE model is a promising tool for studying skin responses. Compared to other tissue types, it has demonstrated strong immune activity with expected high expression of skin-specific genes. Direct exposure of SE to the skin pathogens *M. viscosa* and *T. finnmarkense*, consistently reproduces a panel of immune genes in Atlantic salmon across various growth stages. These responses are regulated in a dose-dependent manner. The prevalence of genes related to signaling and communication suggests that salmon scales act as sentinels, mobilizing immune responses upon bacterial encounters. Although variations are observed between bacterial species, a consistent gene set with high expression responding to bacteria has been identified. The SE model also revealed faster migration of skin cells (keratocytes), facilitating wound closure, and stimulation of genes for epithelial cell cross-linking in higher dietary lipid groups of the fish trial. Exposure to *M. viscosa* further enhanced immune responses in SE with higher lipid levels. This finding corroborated trial observations, where the low dietary lipid group exhibited higher mortality due to winter ulcer disease. Overall, the SE model has proven effective in advancing research on host-pathogen skin interactions.

# A DIATOM-BASED BIOASSAY FOR ENVIRONMENTAL CONTAMINANTS: IMPLICATIONS FOR AQUATIC ECOSYSTEMS AND AQUACULTURE WATER QUALITY

J. Karosienė[1*], G. Petrėnas[1], Ž. Jurgelėnė[1], S. Šemčuk[2], D. Montvydienė[1]

[1]State Scientific Research Institute Nature Research Centre, Akademijos Str. 2, Vilnius, Lithuania

*E-mail: jurate.karosiene@gamtc.lt

**Introduction**

Aquatic ecosystems are highly sensitive to environmental changes and are increasingly affected by a variety of pollutants including heavy metals and nanomaterials such as graphene oxide (GO), especially in regions affected by industrial or military activities. Due to their persistence and potential for bioaccumulation, these pollutants pose a serious risk to ecosystem function, biodiversity, and water quality, with implications for aquaculture and food safety. Among aquatic organisms, primary producers such as diatoms play an important ecological role in water bodies as they form the basis of the food web and drive oxygen production, and nutrient cycling. Due to their ecological importance and high sensitivity to pollutants, diatoms are widely used as effective bioindicators for the assessment of environmental hazards such as heavy metal and nanoparticle contamination.

This study evaluated the potential use of the freshwater diatom *Nitzschia palea* as a model organism in diatom-based bioassays for monitoring water quality, particularly in aquaculture systems and in the ecotoxicological assessment of contaminated or conflict-affected freshwater environments.

**Materials and methods**

A short-term (96 hours) bioassay was performed following the OECD guidelines for freshwater algal growth inhibition tests. *N. palea* was exposed under laboratory conditions to six concentrations of a metal mixture (MIX: Ni (II), Zn (II), Cr (III), Cu (II)) and graphene oxide (GO) individually, as well as in combination (MIX+GO). The concentrations were based on EU maximum permissible concentrations (MPC) for inland waters and were adjusted across a gradient from 0.1× to 80× MPC. Diatom growth rate and morphological changes were determined using a light microscope. Photosynthetic pigment levels (chlorophyll-a and carotenoids) were evaluated spectrophotometrically according to Zavřel et al. (2015). Lipid peroxidation was assessed in terms of malondialdehyde (MDA) content, according to Al-Rashed et al. (2016).

**Results**

Significant inhibition of the growth of *N. palea* and morphological changes, such as valve deformation, were induced by high metal concentrations (≥20 times higher than MPC) and MIX+GO co-exposure (>10 mg/L). Chlorophyll-a and carotenoids content showed a similar trend to the growth rate. In contrast, exposure to GO alone had no significant effect on the species growth, and *N. palea* was observed to utilise GO as a substrate. However, changes in pigment content were observed, with a slight increase at 10 mg/L, indicating a possible compensatory response to light limitation or early oxidative stress, followed by a sharp decrease at ≥20 mg/L. This decrease indicates GO induced photosynthetic inhibition, likely due to a shading effect, marking this concentration as a threshold for photosynthesis.

No significant changes in MDA levels, a marker of lipid peroxidation, were observed at low concentrations (≤10 mg/L) of MIX, GO, and MIX+GO, indicating minimal oxidative stress. However, at higher concentrations (≥20 mg/L), MDA levels decreased significantly, which could reflect either severe cell damage that suppressed lipid peroxidation or activation of antioxidant defence mechanisms.

**Conclusions**

Overall, *N. palea* demonstrated measurable physiological and morphological responses to metals and GO exposure, supporting its use in diatom-based bioassays for water quality monitoring. Such bioassays can provide valuable early-warning indicators of environmental pollution. Their application is particularly important for monitoring water quality in aquaculture systems and in conflict-affected freshwater areas, where maintaining ecosystem health is crucial for ensuring sustainable food production and protecting biodiversity.

# ENHANCING TRUST AND SUSTAINABILITY IN MALTESE SEAFOOD SUPPLY CHAINS

S. Karovic*, S. Paolacci

AquaBioTech Limited
Central Complex
Naggar Street
Targa Gap, Mosta MST 1761 (Malta)
E-mail: ska@aquabt.com

**Introduction**

The FishEUTrust project, funded by the EU Horizon Europe programme, aims to improve trust, transparency, and sustainability in European seafood supply chains. The Malta Living Lab focuses on social innovation and stakeholder engagement. It acts as a collaborative platform uniting industry, government, researchers, civil society, and the public to promote sustainable seafood practices and ocean literacy in Malta, supporting the development of a circular seafood economy.

**Materials and Methods**

The Living Lab has actively engaged over 400 seafood stakeholders through a dynamic mapping process, which was further refined via collaborative workshops, including sister project Sea2See. To broaden public awareness and foster community involvement, the Lab participated in prominent Maltese events such as “FishFest,” “Science in the City,” and “Science in the Citadel,” all supported by European Maritime Day. Recognizing the importance of youth engagement, the Lab organized hackathons that inspire innovation and promote environmental stewardship among younger generations. Industry-focused workshops addressed critical topics such as sustainable sourcing and the valorisation of fish side-streams, facilitating a co-creative environment between stakeholders. Beyond local efforts, the Living Lab contributes to global ocean sustainability by participating in international initiatives, including a UN Ocean Decade event, and supports education through involvement in the Aqua Nor 2023 Student Camp. The Lab’s impact on ocean literacy is further exemplified by its leader’s recognition as a Youth4Ocean Forum Young Ocean Advocate, underscoring the Lab’s commitment to nurturing informed and active ocean stewards.

**Results**

The Malta Living Lab has become a key hub for social innovation and ocean literacy in Malta’s seafood sector. Collaborative workshops with Sea2See improved stakeholder engagement and produced a shared action plan, strengthening outreach. Public events successfully increased awareness of sustainable fisheries. Participation in European Ocean Days and UN Ocean Decade conferences enabled sharing of project outcomes and best practices with European partners, boosting Malta’s role in marine sustainability discussions.Youth hackathons and initiatives like Aqua Nor 2023 inspired creative marine conservation solutions and emphasized traceability and consumer trust. Industry workshops fostered collaboration on circular economy practices. International recognition, including the Youth4Ocean Forum award, has strengthened Malta’s voice in European and global marine sustainability. Plans to form a seafood cluster aim to sustain these collaborative efforts beyond FishEUTrust, supporting ongoing innovation and sustainable development in Maltese aquaculture and fisheries.

# TARGETING *VIBRIO* IN LIVE FEEDS: BACTERIOPHAGE COCKTAILS AS A PREVENTIVE TOOL IN MARINE HATCHERY SYSTEMS

P. Katharios[*,1,2], S. Droubogiannis[1,3], M. Tsertou[2], G. Achthoforidou[3], H. Raza[1,3], C. Kokkari[1]

3. Department of Biology, University of Crete, Voutes, Greece

**Introduction**

Disease outbreaks in marine aquaculture continue to pose major challenges, particularly during early larval stages when fish are highly susceptible to opportunistic infections and their immune system is still immature. Fish larvae depend exclusively on live feeds such as Rotifers and Artemia, which often serve as reservoirs of pathogenic bacteria—especially members of the *Vibrio* genus. Given the global effort to reduce antibiotic use, bacteriophages—viruses that exclusively infect and lyse bacteria—have gained attention as a highly specific, eco-friendly alternative for bacterial control in aquaculture environments.

In this study, we have tested the efficacy of fully characterized phages against known pathogenic vibrios but also against randomly selected vibrios from the live feed section of a research fish hatchery. The goal was to identify optimal phage candidates and cocktail combinations for further application in hatchery systems as a preventive intervention against fish infections by member of the *Vibrio* genus.

**Materials and Methods**

Water samples were collected from Artemia and Rotifer culture tanks at the hatchery of the Institute of Marine Biology, Biotechnology and Aquaculture (IMBBC). Bacterial strains were isolated on thiosulfate-citrate-bile salts-sucrose (TCBS) agar, a selective medium for *Vibrio* species. Seventeen distinct isolates were selected based on colony morphology and preliminary biochemical characteristics for subsequent testing. To enhance the diversity and pathogenic relevance of this bacterial panel, four previously characterized *Vibrio* strains from the IMBBC lab collection were also included; *Vibrio harveyi* VH2, *V. alginolyticus* V1, *V. anguillarum* VAK, and *V. harveyi* KEF80, all of which linked to disease outbreaks in fish hatcheries.

A panel of bacteriophages from IMBBC lab collection was screened against the full bacterial set. Phages had been previously isolated from marine environments and propagated on either *Vibrio alginolyticus* or *V. harveyi.* Five phages (Figure 1), Vibrio phage Virtus (Droubogiannis and Katharios, 2022), Vibrio phage ELK1, Vibrio phage Artemius (Droubogiannis et al., 2022), ST2 (Kalatzis et al., 2016), and Vibrio phage FG which is a novel phage, were selected based on their plaque clarity, host range, and genomic profiles. Whole genome sequencing confirmed the absence of undesirable genes (e.g., lysogeny markers, toxins).

Each phage was evaluated in *in vitro* killing assays against the bacterial panel. Cultures were incubated with phage suspensions in liquid media, and optical density ($OD_{600}$) was monitored over time to generate detailed lysis curves. Phage cocktails were then formulated using two or three phages, targeting maximal bacterial coverage while aiming to reduce the likelihood of resistance emergence. The same *in vitro lysis* assays were applied to test cocktail performance.

**Results and Discussion**

The results highlighted clear variability in host susceptibility. Certain phages, such as Virtus, ST2 and FG, showed strong, rapid lysis and a relative broader host range and were selected for further downstream applications. Several cocktails demonstrated improved bacterial clearance compared to individual phages, suggesting additive or synergistic interactions (Figure 2).

Collectively, our results demonstrate the feasibility of isolating representative bacteria from live feed systems and effectively targeting them with well-characterized phages. These *in vitro* findings establish a strong foundation for the development of phage-based disinfection protocols tailored to hatchery settings. Our findings provide meaningful insights into phage-host interactions, cocktail optimization, and the potential for routine phage supplementation of live feeds to reduce microbial risks during early fish development. Phage therapy could be used to selectively exclude unwanted bacteria from fish hatcheries leaving beneficial bacteria unaffected by a targeted modulation of the microbiome.

## Introduction

Variation in oocyte quality is one of the main constraints for a sustainable production in aquaculture industry. Enhanced knowledge on oocyte quality criteria would contribute to a better reproductive success in the aquaculture industry (Kjørsvik, Mangor-Jensen, & Holmefjord, 1990).Several studies have investigated lipid droplet distribution in various fish species, rainbow trout (Ciereszko, Wojtczak, Dietrich, Kuźmiński, & Dobosz, 2009), brown trout (Mansour, Lahnsteiner, & Patzner, 2007) and Arctic char (Mansour, Lahnsteiner, McNiven, & Richardson, 2008). The current study is based on the area size of the lipid droplet distribution and the study confirms that there is a significant correlation between subgroups and fertilisation outcome.

## Materials & Methods

From 16 females, oocytes from 8 females were selected with fertilisation rates >90 % (high quality) and oocytes from 8 other with fertilisation rates between 85 and 0 % (low quality). A fertilisation assay was performed to obtain fertilisation rate, eyed embryo success and hatching success. Oocytes were picked randomly from each female and imaged under a MZ1500 stereoscopic zoom microscope with the 1×- lens (High Resolution plan Apo 1×) coupled with 10× eyepieces (Nikon Instruments Inc., New York, USA). The Nikon NIS-Elements Research (version 3) software was used to capture images. The images were taken from two angles by first capturing the coalesced lipid area, if there was any, and then turning the oocyte 180◦ for capturing a second image. The area size of the lipid coalescence was measured using free hand tool in Image J software (Rasband, W.S., ImageJ, U.S. National Institutes of Health, Bethesda, Maryland, USA) which is a free, opensource image processing program. All the images were adjusted to the scales (1DIV = 0.01 mm) and processed.

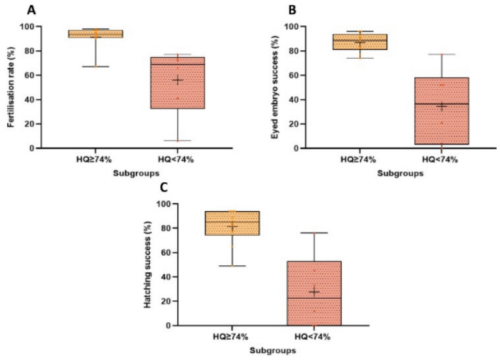

*Figure 1. Box and whisker plots presenting differences in subgroups with lipid distribution patterns based on fertilisation outcome in Atlantic salmon (Salmo salar L).*

*(Continued on next page)*

**Results & Discussion**

Based on the distribution of lipid droplets, five categories of oocytes were classified. Category 1 (C1), lipid droplets were distributed evenly while C2 had one or two small lipid globules starting to coalesce in a smaller area with average area size and standard deviation of 0.34 mm2 ± 0.15. In C3, more lipid droplets had started coalescing and had spread into a greater area with an average area size of 1.0 mm2 ± 0.25. C4 had the largest areas with coalesced lipid droplets which emphasized the area with darker orange colour with an average area size of 2.43 mm2 ± 0.76. In C5, the lipid droplets were almost all coalesced and formed one large lipid globule with an average area size of 8.53 mm2 ± 2.38, which in hatcheries are known as over-ripe. Average area size of an oocyte is approximately 12 $mm^2$ ($n$ = 50).

For further analysis, the categories 1,2,3 were included in subgroup HQ when the number of oocytes (%) in HQ were above or equal to 74 % and 4 and 5 were included in subgroup LQ when the number of oocytes (%) in HQ were below 74 %. To investigate the association between lipid droplet distribution and fertilisation outcome, females were sorted based on the distribution of oocytes within the HQ subgroup. Ten of the females had oocytes with higher or equal to 74 % (range 74–100 %) from subgroup HQ and six females had oocytes with less than 74 % (range 5–64 %) from HQ. According to the results presented in Fig. 2A, a higher fertilisation rate (≥90 %) was obtained when there were more oocytes (≥74 %) from subgroup HQ present in the oocyte batch. The fertilisation rate was significantly lower (<78 %) when less oocytes (≤64 %) from subgroup HQ ≥ 74 % were present in the oocyte batch. A similar pattern is shown in Fig. 2B and C between subgroups and subsequent eyed embryo success and hatching success, which resulted in a higher eyed embryo success (>70 %) and hatching success (>65 %) in the presence of more oocytes from subgroup HQ ≥ 74 %.

# A REVIEW OF THE EFFECTS OF KRILL MEAL ON KEY NON-SALMONID FISH SPECIES IN AQUACULTURE: INSIGHTS FROM 22 NUTRITIONAL STUDIES (1980S-PRESENT)

Kiranpreet Kaur*[1], Silvia Torrecillas [2]

[1]Aker Aker QRILL Company, Norway
[2] Aquaculture Program, Institut de Recerca i Tecnología Agroalimentaries (IRTA), La Rápita, Spain

Email: kiranpreet.kaur@qrill.com

With the growing global demand for fish as a protein source, there's increasing pressure to find sustainable alternatives to traditional aquafeed ingredients like fishmeal (FM) and fish oil (FO), which are facing reduced availability due to environmental and economic constraints. Plant-based substitutes help ease the burden on marine ecosystems but come with challenges such as anti-nutritional factors, low levels of essential omega-3 fatty acids (EPA and DHA), limited amino acid profiles, and reduced palatability—ultimately affecting fish growth, health, and product quality. Moreover, only a few crops like soybean, rapeseed, corn, and wheat are commonly used in aquafeeds, and their availability is influenced by climate change and global socio-economic factors. These plant-based ingredients also compete with human food, livestock, and pet food markets, driving up prices and limiting supply for aquaculture. Novel feed ingredients like insect meals, single-cell proteins, and fish co-products are being explored but are still limited by regulatory, cost, and scalability issues. Antarctic krill (*Euphausia superba*) stands out as a promising low-trophic alternative with minimal environmental impact, sustainable sourcing as it's the most sustainable fishery, aligning with industry standards and consumer demands for eco-friendly products. Moreover, since krill is not consumed by humans, there is no competition between its use for food and feed. Further krill-derived products mainly krill meal (KM) are rich sources of nutrients such as highly digestible proteins and lipids, phospholipids, astaxanthin, and phospholipid-bound omega-3s (EPA and DHA), which are more bioavailable than those in traditional sources and micronutrients such as organic minerals and vitamins. Further, commercially available KM is supported by extensive scientific evidence demonstrating its benefits in various fish species when included in feeds. This review consolidates current knowledge based on 22 nutritional studies from the 1980s to the present on the benefits of KM for the most important non-salmonid fish species to aquaculture, including Gilthead seabream (*Sparus aurata*), European seabass (*Dicentrarchus labrax*), Nile tilapia (*Oreochromis niloticus*), red seabream (*Pagrus major*), Olive flounder (*Paralichthys olivaceus*), and yellowtail (*Seriola quinqueradiata*) (Figure. 1). In addition, this review addresses the possible future perspectives on the application of krill meal in aquaculture feeds. Finally, the review addresses the key challenge of KM's high cost, highlighting the need for comprehensive economic evaluations to assess its cost-effectiveness compared to both conventional and novel feed ingredients.

*(Continued on next page)*

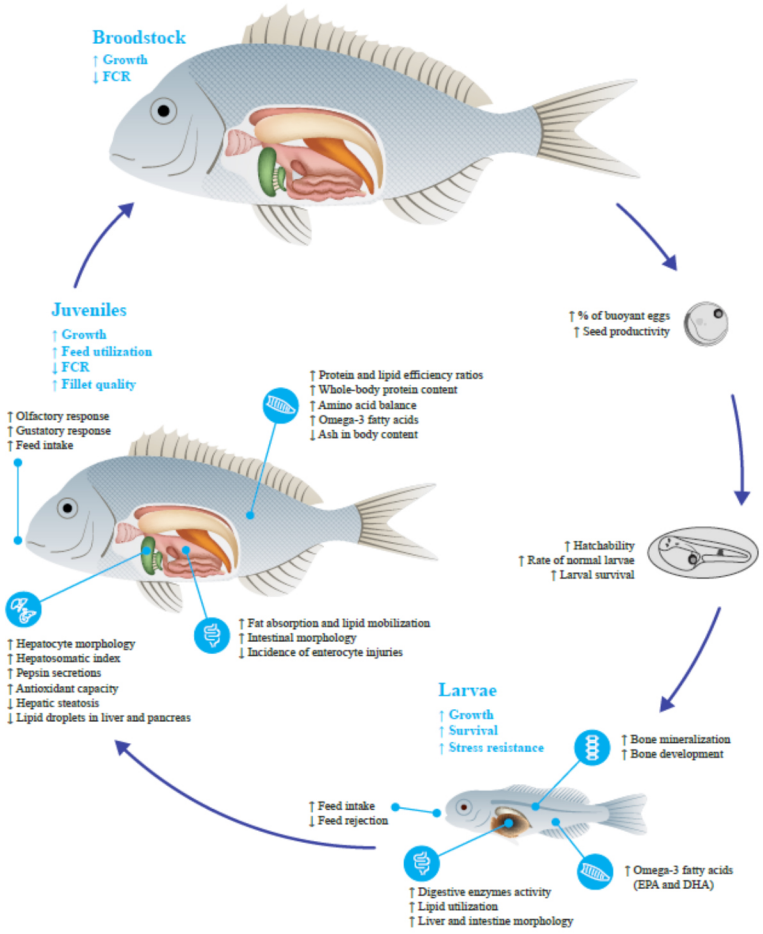

**Figure**: Main effects of krill products on farmed non-salmonid fish, as illustrated on gilthead seabream development stages as a example. In blue, main general effects at each development stage. Effects on specific organs are indicated close to the icon representing the organ(s). FCR, feed conversion ratio.

# A NOVEL NETWORK APPROACH TO ESTIMATE THE ECONOMIC BURDEN OF LISTED AQUATIC ANIMAL DISEASE OUTBREAKS AND CONTROL MEASURES

Adam Kennerley*, Sophie Armitage, Sarah Alewijnse, Mark Thrush, Jason Mewett, Mickael Teixeira Alves

Centre for Environment Fisheries and Aquaculture
The Nothe, Barrack Road
Weymouth, DT4 8UB, United Kingdom
Email: adam.kennerley@cefas.gov.uk

**Introduction**

Serious aquatic diseases, once introduced into a disease-free country or zone, can rapidly spread between aquaculture sites and cause substantial economic losses due to high mortality rates among cultured species. Epidemics can be managed using control measures such as contact tracing, movement restrictions, culling, disinfection, fallowing and surveillance, mitigating further spread and, in turn, reducing overall economic burden. However, controls also cause economic cost to the industry and to those responsible for enforcing them. Understanding the cost-benefit of control measures is, therefore, necessary for evaluating and justifying their merit. Mathematical modelling frameworks offer value in filling this gap. For example, AquaNet-Mod, an aquaculture network model, has previously been applied to simulate viral haemorrhagic septicaemia virus (VHSv) epidemics and controls across the salmonid industry in England and Wales using real-world connectivity data (Guilder et al. 2023). Here, this study extends the model framework by incorporating economic burden data incurred by each aquaculture site due to VHSv infection and control and extrapolate it at a national level. This innovative approach aims to directly strengthen evidence-based decision-making for epidemiological and cost-efficient disease control strategies.

**Materials and Methods**

Economic data that represents expected site level burden during VHSv epidemics was collected using the typical farm approach (Lasner *et al*., 2020). Each site within the network was classified as a certain type of typical aquaculture site based on real world data on culture method and levels of production, such as hatcheries, re-stockers and table producers. Farmers representative of all typical farms took part in an on-site survey to identify changes to monthly revenue and operating costs expected under different disease and control states and any additional one-off costs. The resulting estimations of economic burden at the typical farm level were incorporated into AquaNet-Mod simulations. This was accomplished by applying the relevant costs to each site based on the duration it spent in an infection or control state. Epidemic simulations were run under the current English and Welsh control strategy, and with the removal of contact tracing and all controls. During the simulations, the total national economic burden was calculated by 1) associating the disease and control state of each site with relevant typical farm costs and 2) cumulating these costs across the entire network. This process allows for the estimation of the total national burden based on the number of sites impacted and what those impacts were.

**Results**

Implementing disease controls significantly reduced the number of infected sites and associated costs (Figure 1). In the absence of disease controls, there was a significantly greater chance of larger, long-lasting epidemics with greater economic burdens (Figure 1C). Control measures were shown to decrease the total number of infected sites (Figure 1A), which, in turn, reduced the overall epidemic cost by minimising the need for sites to be culled, disinfected and undergo fallowing, which were the greatest individual site level costs reported during the typical farm surveys. Additionally, the simulations demonstrated the effectiveness of contact tracing in reducing the likelihood of larger and costly epidemics (Figure 1B). Contact tracing had low implementation costs to the industry, whilst reducing the likelihood of the largest and most costly epidemics by effectively reducing spread between sites. Furthermore, the merit of the combination of all controls was shown during the *no controls* scenario, where the likelihood of larger, more costly epidemics increased the average total epidemic cost 12-fold.

*(Continued on next page)*

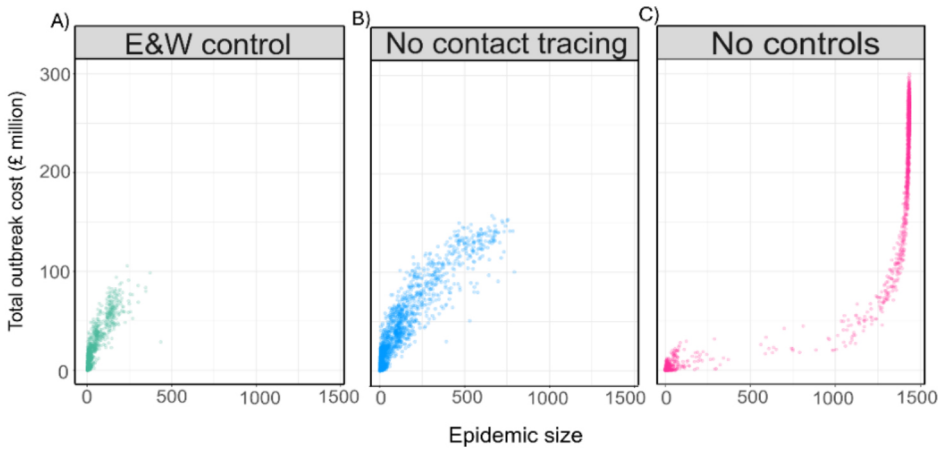

Fig 1. Simulations of viral hemorrhagic septicemia virus (VHSv) epidemics across the England and Wales salmonid sector in terms of epidemic size (number of sites infected) and the associated economic cost to industry. A) Cost and size of epidemics under current control protocols. B) Cost and size of epidemics with contact tracing removed. C) Cost and size of epidemics with all controls removed.

**Discussion**

To our knowledge, this study represents the first assessment of the impact of disease control on national economic burden of epidemics based on the combined use of network modelling and site-level economic assessment methodologies. The integration of estimated site-level costs collected via typical farm surveys into AquaNet-Mod provides key novel insights into the economic impact of VHSv introductions into the salmonid sector in England and Wales. The method generated clear evidence on the merit of control measures in reducing epidemic size and associated costs, providing valuable information to inform optimal control strategies. For instance, if VHSv incursions were to occur within the England and Wales salmonid sector, prioritising contact tracing during the early stages of an outbreak is expected to significantly reduce the likelihood of a widespread epidemics that jeopardise the entire industry. This integrated approach, combining the expertise of epidemiologists, modellers and economists, has demonstrated a flexible and adaptable framework with the potential for application to other diseases and aquaculture sectors.

# DIETARY YEAST HYDROLYSATE IMPROVED THE PERFORMANCE OF JUVENILE AND GROWER ASIAN SEABASS (*Lates calcarifer*)

H. Kettunen[1*], J. Vuorenmaa[1] and O. Jintasataporn[2]

[1]Hankkija Oy, FI-05801 Hyvinkää, Finland
[2]Department of Aquaculture, Faculty of Fisheries, Kasetsart University, Bangkok, Thailand
E-mail: hannele.kettunen@hankkija.fi

## Introduction

Asian seabass (*Lates calcarifer*) is an omnivorous, euryhaline fish with commercial importance especially in Southeast Asian aquaculture. The performance of Asian seabass is often decreased by pathogenic bacteria, such as *Vibrio* spp. or *Aeromonas* spp. Dietary strategies to improve fish performance are needed. The present study investigated the effects of dietary *Saccharomyces* yeast hydrolysate (YH) on the performance of juvenile and grower stage Asian seabass which were grown in earth ponds in Thailand.

## Materials and methods

Two experiments were conducted: E1 for juvenile fish, with a mean body weight 13g on day 1, and E2 for the grower stage, with a mean body weight 270 g on day 1. Both experiments were carried out in net cages, in earth ponds of 0-3 ppt saline water, which was aerated to maintain DO>5 mg/l. Commercial-type feed for Asian seabass was amended with different levels of YH (Progut® Extra, Hankkija Oy, Finland) for the dietary treatments. The set-up for E1 was 30 fish/cage, density of 15 fish/m$^3$, 3 treatments with YH levels of 0.0, 0.15, or 0.30%, 4 pens/tr, and a trial period of 8 weeks. In E2 there were 10 fish/cage, density of 5 fish/m$^3$, 4 treatments with YH levels of 0.0, 0.10, 0.15, or 0.20%, 5 replicates/tr., and trial period of 12 weeks. In both experiments, the fish were fed three times a day at 3-5% of body weight. Remaining feed was siphoned out, dried and weighed for calculating feed intake. Fish weight gain and feed conversion ratio (FCR) were recorded every two weeks. On the final day, blood samples were collected for the analysis of white and red blood cell counts, hemoglobin, hematocrit, immunoglobulin M (IgM), lysozyme activity, and glutathione. Foregut villus length was measured from histological samples. In E2, superoxide dismutase (SOD) activity was measured from blood samples, and the carcass composition was determined. Study design was completely randomized in both experiments, and one-way ANOVA and Duncan's Multiple Range Test were used for data analysis. Limit for statistical significance was set to $p<0.05$.

## Results

In E1 (Table 1), dietary YH significantly increased average daily gain, fish weight on the final day, and feed intake. Feed conversion and mortality were similar in all treatments. Hematocrit was increased by YH, while YH significantly decreased the red and white blood cell counts. The treatments did not significantly affect serum protein concentration, immunoglobulin M, glycogen, lysosome activity, glutathione, or foregut villus length.

In E2 (Table 2), YH significantly and dose-dependently improved the average daily gain, and also increased fish weight at 12 week. Feed conversion was significantly improved by dietary YH amendment. Mortality was 0% in all treatments throughout the experiment. Hematocrit, serum protein concentration, mean villus length, lysozyme activity and glutathione were all unaffected by the dietary treatments. The SOD activity tended to be higher for YH-treated groups than the control group ($p=0.068$). Carcass composition and foregut villus length were not affected by the dietary treatments.

## Discussion and conclusions

In conclusion, dietary YH supplementation had a positive effect on the weight gain and final weight of juvenile and grower Asian seabass. Feed conversion was improved by dietary YH in the grower age group. Dietary YH may be a strategy for improving the performance of Asian seabass. Immunological or physiological mechanisms behind the observed performance effects remained inconclusive, and open for further studies.

# EVALUATION OF FERMENTED SUGAR BEET PULP AS A POTENTIAL INGREDIENT IN THE FEED OF *Labeo rohita* (ROHU)

Noor Khan* and Areej Farooq

Institute of Zoology
University of the Punjab
Lahore-Pakistan
Email: noor.zool@pu.edu.pk

A feeding trial was conducted to evaluate fermented sugar beet pulp (FSBP) as a potential ingredient in the feed for *Labeo rohita* (Rohu). *L. rohita* juveniles (average initial weight 15 g) were selected as experimental fish for this study. The experiment was carried out in 21 glass aquariums. The trial was divided into seven (7) treatments each having three replicates. Seven isonitrogenous diets were formulated by incorporating raw and fermented sugar beet pulp (SBP) at 0% (Control), 7%, 14%, and 21% levels. Baker's yeast waste was used for the fermentation of SBP. After the feeding trial, fish were randomly sampled from each treatment for growth monitoring, body composition, blood and serum biochemical analysis, digestive and antioxidant enzymes. In terms of growth performance of *L. rohita*, diet T6 containing 21% FSBP resulted in a significantly ($P<0.05$) higher growth. The overall performance of *L. rohita* fed fermented FSBP incorporated diets was better in comparison to those fed with RSBP incorporated diets and control. The activities of anti-oxidant and digestive enzymes were observed significantly ($P<0.05$) higher in fish fed with 21% FSBP (T6). The maximum deposition of protein in the carcass was recorded in fish fed with 21% FSBP diet (T6). The supplementation of FSBP in the diets significantly affected the haematological status of fish ($P<0.05$). To assess liver health, serum enzymes (AST, ALT, and ALP), lactate dehydrogenase, cholesterol, triglycerides, and total proteins the fermented sugar beet pulp in the feed positively impacted these health markers. In conclusion, it has been observed that the supplementation of FSBP up to 21% in *L. rohita* diet, effectively improved health parameters without compromising growth performance, haemato-biochemistry, and liver functionality.

# EVALUATION OF DIETARY MICELLE FORM OF COENZYME Q10 IN DIET FOR OLIVE FLOUNDER, *Paralichthys olivaceus*

Wonhoon Kim[1,*], Gunho Eom[1], Kwan-Sik Yun[2], Kyeong-Jun Lee[1,3]

[1]Department of Marine Life Sciences, Jeju National University, Jeju 63243, South Korea

[3]Marine Life Research Institute, Jeju National University, Jeju 63333, South Korea
E-mail: kjlee@jejunu.ac.kr

## Introduction

Coenzyme Q10 (CoQ10), known as ubiquinone, is a coenzyme that functions as an electron transporter in the ATP production. CoQ10 acts as an antioxidant with sparing effect for vitamin C and E. Micelle structures possess an interface between hydrophilic and hydrophobic area, which can protect feed additives and facilitate their absorption in the body. Olive flounder (*P. olivaceus*) is the main aquaculture species in South Korea. This study was conducted to evaluate dietary CoQ10 and micelle form CoQ10 (MCoQ10) supplementations in diet for olive flounder feed.

## Materials and methods

A basal diet (Con) was formulated to contain 600 g/kg fish meal and 120 g/kg soybean meal as main protein sources. Seven other diets were prepared adding 20 and 40 mg CoQ10/kg (CQ2 and CQ4, respectively), and 10, 20, 40, 80 and 160 mg MCoQ10/kg (MQ1, MQ2, MQ4, MQ8 and MQ16, respectively). Experimental fish (initial mean body weight: 24.1 g) were randomly distributed into 24 tanks (300 L), with 30 fish per tank in triplicates, and fed the diets twice daily for a 66-day feeding trial. At the end of feeding trial, all fish were individually counted. To test the disease resistance against *Edwardsiella tarda*, the remaining fish were re-distributed into 24 acrylic tanks (120 L) with 12 fish per tank in triplicates. Each fish was injected with 100 μL of $1.0\times10^7$ CFU/mL *E. tarda* suspension ($5.0\times10^4$ CFU/fish). Mortality was monitored at 6-h intervals for 8 days (186 h).

## Results

The final mean body weight and protein efficiency ratio were significantly higher in MQ4 and MQ8 groups compared to those in Con group. Ig level and lysozyme activity were significantly enhanced in all CQ and MQ groups. Anti-protease and phagocytic activities in MQ2, MQ4, MQ8 and MQ16 groups were significantly higher than in Con group. Antioxidant capacities (superoxide dismutase, glutathione peroxidase and catalase) were significantly improved in fish fed MQ2, MQ4 and MQ8 diets than in fish fed Con diet. Lipase activity was significantly increased in all CQ and MQ supplemented groups. Chymotrypsin and trypsin activities were significantly improved in CQ4, MQ8 and MQ16 groups compared to Con group. Intestine villi length, villi width and goblet cell counts were significantly increased in all CQ and MQ groups compared to Con group. Expression of inflammation-related genes were upregulated in CQ2, MQ1, MQ2, MQ4, MQ8 and MQ16 groups than in Con group. CoQ10 levels in liver and muscle were significantly higher in CQ4, MQ4, MQ8 and MQ16 groups than that in Con group. Vitamin C levels in liver and muscle were increased in MQ2 and MQ4 groups. Vitamin E levels in liver and muscle were the highest in MQ4 group. For intestinal microbiota, MQ8 and MQ16 groups showed significantly higher proportion of lactic acid bacteria, while all CQ and MQ groups exhibited lower proportions of *Vibrio* bacteria compared to Con group. Following the 186-h *E. tarda* challenge test, cumulative survival of all CQ and MQ groups were significantly higher than that of Con group.

## Conclusion

This study suggests that MCoQ10 supplementation could enhance growth performance, immune response, antioxidant capacity, intestinal microbiota and disease resistance against *E. tarda*. The optimal dietary supplementation level of MCoQ10 in diet for olive flounder is likely to be 40-80 mg/kg.

# FISH OIL REPLACEMENT WITH A DHA-RICH *Schizochytrium* OIL ENHANCES GROWTH, IMMUNITY, ANTIOXIDANT CAPACITY AND DISEASE RESISTANCE OF PACIFIC WHITE SHRIMP *Penaeus vannamei*

Sua Kim[1,*], Suhyeok Kim[1], Jin-Young Jeon[2], Hyunwoon Lim[2], Bora Kim[2] and Kyeong-Jun Lee[1,3]

[1]Department of Marine Life Sciences, Jeju National University, Jeju 63243, South Korea

[3]Marine Science Institute, Jeju National University, Jeju 633333, South Korea
E-mail: kjlee@jejunu.ac.kr

**Introduction**

Pacific white shrimp is the most economically valuable shrimp species in the world. Fish oil serves as a primary source of essential fatty acids such as docosahexaenoic acid (DHA) and eicosapentaenoic acid which play critical roles in supporting growth, immune function, and disease resistance in shrimp. However, the decrease in fish stocks and the rise in global demand of fish oil are driving up feed prices and threatening marine ecosystems, underscoring the need for sustainable alternative resources. *Schizochytrium* sp. (SHC), a marine microalga rich in DHA, has emerged as a promising substitute for fish oil. SCH demonstrates environmental sustainability and ensures stable large-scale production and supply, with the distinct advantage of not competing with food sources intended for human consumption. This study was conducted to evaluate the effects of dietary fish oil replacement with SCH oil on the growth performance, innate immunity, antioxidant capacity, and disease resistance of *P. vannamei*.

**Material and methods**

A control diet (Con) was formulated to contain 10% fish meal (anchovy and tuna byproduct) and 4% cod liver oil. The experimental diets were prepared by replacing the fish oil in Con diet with SCH oil and soybean oil at graded levels of 12.5%, 25%, 37.5%, 50%, 62.5%, 75%, 87.5% and 100% (designated as S12.5, S25, S37.5, S50, S62.5, S75, S87.5 and S100, respectively). Total 945 shrimp (0.09 ± 0.01 g) were randomly stocked into 27 tanks (240 L) with 35 shrimp per tank. Triplicate groups of shrimp were fed one of the diets four times daily for 56 days. After the feeding trial, each dietary treatment were randomly stocked into 27 tanks (120 L) with 18 shrimp per tank in triplicate groups for a challenge test. *Vibrio parahaemolyticus* suspension was added to each tank to achieve a final bacterial concentration of $3.5\times10^5$ CFU/mL. The challenge test was carried out over a period of 10 days (240 h) monitoring the mortality hourly.

**Results**

Growth performance (final body weight, weight gain and specific growth rate) and feed conversion ratio were significantly improved in all SCH oil groups than in Con group. Lipase activity was significantly higher in shrimp fed S50, S62.5, S75, S87.5 and S100 diets than in those fed Con diet. Fatty acid oxidation activity was significantly higher in shrimp fed S87.5 and S100 diets than in shrimp fed Con and S12.5 diets. Superoxide dismutase activity was significantly higher in shrimp fed S25 to S100 diets than in shrimp fed Con and S12.5 diets. Catalase activity was significantly higher in all SCH-supplemented groups compared to that of Con group. Malondialdehyde levels were significantly lower in shrimp fed S12.5 to S87.5 diets than in those fed Con diet. Total antioxidant capacity was significantly higher in shrimp fed S50, S62.5 and S87.5 diets than in shrimp fed Con diet. Triglyceride and aspartate aminotransferase levels were significantly lower in all SCH-supplemented groups compared to those in Con group. The proportion of *Vibrio* spp. on TCBS agar was significantly lower in shrimp fed S50 to S100 diets than in shrimp fed Con diet. Total hemocyte count was significantly higher in shrimp fed S25 and S37.5 diets compared to those in Con group. The Hyalinocyte count was significantly higher in shrimp fed S25, S37.5, S50 and S75 diets compared to that in Con group. During the *V. parahaemolyticus* challenge test, Con group showed significantly lower survival compared to S12.5 to S87.5 groups.

**Conclusion**

Dietary fish oil replacement with SCH oil and soybean oil had positive effects on growth performance, feed efficiency, digestive enzyme activity, antioxidant capacity, immune responses, gut microbiota balance and disease resistance in *P. vannamei*. Based on quadratic regression analysis of weight gain, the optimum replacement level of fish oil by SCH oil in shrimp diet was estimated to be approximately 70%.

E-mail: kjlee@jejunu.ac.kr

## Introduction

Coenzyme Q10 (CoQ10) is a hydrophobic antioxidant that has gained attention as a functional feed additive in aquaculture. Micellar encapsulation is an effective technique to enhance intestinal absorption of hydrophobic compounds such as CoQ10. Despite its potential, very limited information is available regarding the comparative effects of dietary CoQ10 and its micellar form for the shrimp. This study was conducted to evaluate the effects of dietary supplementation of CoQ10 and micellar CoQ10 (MQ10) on growth performance, feed utilization, immune response, antioxidant capacity and resistance to acute hepatopancreatic necrosis disease in the shrimp.

## Material and methods

A control diet (Con) was formulated to contain 15% fish meal (anchovy and tuna byproduct) and 4% cod liver oil. The experimental diets included the Con diet supplemented with CoQ10 at 20 and 40 mg/kg (designated as CQ2 and CQ4, respectively), as well as with MQ10 at levels of 10, 20, 40, 80 and 160 mg/kg (designated as MQ1, MQ2, MQ4, MQ8 and MQ16, respectively). Total 720 shrimp (0.70 ± 0.01 g) were randomly stocked into 24 tanks (240 L) with 30 shrimp per tank. Triplicate groups of the shrimp were fed one of the diets six times daily for 56 days. After the feeding trial, *Vibrio parahaemolyticus* suspension was added to each tank to achieve a final bacterial concentration of $3.0\times10^5$ CFU/mL for a challenge test. The challenge test was carried out for 8 days (192 h) monitoring the mortality hourly.

## Results

Final body weight and specific growth rate were significantly higher in shrimp fed CQ2, MQ2, MQ4, MQ8 and MQ16 diet than in shrimp fed Con diet (Table. 1). Feed conversion ratio, protein efficiency ratio and survival were not significantly affected by dietary administration of CoQ10 and MQ10. Digestive enzyme activities (trypsin, chymotrypsin, and lipase) were significantly increased in MQ8 than in all other groups and Con group. Lysozyme activity was significantly higher in all MQ10 supplemented groups than in Con group. Phagocytosis activity was significantly higher in shrimp fed CQ2, CQ4, MQ8 and MQ16 diets than in shrimp fed Con diet. Antioxidant activities (superoxide dismutase and catalase) were significantly improved in CQ2, CQ4 and all MQ10 groups than in Con group. During the *V. parahaemolyticus* challenge test, Con group showed significantly lower survival compared to CQ4, MQ2, MQ4, MQ8 and MQ16 groups.

## Conclusion

Dietary supplementation of CoQ10 had positive effects on non-specific immunity, antioxidant capacity and disease resistance of *P. vannamei*. Micellar encapsulation enhanced the absorption and utilization of CoQ10 in the shrimp, suggesting that MQ10 is a promising delivery form. These findings indicate that CoQ10 is a potential natural feed additive for the improvement of the shrimp health and disease resistance.

E-mail: star0798@jejunu.ac.kr

## Introduction

The Pacific oyster (*Crassostrea gigas*) is one of the most commercially important aquaculture species worldwide, supporting both global shellfish production and coastal economies. However, its cultivation is increasingly threatened by environmental stressors, particularly those associated with climate change. Hypoxia, often occurring alongside elevated summer water temperatures, can exert severe impacts on aquatic organisms, including mass mortality events in oyster farms.

## Material and Methods

In this study, we examined the metabolomic profiles and cellular responses of hemocytes from *C. gigas* subjected to hypoxia alone or in combination with high seawater temperature stress. Oysters were maintained for 13 days under three conditions: control (normoxia at ambient temperature), hypoxia (1 mg $O_2$/L), and combined stress (28 °C with 1 mg $O_2$/L). Hemocyte metabolite compositions were profiled using gas chromatography–mass spectrometry (GC–MS), and phenotypic characteristics were assessed via flow cytometry.

## Results

Both stress treatments, especially the combined condition, induced marked changes in hemocyte metabolism and functionality. Concentrations of most amino acid metabolites linked to anaerobic respiration and the urea cycle declined, whereas lipid metabolites associated with cell proliferation increased. Flow cytometry revealed a reduction in phagocytic hemocyte populations, which aligned with lower levels of lipid metabolites related to phagocytosis. Furthermore, distinct lipid metabolite shifts were identified that are indicative of impaired cellular immunity.

## Discussion

Collectively, these results demonstrate that hypoxia and elevated seawater temperature act synergistically to suppress metabolic processes through modifications in anaerobic respiration pathways while concurrently diminishing immune capacity in Pacific oyster hemocytes, potentially contributing to the summer mortality phenomenon.

# ANNUAL SEXUAL CYCLE OF FEMALE STONE MOROCCO (*Pseudorasbora parva*) - AN INVASIVE SPECIES FROM NORTHWEST POLAND

L. Kirczuk, K. Dziewulska, P. Czerniejewski, A. Brysiewicz, J. Rechulicz and J. Ligięza

Department of Hydrobiology
Institute of Biology
University of Szczecin
Felczaka 3c
71-412 Szczecin, Poland
e-mail**:** lucyna.kirczuk@usz.edu.pl

**Introduction**

Stone morocco (*Pseudorasbora parva*) is a small fish belonging to the cyprinid family (Cyprinidae), native to Southeast Asia. It lives in a variety of habitats, being most abundant in small vegetated channels, ponds and small lakes. In higher densities, it can pose a great threat to rare and disappearing fish species, causes a reduction in biodiversity, and spreads parasitic diseases. In Poland since 1990, now very widespread. Stone morocco has contributed to the reduction in abundance and even disappearance of some indigenous fish species of the cyprinid family by eating their eggs and juvenile stages of fish, causes a reduction in biodiversity, as well as the spread of parasitic diseases. The present study aimed to (I) analyse the reproductive cycle of both stone moroko sexes based on microscopic observations; (II) assess the reproductive potential of a population based on a small watercourse in Central Europe. Histological and microscopic analysis of female gonads allows us to assess the maturity of female gonads, determine the spawning period and the rate of gonad recovery.

**Materials and methods**

The study material consisted of 234 females collected from the Wardynka River (Oder basin, northwest Poland). The age of the fish studied, was estimated by scale analysis. Histological analyses of gonad preparations were performed using a standard paraffin technique, gonads were estimated on a 6-grade maturity scale.

**Result**

Standard length and weight of stone morocco females averaged 46.2 ± 12.4 mm and 1.85 ± 1.66 g, respectively. Females were 0+ - 5+ in age. From September to February, gonads with oocytes in previtellogenesis and early vitellogenesis with degenerating oocytes were observed. Multiple portions spawning took place from April to mid-August. Females had the highest GSI in May, averaging 8.55% (0.53-25.68%) and the lowest in January, 1.79% (0.21-2.91%). GSI of spawning females averaged 12.33% (8.23-25.68%). The wide range in the GSI of spawning females is due to the fact that some of the females were after laying a portion of oocytes and were preparing (at different stages) to lay more portions. The average absolute fecundity is 1372 egg per female (range 225-6620) and the relative fecundity is 1691 egg per g (range 268-4543). The smallest spawning female was 2.5 cm (SL).

**Conclusion**

The study population in the settled new habitat showed a higher reproductive potential than native populations of stone morocco. The fish were characterized by very rapid sexual maturity as early as in the first year of life, high fecundity, abortive spawning, and a long-lasting four-month reproductive period, which allows for a rapid increase in population size and density in the new area. Reproductive potential, together with low subsistence requirements and adaptability to different habitat conditions, contribute to the colonization success of this species in a new habitat.

# UV-B LIGHT STIMULATES THE PRODUCTION OF VITAMIN $D_3$ IN ATLANTIC SALMON

Øystein Klakegg[1], Inge Fossen[2], Tobias Backström[1], Tomas Holte[3]

[1]Faculty of logistics, Molde University College, Campus Kristiansund, Fosnagata 12, 6509 Kristiansund, Norway
oystein.klakegg@himolde.no
[2]Salmon Evolution ASA, Torget 5, 6440 Elnesvågen, Norway
[3]Salmon Evolution Dale AS, Dalsbygdvegen,6120 Folkestad, Norway

## Introduction

Vitamin D is an essential fat-soluble micronutrient in animals, and the two most important derivates are vitamin $D_2$ (ergocalciferol) and vitamin $D_3$ (cholecalciferol). The $D_2$ originates from vegetable and fungal origins and the D3 from animal origins (Cardwell et al., 2018). Mammals can additionally synthesize pre-vitamin D3 in the skin from 7-dehydrocholesterol (7-DHC). This is done in humans by UV-B radiation of 290-315 nm which causes the epidermal 7-DHC to rearrange and form pre-vitamin $D_3$. (Holick et al., 1977). This is also common among land vertebrates such as lizards and birds and also among some insects (Oonincx et al., 2018).

The main origin of D3 in fish such as Atlantic salmon, has been thought to be via the food chain (Lock et al., 2009). It has been stated that fish is fully dependent on dietary D3 (Lock et al., 2009; Soto-Dávila et al., 2020).

We wanted to test whether UV-B light stimulated the production of vitamin D3 in Atlantic salmon.

## Material and methods

For the trials, 4 indoor holding tanks (3 x 3 m, 8 angular) with a water volume of ~ 10.8 m3 (depth 1.2 m) were used. The indoor area was enlightened with ordinary white light from tube lights in the roof, at a continuous 24/7 light regime for all tanks. In addition, two UV-B-light sources (LumenIZE Pro T5 Forest 6% 54W, Arcadia reptile, Great Britain) were installed 30 cm above the water surface in two of the tanks (UV-B exposed fish) at a 24/7 light regime. For comparison fish from two random tanks were used (control/non-exposed fish). Atlantic salmon were reared from roe (Benchmark genetics, Norway) at Salmon Evolutions smolt facility at Dale in Norway following the normal smolt production. The average weight in start of the trial was 6g. Two separate trials were done.

Fish were sampled from the 4 indoor tanks at 3 separate occasions in both trials, at day 0 (start of the trial), day 31, and day 77 in trial 1 and day 0, day 27, and day 68 in trial 2. Fish were tawed, and filets with pin bones extracted was analysed for Cholecalciferol ($D_3$) by Eurofins Food & Feed Testing Norway AS (EN 12821:2009 mod.). The method consists of saponification and extraction followed by HPLC analysis and detection.

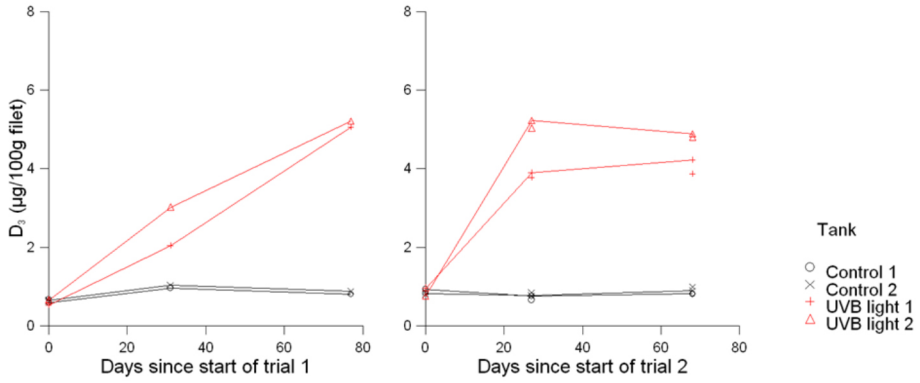

Figure: $D_3$ levels in samples from the tanks plotted against day since the trial started.

*(Continued on next page)*

**Results**

The level of D3 in muscle was markedly affected by the presence of a UV-B light source. Filet $D_3$ levels started out at ≤ 1 µg/100 g in all tanks during both trials. $D_3$ levels in fish exposed to UV-B increased during both trials, whereas in the control groups $D_3$ levels remained at low levels throughout. Fish from UV-B treated tanks had significantly higher $D_3$ levels than fish from the control tanks.

**Conclusion**

The groups exposed to UV-B light had 2,5 to 6 times higher Vitamin $D_3$ in the muscle after 4 weeks and more than 5 times as much after about 10 weeks than the control groups. The study suggests that Atlantic salmon in the freshwater phase synthesize pre-vitamin $D_3$ from 7-dehydrocholesterol using UV-B light.

In today's salmon farming, where more of the farming occurs in closed and submerged facilities with no or limited access to UV-B from natural sunlight, this knowledge is important.

## Introduction

With the rapid growth of the Norwegian aquaculture industry, also the demand for suitable aquaculture waste management is rising. Current waste treatment practices include both partial release into the surrounding water as well as capture, dewatering and shipment to other countries such as Denmark or Vietnam where it is used in biogas production or as fertilizer. Here we evaluated a waste-treatment process in Norway, where anaerobic digestion of the fish sludge was used for biogas production in Norway and the leftover nutrients, such as nitrogen (N) and phosphorous (P) from the aquaculture effluent water were used for microalgae cultivation. The final products from this proposed value chain are energy and heat from biogas, liquid digestate (organic fertilizer), as well as microalgae biomass. To create a better understanding of the environmental and economic benefits of the proposed value chain, as well as any drawbacks, a life cycle analysis as well as preliminary economic assessment was performed.

## Material and Methods

Four different scenarios were investigated: 1) representing the current situation of sludge treatment from an average fish production site with sludge-capturing mechanisms and shipping 50% of the captured sludge to Denmark for biogas production, 2) assuming 100% of the captured sludge to be shipped to Denmark for biogas production, 3) nutrients of the reject water from sludge dewatering are remediated through microalgae cultivation, and the dewatered fish sludge is used as sole substrate for biogas production in Norway, and 4) the same as in 3, though with the distinction that the dewatered fish sludge is added as an additional feedstock to a municipal anaerobic digestion plant in Norway. All scenarios were based on the aquaculture waste streams from an assumed average-sized fish production facility located on the west coast of Norway. A life cycle assessment was performed to compare the potential environmental impact of these four different fish sludge treatment scenarios with each other and identify environmental hotspots in the proposed value chains. The assessment followed the ISO14040 and ISO 14044 guidelines. One year of treatment of fish sludge and reject water from an average salmon production site using Recirculating Aquaculture System (RAS) and producing 5000 tons fish per year (Bregnballe, 2022), was chosen as the functional unit for the LCA. Moreover, A preliminary economic assessment was performed to quantify the differences in operational costs of the scenarios.

## Results and Discussion

Shipping and treatment of 100% of the fish sludge in Denmark, as described in scenario 2, gave lower environmental impacts than the baseline scenario where only 50% of the fish sludge was shipped and treated in Denmark. Geographical differences in electricity sources in Norway and Denmark are a major factor that determine the environmental sustainability. System expansion, for example to account for the lack of imported sludge in Denmark and subsequent local energy production (biogas) compensated by energy from the local grid, was a major contributor to the environmental impacts. Even though the amount of energy produced from the biogas production in scenario 2 and 4 was the same, the compensated energy coming from the local grid had a significantly different environmental footprint, with the Danish energy mix based on wind power (58%), biofuels (16%), 10% solar power, and 16% non-renewable energy, and the Norwegian energy mix based for 89% on hydropower, and another 10% based on other low-carbon energy sources.

In scenarios 1 and 2, the system was expanded with the production of microalgae on commercial fertilizer and electricity from the national Norwegian grid alone. This was a major contributor to the environmental impacts and had a greater impact than the treatment of fish sludge in Denmark. When all scenarios were compared without a system expansion for compensation of local energy production in either Norway or Denmark, scenarios 3 and 4 became the most environmentally sustainable scenarios in all impact categories.

*(Continued on next page)*

Scenario 4, where fish sludge was co-digested with other feedstock, showed a potentially lower environmental impact than when fish sludge was the sole substrate for anaerobic digestion (scenario 3), due to variations in the biogas productivity, and thus production of less energy that could be used in the microalgae production. Optimisation of anaerobic digestion with high inclusion levels of fish sludge can play an important role here.

As expected, in the scenarios where microalgae were cultivated on aquaculture wastewater and thus recovered the nitrogen from this water, the impact category marine eutrophication was clearly improved.

The direct comparison of only the treatment of fish sludge for biogas production (when using co-digestion with other feedstocks) showed that local treatment of the sludge in Norway resulted in less environmental impact in most of the impact categories compared to treatment in Denmark. This is mainly caused by a lower energy consumption (as no drying of fish sludge is necessary, only dewatering up to 20 % DW) and shorter transport distances (no shipment, only transport by road). However, infrastructure for anaerobic digestion is far less developed in Norway, and the use of the produced digestate needs also to be taken into account.

# REVIEW OF GROWTH MODELS FOR POST-SMOLT TO ADULT ATLANTIC SALMON *Salmo salar*

Stian K. Kleiven*

Department of Technology and Safety
UiT The Arctic University of Norway
Tromsø, Norway
E-mail: stian.k.kleiven@uit.no

## Introduction

Atlantic salmon (*Salmo salar*) is among the top ten most produced and valuable marine fish worldwide in the aquaculture industry, with Norway producing 1.5 million metric tonnes (MMT) in 2023, making it the leading global producer. However, this high level of production has been accompanied by significant challenges, notably the issue of salmon louse (*Lepeophtheirus salmonis*), a parasite responsible for significant welfare concerns and an estimated economic impact of around €610 million annually in Norway. The problem has seemingly escalated due to increased production volumes, reduced efficiency of treatments and rising sea surface temperatures (SST). For instance, in Northern Norway, record-high SSTs during July and August 2024 led to a surge in salmon lice larvae production. Rising SST can also lead to a higher frequency of harmful algal blooms and jellyfish blooms. SST are projected to increase by 1-3 °C this century and therefore understanding the potential future scale of salmon lice infestations, especially under conditions of higher SSTs anticipated with climate change, is crucial.

One effective approach to assess the impact of rising salmon lice populations linked to increased SSTs is through simulation studies. Simulation-based approaches, particularly growth models, provide valuable tools for linking environmental changes to fish growth, mortality, and economic outcomes. While empirical models like specific growth rate (SGR) and thermal growth coefficient (TGC) offer simplicity for operational use, mechanistic bioenergetic models better capture complex interactions between temperature, feeding, metabolism, and parasite burdens. Integrated frameworks that combine bioenergetics with epidemiological and economic modules are especially suited for evaluating adaptation strategies, as they can simultaneously simulate reduced growth, lice-induced mortality, and treatment-related losses to inform robust, climate-resilient management of Norwegian salmon aquaculture. To support climate change adaptation (CCA) in Norwegian Atlantic salmon aquaculture, our review sought growth-modelling frameworks that can simulate the combined impacts of rising SST and heightened salmon-lice infestation while also incorporating farm-management levers, growth, mortality and cost from the post-smolt to adult phase.

## Method

In this review, we compiled and synthesised literature on growth models for post-smolt to adult salmonids, following PRISMA guidelines. An initial Web of Science and Oria search targeting “Atlantic salmon” and “growth model*” returned only 12 relevant papers, so the scope was broadened to include other salmonids (salmon, trout, charr) to capture a wider range of modelling approaches applicable to Atlantic salmon, while excluding non-salmonid species from multi-species studies. The expanded search retrieved 267 papers, of which 83 met inclusion criteria after screening titles, abstracts, and methods. These studies were classified by species, production system, and whether their models measured growth, weight, mortality, and cost, and incorporated temperature or salmon lice as drivers, with growth and temperature as the minimum requirements for recommendation. From this set, 28 key studies most relevant to the review’s aims were examined in depth, grouped into main model categories, and analysed to identify the most suitable frameworks for simulating climate- and parasite-related impacts on Atlantic salmon.

## Results

The literature on post-smolt to adult Atlantic salmon growth models spans a spectrum from simple empirical frameworks to fully integrated farm-scale systems, differing in their ability to capture environmental and biological stressors. Empirical index models, such as TGC, provide rapid temperature-based growth estimates but generally ignore parasite effects. Phenomenological or allometric curve models fit observed growth trajectories, while bioenergetic mass-balance models explicitly link feeding, metabolism, temperature, and parasite loads to produce more mechanistic projections. Nutrient-budget/DEB-style models extend these capabilities by tracking protein, lipid, and other nutrient fluxes, enabling precision feeding and environmental

*(Continued on next page)*

impact assessments. At the most comprehensive level, integrated farm- or system-scale platforms embed bioenergetics within epidemiological and economic modules, allowing simulation of lice impacts, mortality, and production costs under varying SST scenarios. Spatially explicit and tissue turnover–based approaches add further refinement by incorporating habitat-specific parameters and reproductive energy costs. Among the 83 studies screened, most measured growth (often converted to weight), but relatively few addressed mortality, costs, or health effects, and only one explicitly linked lice to growth, highlighting a need for more holistic models. The 28 most relevant studies were grouped into five categories: (1) empirical/index models, (2) phenomenological/allometric curve models, (3) bioenergetic (mass-balance) models, (4) nutrient-budget/DEB-style models, and (5) integrated farm- or system-scale models.

**Discussion**

Choosing an optimal model for predicting Atlantic salmon performance under climate change requires balancing simplicity, mechanistic accuracy, and the ability to incorporate multiple stressors. Empirical indices like TGC are effective for rapid forecasts but cannot account for interactions between temperature, feeding, and parasite loads. Bioenergetic models, particularly when integrated with epidemiological and economic modules, allow scenario testing for feed strategies, lice-induced growth suppression, and treatment-related mortality, while incorporating spatial, temporal, and physiological dynamics. Stage-structured epidemiological models are good for simulating lice pressure, as they capture life-cycle stages, temperature-dependent development, and treatment effects, and can be parameterised for local conditions and climate projections. The most robust framework for sea-cage aquaculture is an integrated farm-scale system embedding a mechanistic bioenergetic core within parasite and economic sub-models, generating simultaneous outputs for growth, mortality, lice burdens, and costs. Such hybrids, already used to optimise treatment timing and assess climate-driven site changes, provide the precision and management flexibility needed for evidence-based decision support in modern salmon farming.

**Conclusion**

This review synthesises empirical, mechanistic, and integrated modelling approaches for post-smolt to adult Atlantic salmon under thermal and parasitic stress. Empirical models are operationally simple but lack mechanistic realism, while bioenergetic models offer greater predictive accuracy at the cost of higher data demands. Integrated bioenergetics–epidemiology–economics frameworks emerge as the most robust for climate adaptation planning, enabling simultaneous assessment of growth suppression, mortality, and economic impacts. Future developments should incorporate tissue turnover and reproductive energetics, integrate spatial–temporal environmental variability to capture site-specific differences, and link biological and economic modules to assess cost-effectiveness of adaptation measures. As warming seas and parasite pressures intensify, adopting holistic, mechanistically grounded models will be essential to maintain productivity, welfare, and profitability in Norwegian salmon aquaculture.

# USE OF β-GLUCANS IN FISH: AN UPDATE ON KEY FINDINGS AND EMERGING APPLICATIONS

João Fernando Albers Koch*, Robson Sfaciotti Barducci, Eduardo Yugo Yamashita

*Biorigin Company
18680-900, Lençóis Paulista
São Paulo, Brazil
e-mail: joao.koch@biorigin.net

**Introduction**

Aquaculture is rapidly emerging as a vital sector in global food production. However, one of its persistent challenges is effective health management. Increasing fish stocking densities often lead to heightened stress levels, which in turn contribute to the outbreak of serious diseases. While antibiotics have traditionally been used to address these issues, their application is now heavily regulated or even banned in many regions. As a result, there is a clear need for alternative strategies to enhance immune responses in fish. One promising approach involves the use of β-glucans, which have been studied for their immunostimulatory effects in fish for several decades.

This presentation will highlight key findings on the use of β-glucans in fish, demonstrating increased survival rates across various species when challenged with a broad range of bacterial pathogens. Data will be presented for both cold-water and tropical fish species. We will also discuss recent advances regarding the role of β-glucans in wound healing - an important factor in disease proliferation - as well as their capacity to enhance vaccine efficacy in salmon. Notably, pre-vaccination intake of β-glucans has shown to improve immune responses to both bacterial and viral infections.

Additionally, we will present findings on the dose-response relationship of β-glucans in tilapia at both optimal and suboptimal water temperatures. These results suggest that water temperature influences how different dosages modulate the immune system. Lastly, we will explore how β-glucans can significantly alter lipid metabolism in fish. Altogether, this presentation aims to provide a comprehensive overview of the multifaceted benefits of incorporating this important additive into fish nutrition, positioning them as a natural, sustainable strategy for improving aquaculture health and performance.

Glucan is a general term used to describe a group of polysaccharide polymers that are classified based on the type of glycosidic linkage they contain—either β- or α-linked. β-glucans derived from different biological sources often exhibit variations in their primary structures and conformations. The primary structure is defined by the type of glycosidic bonds, degree of polymerization, and branching patterns. In contrast, β-glucans conformations can appear as random coils, single helices, or triple helices, depending on factors such as the primary structure, intermolecular interactions, temperature, and solvent conditions.

β-glucans are found across a wide range of organisms, including bacteria, algae, fungi, and plants, each source producing structurally distinct types. Typically, their structure consists of a backbone made up of β-(1,3)- and/or β-(1,4)-linked D-glucopyranosyl units arranged in a non-repeating but non-random manner, with variable side chains branching off the main chain. Because of this structural diversity, the immunomodulatory activity and effectiveness of different β-glucans molecules can vary significantly, even among those with similar molecular weights, structures, and conformations.

Numerous studies have explored correlations between β-glucans biological activity and their molecular structure, size, branching frequency, degree of chemical modification, conformation, and solubility. However, due to often inconsistent or contradictory findings, broad generalizations should be approached with caution. A wide range of concentrations and administration routes, including oral delivery, have been tested, yet no consensus has been reached regarding the optimal source, molecular size, or physicochemical characteristics of β-glucans for immunomodulatory purposes.

**Method**

This presentation will summarize nine recently published scientific articles from leading international journals. These studies were carefully selected to highlight the diverse approaches and applications of β-glucans in fish nutrition. The articles written by Roberti Filho et al 2019, Do-Huu et al 2016, Koch et al 2021 and Fronte et al 2019 will be highlighted in the presentation.

*(Continued on next page)*

**Results**

The use of beta-glucan for fish:

1. Improves growth, survival rate against several bacterial pathogens;
2. Long periods of use of β-glucans, at the correct dosage, are beneficial to fish;
3. Acts in the modulation of the immune system and wound healing;
4. Increases tolerance to temperature stress;
5. Acts as a vaccine adjuvant;
6. Is associated with a modulation of the physiology, immunity and microbiota of the fish larvae;
7. Strengthen the salmon lice preventing effect;
8. Presents a synergistic association with vitamins important to antioxidant system;
9. Increases tolerance to stress due to exposure to ammonia;

**Conclusion**

To date, more than 3,000 studies have investigated the effects of beta-glucans on immune responses in fish. Despite this extensive body of research, several key questions remain unresolved. In particular, there is still limited understanding of the receptors involved in beta-glucan recognition and the downstream signaling pathways in teleosts. As a result, it remains unclear whether the observed immunostimulatory effects are due to direct action on leukocytes or indirect mechanisms—such as alterations in the gut microbiota composition.

Most existing studies have focused on short-term immune responses, typically lasting from a few days to several weeks. However, emerging research in innate immunity suggests that beta-glucans may also exert longer-lasting effects, potentially through a mechanism known as “trained immunity,” which may provide prolonged enhancement of immune function.

São Paulo, Brazil
e-mail: joao.koch@biorigin.net

**Introduction**

As shrimp farming techniques have evolved and intensified, concerns have arisen regarding the physiological stress and immune status of farmed shrimp. Historically, chemotherapy, such as the use of antibiotics, has been used to control disease outbreaks in shrimp farming. This has resulted in the broad spread of antibiotic-resistant pathogens and significant environmental contamination. As an alternative, a new generation of MOS-based prebiotics is emerging that achieves solubilization of the mannan layer within the yeast cell wall, making it more accessible and partially exposing the glucan layer. This synergistic process enhances the overall efficacy of these prebiotics. β-Glucan is a complex polysaccharide that has been shown to have remarkable immunostimulatory, anti-inflammatory and antioxidant properties in aquatic animals. The objective of this study is to evaluate the efficacy of second-generation MOS (solubilized MOS) at different levels in the diet of *P. vannamei*.

**Material and methods**

A control diet (C) containing commercial ingredients from the Brazilian feed industry was formulated to meet the recommended nutritional requirements for juvenile Penaeus vannamei. The diet was designed to be isoproteinic (360 g kg-1), and isoenergetic (4400 kcal kg-1). The commercial mannanoligosaccharides (MOS) source consists of 27.2% solubilized mannanoligosaccharides (Hypergen, Biorigin, São Paulo, Brazil). Additionally, three experimental diets were formulated, based on the control diet, incorporating a commercial MOS source to replace wheat flour at inclusion levels of 1.0g (0.27g mannans), 2.0 (0.54g mannans), and 4.0 g (1.08g mannans), of commercial solubilized MOS per kg feed-1. These diets were designated as M1.0, M2.0 and M4.0, respectively. The study was conducted over 60 days at the Laboratório de Carcinicultura (LACAR), of the Departamento de Pesca e Aquicultura (DEPAq) at the Universidade Federal Rural de Pernambuco (UFRPE), Brazil. During the feeding trial, the shrimps (initial weight 3.0 ± 0.04 g) were fed three times daily (8.00 am, 01:00 pm and 5:00 pm) with the experimental diets.

**Results**

At the end of the trial, higher performance (table 1) was observed in shrimp fed the diet supplemented with 1.0g solubilized MOS kg-1 ($p < 0.05$). MOS (1.0 g kg-1, 2.0 g kg-1) supplementation resulted in a significant improvement in gut morphology as evidenced by increased villus and enterocyte heights. In the ammonia (table 2) and nitrite stress tests, shrimp fed the MOS supplement showed improved resistance as indicated by higher survival rates and lower histological alterations in the gills (table 3) during stress periods. The economic benefits in the M1.0 and M2.0 treatment were the most favorable. The results show that MOS supplementation improves shrimp performance, shrimp gut health, and economic benefits.

**Conclusion**

To optimize economic and health benefits to *P. vannamei* in intensive synbiotic systems, supplementation with solubilized MOS at a level of 1.0 to 2.0 $kg^{-1}$ feed is recommended.

*(Continued on next page)*

Table 1. Performance of *P. vannamei* juveniles fed control and test diets with commercially solubilized mannanoligosaccharides in a synbiotic system for 60 days.

| Variables | Treatments | | | |

# EVALUATION OF THE INFLUENCE OF SELECTED FACTORS ON THE QUALITY OF GAMETES AND EMBRYONIC DEVELOPMENT OF GRAYLING (*Thymallus thymallus*)

T. Kodela, Simona Sušnik Bajec

Fisheries Research Institute of Slovenia
Ljubljana (Slovenia)
E-mail: tjasa.kodela@zzrs.si

## Introduction

Populations of grayling are declining across Europe due to a number of factors including climate change, pollution, regulation of watercourses and predation by piscivores (Persat, 1996; Uiblein in sod., 2005; Turek in sod., 2013; Didenko in sod., 2018). One measure to mitigate this decline is artificial breeding in fish farms and reintroduction into watercourses (Nykänen in sod., 2001; Ovidio in sod., 2004; Szmyt in sod., 2013). As grayling is not a commercially important species, breeding protocols for farms have not yet been optimized and the reproductive parameters of this species are poorly known, resulting in lower breeding success compared to more commercially interesting species. In our study, we therefore investigated the influence of various factors, with a focus on feed, on the quality of grayling gametes in order to improve the breeding process in fish farms.

## Materials and methods

The practical part of the study was carried out in two consecutive years at the Soča fish farm in Kobarid. At the beginning of the experiment, the breeding stock of grayling was divided into four tanks. In the first year, 50 fish aged three years (fish between the first and second spawning - first-year fish) were placed in each tank. In the second year, we continued the study with one-year-old fish that had survived the first year. Since there is no optimized feed specifically developed for grayling, we tested three different commercial feeds in the experiment. These included:: the lower-carbohydrate commercial salmonid feed INICIO 702 (feed 1), the carbohydrate-rich commercial feed INICIO Plus (feed 2) and a carotenoid-enriched feed, EFICIO Enviro 978 from the same manufacturer (feed 3). The main parameters used to assess the quality of the gametes were the fertilisation rate of the eggs after two hours, the survival rate to the eye stage and the hatching rate of the embryos. Egg quality was further assessed by analysing their biochemical composition, while sperm quality was determined by measuring progressive motility, sperm velocity and sperm concentration in seminal fluid.

## Results

When analysing the results, we found that the average fertilization rate of grayling was 70%, the survival rate to the embryonic stage with developed eyes was 25%, while the hatching rate of larvae was only 5%. Most eggs were lost by the end of gastrulation. We found that several factors influence the rearing of grayling on the farm, one of which is the age of the broodstock. The first time spawners had almost half the average absolute fecundity of the older fish, which was also reflected in the characteristics of their eggs. The eggs of the first fish were smaller (2.5 mm) and lighter (25 mg) than those of the older fish, whose eggs measured 2.7 mm and weighed 32 mg. The greatest differences between the eggs of first time spawners and older fish were found in the group of polyunsaturated fatty acids (PUFA) such as EPA, C18:4 n-3, C18:3 n-6 and C20:4 n-3, the content of which was lower in the eggs of first time spawners. The higher DHA/EPA ratio in the eggs of first time spawners makes them more likely that they will develop early mortality syndrome. The influence of age was also evident in males. Males at three years of age had significantly lower sperm velocity and progressive motility than males four years of age. In contrast, male grayling in the first year of the study had a higher sperm concentration in the seminal fluid than in the second year.

*(Continued on next page)*

The effect of feed on the reproduction of grayling was less than expected. The survival rate of embryos and larvae showed no differences depending on the type of feed fed to the broodstock, and there were also no differences in the average absolute fecundity. Nevertheless, we observed certain effects of the feed on the fatty acid composition of the eggs and the sperm concentration in the seminal fluid. In the females fed the carbohydrate-rich diet (feed 2), we observed lower levels of n-6 PUFA and higher levels of long-chain PUFA (LC PUFA) and long-chain n-3 PUFA (LC n-3 PUFA) in the biochemical composition of the eggs than in the other two groups. However, a higher sperm concentration in the seminal fluid was found in males fed a higher proportion of vegetable fats than in males fed a higher proportion of animal fats. A number of developmental deformities were observed In farm-raised eggs we noticed a number of developmental abnormalities such as the development of the head, eyes, jaws, malformed and curved spine and a deformed tail. These malformations did not occur in the wild-origin roe.

## Conclusion

We conclude that none of the commercial feeds used significantly improved the reproductive parameters of grayling. This may be attributed to the fact that the feeds were not specifically formulated to meet the nutritional requirements of this species. For successful grayling rearing in fish farms, new diets should be developed based on the biochemical composition of grayling eggs.

***Introduction:***
While fishmeal (FM) and fish oil (FO) offer optimal nutritional profiles for most farmed fish, their reliance on wild-caught stocks presents significant environmental challenges. In response, over the past decades, the aquaculture sector systematically re-evaluates feed formulations using potentially more sustainable alternatives, to reduce its dependency on capture fisheries. The shift to alternative ingredients affects key components like ω-3 long chain polyunsaturated fatty acids (LC-PUFAs), crucial for fish health and the nutritional value of the final product. Among them, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are known to modulate immune cell activity—including macrophages, neutrophils, T-cells, and others—by enhancing phagocytosis, cytokine and chemokine secretion, and cellular polarization. Recent studies have shown that the regulation of fatty acid metabolism-related genes (Xue *et al.*, 2020), as well as immune and disease resistance-related genes (Santigosa *et al.*, 2023), is affected when fish are fed diets with altered EPA:DHA ratios. These findings underline the critical role of EPA and DHA not only in growth and survival, but also in immune competence and overall fish welfare.

Within the Millennial Salmon project (Research Council of Norway #319987), we investigated the potential of novel feed ingredients to replace FM and FO in Atlantic salmon diets without compromising fish performance or health. The Millennial salmon project is a strategic partnership among world-leading European organisations spanning the value chain of the salmon farming industry. A key focus of the project was the evaluation of AlgaPrime™ DHA LS, a DHA-rich microalgae oil suspension (from *Schizochytrium sp*.) produced by Corbion, as an alternative to FO in salmon diets.

***Material & Methods:***
Atlantic salmon post-smolts (600 g) were reared to commercial size (~3.5 kg) in 20 sea cages in Mowi's field trial station (Averøy, Norway) using 6 diets where EPA+DHA from FO was replaced 0%, 20%, 40%, 60%, 80% and to 100%, with DHA from AlgaPrime™ DHA Liquid Suspension (DHA-Algae). Fish growth, health, welfare and different tissue proximate composition were assessed by Nofima, while smoked fillet quality was evaluated by both Nofima's professional sensory panel and Labeyrie Fine Foods laboratories. To investigate potential immunological effects of varying EPA:DHA ratios in the diet, head kidney macrophages were isolated from fish in the cage trial and stimulated *in vitro* with inactivated *Moritella viscosa* to mimic a bacterial challenge. Two timepoints (12 and 48 hours) were selected, representing the early and the late phase of inflammation, to assess whether elevated dietary DHA/EPA modulates the gene expression of immune and inflammatory response markers.

***Results & Discussion:***
Results demonstrated that 100% dietary FO replacement with DHA-Algae had no negative effect on salmon's performance parameters. Whole-body ω-3 content increased in proportion to dietary DHA-Algae inclusion, whereas the sum of fillet EPA+DHA levels gradually increased with replacement of FO with DHA-Algae in the diet, statistically significantly only between the control and 40% FO/ 60% DHA-Algae. These findings align with a similar study by Kousoulaki *et al.* (2020), reporting no adverse effects on salmon performance reared in sea cages alongside enhanced DHA content in the flesh replacing FO with *Schizochytrium sp.* biomass. Sensory profiling of both raw and smoked fillets revealed that diet has a subtle influence on flavour attributes (fish, feed, rancid, total flavour intensity) and juiciness. Collectively, these results indicate that DHA-Algae is a nutritionally valuable and organoleptically acceptable alternative to FO in salmon aquafeeds.

*(Continued on next page)*

Gene expression profiling of immune-related markers in head kidney macrophages revealed that dietary EPA/DHA levels modulated transcriptional responses following *in vitro* bacterial stimulation. Several genes showed significant or trending regulation by diet, immune stimulation phase (acute or recovery), or both. Notably, *cfdl, lox3, LOC106609000, LOC106594896, LOC101448046, and LOC106584449*—associated with macrophage activation, complement-mediated defence, and inflammatory signalling—exhibited clear time- and diet-dependent responses, supporting roles in innate pathogen sensing and inflammation. This aligns with previous studies showing PUFA-mediated modulation of pathogen recognition receptor (PRR) and cytokine signalling (Li *et al.*, 2020). Diet significantly influenced *cfdl, LOC106609000*, and *LOC101448046*, with *cfdl* and *LOC101448046* showing diet-related differences at both time points. In addition, *LOC106594896* and *LOC106584449* were strongly influenced by both diet and stimulation phase, suggesting roles in cytokine signalling or macrophage metabolic reprogramming—consistent with immune–metabolic shifts described in fish macrophages (Wentzel *et al.,* 2020). During the recovery phase, most responsive genes showed downregulation across diets, with *LOC106594896* in some diets (control and 60%FO) shifting towards increased expression—indicating potential immune resolution and reprogramming. Such patterns support previous findings that dietary DHA/EPA ratios can modulate immune gene expression (Zuo *et al.,* 2012). Together, these shifts reflect the differential regulation of salmon macrophage responses by dietary fatty acids across immune activation and recovery phases.

## Introduction

Feed is considered as one of the major factors for sustainable aquaculture development in the world, and its composition directly influences feed intake and efficiency of fed aquatic animal production. At the same time, the dietary composition of the aquafeeds can have a direct impact on the gut microbiota modulation, ultimately affecting host growth and health (Butt & Volkoff, 2019). Besides the diet, various factors, such as host genetics, age and environmental conditions, are also known to have an influence on the gut microbiota of aquatic species (Mougin & Joyce, 2023). Especially the role of genetics on the microbiota composition of aquaculture fish has been less explored, but few studies have shown that host genotype variability can also alter the microbiota composition (Kokou et al., 2018; Piazzon et al., 2020). At the same time, the host genotype or strain can affect the nutritional utilization of the diet and fish growth rates (Li et al., 2019). Whether differences in the feed utilization between different fish strains link to differences in the gut microbiota composition, remains largely unexplored. In the present study, we explored this research question, by testing three strains of European seabass, fed with two diets, differing in macronutrient composition. Moreover, we utilized a long-read sequencing approach targeting the full-length 16S ribosomal gene for the first time in European seabass, in order to evaluate its applicability in characterizing its mucosal microbial communities under different experimental conditions.

## Materials & Methods

A 10-week feeding trial was performed, evaluating two diets with different macronutrient composition: a diet with high carbohydrate content (HOD), and a diet with high fat content (LOD). The diets were formulated to have a similar dietary protein/dietary energy ratio (DP/DE; ~19 kJ/g dry matter). Three strains of European seabass (average weight 67.8g ± 0.58), originating from IFREMER (Palavas-les-Flots, France) were stocked in separate tanks; an Atlantic strain (ATL), an East Mediterranean strain (MEDEAST) and a West Mediterranean strain (MEDW). The fish were fed twice daily (09.00 and 15.00) up to satiation level. At the end of the five-week period, the diets were switched, and the feeding resumed for five more weeks. Gut mucosal samples were taken for microbiota analysis at week 5 and week 10 from 3 fish per tank. Prior to characterizing the microbial communities of the gut samples, we performed a comparative analysis using both Illumina and Oxford long-read sequencing, targeting the 16S rRNA gene, to understand whether profiling of gut microbial communities is affected by the sequencing platform, and in order to optimize the sequencing conditions. After DNA extraction, gut mucosal samples were sequenced using our optimized protocol for Oxford Nanopore targeting the full-length 16S. Diversity and microbial composition analysis, along with statistical analysis were performed using the microeco R package.

## Results & Discussion

Comparison of different sample types using Illumina MiSeq targeting the V3-V4 region, and long-read sequencing using Oxford Nanopore targeting the full-legth of the 16S rRNA gene, showed some differences in the microbial profiling, especially with relation to the abundance of Proteobacteria and Firmicutes phyla. This has been also previously reported in gilthead seabream microbiota, when performing a similar comparison (Toxqui-Rodríguez et al., 2023). However, when testing whether these differences are affecting the sensitivity of our platform, no significant effects were observed, suggesting that Oxford Nanopore can be used for the characterization of mucosal microbiota.

*(Continued on next page)*

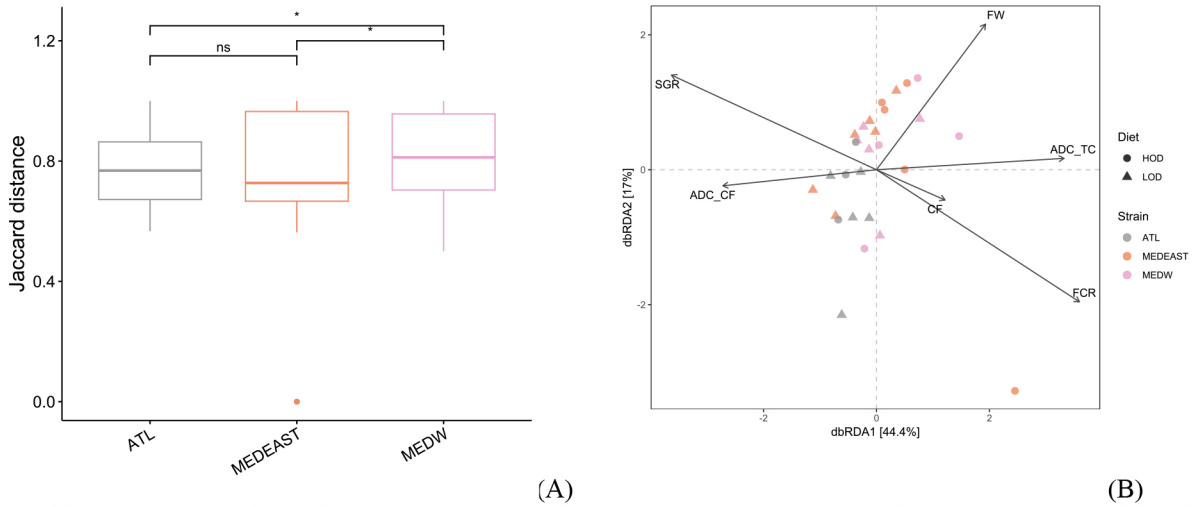

*Fig1. (A) Within group dissimilarity, indicating the level of variance in the microbiota composition of the three European seabass strains. (B) Distance-based redundancy analysis, using growth performance, feed efficiency and digestibility as explanatory variables. SGR, Specific growth rate; FW, final weight; CF, condition factor; FCR, feed conversion ratio; ADC, Apparent Digestibility Coefficient; CF, crude fat; TC, total carbohydrates.*

When comparing the mucosal samples coming from different diets, microbial alpha diversity did not show any significant differences ($P > 0.05$); however, an effect of the strain was found to affect gut microbial structure. Interestingly, we found a higher dissimilarity within the gut microbiota composition of the West Mediterranean strain compared to that of the Atlantic and East Mediterranean strain. Specifically, we found a lower individual variability within the Atlantic strain (Fig1A), which could indicate a more homogenous genetic structure of this strain, making the microbiota of those individuals more similar to each other.

In a similar fashion, a clear separation of Atlantic strain was observed when correlating the structure of microbiota data with growth and digestibility parameters by the distance-based redundancy analysis (dbRDA; Fig1B). The dbRDA plot also may indicate a different capacity of the Atlantic strain in the utilization of different diets. These could be potentially explained by a different coping capacity with dietary changes, and particularly carbohydrate digestion. Similar observations in genetically selected fish were reported by Torecillas et al. (2023), demonstrating capacity to reshape their microbiota to better adapt to the diet.

To conclude, diet did not cause any clear patterns in the gut microbiota diversity of European seabass. However, we observed an effect of the fish strain on the gut microbiota structure and variability, which correlated to different growth rates in the Atlantic strain.

# SHORT-TERM STORAGE OF RAINBOW TROUT (*Oncorhynchus mykiss*) SPERM: DETERMINATION OF DIFFERENT EXTENDERS, EXTENSION RATES AND IN VITRO CONDITIONS

Saheed Kolawole *, Güneş Yamaner

Department of Aquaculture
Faculty of Aquatic Sciences
İstanbul University
Onaltı Mart Şehitleri 2
34134, İstanbul, Turkey
solakolawole62@gmail.com

## Introduction

Aquaculture is vital for addressing global protein demands, yet broodstock management challenges, particularly in gamete quality, hinder its progress (Liao & Chao, 2009). Short-term sperm storage is a practical technique to synchronize gamete availability in species like rainbow trout (*Oncorhynchus mykiss*), where asynchronous maturation between males and females is common (Mañanós et al., 2009). Sperm quality during storage is influenced by oxidative stress, which can be mitigated by antioxidants such as Vitamin C, Vitamin E, melatonin, and glutathione peroxidase (Shaliutina et al., 2013). This study evaluates the effect of these antioxidants on the quality and fertilization capacity of rainbow trout sperm during short-term storage, comparing broodstocks from their 1st and 3rd spawning years.

## Materials and methods

Sperm samples were collected from rainbow trout broodstocks in their 1st and 3rd spawning years (Year 1 and Year 3). Samples were stored for 28 days at 4°C, either undiluted (fresh sperm) or diluted with extenders containing Artificial Seminal Plasma (ASP), Vitamin C, Vitamin E, Vitamin C+E, Glutathione, Melatonin, or Glutathione + Melatonin. Sperm quality was assessed through motility duration (seconds), live sperm percentage, spermatozoa concentration ($x10^9$/mL), fertilization rates, and morphological characteristics (head and flagellum length). Statistical analyses included ANOVA and Games-Howell Post hoc tests to evaluate differences across treatments, storage days, and spawning years.

## Result and Discussion

Vitamin E significantly enhanced sperm motility across both spawning years, achieving the highest average motility in Year 1 (43.4%) and Year 3 (48.9%), outperforming Vitamin C (23.1% in Year 1, 22.1% in Year 3) and Vitamin C+E (23.4% in Year 1, 23.2% in Year 3) ($p < 0.0001$), likely due to its role in reducing lipid peroxidation (Aitken & Clarkson, 1988). A three-way ANOVA confirmed significant effects of year ($F = 169.792$, $p < 0.0001$), treatment ($F = 274.846$, $p < 0.0001$), and storage day ($F = 7523.168$, $p < 0.0001$) on motility, with Year 3 generally showing higher motility. The Year × Treatment interaction ($F = 17.369$, $p < 0.0001$) indicated varying treatment effects between years, with melatonin improving in Year 3. Figure 1 shows that motility declined over 28 days, with Vitamin E and Artificial Seminal Plasma (ASP) maintaining higher motility longer than Vitamin C and Vitamin C+E. Live sperm percentages also decreased over time, with Vitamin E maintaining the highest viability (60.2% in both years). Fertilization rates dropped to 0% by Day 28, with Year 3 showing higher initial rates (18.56% on Day 0 vs. 16.11% in Year 1), reflecting better baseline quality in older fish (Büyükhatipoglu & Holtz, 1978). Spermatozoa concentration was higher in Year 1 (e.g., 7.43 $x10^9$/mL for fresh sperm) than Year 3 (5.43 $x10^9$/mL) ($p = 0.005$). Morphological analysis revealed larger head lengths in Year 3 (e.g., 3.46 μm for melatonin) and shorter flagellum lengths (e.g., 26.80 μm for Vitamin C) compared to Year 1 ($p < 0.0001$), indicating age-related changes (Billard, 1992). Table 1 summarizes average motility percentages, highlighting Vitamin E's superior performance. These findings suggest Vitamin E is a promising antioxidant for short-term sperm storage in rainbow trout, with age influencing treatment efficacy.

Email:adiallo@clonbioeng.com

Barley protein is emerging as a transformative, sustainable alternative to traditional protein sources in aquaculture feeds. Developed through innovative processing techniques that concentrate the protein fraction from the grain, Barley Protein Concentrate (BPC) addresses both the nutritional and environmental challenges facing the industry. Extensive trials have demonstrated that BPC can fully or partially replace fishmeal without compromising growth, feed conversion efficiency, or product quality across a range of commercially relevant species, including Atlantic salmon, Sea bream, Sea bass, Rainbow trout, and Yellowtail.

In large-scale commercial and research settings, BPC-based diets have consistently matched or exceeded the performance of conventional feeds. For example, trout fed diets with significant BPC inclusion (up to 26%) showed equivalent growth rates (SGR 1.43 %/day), feed conversion (1.05) and protein efficiency ratios (2.32), compared to those fed fishmeal-based diets, with some trials indicating improved energy retention and protein digestibility (up to 89%). Similar positive outcomes have been observed in sea bream and yellowtail, confirming the versatility and efficacy of BPC across both freshwater and marine species.

Beyond nutritional performance, BPC offers substantial sustainability benefits. Barley cultivation is less resource-intensive than other major crops, requiring less water and grown typically without irrigation across diverse climates, while the BPC production process eliminating any waste by utilizing all fractions of the grain. By reducing reliance on fishmeal and soy protein-both associated with significant environmental impacts, BPC supports the development of a more resilient and eco-friendly aquaculture sector while delivering excellent growth performance with no antinutrient factors.

This presentation highlights the production processes, testing, and commercial application of barley protein concentrate, underscoring its proven performance and critical role in advancing sustainable aquaculture.

# POLAR LIPIDS IN FEED FOR ATLANTIC SALMON FARMED UNDER ARCTIC CONDITIONS

## Introduction

Replacing fishmeal and fish oil with plant-based ingredients in Atlantic salmon diets has led to concerns regarding gut health and welfare, including excessive lipid accumulation (intestinal steatosis) and inflammatory reactions. Some of these issues are likely linked to altered nutrient profiles, including low choline levels in plant ingredients. Choline is critical for lipid transport, membrane structure, and methylation, and its deficiency is strongly associated with intestinal steatosis in salmon. Studies have shown that dietary choline, particularly as phosphatidylcholine or choline chloride, can prevent such symptoms [1]. Factors such as high dietary fat, warmer water temperatures, and rapid growth increase choline demand, especially in Arctic farming conditions where steatosis prevalence shows large seasonal variations. Data from the Arctic Salmon Research Centre (2016–2024) show a marked increase in steatosis during September–December, i.e. during the warmest period with high growth and feed intake. The current study aimed to assess the effect of krill meal - rich in phosphatidylcholine - on intestinal steatosis, mucosal health in gut and skin, flesh quality, and overall performance of Atlantic salmon farmed under Arctic conditions. It also sought to determine whether krill-derived choline differs from choline chloride in preventing steatosis, potentially supporting more targeted supplementation strategies for enhanced health and production outcomes.

## Materials and methods

The trial was conducted at the Cermaq farming site at Storholmen (Bekkarfjorden, Finnmark, 70°20′09″N 23°19′36″E) using 9 open 120 $m^2$ sea cages, each stocked with 200,000 smolts averaging 108 g in Aug 2023. The trial started when fish reached an average estimated body weight of 300 g in Oct 2023. The fish were fed either a commercial diet with total choline supplied from 15% fishmeal only (Ctr) or a diet with high total choline from 10% krill meal + 5% of fishmeal (KM) or a diet with high total choline similar to KM diet from a combination of 15% fishmeal and choline chloride supplementation, respectively (ChCl), in triplicate cages each. Fish were fed Ctr and ChCl diets throughout the trial period (Oct 2023-Dec 2024) while fish were fed KM diet from Oct 2023-May 2024 and then continued to be fed the Ctr diet for rest of the trial period. All three diets contained similar gross composition, designed to meet the known nutritional requirements of Atlantic salmon. Pellet size and dietary composition were adjusted to fish size. Fish were initially sampled in Oct 2023 after being fed a commercial diet and subsequently at four sampling time points in Dec 2023, Apr, Sep, and Dec 2024, after feeding the experimental diets. Possible effects of the diets on performance, general morphology, fish welfare, gut- and skin health, nutritional status and sensory quality were evaluated by a comprehensive analytical package.

## Results and discussion

The fish grew from an initial body weight of 0.3 kg to an overall average body weight of 3.8 kg during the feeding trial, corresponding with an overall thermal growth coefficient of 3.44 from Oct 2023-Jan 2024. The body weight of the fish was affected by both the diet and time. Fish fed the diet supplemented with choline from krill meal (KM) as main source or fish meal and choline chloride (ChCl) in the diet showed generally lower growth compared to the fish fed the control diet with choline supplied only from fish meal. The final weights of Ctr, KM and ChCl groups were 4.1, 3.6 and 3.7 kg respectively in the last sampling point in Dec 2024. Feed conversion ratio and average mortalities for the trial period did not differ significantly among diet groups. Average mortalities were 3.8% in Ctr, 4.1% in KM and 3.5% in ChCl groups, mainly due to infections caused by *Parvicapsula pseudobranchicola*.

*(Continued on next page)*

Occurrence of skin ulcers was low across the feeding groups, with no significant difference due to dietary treatment. On the contrary, supplementation of KM or ChCl showed indications of reduced welfare in terms of increased scale loss (ChCl), eye bleeding and higher scores for red belly (both ChCl and KM) in Sept 2024. Skin health, as evaluated by blood plasma antibody levels, skin morphometrics and transcriptomics showed generally few clear effects of diet. KM supplementation seemed to enhance the integumentary health of Atlantic salmon; however, this improvement was not sustained after supplementation ended.

With regards to sensory quality, high inclusion level of choline from fish meal and choline chloride showed positive effects on fillet yield, however there was no effect on fillet color. Some negative effects with reference to melanin deposition, gaping, and texture, were observed. The fatty acid composition of the muscle generally reflected the type of feed treatment for each group, which was expected.

The prevalence and severity of intestinal steatosis symptoms were relatively low in all three diet groups during the period Oct 2023-Sept 2024, indicating that the choline requirement was met for most of the fish during this period. In contrast, moderate to marked intestinal steatosis was observed in most of the fish at the last sampling time point in Dec 2024. No statistically significant differences among diet groups were registered, but there was a trend towards ChCl-fed fish (having the highest dietary choline levels) displaying less severe steatosis symptoms. In this regard, it should be mentioned that analysed choline levels varied less than originally formulated between Ctr, KM, and ChCl fish groups. Dietary choline levels in the diets that were fed from April 2024 and throughout the remaining part of the trial, were 3.1 and 3.4 g/kg for the Ctr and ChCl diets, respectively. These levels fall within the range of the estimated choline requirement of 3.4 g/kg for post-smolt salmon of about 0.5 kg when fed a diet with 29% lipid [1]. However, the lipid level of the current diets was higher, about 34%. As increasing dietary lipid level has been shown to increase severity of steatosis, and thereby the choline requirement [2], it is possible that the choline requirement was not fully met in the latter part of the present trial. Further studies with greater contrasts in dietary choline levels are needed to better understand choline requirements in salmon under varying production conditions.

Overall, this study found that 11% inclusion of krill meal replacing fish meal from a diet containing 16% fish meal had no positive effect on growth, feed utilization, overall mortality and welfare, skin and gut mucosal health, or fillet quality.

## Introduction

The widespread use of conventional plastics in food packaging has led to major environmental concerns due to their non-renewable origin, persistence, limited biodegradability and inefficient waste management (Bucci et al., 2005; North & Halden, 2013). In response, there is a growing focus on sustainable alternatives such as bioplastics - biodegradable material derived from renewable sources - aiming to reduce the environmental footprint and support circular economy goals (Joseph et al., 2023; Rosenboom et al., 2022). In addition, the food industry is confronted with the urgent challenge of minimizing food waste while maintaining food safety and quality (Uysal-Unalan et al., 2024). Fish are among the variety of food products demanding effective packaging solutions (Lionetto & Esposito Corcione, 2021). Therefore, this study investigated the development of plasticized poly(3-hydroxybutyrate) (PHB) films for application as sealing layers in the packaging of sea bream (*Sparus aurata*) fillets. The objective was to assess their performance in microbial load control and propose a novel, environmentally sustainable packaging solution that preserves the quality of the product.

## Materials and methods

The films produced via the solvent casting method were prepared from film-forming solutions (FFS), using PHB dissolved in chloroform, with the addition of plasticizers such as polyethylene glycol (PEG 200, 3350, 8000). A series of preliminary experiments optimized key parameters including polymer concentration (8–10% w/v), solvent type, temperature and mixing time, to achieve homogeneous solutions and films with suitable thickness and integrity. Final films were standardized to 80-100μm thickness using a precision applicator and evaluated for their mechanical (tensile strength, elongation at break, Young's modulus), optical (CIELab color, UV-Vis light transmittance, opacity) and barrier (water vapor transmission rate) properties. Additional analyses included swelling behavior in aqueous media, surface wettability (contact angle), and surface free energy (SFE), providing a comprehensive assessment of the material's performance. The film with the most desired mechanical properties was selected and placed as a sealing layer in the packaging of sea bream (*Sparus aurata*) fillets. Microbiological tests were performed to monitor microbial spoilage in fillets stored under controlled refrigeration conditions (4°C) for shelf life evaluation.

## Results and Discussion

The investigation into PHB film production revealed that polymer and plasticizer concentration, stirring/heating duration, and casting temperature significantly influenced the films' final properties. The desired formulation was achieved by dissolving 8% w/v PHB with 20% w/w PEG200 in chloroform under prolonged stirring near the solvent's boiling point, followed by solvent casting at 60ºC. This composition yielded films with superior mechanical stability, high elongation at break, and a uniform appearance. PEG3350 and PEG8000 showed poorer compatibility and performance, with PEG8000 also presenting miscibility issues at higher concentrations. The selected formulation (C20PEG200) exhibited favorable visual and UV-Vis barrier properties but showed limitations in water contact, including increased hydrophilicity, water-induced shrinkage, and high water vapor permeability. Microbial spoilage and sensory degradation in fish fillets demonstrated that PHB-based films can serve as alternative packaging materials for fresh fish fillets, without compromising quality and shelf life. The shelf life of gilthead seabream fillets was estimated at 5-6 days at 4 °C for all tested packaging materials.

**Introduction**

Phosphorus (P) plays a vital role in fish diets, contributing to bone formation and mineralization (Lall, 2002). Zebrafish (*Danio rerio*) is an established model in nutritional research (Antinero et al., 2023, Molinari et al., 2025) and is responsive to the same factors known to cause deformities in farmed fish (Costa et al., 2018; Printzi et al., 2024). Previous studies have shown that dietary P influences bone mineralization in zebrafish and other species post-metamorphosis i.e., after the development of the skeleton has been completed (Witten et al., 2019; Cotti et al., 2020). However, little is known about its impact during the early larval period, i.e., during the development of zebrafish skeleton. This study investigates how varying dietary phosphorus and calcium levels affect skeletal development, mineralization patterns, and deformities in zebrafish larvae and the the post-metamorphosis skeleton, with the aim of improving larval nutrition and skeletal health.

**Materials and methods**

To evaluate the effects of dietary phosphorus (P) and calcium (Ca) on zebrafish larval skeletal development, three experimental diets with varying P/Ca levels were formulated: Diet A (3.20% P / 1.67% Ca), Diet C (2.20% P / 1.90% Ca), and Diet G (2.22% P / 1.62% Ca). A commercial zebrafish feed (Zebrafeed, Sparos) served as a control. Skeletal quality was assessed at approximately 7 mm and 10 mm total length (TL) by analyzing vertebral column mineralization and skeletal abnormalities, respectively. At 10–11 mm TL, fish underwent a swimming challenge test (SCT) to evaluate vertebral resilience against haemal lordosis.

**Results and discussion**

The mineralization rate of the vertebral column was significantly influenced by dietary phosphorus and calcium during the critical growth window of 5.5–7.5 mm total length (TL) (ANOVA, $p < 0.05$). Fish under regime G (low P / low Ca) exhibited significantly lower centra mineralization (6–7 mm TL: 12.5 ± 11.9; 7–8 mm TL: 24 ± 9.9) than those in regimes A (high P / low Ca), C (low P / high Ca), and N (control), which all showed similarly higher values (e.g., A: 6–7 mm TL: 25.2 ± 10.6; 7–8 mm TL: 30.7 ± 1.2).

Skeletal deformities were significantly influenced by diet ($p < 0.05$). Regime A (high P / low Ca) showed the lowest rates of light kyphosis (10 ± 6%), scoliosis (7 ± 6%), resorption (1 ± 1%), and branchiostegal ray twisting (41 ± 5%). These rates increased in regime N (control) (25–57%), were higher in C (42–59%), and peaked in G (low P / low Ca) with 34%, 47%, 28%, and 77% respectively.

Fish from regime A exhibited the lowest overall incidence of haemal lordosis (74.7%), significantly lower than those from regimes C and G (92.2% and 91.4%, respectively). In severe cases, only 15.7% of regime A individuals were affected with significantly higher 57.8% and 45.7% in regimes C and G, respectively.

Overall, our results demonstrate that increased dietary phosphorus significantly enhanced skeletal development, mineralization, and deformity resistance in zebrafish larvae while higher dietary calcium levels partly compensated for low phosphorus.

*(Continued on next page)*

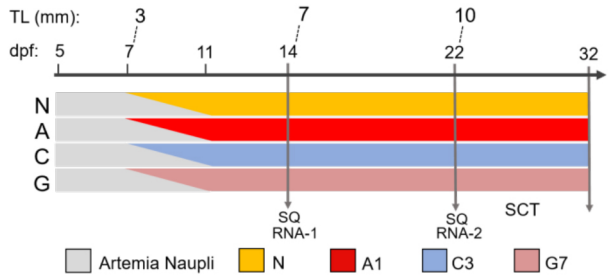

Figure 1. The feeding regime followed Printzi et al., (2021). Samplings for larval skeletal quality (SQ) took place at early (14 dpf) and late larval stages (22 dpf). The swimming challenge test (SCT) took place after the last sampling. Trials were performed in triplicate. Dpf, days post fertilization.

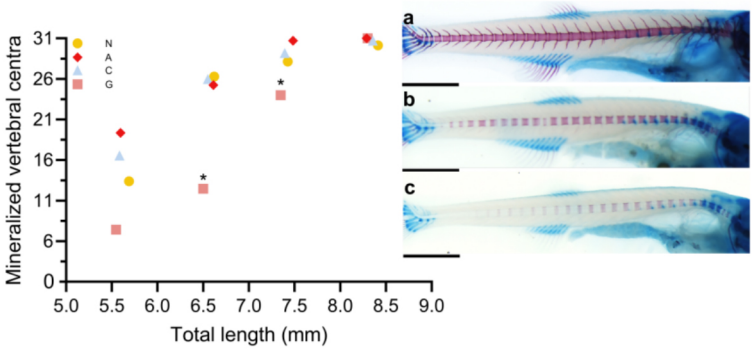

**Figure 2.** Effect of dietary components on the mean number of mineralized vertebral centra at 14 dpf. Significant differences are indicated by the asterisk (*) ($p<0.05$). (a-c) Representative samples for each regime of the same length (7.2 mm TL) but with different mineralization status. a) Regime A b) Regimes N and C, and c) Regime G.

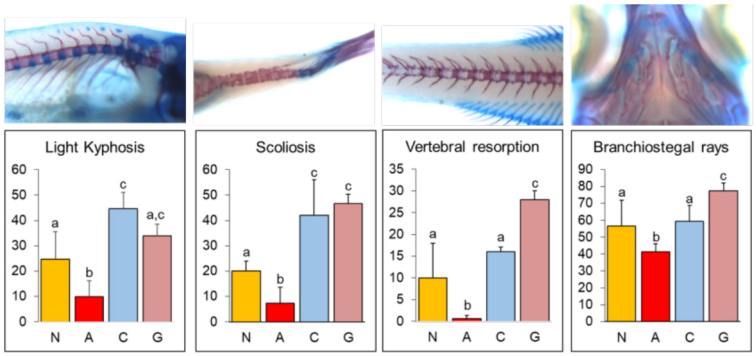

**Figure 3.** (a-g) Effect of dietary components on the frequency (±SE) of skeletal abnormalities in zebrafish larvae at 22 dpf. (a) Light kyphosis. (b) Scoliosis. (c) vertebral resorption (d) twisted branchiostegal rays.

*(Continued on next page)*

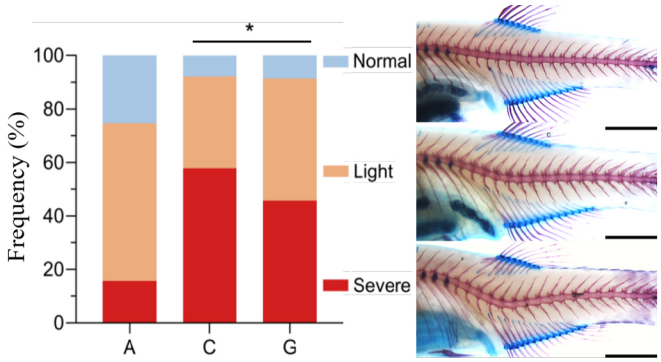

**Figure 4.** Proportion (%) of normal, light and severe lordotic fish per each diet.

Overall, our results demonstrate that increased dietary phosphorus significantly enhanced skeletal development, mineralization, and deformity resistance in zebrafish larvae while higher dietary calcium levels partly compensated for low phosphorus.

E-mail: krasilnikova@frov.jcu.cz

**Introduction**

Sturgeons (Acipenseriformes) are ecologically and economically significant fish facing severe population declines, necessitating advanced conservation strategies. Sperm cryopreservation is critical for ex-situ genetic preservation and enhancing aquaculture productivity through artificial fertilization. Developing effective cryopreservation protocols requires understanding the unique characteristics of sturgeon spermatozoa, particularly their dependence on potassium ions (K+), which are critical for inhibiting motility. We hypothesized that a hypotonic extender containing only 1 mM KCl could effectively inhibit sperm motility and support successful cryopreservation, offering an alternative approach compared to standard sturgeon protocols.

**Materials and methods**

This study evaluated sperm cryopreservation protocols across sterlet (*Acipenser ruthenus*), Siberian (*A. baerii*), Russian (*A. gueldenstaedtii*), and stellate (*A. stellatus*) sturgeons, comparing a novel cryomedium (1 mM KCl, 11% methanol, 2.5% ethylene glycol) against a traditional cryomedium. Two cryopreservation formats were tested: 0.5 ml straws with rapid cooling on a polystyrene raft in a Styrofoam box, and 4.5 ml and 10 ml cryotubes with slow, controlled cooling in a programmable freezer. Post-thaw motility, spermatozoa volume changes during equilibration, fertilization success, and embryogenesis were assessed.

**Results**

The hypotonic cryomedium preserved high post-thaw motility: Siberian sturgeon achieved 46±6% (0.5 ml straws and 4.5 ml cryotubes); Russian sturgeon, 31±10% (0.5 ml straws) and 40±12% (10 ml cryotubes); and stellate sturgeon, 46±10% (0.5 ml straws), 39±8% (4.5 ml cryotubes), and 44±11% (10 ml cryotubes). Fertilization and hatching rates were robust, with Siberian sturgeon reaching 81±16% and 79±15% (0.5 ml straws), and 84±6% and 82±7% (4.5 ml cryotubes), and Russian sturgeon achieving 60±20% and 57±20% (0.5 ml straws), and 62±11% and 48±13% (10 ml cryotubes). Ethylene glycol induced initial sperm cell shrinkage followed by volume normalization, unlike methanol, which caused minimal volume changes. Although curvilinear velocity (VCL) was significantly reduced in the hypotonic cryomedium compared to fresh sperm and traditional cryomedium ($p<0.05$), fertilization success remained unaffected, and embryos showed no significant morphological abnormalities.

**Conclusion**

This study confirms the effectiveness of the 1 mM KCl-based hypotonic cryomedium for cryopreserving sperm across multiple sturgeon species, and sample volumes, supporting both small-scale (0.5 ml straws) and large-scale (4.5–10 ml cryotubes) cryopreservation without compromising reproductive outcomes. This protocol offers a versatile, scalable approach for sturgeon sperm cryopreservation, advancing conservation and aquaculture practices by facilitating large-scale breeding.

# DO YOU KNOW YOUR SYSTEM'S MICROBIOME? – MICROBIOME MONITORING AS A KEY MANAGEMENT TOOL FOR AQUATIC ANIMAL HEALTH

T. Krebs[1,*], M. Adamek[2], V. Jung-Schroers[2] and M. Kählig[1]

[1]Kählig Antriebstechnik GmbH, Pappelweg 4, D-30179 Hannover, Germany
[2] Fish Disease Research Unit, University of Veterinary Medicine Hannover, Bünteweg 17, D-30559 Hannover, Germany
E-Mail: krebs@kag-hannover.de

The microbiome plays a key role in maintaining health and ecological stability in aquatic systems, especially in closed and controlled environments such as recirculating aquaculture systems (RAS), aquaria and other closed aquatic environments. Recent progress in microbial research and molecular analysis has exposed the intricacies and variability of these communities, highlighting their influence on water quality, pathogen control and the overall well-being of aquatic animals.

Despite its importance, microbiome monitoring has rarely been integrated into routine husbandry, largely due to the lack of accessible tools. This project presents a newly developed, user-friendly test kit that allows microbiome composition in keeping systems to be assessed in a practical, standardized and reliable way. By analyzing bacterial community diversity, the tool enables the early detection of microbial imbalances and facilitates informed intervention. Case studies from both private aquaria and professional facilities demonstrate that routine microbiome monitoring can lead to measurable improvements in water quality and animal health.

Integrating microbiome diagnostics into regular husbandry offers significant potential for research, conservation and education, as well as operational benefits. Standardized sampling protocols and the sharing of microbial data across institutions could facilitate large-scale comparative studies and advance our understanding of aquatic microbiomes. This could also support the development of best practice guidelines.

Our test kit promotes the wider use of microbiome-based diagnostics as a preventive management tool based on evidence, connecting cutting-edge microbial science with practical aquaculture health management.

# EFFECT OF ELEVATED CARBON DIOXIDE ON GROWTH PERFORMANCE AND SOMATIC PARAMETERS IN RAS-BASED JUVENILE PIKEPERCH (*Sander lucioperca*)

T. Pěnka, V. Kučera*, L. Ostolasa Perez-Cruz, O. Malinovskyi, J. Kolářová, and T. Policar

## Introduction

In recirculating aquaculture systems (RAS), carbon dioxide ($CO_2$) accumulates due to respiration and microbial activity, potentially impairing fish growth performance. Pikeperch (*Sander lucioperca*) is a promising candidate for intensive aquaculture in Europe (Müller-Belecke and Zienert, 2008; Overton et al., 2015; Policar et al., 2019), yet limited information is available regarding its tolerance to elevated $CO_2$ levels (Skov, 2019). This study aimed to evaluate the effects of three dissolved $CO_2$concentrations (0, 15, and 30 mg/L) on the growth, feed efficiency, and physiological condition of juvenile pikeperch over a rearing period. Understanding $CO_2$ related responses is essential to optimize water quality management and welfare in intensive RAS.

## Materials and Methods

Juvenile pikeperch (initial total length ~254 mm, body weight ~117 g) were randomly assigned to one of three $CO_2$ treatments: Low (0 mg/L), Medium (15 mg/L), and High (30 mg/L). Each treatment was replicated in triplicate tanks (50 fish per tank) connected to a shared RAS with controlled temperature, oxygen, and photoperiod. Fish were reared for 112 days and fed a commercial diet to apparent satiation by belt feeders. Key performance parameters, including total length (TL), standard length (SL), body weight (BW), and Fulton's condition factor (K). Fish were measured at the beginning and end of the trial. Feed conversion ratio (FCR), specific growth rate (SGR), thermal growth coefficient (TGC), and survival rate (S) were calculated. Additionally, organosomatic indices (HSI, FSI, GSI, KSI) were determined at the end of the experiment. Fin erosion among tested groups was assessed at the beginning and end of the experiment. Variation in body weight was assessed using coefficient of variation (CVBW). Differences between treatments were analyzed by one-way ANOVA with Tukey's post-hoc test ($\alpha$ = 0.05). The assessment of the pectoral, ventral, dorsal, caudal, and anal fins, along with the rate of fin erosion, was conducted based on the methodology described by Policar et al. (2016).

## Results

Initial biometric data showed no significant differences among treatment groups ($P > 0.05$). At the end of the trial, fish reared under high $CO_2$ (30 mg/L) had significantly lower TL, SL, BW, and K compared to the low $CO_2$ group ($P < 0.05$). Final BW was highest in the low $CO_2$ group (297.34 ± 69.60 g), compared to medium (250.02 ± 69.62 g) and high (232.93 ± 60.81 g) $CO_2$. Feed efficiency was negatively affected at higher $CO_2$ concentrations, with FCR increasing from 1.09 (low $CO_2$) to 1.82 (high $CO_2$). SGR and TGC decreased with increasing $CO_2$, though differences were marginally non-significant ($P = 0.063$ and $P = 0.066$, respectively). No significant differences were observed in survival, organosomatic indices, or CVBW. No differences in fin erosion were observed between the tested groups.

## Discussion

Elevated $CO_2$ concentrations in RAS significantly reduced the growth and condition of pikeperch, likely due to increased metabolic costs and reduced feed efficiency. These findings suggest that $CO_2$ concentrations above 15 mg/L may compromise fish performance, despite not affecting survival or physiological indices. Maintaining lower $CO_2$ levels appears beneficial for maximizing growth and feed efficiency in intensive pikeperch culture. The study highlights the need for $CO_2$ control in RAS design and operation to ensure optimal fish welfare and production outcomes.

# ASSESSEMENT OF CHARACTERISTICS OF SOME PLANT VARIETIES (BASIL, MULLEIN, AND ROSEMARY) ON GOLDFISH (*Carassius auratus*)

Gencer Bakan[1], Semra Küçük[2]

[1]Adnan Menderes Üniversitesi Fen Bilimleri Enstitüsü, 09100 Aydın
[2]Adnan Menderes Üniversitesi Su ürünleri Mühendisliği Bölümü, 09100 Aydın

**Introduction**

Nowadays, anesthetics are the important substances in aquaculture applications. They are consist of two kinds, chemicals and herbals. In our research, 3 different anesthetic plants were used in order to see the efficiency of them to goldfish. Actually, anesthesia is virtual things to eleviate stress reactions and injury damages during handling procedures (measuring weighing, grading, tagging, vacination, transport, blood sampling, biopsies of gonads, gamet collection, etc.) in aquaculture (Coyle et al., 2004; Mylonas et al., 2005). Several anesthetics are commonly used for many differnt fish species such as tricaine metansulfonate (MS-222), phenoxyethanol, quinaldin, benzocain, clove oil and lavander (Mercy et al., 2013). There is a lot of considerations to decide which anesthetics is suitable for which species of fish. In this study, the anesthetic effects of three different herbal anaesthetics (basil, mullein and rosemary) on goldfish were investigated.

**Materials and amethods**

Basil was perchased and mullein and rosemary were collected from located area. Then, they were dried in the laboratory. Then dried plants were grained and each powdered plant samples were added to 100 g, 200 g ve 300 g to 1.5 L distiled water. Each mixture was mix a time a day within 3 days in the frige +4 ºC condition and saved and plant solutions were prepared. Then, they were used to prepare the concentrations of 30, 40, 50, 60, and 70 ml/L for each plant. Induction and recovery times were indicated and saved for those concentrations. For each concentration, 5-10 fish were used and totally 225-450 fish were used. These anesthetic efficiency of 3 herbal plant species were researhed to evaluate for aquaculture applications.

**Results**

For 100 g, 200 g, 300 g of rosemary plant dose and 30-70 ml/L concentrations were formed 0.16-0.98 in I1, 1.90-5.02, in I2, 0.20-1.29 in R1 and 1.53-3.47 in R2. For 100 g, 200 g, 300 g ofmullein plant dose and 30-70 ml/L concentrations were found as 0.14-0.55 in I1, 3.07-8.18 in I2, 0.22-2.84 in R1 and 1.26-6.58 in R2. For 100 g, 200 g 300 g of basil plant döşe and 30-70 ml/L concentrations were saved as 0.15-0.73 in I1, 1.29-6.23 in I2, 0.31-1.33in R1 and 1.32-3.59 in R2.

Herbal anesthetic usege caused some histological disorders in goldfish in this research. In rosemary usage, hyperplasia, degenerations; in mullein usage, fusion, hyperplasia and edemma; in basil usage, hyperplasia, and aneurism were seen in gills. In rosemary usage, degenerations in cell walls, necrotic structure formation, granulomatic structure developments; in mullein usage, valuolations, picnotic nuclei, necrotic structure formation; in basil usage, picnotic nuclei, necrotic structure formation, and granulomatic structure developments were dedected in liver. In rosemary usage, renal tubular vacuolations, renal tubular degenerations, and granulomatic structure developments; in mullein usage, renal tubular vacuolations, granulomatic structure developments and renal tubular degenerations; in basil usage, renal tubular vacuolations, renal tubular degenerations, granulomatic structure developments were occured in kidney.

# APPLICATION OF LOW-COVERAGE WHOLE GENOME SEQUENCING FOR UNCOVERING THE GENETIC BASIS OF FERTILITY IN ARCTIC CHARR (*Salvelinus alpinus*)

K. Kurta[1], S. Immler[2], H. Jeuthe[3], C. Palaiokostas[1]

[1]Swedish University of Agricultural Sciences, 750 07, Uppsala, Sweden
[2]School of Biological Sciences, University of East Anglia, NR4 7TJ, Norwich, UK
[3]Aquaculture Center North, Åvägen 17, 844 61 Kälarne, Sweden
E-mail: khrystyna.kurta@slu.se

## Introduction

Arctic charr (*Salvelinus alpinus*) is a key cold-water salmonid for aquaculture in the Nordic countries (Olk et al., 2020) and a species of high ecological (Jónsdóttir et al., 2024) and evolutionary interest (Kess et al., 2021; Kurta et al., 2025; Skoglund et al., 2015). In Sweden, the national Arctic charr breeding programme was initiated over 40 years ago and continues to deliver consistent genetic gains of about 10% per generation (Carlberg et al., 2018). While the programme has successfully improved growth performance through selective breeding (Nilsson et al., 2010), fertility and other reproductive traits have received relatively little attention, despite their critical importance for production efficiency. Sperm quality traits such as concentration and motility have been reported as important bioindicators of male fertility in fish (Gallego et al., 2013) and livestock (Ramirez-Diaz et al., 2023), and are therefore of high interest in genetic studies.

Whole genome sequencing (WGS) has been shown to successfully reveal fine-scale, "cryptic" genomic variation that may not be detected with limited marker sets (Andersson et al., 2024). Low-coverage whole genome sequencing (lcWGS) offers a cost-efficient way to genotype hundreds to thousands of individuals at genome-wide scale. This approach enables the discovery of variants associated with complex traits, and characterization of population-genetic structure in both wild and farmed stocks.

This study focused on applying lcWGS to identify genomic regions linked to sperm quality traits in Swedish Arctic charr. By aligning the sequencing reads to a newly assembled reference genome developed for the same selectively bred Arctic charr strain, we aim to improve mapping accuracy and enhance the resolution of detected fertility-associated loci, strengthening the genomic resources available for selective breeding.

## Materials and methods

At this stage of the study, 150 selectively bred males were sequenced and phenotyped for sperm concentration, motility, and swimming velocity, forming the basis for a pilot genome-wide association analysis. These individuals represent a subset of a larger phenotyped cohort of ~1,000 fish, providing substantial scope for future expansion of the genomic dataset. At the first stage of the study, individual whole genome sequencing libraries were prepared for n = 150 DNA sample using a custom Tn5-based protocol (Picelli et al., 2014) and pooled for sequencing on Illumina NovaSeq S4 lanes. The obtained reads were aligned to newly assembled reference genome available for the Swedish selectively bred Arctic charr. Low-coverage (1-2×) sequencing data were processed using ANGSD v0.933, a toolkit specifically designed for genotype likelihood estimation from low-coverage sequencing data. Genotype likelihoods were used to estimate population-specific allele frequencies and assess the population structure. In addition, a genome-wide association study (GWAS) was performed to identify genomic regions associated with sperm quality traits in the selectively bred Arctic charr strain.

## Results

Preliminary QC metrics indicated consistent sequencing depth and uniform genome coverage across individuals, enabling reliable estimation of genotype likelihoods. We further expect to identify genome-wide regions associated with sperm quality traits that could not be detected using smaller SNP panels (Kurta et al., 2022) or limited sample size (Kurta et al., 2023). Analyses will also leverage a newly available, high-quality reference genome for selectively bred Arctic charr, increasing mapping accuracy and enabling finer resolution of candidate regions. These findings will provide valuable insights into the genomic architecture of male fertility in Arctic charr and support the integration of fertility traits into ongoing selective breeding programmes.

**Introduction**

Sea lice has for many years been a headache and a major cost driver for the Atlantic salmon (*Salmo salar* L.) farming industry, and many different technologies for removing the sea lice on infected salmon have been developed in the last decades. Blue Lice is a start-up company which has developed a system for capturing the free-swimming sea lice life stages before they are able to attach to their host by using specific illumination signals to attract and capture them via pumps and filters. The system is currently deployed at several sea farms, but although the farmers claim the technology has a positive effect on the sea lice levels, , the actual effect has still not been quantified and documented due to the many challenges related to conducting research in full-scale field trials. In order to assess how effective Blue Lice's technology is in capturing free-swimming sea lice at salmon sea farms, we developed a system for counting the number of captured sea lice in real-time using camera systems and machine learning.

**Materials and method**

We present a high-speed flow-through imaging system (measuring 400mm x 200mm x 130mm) capable of acquiring sharp, high-resolution (22 MP) images of small particles (0.2 mm x 0.2 mm) passing through a flow cell with sea water passing through at velocities up to 0.5 m/s, the system is capable of imaging and processing 14L of water per minute. Built into this system is a state-of-the-art edge computer (Nivida Jetson AGX Orin) for real-time processing of the imaging data and a 4G modem for automatically transmitting the results to the cloud for real-time visualization of the estimated amount of sea lice captured by the Blue Lice technology.

The technology includes a water filtering system that automatically cleans the filters by reversing the flow direction through the filter, re-directing it to a buffer tank where sea lice and other particles with the seawater can pour through to an interchangeable filter bag, essentially up concentrating the seawater. The system is capable of pumping 900 L/m, meaning when implementing the flow-through imaging system between the buffer tank and the interchangeable filter (see Fig. 1), we are also capable of imaging and processing 900 L/m.

**Results**

So far, a prototype has been thoroughly tested in a lab environment at SINTEF SeaLab in over 200 simulated filter cleaning operations. In this process, we have gathered over 150.000 images of seawater containing salmon louse copepodids and nauplii, copepods (*Acartia tonsa*) and preserved samples collected from the Blue Lice technology deployed at a fish farm. The data has been used to train a neural net (FCN; Fully Convolutional Network) to automatically detect sea lice (Fig. 2).

**Conclusions**

So far, the system has been proven accurate for detecting and counting sea lice in a simulated lab setup. However, when it is implemented in a real-world scenario, we expect the image data to be very different, with higher biodiversity and changes between seasons. Using the 4G modem, we can upload image data while the system is in the field so that we are able to improve the detection algorithm and training data on the go, increasing the systems capability and accuracy over time. This system can also, with time, detect other species, giving it a use-case beyond only counting sea lice.

## Introduction

The rising price and limited availability of fish meal (FM) is driving the search for an alternative protein source to ensure sustainable aquaculture (Hussain et al., 2024). Pollock by-product meal (PPBM) is one of fishery by-products after processing dried fish. It is mainly composed of dried head, fin, skin, and flesh remaining after manufacturing process of the dried pollock. This study aims to evaluate dietary substitution effect of FM with PPBM on growth of olive flounder (*P. olivaceus*), and economic analysis.

## Materials and Methods

A total of 600 juvenile (6.48 ± 0.016 g; mean ± SEM) fish were randomly assigned to 15, 300-L flow-through tanks (40 fish/tank) in triplicate. All experimental diets were formulated to be isoproteic (51.0%) and isolipidic (12.0%). The control (Con) diet contained 60% FM. In the Con diet, 20%, 40%, 60%, and 80% of FM were substituted with PPBM, referred to as the PPBM20, PPBM40, PPBM60, and PPBM80 diets, respectively (Table 1). Fish were hand-fed to apparent satiation twice a day for 50 days. The formula of economic profit index (EPI) was employed by Montenegro et al. (2022)'s study. One-way ANOVA and Duncan's multiple range test were used.

## Results

At the end of the 50-day feeding trial, weight gain (WG) and specific growth rate (SGR) of olive flounder fed the Con, PPBM20, and PPBM40 diets were significantly ($P < 0.0001$ for both) higher than those of fish fed the PPBM60 and PPBM80 diets (Fig. 1).

## Conclusion

In conclusion, up to 40% of FM could be substituted with PPBM in the 60% FM-based diet without significantly negative effects on the growth performance of olive flounder, and EPI.

# INCLUSION EFFECT OF VARIOUS LEVELS OF JACK MACKEREL MEAL IN OLIVE FLOUNDER (*Paralichthys olivaceus*) DIETS SUBSTITUTING 50% OF FISH MEAL WITH CHICKEN BY-PRODUCT MEAL ON THE GROWTH PERFORMANCE, FEED UTILIZATION, AND ECONOMIC ANALYSIS

Yong Woo Kwon[1*] and Sung Hwoan Cho[2]

[1]Ocean Science and Technology School, National Korea Maritime and Ocean University (Republic of Korea)
[2]Division of Convergence on Marine Science, National Korea Maritime and Ocean University (Republic of Korea)
E-mail: yosecimi@g.kmou.co.kr

## Introduction

The low-fish meal (FM) diets often lead to deteriorated palatability, reduced feed consumption, and lowered growth performance of fish. Incorporating feed enhancer or feed ingredient exhibiting strong feed enhancer response to a target fish into the low-FM diets could improve their palatability and feed consumption by fish. Jack mackerel meal (JMM) has been reported to exhibit the strongest attractiveness to olive flounder among 15 protein ingredient sources (Jeong et al., 2022) and its inclusion in the low-FM diets substituting various levels of FM with animal protein sources could improve feed consumption and growth performance of olive flounder (Islam et al., 2024 a). This study aims to evaluate the inclusion effect of various levels of jack mackerel meal in diets substituting 50% of FM with chicken by-product meal (CBM) on the growth performance and feed utilization of olive flounder (*Paralichthys olivaceus*), and economic analysis.

## Materials and Methods

Seven experimental diets with isoproteic (55.0%) and isolipidic (12.0%) were prepared (Table 1). In the control (Con) diet, 60% FM was included. In the Con diet, 50% of FM was substituted with CBM, and then 0%, 10%, 20%, 30%, 40%, and 50% levels of JMM were included at the expense of FM, referred to as the CJ0, CJ10, CJ20, CJ30, CJ40, and CJ50 diets, respectively. A total of 525 juvenile olive flounder (initial mean weight of fish of 12.1g) were distributed into 21, 50-L flow-through tanks (25 fish/tank) with triplicate. All fish were hand-fed to apparent satiation twice a day for 8 weeks. All chemical composition was analyzed according to AOAC methods (1990). Also, the economic analysis was conducted. One-way ANOVA and Tukey's honestly significant difference tests were applied using IBM SPSS Statistics (version 24.0; IBM Corp., Armonk, NY, USA), followed by regression analysis to identify the best-fit model when significant difference was found, and orthogonal polynomial contrast (linear, quadratic, and cubic) was conducted to determine the most suitable model between all dependent variables and the inclusion levels of JMM.

Table 1. Ingredient and chemical composition of the experimental diets (%, DM basis)

| Ash | 11.7 | 11.6 | 11.5 | 11.4 | 11.4 | 11.4 | 11.3 |

*(Continued on next page)*

**Results**

At the end of the 8-week feeding trial, weight gain and specific growth rate (SGR) of fish fed the CJ50 were significantly ($P < 0.005$ for both) higher than those of fish fed the CJ0, CJ10, and CJ20 diets. Feed consumption of fish fed the CJ50 diet was significantly ($P < 0.001$) higher than that of fish fed the CJ0 and CJ10 diets. However, no significant ($P > 0.05$) difference in feed utilization was found among dietary treatments. In orthogonal polynomial contrast, weight gain, SGR, and feed consumption of olive flounder were revealed linear ($P = 0.0001$ for all) relationships with inclusion levels of JMM in diets substituting 50% of FM with CBM. Linear relationships were determined to be the most suitable models between inclusion levels of JMM in diets substituting 50% of FM with CBM and weight gain ($Y = 0.073619X + 34.9873$, $P < 0.0001$, $R^2 = 0.7319$), SGR ($Y = 0.000025X + 0.0243$, $P < 0.0001$, $R^2 = 0.6735$), and FC ($Y = 0.083305X + 33.8201$, $P < 0.0001$, $R^2 = 0.6573$) in regression analysis. Economic profit index (EPI) of the CJ50 diet was significantly ($P < 0.01$) higher than that of the Con, CJ0, and CJ10 diets.

**Conclusion**

Inclusion of 50% of JMM in the low-FM diet replacing 50% FM with CBM is the most recommended treatment based on the growth performance and feed availability of olive flounder as well as the economic return (EPI) to farmers.

## Introduction

Automation technologies are increasingly influencing aquaculture by enhancing fish monitoring, biomass estimation, and feeding management. Traditional manual sampling methods remain labor-intensive, invasive, and subject to bias, underscoring the need for non-intrusive and scalable alternatives (Fernandes et al., 2020). Stereo vision systems combined with deep learning (DL) provide potential solutions; however, existing applications are often expensive, have depth limitations, or are complex to implement. In this study, we present a compact, portable, and cost-effective stereo vision system integrated with a DL model for automated fish weight estimation, developed for offshore aquaculture environments.

## Materials and methods

The proposed system consists of a Luxonis OAK-D PoE stereo camera and a PoE-48V portable power supply, both housed in a waterproof enclosure (Figure 1, left panel). The camera captures synchronized RGB and depth images at 20 frames per second (FPS) and operates within a depth sensing range of 0.7 to 12 meters. The system was deployed in a commercial offshore aquaculture cage managed by Kimagro Fishfarming Ltd. (Figure 1, middle panel) stocked with Mediterranean gilthead seabream (Sparus aurata), following an underwater calibration procedure to optimize the camera parameters. During the field study, the system was suspended 2 meters below the sea surface and recorded continuously for 30 minutes, resulting in 291 RGB-depth image pairs. Simultaneously, 220 fish were manually weighed (mean weight=122.91 g, standard error of the mean (SEM)=1.69 g) to provide ground truth (GT) data. The weighed fish were isolated with a splitting net in the cage to ensure accurate correspondence between estimated and measured weights. Three anatomical keypoints—the snout tip, body midpoint, and middle caudal rays—were detected on the fish body in RGB images using the DL model (YOLOv11n-Pose) and subsequently aligned with corresponding depth data to enable 3D reconstruction of the fish body. Fish length was computed as the Euclidean distance between the three identified keypoints (Figure 1, right panel) and converted to weight using a species-specific empirical length–weight relationship: $W=0.0123L^{3.0284}$ (Mehanna, 2007). An overview of the proposed methodological framework is presented in Figure 2.

## Results and discussion

The system achieved a mean estimated weight of 124.29 g (SEM=6.00 g) after the removal of outliers using the interquartile range (IQR) method, resulting in an absolute error (AE) of 1.39 g and a percentage error (PE) of 1.12% compared to the ground truth (GT) mean weight. Further analysis indicated that training the DL model on ~250 annotated fish instances was sufficient for accurate keypoint localization, while stable weight estimations could be obtained using 60 inference images, corresponding to approximately 9 minutes of camera recording time. Results also demonstrated that including the fish body midpoint as a third keypoint in length and weight estimation improved the system's accuracy and precision by better accounting for body curvature. Outlier analysis further revealed that deviations in weight estimations were primarily associated with artifacts in the depth maps rather than inaccuracies in the DL-based keypoint detections or morphological abnormalities on fish body, highlighting the importance of reliable depth acquisition. The system's compact dimensions (17.8 cm (L) × 10.2 cm (W) × 25.4 cm (H)), low production cost (~€620), minimal operational requirements (9 minutes), and straightforward installation further support its viable application for automated fish biomass monitoring in offshore aquacultures.

## Conclusion

This study demonstrates that integrating a portable stereo vision system with DL enables accurate, efficient, and non-invasive fish weight estimation in offshore aquaculture settings. By reducing time, operational costs, and labor demands, the proposed system represents a robust, accurate, and scalable solution for advancing precision aquaculture practices.

## Introduction

Aquaculture is one of the main levers for feeding tomorrow's world, but this activity is affected by the global warming and the increase in ocean temperatures, which strongly affect the oxygen level in the water, a key parameter for the fish health and fish appetite -regulated by both temperature and oxygen level-. Oxygen fluctuation will lead to a daily change in fish appetite for Atlantic salmon Salmo *sala***r** *(Remen 2016),* called DFI – *Daily Feed Intake-* and will affect the operations in the sea, mainly on cage feeding management.

In this context, management support through live environmental data is no longer sufficient, and the predictive need becomes essential to adjust daily decisions, in particular feeding actions, which concentrate the environmental impact of the activity, through its production -origin of raw materials- and its use -can be polluting if poorly managed and wasted.

BiOceanOr's predictive tools, based on AI and machine learning from local and external data collection, which help the aquaculture industry by reducing the environmental footprint of activities while maintaining high performance, is one of the solutions to tomorrow's challenges.

## Results

Based on temperature and oxygen prediction (Figure 1), we can identify the ideal and less opportune windows times for feeding during the next working days, anticipating the best appetite window for fish.
By analyzing farmer's state of the art, we can estimate how much feed is given into suboptimal period (Figure 2) and asses the margin of improvement. The Figure 2 below illustrates a pre-deployment analysis in Chile, where 21.2% of the feed is given outside the optimal periods, resulting in feed waste, inefficient productivity, economic loss and unnecessary environmental impact.

By adjusting the feeding time based on the prediction, it becomes possible to move from the red-orange suboptimal zone -21,2% feeding- (Figure 2) to the optimal green zone.

This new feeding management process led to (i) a reduction in the amount of feed not consumed, and improvement in the eFCR of production, (ii) an improvement in the growth performance SGR, by optimising the amount of feed assimilation.

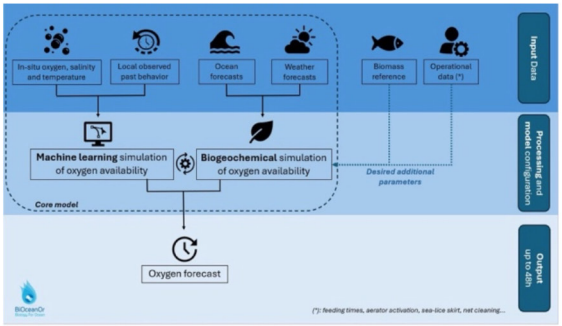

**Figure 1**: AI Technology use -Machine Learning and Biogeochimical model- to enable environmental oxygen forecast in the sea cage production.

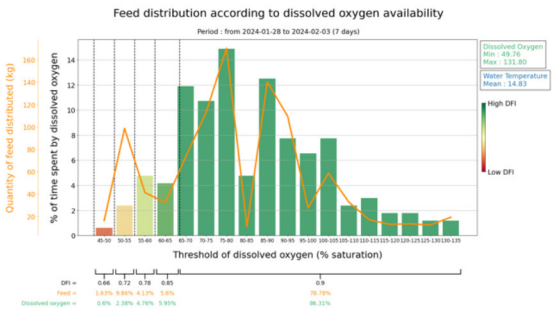

**Figure 2**: : Feeding analysis done before the use of digital tools highlighting the suboptimal feeding done when fish appetite DFI -Salmo *salar* -is low

*(Continued on next page)*

**Conclusion**

As the cost of feed to the farmer represents up to 70% of the annual expenditure in the salmon industry and in the carnivorous species in general, this marine oxygen modelling in the sea has a specific value proposition to assist the farmers in their day to day operations, helping them to better manage the feeding process. It is a good example of how technical innovation can lead to both (i) a positive environmental impact through less food lost to wildlife, and (ii) an economic gain for the activity through eFCR & SGR improvement.

**Discussion and perspective**

The tool has been developed through two main innovations, (i) oxygen prediction capacity (Figure 1) and the (ii) specific knowledge of the Atlantic salmon -Salmo *salar*- metabolism. The application to other species is a new challenge, as the effects of global warming are strongly observed in the Mediterranean Sea, where the temperature each summer is approaching the maximum tolerance threshold for commercial fish such as sea bass -Dicentrarchus *labrax*- and sea bream -Sparus *aurata*-, and where the improvement could be much higher than what we use to observe with the Atlantic salmon.

# FADING OF MELANIN SKIN SPOTS: A POTENTIAL FOR NON-INVASIVE AND AUTOMATED MONITORING OF STRESS AND WELFARE IN ATLANTIC SALMON *SALMO SALAR* USING COMPUTER VISION

## Introduction

Intensive salmon farming is challenged by unsustainable mortality rates, which necessitate the need for new welfare indicators aiming at reducing these losses. Current welfare indicators in the industry are either invasive or yield a signal only after a problem has developed (e.g. external indicators such as emaciation, wounds, scale loss, etc). Previously, it has been shown that heritable variation in stress responsiveness is reflected in melanin pigment patterns in several vertebrate species, including salmonid fish (Kittilsen et al., 2009). In the case of Atlantic salmon and rainbow trout, high post-stress cortisol levels are specifically associated with a reduced incidence of melanin – based markings (i.e., black skin spots). In the current study, we have investigated the possibility of using these spots as a non-invasive indicator of welfare in salmon based on our hypothesis that fading (or bleaching) of these spots occur in stressed salmon.

## Methods and Methodology

A dataset of 130 salmon was collected by photographing each fish before and after a 17-hour standardized confinement stress, during which they were kept in a tank with reduced water levels until their dorsal fins were completely submerged. All images were standardized using image-preprocessing technique based on the darkest and brightest pixels in each image. These processed images were used to train computer vision models to identify the operculum region and detect spots within it. Spot localization data from the model was then used to extract grayscale values and spot areas, which were analyzed to assess changes in response to stress.

## Results and Discussion

The grayscale values and areas of 676 uniquely identified spots were compared before and after stress. The grayscale values were clustered and plotted on a grayscale. We observed significant bleaching, as well as a reduction in the areas of the post-stress spots (P-value < 0.0001, two-way ANOVA). The spots were also analyzed sidewise, but no significant effect was observed on bleaching or the changes in spot areas.

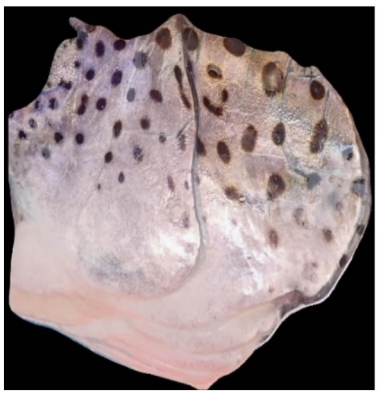

Fig 1: Left side operculum region of interest

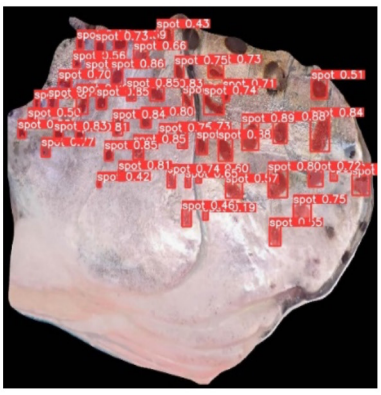

Fig 2: Detected Spots in operculum ROI

*(Continued on next page)*

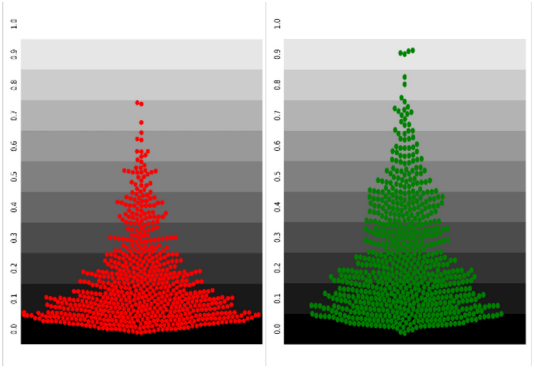

Fig 3: The red cluster (mean = 0.1934, median = 0.144) represents pre-stress grayscale values, while the green cluster (mean = 0.275, median = 0.22) shows post-stress values.

This work addresses a significant challenge in the Chilean salmon farming industry, the world's second-largest producer, by developing an innovative microencapsulated feed additive containing recombinant antimicrobial peptides derived from the innate immunity of salmonids (CATH-FLA). The aim is to reduce dependence on antibiotics and combat diseases such as *Piscirickettsia salmonis*. Using bioinformatics and *E. coli* fermentation, the chitosan-encapsulated peptides provide gastric protection and targeted intestinal delivery, thereby reducing pathogen-induced cell death while minimizing inflammation. In this work, we scale up the production to 20L fermentation and evaluate the stability and biological activity of chitosan-microencapsulated CATH-FLA peptide under different storage conditions over 120 days. Results demonstrated that the microencapsulated peptide remained stable at 10°C and 20°C for 120 days, with minimal release at pH 2, and controlled release at pH 8. Scanning electron microscopy revealed pseudo-spherical microparticles with temperature-dependent size reduction over time, with the smallest particles observed at 37°C. Biological activity evaluated in SHK-1 salmon kidney cells treated with the pH 8-released peptide showed significant upregulation of pro-inflammatory markers IL-1β (1.5–2.5-fold) and IL-8 (2.0–2.7-fold), suggesting that CATH-FLA maintains its immunostimulatory properties. The optimal storage temperature was determined to be 4°C, balancing stability and particle integrity. This study supports the potential of chitosan-microencapsulated CATH-FLA as a stable and bioactive delivery system for aquaculture applications. This sustainable solution could cut antibiotic use by 10–20%, lower production costs, and improve market competitiveness, aligning with global demand for eco-friendly aquaculture.

# INCORPORATING PALM KERNEL MEAL, COWPEA HUSK AND SOYBEAN HUSK AS PROTEIN SOURCES IN CATFISH DIETS: EFFECTS ON GROWTH, HEMATOLOGY AND INTESTINAL HISTOLOGY

## Introduction

Feed is necessary in aquaculture, just like in animal husbandry, to guarantee good production, particularly in intensive culture systems that demand a lot of input (Boyd, 2020). _Since feed makes up over 50% of the entire production expenses in the aquaculture business, feed is a crucial component (Mzengereza et al., 2014). The costliest feed ingredient in aquafeeds is the source of protein (Lim et al., 2023). Fishmeal is considered the gold standard protein due to its balanced amino acid content, which is perfect for the healthy growth and development of fish (Perez-Velazquez et al., 2019). Fish by-products and wild-caught fish are used to make fish-meal, an industrial product (Wan, 2015)._Fishmeal is a major source of aquafeed worldwide. However, the rising demand for fish and fish products has caused its price to continuously rise, greatly affecting the market price (Jannathulla et al., 2019). To cut feed costs, several plant-based proteins are now utilized in place of fish-meal, either totally or partially (Jannathulla et al., 2019). The main objective of using plant-based proteins is to offer fish-meal as a more affordable substitute. Finding a less expensive option isn't the only factor, though (Gutasi, 2021). Moreover, the production of these plant-based proteins needs to be sustainable without affecting the health and growth of fish (Magbanua and Ragaza, 2024). Consequently, the aim of this study was to evaluate the effects of soybean husk, cowpea husk, and palm kernel meal as protein sources on growth performance, feed utilization, intestinal histology, and health of catfish using full blood count and liver function test as indicators.

## Materials and Methods

### *Formulation of the experimental diets and feeding*

Table 1 shows the experimental diets used for this study. In formulating the diets, substantial amount of fish meal was progressively replaced with soybean husk (SBH), cowpea husk (CPH) and palm kernel meal (PKM) until equal amounts of protein (approximately 35%) were obtained. Following procedures previously described by Ayisi et al. (2017), the formulated diets were prepared. *C. gariepinus* were fed to apparent satiation, three times daily at 8:00 am, 12 noon and 4:00 pm for ten weeks.

### *2.2. Experimental conditions and design*

The experiment was carried out in concrete tanks with dimensions of 1.5 m x 1.5m x 1.2 m (length, breadth and depth). Five hundred healthy *C. gariepinus* with initial weight of approximately 2.5 g were purchased from a commercial farm and transported to the rearing facility. Prior to the onset of the trial, fish were acclimatized to the rearing conditions for 2 weeks and fed on commercial diet with protein content of 32%. At the onset of the trial, the fish were distributed into four groups with duplicates and fed their respective diets. Each tank was stocked with fifty fish.

### *2.3 Measurements of the biological indices*

Feed utilization and growth performance were measured following formulas previously used by Mutalib et al. (2023).

### *2.4 Blood biochemical analysis*

After 10 weeks of feeding trial, blood from experimental fish were sampled and blood biochemical analysis performed as previously described by Abarike et al. (2018).

*(Continued on next page)*

### *2.5 Proximate composition*

Samples from whole body fish and experimental diets were sent to the laboratory for protein, lipid, moisture, and ash analyses. The AOAC (2003) standard methods, as reported by Ayisi et al. (2021), were employed to analyze the aforementioned parameters.

### *2.6 Histological examination*

Six fish per group had sections of their intestines removed, which were then quickly preserved in a Bouin solution for histological examinations. Samples of tissue were promptly preserved in a Bouin solution. After that, fixed samples were subjected to a series of alcohol solutions with increasing grades (70–100 percent) to dehydrate them. Following the dehydration procedure, tissues underwent xylene deparaffinization, paraffin embedding, 5 µm sectioning, and Hematoxylin and Eosin (H&E) staining (Ismail, et al. 2020). A Leica light microscope was used to examine the slides, and an eyepiece camera was used to capture the images. ImageJ version 1.54 was used to determine the target cells in each section.s

### *2.7 Statistical analysis*

The gathered data was statistically analyzed using Graph Pad Prism (V.5.03). The data is presented in tables using the standard error of the mean (SEM), which is represented as the mean ±. To compare treatment means, One-way Analysis of Variance and Tukey's multiple tests were applied to all the data. Differences are considered significant for all data at the 0.05 probability level ($P<0.05$). Pearson's correlation was conducted to ascertain the relationship between selected parameters. Results of correlation analysis is presented in figures.

## Results

The results indicated that inclusion of these alternative protein sources had significant effects on growth performance and feed utilization compared to FM diet. The weight gain recorded in this study was as follows: SBH (119.5±68.02) > CPH (113.2±53.14) > FM (104.3±56.82) > PKM (86.73±31.51). Feed conversion ratio ranged from 1.25±0.57 (SBH) to 1.52±0.56 (PKM). *C. gariepinus* fed the diet PKM had the lowest protein efficiency ratio (2.09±0.76), followed by those fed the FM (2.57±1.40) and the CPH diet (2.74±1.28). To a larger extent, the dietary protein sources significantly influenced serum hematology parameters. *C. gariepinus* fed the FM diet had the highest white blood cells count (133.0±2.51), which was significantly higher than all other groups ($p < 0.0001$). The range of red blood cell values observed in this study was 2.08±0.13 to 2.62±0.13. Histological examination indicated modifications in intestinal morphology, suggesting possible metabolic adjustments to the experimental diets. Fish fed the FM had the highest villus height (441.2±22.6), followed by SBH (398.3±7.51), PKM (279.2±15.65), and CPH (142.3±10.84). Villus width and muscular thickness also followed this pattern, with fish fed the FM diet having the largest villus width (153.7±9.06), significantly greater than all other groups ($p<0.0001$). Overall, incorporating CPH, and SBH into catfish diets appears to be a viable replacement for conventional fishmeal-based diets; however, further studies are required to determine optimal inclusion levels for achieving maximum growth and well-being.

# NEW TECHNOLOGY FOR MAPPING OF DARK SPOTS IN SALMON FILLETS

T. Larsson

Norwegian Institute of Food, Fisheries and Aquaculture Research (Nofima)
Box 210
NO-1431 Ås, Norway
E-mail: Thomas.larsson@nofima.no

Dark spots in salmon fillets represent a significant and costly quality issue for the aquaculture industry; distinct and large spots have been reported to cause an economical loss of 24 to 44%. Previous surveys have shown that the occurrence of dark spots in Norwegian salmon farming averages around 15-20%, with considerable variation between fish groups.

The current project aims to continue the survey by first developing new technology for easy and efficient registration of dark spots on the fillet line. In addition to presenting preliminary data from the survey, the presentation will showcase the technology developed in the project: 1) a camera for automatic detection of dark spots through image analysis; 2) a touchscreen-based solution for manual registration. Data from the registrations are collected in a database, where it is anonymized and used for mapping. Users can also visualize and download their own registrations.

The survey has the potential to form an important data basis for the search for causal relationships. Better knowledge of this complex quality deviation could help reduce its extent, thereby increasing the yield in salmon aquaculture, which is considered important in the work towards sustainable aquaculture.

E-mail: sofia.latorreredoli@uma.es

The zebrafish (*Danio rerio*) has become an established model organism across multiple research fields. In terms of aquaculture, some international groups have recently used it as a model species for feeding assays due to its rapid development, small size, suitability for high-throughput experimentation and its deep genetic knowledge. Although species-specific differences exist, zebrafish offers a practical platform for the early-stage evaluation of aquafeed supplements, providing valuable insights into the nutritional regulation of growth prior to conducting large-scale trials in commercial finfish species.

Recent studies have demonstrated the utility of zebrafish in assessing dietary effects on growth performance. The present work is part of a broader research initiative aimed at improving sustainability and productivity in aquaculture through the development of functional feeds, supported by two interrelated experimental grants. These projects explore feed supplementation with compounds of microbial and algal origin, such as marine polysaccharides or extracts and bacterial extracellular polymers (ECPs), selected for their potential to enhance fish growth and resilience against pathogens of economic relevance.

In this communication, we present results from our research group evaluating the effects of selected feed supplements on zebrafish growth during the presexual maturity stage and under controlled water temperature, salinity, light, and dissolved oxygen (DO) conditions. After a generalized live food regime and the palatability studies, three different functional feeds were daily administrated “ad libitum” to a constant population of one-month fishes under a constant feeding regime to reduce potential compensatory growth. Non-supplemented or commercial feeds were also administrated to negative or positive control groups. During this procedure, stocking density, natural size heterogeneity, food particle size and ration level were also controlled. Viability, initial and final body lengths and weights were measured and plotted to analyse either global or separately subpopulations of low-, medium-, and heavy-weights. Parameters regarding coefficients of variations in weight, body mass index, body condition scoring, and the nutritional properties of food were also considered.

Nonetheless, careful consideration must be given when extrapolating zebrafish data to commercially relevant species, due to physiological and ecological differences. These limitations emphasize the need for greater standardization in zebrafish research and a cautious interpretation of findings when applied to industrial aquaculture.

# DEMAND COVERAGE IS NOT ENOUGH: THE INFLUENCE OF VARYING LYS TO MET + CYS RATIOS ON FEED INTAKE IN RAINBOW TROUT (*Oncorhynchus mykiss*)

Nadine Lau [1 2] *, Carsten Schulz[1 2] and Frederik Kaiser[1 2]

[1]Institute for Animal Breeding and Husbandry, Department of Marine Aquaculture, Christian-Albrechts-University Kiel, Hermann-Rodewald-Str. 6, 24118 Kiel, Germany

## Introduction

Fishmeal is still one of the main protein sources in fish feed, but its increasing demand can only be covered by sustainable aquaculture that uses alternative protein sources (FAO, 2022; Hua et al., 2019; Sarker et al., 2020). Therefore, in this project, raw materials that were suitable for organic production were used. Although plant-based protein sources have been tested as substitutes for fishmeal, these often have negative effects on digestion, taste, and growth due to a suboptimal amino acid composition (de Francesco et al., 2004; Francis et al., 2001; Lazzarotto et al., 2018; Kaiser, 2021; Nagel et al., 2012; Slawski, 2012). There are also indications that an amino acid imbalance could reduce feed intake (Bak et al., 2012; Comesaña et al., 2017; Comesaña et al., 2020). The purpose of this study was to test raw materials as fishmeal substitutes to investigate the influence of varying Lys to Met+ Cys ratios above demand, because it is assumed that these higher ratios can positively affect feed intake and growth.

## Material and Methods

Six different diets were formulated, which varied in terms of raw material and amino acid composition in terms of Lys to Met+ Cys ratios. The control diet included fishmeal and soy protein as the main protein sources. In five experimental diets, the fishmeal and soy protein were completely replaced by different combinations of pea protein, poultry meal, soldier fly larvae meal, and feather meal, resulting in different dietary amino acid compositions in terms of Lys to Met+ Cys ratios (Table 1). All diets were isonitrogenous and isoenergetic at the digestible level and were tested in triplicates. Rainbow trout with an initial weight of ~26g were held in a recirculation aquaculture system and fed daily to apparent satiation for 52 days.

## Results and Discussion

The group fed the diet with a lysine to methionine+ cysteine ratio of 1:0.40 showed a significantly higher DFI (3.11±0.06) than the overall mean. Fish fed the diet with a ratio of 1L:0.49M+C showed a significantly lower FCR (1.05±0.03). Both diets showed a higher SGR (2.86±0.03). Both treatments contained the highest levels of pea protein (25.1%; 17.4%), which, according to Gatlin III et al. (2007), is suitable as a moderate fishmeal substitute as a high proportion of lysine and methionine is provided. The amino acid composition might affect the higher feed intake of the diet 1L:0.40M+C. This diet contained the highest levels of isoleucine, leucine and arginine. According to Yamashita, Yamada & Hara (2005), isoleucine and leucine have a positive effect on feed intake in rainbow trout. However, Comesaña et al. (2020) showed a negative effect on the provision of leucine on feed intake. Arginine is an effective taste stimulant in fish, but its influence is negligible due to the husbandry conditions prevailing in this experiment, as their receptors are active only at a pH of 8.5 (Marui et al., 1983). The SGR and FCR values of the diet 1L:0.49M+C could also be attributed to the amino acid composition, with a methionine and cysteine ratio of 1:1, which may benefit starch and fat digestion (Nordrum et al.,1999). Some studies showed that cysteine might be a positive stimulant for locomotory activity in rainbow trout and feed intake (Yamashita, Yamada & Hara, 2005; Kasumyan & Doving, 2003).

*Table 1: Dietary amino acid contents of Lysine and Methionine+ Cysteine in g per 100g dry matter of the test diets (Treatment=Name). Tested ratios of the amino acids and the respective amino acid requirement for rainbow trout (Rodehutscord et al. 1997, Hardy & Kaushik 2021).*

| Treatment | Lys (dietary) | Met+ Cys (dietary) | Ratio Lys: Met+ Cys | Demand Lys | Demand Met+ Cys |

*(Continued on next page)*

**Conclusion**

The results show that organically produced raw materials in fish nutrition can offer sustainable alternatives to conventionally produced feeds. It could also be demonstrated that feed formulations with different ratios of lysine to methionine+ cysteine significantly influence feed intake, feed conversion and specific growth rate in fish. In addition, the ratio of methionine to cysteine appears to influence nutrient digestion, which could improve growth performance. Follow-up experiments examine more closely the optimal balance of these amino acids and the potential of ecological resources to maximise feed efficiency and growth in aquaculture.

# PROTEIN-SPARING EFFECTS OF A MODIFIED HIGH FAT DIET IN PACIFIC WHITELEG SHRIMP *Litopenaeus vannamei*

Brett Laudato*, Joren Alutaya

VDS Premix Solution (VDS, N.V.)
Paanderstraat 40, 8540 Deerlijk (BELGIUM)
Email: brett@vdspremix.be

## Introduction

Aquaculture significantly contributes to global seafood production (FAO, 2022) and *Litopenaeus vannamei* is one of the key aquaculture species due to its adaptability and disease resistance (Danya Babu Ravuru, 2015). However, high feed costs necessitate alternative strategies like protein-sparing, which involves substituting dietary protein with lipids (Wang et al., 2015). This study evaluated the protein-sparing effects of modified diets on the growth performance and metabolic effects on *L. vannamei*. Diet modification was made by adding the following compounds: *L*-carnitine, choline chloride, glycerol monolaurate, and lysophospholipids.

## Materials and Methods

All diet feeds were produced in-house at VDS, N.V. in Deerlijk, Belgium. The study consisted of two feeding trials conducted over 57 days.

The initial average weight of the shrimp for the first feeding trial was 11.19±0.06 grams. For the second feeding trial, the initial average weight of the shrimp was 0.86±0.00 gram. Shrimps were cultured in a recirculating aquaculture system. Water quality parameters were monitored and controlled to ensure optimal culture conditions. At the end of the feeding trials, growth performance metrics and metabolic effects were determined.

## Results

For the first feeding trial (*Table 1*), the MPOS treatment had significantly higher body weight than the NEG treatment. Other parameters did not show significant differences among the treatments. It is also noteworthy that the MPOS showed better growth performance tendencies, although not significant.

In terms of whole body protein (*Figure 1*, left), NEG treatment had an expectedly significant lower body protein content (%) compared to other treatments and the initial body protein, indicating low protein assimilation from a low protein diet. This effect was mitigated by the modification of the NEG diet (MNEG). For the whole body fat content (*Figure 1*, right), there was an expected significant increase of whole body fat of treatments NEG and MNEG. It appears that diet modification did not decrease the body fat of the shrimps.

For the second feeding trial, the results confirmed the previous feeding trial results on POS and MPOS (*Table 2*). Additionally, the Protein Efficiency Ratio (PER) of MCON was significantly higher than CON treatment.

## Conclusion

The diet modification showed best results in a high-protein, low-fat diet of shrimp throughout its growing stage (from 0.8 gram to 27 grams). It also improved some growth parameters and metabolic effects in the low protein, high-fat diet, indicating an amelioration of its negative effects. Additionally, the diet modification demonstrated a protein-sparing effect in the high-fat diet, as confirmed by the whole body protein analysis of the shrimp, although it did not reduce the total body fat content.

## Introduction

Recirculating aquaculture systems (RAS) are increasingly being adopted for land-based Atlantic salmon farming in Norway. While RAS provides relatively higher biosecurity compared to flow-through systems, disease outbreaks can still occur. One such disease is spironucleosis, which may be introduced into the system via the water intake. In Northern Norway, outbreaks of spironucleosis in farmed salmon remain a persistent problem, leading to mass mortality, compromised welfare and significant economic losses.

The diplomonad parasite *Spironucleus salmonicida* (Figure 1) is the causative agent of these systemic infections, which are characterised by internal haemorrhaging, splenomegaly, and granulomatous lesions in the liver and spleen. Environmental conditions significantly influence the severity and distribution of the disease. Currently, no known treatment for spironucleosis exists, making prevention the primary means of control. Anecdotal reports from the industry suggest that the parasite may be sensitive to UV disinfection.

This study investigated the use of UV and ozone as water disinfection methods within the RAS loop to prevent spironucleosis outbreaks following a biosecurity breach in Atlantic salmon RAS.

## Materials and methods

*In situ* and *in vivo* trials were conducted to evaluate the effects of disinfection on the viability and potential proliferation of *Spironucleus salmonicida* in RAS.

In the *in situ* trial, the survival of *S. salmonicida* flagellates following UV treatment was assessed under controlled laboratory conditions. The flagellates were exposed to two types of UV lamps: low-pressure (dose range: 10–200 mJ/cm²) and medium-pressure (dose range: 10–75 mJ/cm²). Parasite survival was evaluated immediately after UV exposure and again at 24 and 48 hours post-treatment.

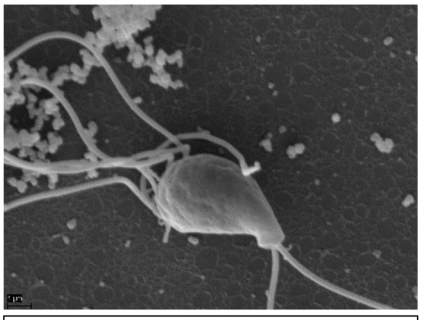

Figure 1. *S. salmonicida* under SEM.

*(Continued on next page)*

In the *in vivo* trial, brackish water-adapted Atlantic salmon smolts were reared in nine individual RAS units. Three units received UV disinfection in the RAS loop at a continuous dose of 100 mJ/cm². Another three units were disinfected using ozone, targeting an oxidation-reduction potential (ORP) of 320–350 mV. The remaining three units, which received no RAS loop disinfection, served as controls.

The parasite (approximately $10^5$ cells/mL) was introduced via the make-up water over three consecutive days at a concentration of 1% (v/v) of the total daily water volume (approximately 20 L/day). Disease progression was monitored over a four-week period, including assessments of water quality parameters, collection of swab samples for microbial profiling, and tissue sampling for histology and qPCR analysis.

**Results**

No parasites survived treatment with medium-pressure UV lamps at a dose of 50 mJ/cm² or higher at any time point. At lower doses (10 and 25 mJ/cm²), the parasites were not viable over time and were unable to reproduce, despite appearing alive under the microscope at 0 and 24 hours post-treatment. However, they were significantly weakened and all died within 48 hours.

Water quality in the nine experimental RAS units remained within favourable thresholds for Atlantic salmon smolts. UV transmittance was highest in the UV-treated units and lowest in the control group.

All fish tested negative for the presence of the parasite. Molecular markers associated with innate immunity and stress response were differentially regulated in the foregut, hindgut, skin, and gills. Histological indicators of skin and gill health changed significantly over time, particularly in the control group, although inter-treatment differences were minimal.

RAS loop disinfection influenced the microbial communities in the system, including those on tank walls and biomedia. Microbial composition evolved over time in all treatment groups. Certain members of Alphaproteobacteria were enriched in the ozone-treated group but not in the UV-treated group, relative to the control.

**Conclusion**

Medium-pressure UV treatment at 50 mJ/cm² effectively inactivated *Spironucleus salmonicida*. The *in vivo* biosecurity breach of the parasite in RAS did not cause infection, and water quality remained within optimal ranges across all RAS units. Disinfection methods influenced microbial community composition, particularly with ozone, which enriched certain Alphaproteobacteria.

# ATLANTIC SALMON BROODSTOCK ENVIRONMENT AND ITS EFFECTS ON OFFSPRING IMMUNE AND STRESS RESPONSES

C.C. Lazado[1*], A. S. Bogevik[1], E. Burgerhout[1], H. Brenne[1], V. Voldvik[1], G. Timmerhaus[1], K. Hjelde[1], K. Skjærven[2], N. Robinson[1]

## Introduction

Genetic variation is key in determining traits important for Atlantic salmon aquaculture, and selective breeding has been widely used to improve performance. However, environmental conditions such as nutrition, handling, disease exposure, temperature, and oxygen availability also significantly affect the development and health of fish. Increasing attention is being given to how the broodstock (G0) environment may influence the performance of their offspring (G1), including immune function and stress resilience. In Norwegian aquaculture, different rearing and maturation practices across breeding and multiplier companies may be contributing to variation in offspring health and robustness. Understanding these environmental influences is essential for improving fish welfare and production outcomes. As part of the project, EpiBrood, we explore how variations in broodstock rearing conditions affect immune and stress responses in the offspring of Atlantic salmon.

## Materials and methods

Two major salmon egg producers provided experimental materials for this project. Eggs from Producer 1 originated from broodstock reared in southern and mid-Norway. In contrast, eggs from Producer 2 came from broodstock reared in three different locations: on-land and at-sea facilities in Norway, and an on-land facility in Iceland. Before the first feeding stage, the alevins were subjected to transport stress and a pathogen challenge. When fish from Producer 1 reached approximately 20 grams, they underwent a stress test. Additionally, head kidney leukocytes and hepatocytes were isolated, cultured, and exposed to various model stressors for further analysis.

## Results

Alevins from Producer 1 showed no significant mortality following transport. However, after 24 hours, alevins originating from Mid-Norway had higher survival rates than those from South-Norway. Following exposure to *Yersinia ruckeri*, one Mid-Norway group demonstrated a higher survival rate than the other group. This difference was partially supported by gene expression profiles related to inflammation and antibacterial defence at mucosal sites. Upon exposure to handling and confinement stress, parr from Mid-Norway exhibited a higher cortisol response than parr from South-Norway. At the cellular level, exposure to stressors simulating oxidative stress, hypoxia, and bacterial infection revealed no consistent origin-dependent patterns.

Similarly, alevins from Producer 2 did not exhibit transport-related mortality. However, after 24 hours, alevins derived from Norwegian broodstock had higher survival rates than those from Icelandic broodstock. No clear differences were observed in gene expression profiles between the groups following pathogen exposure. Nonetheless, behavioural differences were noted among the groups.

## Conclusion

The broodstock environment had variable effects on immune and stress responses of the offspring, with some physiological attributes showing origin-dependent differences. These findings suggest that parental rearing conditions can influence offspring robustness and should be considered in broodstock management strategies.

## Introduction

Heatwaves are causing a serious threat to rainbow trout aquaculture (FAO, 2020) and there is urgent need to find solutions how the resilience of fish against heatwaves could be increased. One organ that is influenced by temperature is heart and at high temperatures cardiac arrhythmias are commonly observed (Eliason and Anttila, 2017). Therefore, one way the thermal resilience of aquaculture fish might be increased could be via increasing the cardiac performance of fish. Exercise training has been shown to improve the cardiovascular functions in fish (Palstra and Planas, 2011) and evidence suggests that exercise may even enhance their cardiovascular thermal tolerance (Pettinau et al., 2022). Nevertheless, it is unclear how heart rate changes during the exercise training program and thermal stress challenge. One innovative method to investigate these changes is with bio-logging. Bio-loggers allow continuous collection of heart rate data while the fish are swimming or resting while also continuously monitoring adaptations through time. In this study, bio-loggers were used to assess heart rate variability of rainbow trout during a 4-week exercise training period and thermal stress. The main aim was to get insights how fast the exercise training affects heart rate in fish during swimming and resting to optimize the training duration for aquaculture purposes. Furthermore, the aim was to investigate how training affects the heart rate during a temperature stress.

## Materials and Methods

Rainbow trout (n=115) were acclimated for 1 month to experimental tanks with continuous flow-through freshwater. After acclimation, 40 fish were used for surgical bio-logger implantation. Fish were allowed four weeks to recover from the surgery. The trout were then divided into two groups (control and trained) to triplicate tanks (n=19 fish per experimental tank) including 20 fish with the bio-logger in each group. The loggers recorded the heart rate every 1 hour, for 10 seconds/time at a frequency of 150Hz. Fish were swimming at water velocities of 0.3 body lengths per second (bl/s) for controls and 0.9 bl/s for trained, from 8:30 am - 2:30 pm, 5 days per week for 4 weeks. Weekends were recovery periods as well as rest of the day for trained fish when the velocity was reduced to 0.3 bl/s. After four weeks of training the critical thermal tolerance ($CT_{max}$) of the fish was measured. For this both the trained and untrained fish (n=20/group) were placed in a temperature-controlled tank where temperature was elevated at a rate of 2°C per hour (started from 18°C). Fish were monitored for loss of equilibrium (LOE) at which point fish were determine to have reached $CT_{max}$, bio-loggers recorded the heart rate every 5 minutes during the temperature challenge.

## Results

The heart rate changed significantly during the training period. During the first three weeks the trained fish had significantly elevated heart rate during the exercise periods ($p<0.05$) and even during the resting periods with few exceptional days when the difference did not reach statistical significance. However, by the beginning of week four, the heart rate of the trained fish returned to control levels (no significant differences, $p>0.05$) even for training periods. From the mid-week of week four onwards the resting heart rate of trained fish decreased compared to control group ($p<0.05$).

While the average heart rate of trained fish was higher during the $CT_{max}$ experiment ($P<0.05$) than the one of control fish, there were no significant statistical differences in the CTmax temperature or the temperature where cardiac arrhythmias were observed between groups.

*(Continued on next page)*

**Discussion**

The results show that training is effective tool to modify the cardiac function of fish, but it takes more than three weeks to achieve significant functional improvements i.e. efficiency of contraction improving so much that heart rate do not need to be elevated during swimming. However, the training program did not influence the acute critical thermal tolerance of resting fish even though they were able to keep higher heart rate during the challenge. Further studies are needed to see if the training can be optimized so that also in the resting fish the thermal tolerance can be improved as previously shown with maximal heart performance (Pettinau et al. 2022).

Microalgae and insects are becoming a vital part of aquaculture feeds, offering a sustainable and nutritious alternative to traditional ingredients at the basis of feed formulation. They provide essential nutrients like long-chain polyunsaturated fatty acids, amino acids, proteins, and pigments, which are crucial for larval survival and growth in fish and shellfish. They are increasingly being considered as sustainable nutrients sources for aquaculture feeds due to their high protein content, ability to recycle organic waste, and recycling of resources. Another yet untargeted potential use of insects and microalgae is the production of alternative baits for crustacean fisheries. Indeed, conservation challenges are rapidly unfolding in crustacean fisheries relying heavily on declining, resource-consuming forage fish for use as bait. The "bait crisis" is forcing stakeholders to take measure of the situation and to rapidly develop alternative strategies. The most effective, the identification of viable replacements for the fish-based traditional bait, could reduce fishing pressure, stem forage fish depletion and eliminate the negative impacts of fluctuations in bait supply availability, prices and observed unsustainability. The aim of this review is to provide general information of the fisheries, ecology and biology of the American lobster (*Homarus americanus*) and the snow crab (*Chionoecetes opilio*) and summarize the latest research efforts aimed at the identification of suitable alternative baits for their harvesting and/or as feed ingredients for their cultivation. We discuss the use of emergent sources free from aquatic resources fluctuations and regulations. The concept is based on the use of cost-efficient innovative technologies and circular economy transformations of industrial or agriculture side stream by-products (ex: carbon dioxide ($CO_2$) or food wastes) as primary source for sustainable production of low trophic species such as microalgae or insects. This biomass in turn may be used as the main constituent or as an attractant (or a supplement) in the composition of alternative feeds and baits for the crustacean fisheries towards sustainable profitability. Major challenges still reside in the development of a sustainable alternative ingredients market: the emergence of efficient large-scale cultivation technologies and the creation of attractive species-specific olfactive signatures that will promote movement patterns that translate in survival, growth and/or catchability. If carried out and proven cost-effective, the use of emergent sources could significantly contribute to the alleviation of ecosystem collapse due to overexploitation of the pelagic fish populations.

# HIGHER DIETARY EPA & DHA LEVELS IMPROVE COMMERCIAL SALMON FARMING PRODUCTIVITY AND PREDICTABILITY

## Introduction

It has been widely reported that investing in Omega-3 EPA & DHA rich feeds boosts fish health and consistently produces better quality whole fish and fillets across the value chain. But how do we know? And what's the return on investment in better Omega nutrition for salmon farmers? The objective of this study is to help further close the gap between nutritional science and commercial feeding practice, using so-called 'big data'.

## Methods

This study compared the performance and quality differences of almost half a billion Atlantic salmon on commercial farms in Norway over a 10-year period based on varying dietary levels of EPA & DHA. The study method involved preparing large-scale, complex commercial datasets, or 'big data', and interrogating this with Inverse Probability Weighted Regression Adjustment (IPWRA) analysis to quantify the benefits of increased dietary EPA & DHA levels on salmon populations.

## Results

This study confirmed that higher dietary levels of EPA & DHA lead to significant improvements across a range of production metrics, including an 8% reduction in total mortality, a 13% improvement in economic Feed Conversion Ratio (eFCR) and a 2% increase in superior quality at harvest. Improvements in predictability also increased by up to 50%. Data from processors revealed that above-average levels of EPA & DHA in fish feed consistently delivered better flesh quality, including a 7% melanosis and a 40% blood spots reduction.

## Conclusions

We conclude that these results are extremely important for the salmon industry. It provides valuable insights for strategic, data-driven decision making by importers, retailers, and farmers. Any reduction in eFCR and mortality translates to improved fish health and welfare, reduced waste, and a lower environmental footprint through more efficient use of resources. Predictability improvements translate into greater control over outcomes and more reliable business. Furthermore, a reliable uptick in the superior quality at harvest and reduced melanosis and blood spots in salmon flesh mean stable, higher average selling prices along with customer satisfaction and trust. New sources of Omega-3 fatty acids help to ensure nutritional quality of feed whilst de-risking growth of the industry by diversifying the raw material basket.

# FEEDING RESPONSES OF WHITE-LEGGED SHRIMP (*Penaeus vannamei*) TO VARYING RATIOS OF BREWERY SPENT GRAIN (BSG) AND YEAST (BSY) WITH OR WITHOUT BSG SPONTANEOUS FERMENTATION

Margaux Le Gourrierec[1]*, Eva Rondeau[1], Mathis Raysseguier[1], Hassane Zabibou[1], Margot Copet-astier[1], Guillaume Le Reste[1]

[1] Halieutica
CEAC
Angers, France
E-mail: m.legourrierec@halieutica.net

## Introduction

The cost and availability of protein ingredients is a challenge for the development of the aquaculture feed sector, especially in developing areas. As a result, ingredient such as brewery spent grains (BSG) and yeast (BSY) constitute an interesting option. BSG has been the focus of several nutritional studies since the 90' with various results (1). The high-water content (75-85%) of BSG when exiting the brewery limits its use due to the heterogenous mastering of drying process in factories (2). Then, spontaneous fermentation as a low-cost conservation method seems to be an interesting opportunity. BSY have been widely studied for their role in boosting immunity. However, their interest as a palatability and attractivity enhancer remains little studied. Therefore, this trial aims to determine whether the fermentation state of BSG influence feeding behaviour of shrimp depending on the BSY/BSG ratio.

## Material & methods

The behavioural trial aims to study whether feed attractivity and palatability are influenced by the state of fermentation of BSG and by the ratio BSG/BSY following a factorial design described in Table 1. 35 shrimp will be distributed in 7, 50L reserve tanks with 5 shrimp per tank. 7 isoproteic (17,4%) experimental feeds containing a neutral base and 30% of BSG and BSY mixture will be crafted. During 5 days, shrimp will be presented by group of five to the feeds in a tank dedicated to behavioural studies equipped with cameras. Each group is only presented to a feed once a day and is never presented to the same feed twice.

Recorded videos will then be analysed with an AI based tracking software to generate data on palatability and attractiveness based on parameters such as prehension speed, time spent in the feeding zone, shrimp activity. Feed consumption will also be monitored. Data will then be analysed via statistical analysis.

## Objectives

Experiments assessing ingredient attractivity and palatability took place in April 2025. The growth trial started the end of April 2024 and will end in June 2025. These experiments will help to fill the data gap while providing information on the interest of BSG and BSY for aquafeed.

Table 1. Behavioural and growth trials factorial design

| | Non fermented BSG | Fermented BSG |
|---|---|---|
| 90% BSG / 10% BSY | r=5 | r=5 |
| 70% BSG / 30% BSY | r=5 | r=5 |
| 50% BSG / 50% BSY | r=5 | r=5 |

| Control |

# METHODS IN NUTRITIONAL RESEARCH IN *Penaeus vannamei*: A META-ANALYSIS OF RECENTLY PUBLISHED SCIENTIFIC PAPERS

Guillaume Le Reste[1]*, Eva Rondeau[1], Mathis Raysseguier[1]

[1] Halieutica
CEAC
Angers, France
E-mail: g.lereste@halieutica.net

Improving the sustainability of *Penaeus vannamei* farming relies on a better understanding of its nutritional requirements, enabling the development of feeds and feeding strategies that enhance productivity while reducing environmental impact. This meta-analysis compiles data from 45 studies published in 2024-2025 across 4 scientific journals: Aquaculture International, Aquaculture Nutrition, Aquaculture Research, and Aquaculture. The aim is to compare the conditions under which nutritional trials are performed and assess their potential impact on P. *vannamei* performance.

A rigorous selection process was applied to include only studies dealing with feeding rate (FR), stocking density, frequency of daily feed distribution, considered as the parameters directly influence shrimp performance, and their effects on key performance indicators such as specific growth rate (SGR), feed conversion ratio (FCR) and survival rate (SR). Spearman correlations and regressions quantified and illustrated these effects on growth.

Results indicate heterogeneity in experimental conditions, impacting growth performance outcomes. The average trial duration was 51 ±14 days. Similarly, initial body weight (BW) varied widely with a mean of 2.5 ±2.35 grams. Stocking density also exhibited significant variation, averaging 158 ±109 shrimp per $m^3$. Most studies apply 3 to 4 daily meals, with daily FR of 6 ±2 % of the biomass.

SR, SGR and FCR all exhibited high variability across studies. SR fluctuates significantly, with a mean of 85.5 ± 10.7%. SGR varied considerably, with an average of 3.87±2.12 % per day. Similarly, FCR also showed notable dispersion, averaging 1.63 ±0.39, reflecting variations in feed efficiency and experimental setups.

This meta-analysis shows a strong positive correlation ($r = 0.78$) between FR and SGR, confirming the fundamental role of nutrition in growth performance.

This study reveals significant heterogeneity in experimental protocols, impacting shrimp performance assessments. To address this, we established benchmarks to facilitate inter-trial comparisons. Establishing common research frameworks would facilitate meaningful performance assessments and improve the applicability of nutritional findings to shrimp farming. Future work will integrate water quality for better models and efficiency.

# ASSESING FISH WELFARE TROUGH LESS-INVASIVE HORMONAL DETERMINATION

**Introduction**

Society is increasingly aware of animal welfare, and understanding the stress animals' experience due to their farming conditions is becoming critical. Stress can be defined as a state of threat to the organism homeostasis, which tries to restore itself by activating a complex repertoire of behavioral and physiological processes that are integrated in its adaptive response. This response primary involves the synthesis and secretion of adrenal glucocorticoids. In both, fish and humans, cortisol is the main glucocorticoid and its plasma levels are commonly used as an indicator of the acute stress levels (Sadoul & Greffoy, 2019). However, prolonged exposure to stressors induces desensitisation of the HPI axis to the stressor as a result of allostatic overload (Agulleiro et al., 2013; Aerts et al., 2015). Recent studies have shown that structures such as hair, feathers or scales accumulate cortisol and hormone levels could therefore be a good indicator of cumulative or chronic stress or, in other words, an excellent way of obtaining a history of non-specific stressful events (Aerts et al. 2015). Our studies show that chronical stress significant increase scale and fin cortisol in Mediterranean farmed species such as sea bass, sea bream and meagre supporting its use as potential indicator of accumulative stress in fish.

**Materials and methods**

Animals: Sea bass (*D. labrax*), sea bream (*S. aurata*) and meagre (*A. regius*), weighing aprox 200g, were kept in 500-litre tanks at 18 °C with a 12-hour light/dark photoperiod and fed a commercial feed. Prior to handling, the fish were anaesthetised with tricaine and euthanised with an overdose of the same anaesthetic.

Mechanical stress: The fish were divided into two groups (control and stressed). The stressed group underwent the stress protocol three times a week for one month by lowering the water level in the tank and exposing the fish to air for one minute. The control group was not subjected to any stressors. Finally, blood, scales, and fin (pectoral and caudal) samples were extracted from 12 animals per group to evaluate cortisol levels.

Cortisol levels in serum, scales and fins: Cortisol levels in the different tissue matrixes were evaluated by ELISA (Cayman) according to the manufacturer's instructions. Scales and fins were washed three times in saline phosphate buffer and incubated O/N in methanol that was subsequently evaporated. The samples were then resuspended in acetate buffer and purified using chromatographic columns (Superclean L-18 SPE, Sigma) prior to assay.

**Results and discussion**

The stress-inducing protocol was evaluated in previous studies (Leal et al., 2011). In all three species, cortisol levels significantly increased in various tissue matrices, including scales, pectoral and caudal fins, following the stress protocol. However, hormonal levels in scales were much lower than in other tissues. Plasma cortisol levels were also elevated in all three species. Seabass exhibited the highest hormonal levels in all four tissue types, which suggests that a higher hormonal response leads to greater cortisol accumulation in peripheral structures. Previous studies have reported the accumulation of cortisol in the scales of sea bass and goldfish following stress protocols (Laberge et al., 2019). However, our results show that the caudal and pectoral fins accumulate higher levels of cortisol following long-term stress protocols, thus supporting their use as excellent matrices for long-term stress monitoring. We also demonstrate that this hormonal accumulation extends to other species reared in captivity, such as seabream and meagre.

*(Continued on next page)*

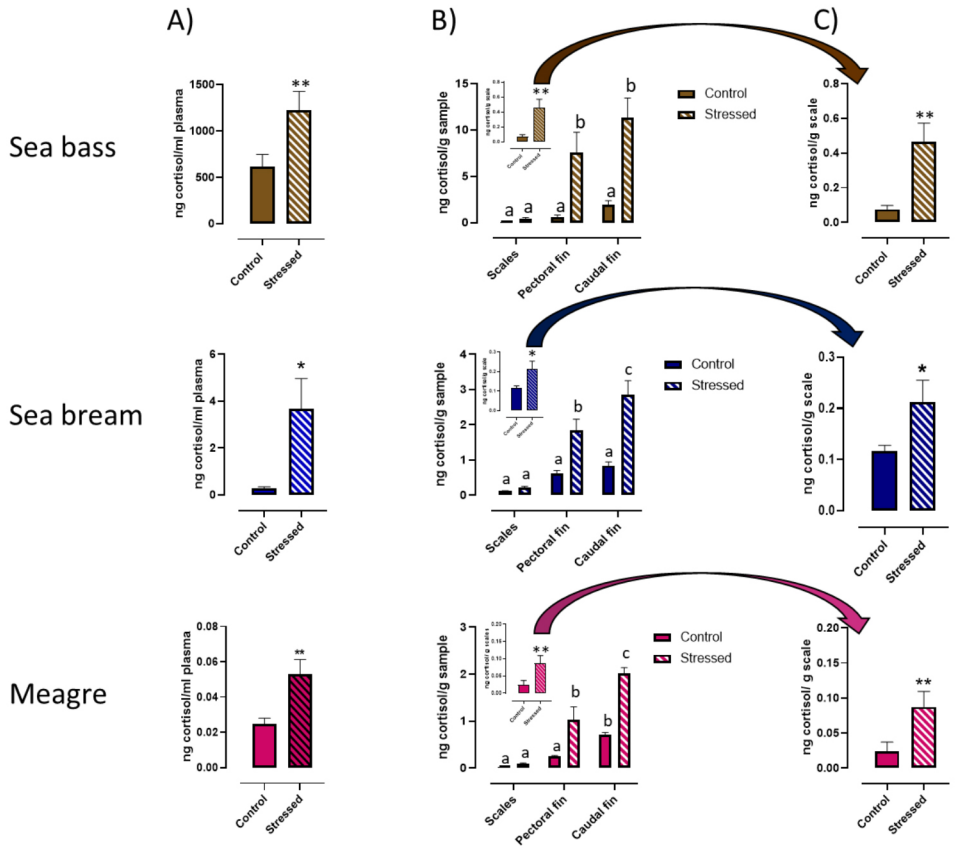

**Fig. 1. Determination of cortisol levels after physical disturbance imposed in sea bass, sea bream and meagre.** A) Quantification of cortisol plasmatic levels. B) Cortisol levels in scales and fins. Different letters denote significant differences after Two-way ANOVA ($p< 0.05$) and asterisk significant differences after *T-student* test. (*$p<0.05$, **$p<0.01$). C) Levels of cortisol in scales. Asterisk indicates significant differences after *T-student* test. (*$p<0.05$, **$p<0.01$).

## Conclusions

- Sea bass has the highest cortisol levels, followed by sea bream and meagre.
- Mechanical induced stress for 30 days significantly increases cortisol levels in serum, scales and fins (pectoral and caudal) in all three species.
- The caudal accumulated the highest glucocorticoid levels after long-term stress protocols.

## Introduction

Water monitoring, with high spatial and temporal resolution, is important to maintain its quality. In fact, in addition to the environmental damage that can be irreparable, the costs of pollution remediation are often higher than the cost of prevention or early intervention. Research must be directed towards proposing economically sustainable systems and procedures; only in this way it is possible to hypothesize an extensive use of water quality control and management systems. In order to create a qualitative/semi-quantitative water monitoring system, since it is impossible to monitor every specific pollutant, it is essential to establish an Early Warning criterion. In other words, we need to establish which parameters to measure and how to derive a synthetic pollution index from them that activates the rapid alert system. It is essential that the correlations between parameters must be identified in order to identify potentially redundant variables. To establish the Early Warning, it is useful that alarm thresholds are not "individually" established for each of the monitored parameters. In fact, it would be useful to identify a numerical index that can validly and correctly characterize the phenomenon from both a qualitative and possibly quantitative point of view. In general, the requirements that a numerical "alarm" index must have are mainly two:

a. relevance of the index components to the identification of the phenomenon in a significant and unequivocal way;
b. validity of the index limited within a well-defined scope and/or numerical interval, identified by pre-established minimum and maximum values.

In order to define a syntetic index that allows to generate an Early Warning, the paper explores metrological aspects that should allow to define a minimal set of physical/chemical parametrs to monitor.

## Laboratory Water Quality Testing

In order to verify the theoretical approach a series of test have been performed in laboratory using a suitable and calibrated multiparametric probe (Fig. 1): the SMx-485 of GEOVES s.r.l.. The probe has been inserted as sensor in a new automatic system able to analyze the quality of the water and to store samples of water in bottles if the Early Warning is generated. The system has been designed aiming to semplicity, reliability and robustness so allowing it to be mounted even on rovers as MAR – Multipurpose Amphibious Rover, which does not offer an environment particularly comfortable.

Fig.1. SMx-485 of GEOVES s.r.l.

# ENHANCED RESILIENCE TO *Tenacibaculum maritimum* IN ATLANTIC SALMON SUPPLEMENTED WITH A NOVEL YEAST-BASED INGREDIENT

C. Houdelet[1*], M. Rawling[2], E. Leclercq[1]

[1] Lallemand SAS, 19 rue des briquetiers, 31702 Blagnac, France
[2] School of Biological, Plymouth University, PL4 8AA Plymouth, UK
*choudelet@lallemand.com

## Introduction

Farmed Atlantic salmon are frequently exposed to infectious and non-infectious factors as well as necessary management practices causing serious mucosal health issues. Functional feeds are widely used as preventive measures to enhance fish health and well-fare among which yeast cell wall (YCW) products are well-established. We evaluated the potential benefits of in-feed supplementation with specific YCW products against *T. maritimum* tenacibaculosis which causes severe ulcerative lesions at mucosal surfaces and mortalities.

## Materials and Methods

A base-feed recipe was formulated according to current practices in the European Atlantic salmon industry. The trial tested 3 diets in quadruplicate: The base diet either non-supplemented (Control) or supplemented with one of two novel YCW products (Proto or Y+ respectively; Lallemand, France). Fish were fed to apparent satiation over the trial's duration. The trial lasted 15 weeks with fish exposed to *T. maritimum* by immersion end of week 6. Growth, feed performance and survival were monitored; skin and gill mucosal barrier were assessed; development of the disease was quantified by visual scoring of the gross skin and gill lesions at frequent interval post-challenge.

## Results and Conclusion

Compared to the Control; Y+ or Proto significantly improved survival (65.6% and 62.1% compared to 50.1%; +31.1% RPS for Y+; Fig A). However, only Y+ further improved the profile of skin lesion severity at end-point (Fig B). Analyses of histology, gene expression and mucus qualities are on-going to decipher the beneficial effects of the YCW product on mucosal robustness and disease resilience.

**In conclusion**, the novel-YCW product Y+ has the potential to contribute to the preventive management of tenacibaculosis in seawater Atlantic salmon.

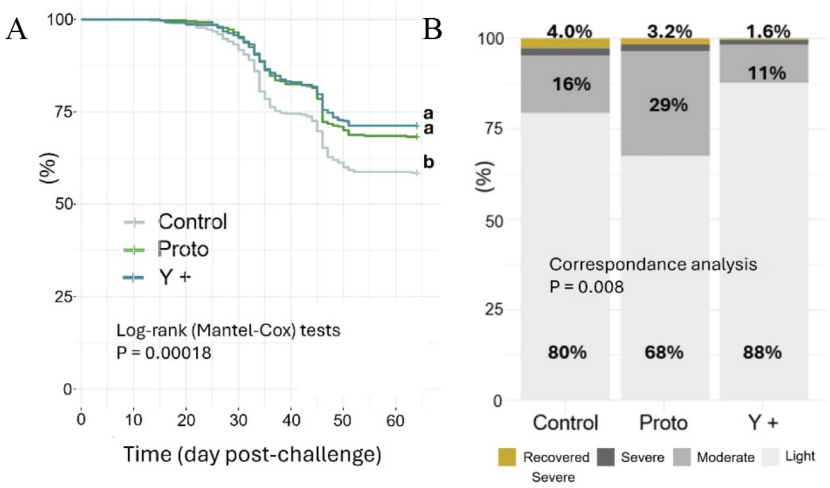

**Figure 1:** A) Survival profile and B) proportion of skin lesion category per diet at the end of the trial. Different letters indicate significant differences between diet.

# ROLE OF INTERLEUKIN-6 IN *Edwardsiella piscicida* INFECTION REVEALED THROUGH CRISPR/CAS9 GENE EDITING IN ZEBRAFISH

Yoon-Ji Lee [a*], Kishanthini Nadarajapillai [a,b], Sumi Jung [a,b], and Jehee Lee [a,b]

E-mail: leejenny66@gmail.com

## Introduction

Interleukin-6 (IL-6) is a key cytokine that orchestrates immune responses and is widely recognized for its roles in promoting inflammation, regulating cell survival and apoptosis, and providing protection against bacterial and viral infections. Previous research using *il-6* knockout mice has highlighted its importance in bacterial defence; these mice exhibited lower survival rates and impaired bacterial clearance. While the immunological functions of IL-6 have been well characterized in mammals, its roles in teleost remain unclear. In this study, we utilized zebrafish (*Danio rerio*) to investigate the significance of IL-6 in antibacterial defence against *Edwardsiella piscicida (E. piscicida)*. *E. piscicida,* a gram-negative bacterium of the Enterobacteriaceae family, is known to pose major threats by causing organ damage, ulceration, and eye abnormalities, often resulting in high mortality of various freshwater and marine organisms. We employed CRISPR/Cas9 gene editing technology for comparative analyses between wild-type (WT) and *il-6* knockout (*il-6* $^{-/-}$) zebrafish.

## Materials and methods

Utilizing the CRISPR/Cas9 technology, we constructed an *il-6* $^{-/-}$ zebrafish line. Both WT and *il-6* $^{-/-}$ fish were challenged with a low ($1x10^7$ CFU/ml) and high ($1x10^8$ CFU/ml) concentration of *E. piscicida* though immersion. To assess the host's susceptibility to the pathogen, we monitored cumulative mortality up to 11 days post-infection (dpi) and measured the amount of *E. piscicida* gDNA within the fish. Lastly, expression patterns of immune related genes such as pro-inflammatory cytokines (*il-1β*, *tnf*-α), signalling molecules (*stat3*, *socs3*), and antimicrobial peptides (*mpx*, *mpeg*) were observed through RT-qPCR.

## Results

A 7 base pair deletion was formed in the *il-6* sequence, resulting in a knockout of the gene which yielded a non-functional IL-6 protein. The genetic alteration led to dysregulated expression of immune related genes. These fish showed significantly elevated expression levels of proinflammatory cytokines, which coincided with a downregulation of the negative immune regulator *socs3*. Meanwhile, antimicrobial peptides were suppressed. The *E. piscicida* challenge assay revealed an increase in susceptibility to *E. piscicida* infection in knockout fish. These fish showed significantly higher mortality rates with earliest deaths occurring at 3 dpi. This heightened vulnerability corresponded with higher bacterial loads, indicating a flawed pathogen clearance. After the bacterial challenge, immune related gene expression in *il-6*$^{-/-}$ fish mostly peaked at 24 hours post-infection, although *il-1β* and *mpx* showed delayed expression peaks at 48 hours. Overall, the altered expression profiles of key immune genes indicate a disrupted antibacterial signalling network in the absence of IL-6. These findings underscore the critical role of IL-6 in initiating and coordinating immune responses following bacterial infections in zebrafish.

# LONG-TERM FISH MEAL REPLACEMENT WITH ANIMAL AND PLANT PROTEINS IN EXTRUDED PELLET DIET FOR OLIVE FLOUNDER *Paralichthys olivaceus*

Daehyun Ko[1], Jinho Bae[2], Byung Hwa Min[2] and Kyeong-Jun Lee[1,3*]

[1]Department of Marine Life Sciences, Jeju National University, Jeju 63243, South Korea
[2]Aquafeed Research Center, National Institute of Fisheries Science, Pohang 37517, South Korea
[3]Marine Life Research Institute, Jeju National University, Jeju 63333, South Korea

E-mail: kjlee@jejunu.ac.kr

## Introduction

Fish meal (FM) remains a primary and costly protein source in formulated fish diets, due to its high nutritional value and excellent palatability. The global FM production has decreased by a yearly average of 1.7% since 1995. Animal or plant protein sources have been investigated as potential substitutes for FM. Olive flounder is a carnivorous marine species and the most cultured species in South Korea. In 2024, olive flounder production reached 40,125 tons accounting for approximately 50% of the total finfish production. Therefore, this study was conducted to evaluate the effects of FM replacement with combinational animal and plant protein sources in extruded pellet diet for the fish through a long-term feeding trial evaluation.

## Materials and Methods

A control diet (F70) was formulated to contain 70% sardine and anchovy FM (1:1, v:v). Two other diets were formulated by reducing FM levels from F70 diet to 35 (F35) and 25% (F25), while incorporating increasing proportions of both animal proteins (poultry byproduct meal and tankage meal) and plant proteins (soy protein concentrate and wheat gluten meal). The replaced diets were supplemented with lysine, methionine, taurine and betaine to meet the requirements and to increase the palatability of the fish. Additional additives included choline, lecithin, vitamin C, vitamin E and monocalcium phosphate. Total 540 fish (average body weight: 178 ± 1 g) were stocked into nine 900-L polypropylene tanks (60 fish per tank) in triplicates per dietary group. The fish were fed two times daily (08:30 and 17:30 h) until they were apparently satiated for 4 months.

## Results

After 4-month feeding trails, fish growth was not significantly affected by dietary FM levels (Table 1). Also, feed utilization, survival and biological indices were not significantly affected by the dietary FM levels. The results on immune-related gene expression and intestinal morphology will be further discussed in detail.

Table 1. Growth, feed utilization and survival of olive flounder (*Paralichthys olivaceus*) fed the experimental diets for 4-month.

| Diets | FMBW (g) | WG (%) | FCR | Survival (%) |
|---|---|---|---|---|
| F70 | 319±19 | 80±12 | 1.38±0.18 | 97.2±3.5 |
| F35 | 312±23 | 74±11 | 1.44±0.24 | 94.4±5.9 |
| F25 | 315±33 | 77±18 | 1.41±0.32 | 94.4±5.4 |

# SUSTAINABLE ALTERNATIVES IN MEAGRE AQUACULTURE: EVALUATING POULTRY BY-PRODUCT MEAL AS A FISHMEAL SUBSTITUTE

tsegvic@izor.hr

**Introduction**

The aquaculture sector faces the challenge of balancing the growing demand for high-quality fish products with the need to reduce pressure on wild fisheries (Fao, 2018). As feed represents the highest operational cost in aquaculture, identifying alternative protein sources that are both cost-effective and environmentally sustainable has become a top priority. Processed animal proteins (PAPs) emerge as promising options, combining high nutritional quality with a low environmental impact, fully adhering to the principles of the circular bioeconomy (Galkanda-Arachchige *et al*. 2020). Meagre (*Argyrosomus regius*), a first-class whitefish species once abundant in the Adriatic Sea, has gained renewed interest in Mediterranean aquaculture due to its quality, rapid growth rate, and adaptability to farming conditions (Kružić *et al*. 2016). This study investigates the potential of poultry by-products (PBM) as a fishmeal substitute in meagre diets. Developing more sustainable feed formulations for meagre is crucial to support the aquaculture industry in producing these species in a way that maintains economic viability and environmental responsibility, without compromising product quality. Sustainable feed innovations not only help reduce reliance on marine resources but also enhance the long-term resilience and profitability of the sector (Tacon and Metian, 2015).

**Material and methods**

Three experimental diets were formulated to meet the nutritional requirements of meagre, each incorporating PBM as a partial replacement for fishmeal at different inclusion levels. One control diet, containing fishmeal as the primary protein source, was also included. The feeding trial was conducted in an open-circuit, outdoor water system at the Laboratory of Aquaculture, Institute of Oceanography and Fisheries (Split, Croatia). A total of 110 meagre (initial mean body weight: 1220 ± 154 g), obtained from a local farm, were acclimated for four weeks on a commercial diet before the experiment. Fish were then randomly distributed into six concrete tanks (600 L), with 18 fish per tank and two replicate tanks per dietary treatment. Growth performance was assessed through bi-monthly biometric measurements throughout the trial, while final evaluations of feed conversion ratio (FCR) and gut bacterial community composition will be performed at the conclusion of the experiment to comprehensively determine the impact of different dietary treatments.

**Results and discussion**

Our preliminary results from bi-monthly biometric measurements indicate that PBM holds significant promise as an alternative protein source in meagre diets. Fish fed with PBM-inclusive diets showed no compromise in growth performance or overall fitness compared to those receiving traditional fishmeal-based diets. These findings suggest that PBM can effectively support the rapid growth rate and adaptability characteristic of meagre in aquaculture settings. Moreover, economic analysis revealed that PBM diets were the more cost-effective than fish-meal based diets, exhibiting the lower estimated production costs. This positions PBM as not only a nutritionally viable but also an economically sustainable solution, aligning well with the industry's goals to balance cost efficiency with sustainability. By reducing dependence on fishmeal and fish oil, PBM-based diets contribute to alleviating pressure on wild fisheries while supporting the circular bioeconomy principles. As our experimental feeding trial approaches its final stages, ongoing monitoring will provide further insights into the long-term impacts of PBM on health parameters and product quality.

# SOLID PHASE IN-LINE DENITRIFICATION IN MARINE RAS USING BIODEGRADABLE PLASTIC (FORZEAS™)

Carlos Letelier-Gordo

Technical University of Denmark
National Institute of Aquatic Resource (DTU Aqua)
Email: colg@aqua.dtu.dk

For recirculating aquaculture systems to be environmentally sustainable nutrient wise, removal of N at the RAS or at the end-of pipe treatment is required. In-line denitrification configuration has advantages such as allowing more intensive use of water, reducing heating/cooling as well as a reduced usage of makeup water. In-line denitrification systems are not frequently used due to their complexity on the addition of carbon sources (methanol, ethanol) that can hamper the RAS water quality. Solid-phase denitrification could be a safer alternative technology, as carbon sources are not dosed in the reactor, but rather bacteria harvest the carbon on demand from the solid phase material (Forzeas™).

The application of solid-phase in-line denitrification in a marine RAS rearing rainbow trout was evaluated at different hydraulic retention times (5.6, 3.2 and 1 hour) for 117 days, using Forzeas™ biodegradable plastic as material in a serial configuration reactor. The solid-phase in-line denitrification reactor showed the highest N removal capacity (411 gN/m$^3$ Forzeas™) at HRT 1 hour with a removal efficiency of 40% NOx entering the reactor. The usage rate of the reactor at evaluated conditions during the 117 days trial was 2.7 kg Forzeas™ /kg N considering an entering oxygen concentration of 7 mg/L in the RAS system.

The configuration of the reactor allows low energy consumption (0.4-0.6 w/kg N), no addition of suspended solids to the RAS and a minimal operational dedication. Presenting an easy, efficient and sustainable technology for in-line denitrification.

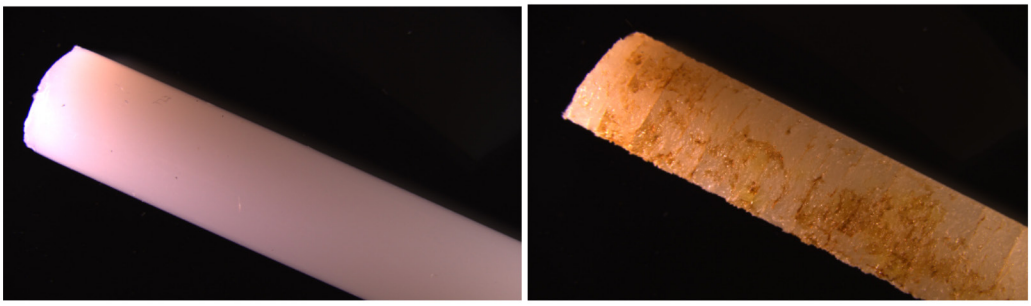

Figure 1: Biodegradable plastic FORZEAS™ before and after trial evaluation (117 days) in a Marine recirculating aquaculture system.

# TILAPIA GROWTH PERFORMANCE IN COUPLED AND DECOUPLED AQUAPONICS INCORPORATING A TRI-TROPHIC CYCLE

**Introduction**

Aquaponics, which is a symbiotic integration of recirculating aquaculture and hydroponics constitutes an exemplary farming technique for water and nutrient recycling in a closed-loop system, thereby diminishing nutrient waste, water consumption, and land use. A critical evaluation of the coupled aquaponic system reveals that, despite its sustainability benefits, it faces certain limitations when compared to conventional cultivation methods, generally associated with decreased nutrient availability in the fish water (Tsoumalakou et al. 2022). The sustainability of the aquaponics system is also questioned in terms of aquafeed production, which is the only source of nutrients in the fish-crop system (Shaw et al. 2022). The primary protein component of conventional aquafeed is fish meal, which is mainly produced from wild fish populations. A promising alternative protein source for aquafeed is insect meal (Shaw et al. 2022).

In the present study a circular tri-trophic system is introduced which incorporates three organisms, plants, fish and insects, which feed each other. The black soldier fly (BSF, *Hermetia illucens*) larvae are used to produce insect meal, which is incorporated in the fish feed, the fish excrements give essential nutrients to the plants (aquaponics), and closing the circle, the plant residues (old leaves or other pruning material and fruits) feed the larvae of BSF. This system is designed to implement the circular economy, transforming waste from one organism into a resource for the next.

In this presentation, the fish growth results, aquaponics water physicochemical parameters and crop productivity/fish biomass gain indices are reported, concerning two consecutive experiments. These were performed with the crops being the only organism varying in the system; a cucumber-tilapia co-cultivation was performed in a three-month period during autumn, and a lettuce-tilapia in a 45-day experiment during the winter.

**Materials and Methods**

The experiment was conducted in the pilot-scale aquaponic greenhouse of the University of Thessaly, located in Velestino (39◦44′ N, 22◦79′ E), Central Greece. The total area occupied by the aquaponic facility is 432m$^2$ and is divided into the hydroponic subsystem (352 m$^2$) where crops are grown and the closed chamber (80 m$^2$) where the rearing of fish takes place (RAS), under controlled environmental conditions. Two aquaponics treatments were implemented: a) coupled aquaponics, in which the crops were irrigated only with fish-derived water and b) decoupled aquaponics, in which the fish water was enriched with fertilizers to reach the target of hydroponic cultivation of the specific crop.

The RAS system consisted of three fish rearing tanks of 1.5 m$^3$ water capacity, the mechanical filter that withholds solid fish excrements and the biofilter occupying nitrifying bacteria, which are an essential system component transforming the ammonia-rich fish excretion to nitrates for plant absorption. Temperature pH, EC and dissolved oxygen (DO) sensors were placed in the fish tanks for monitoring critical quality characteristics of the water (pH/EC/O2-measuring transducer, GHM-Greisinger, Regenstauf, Germany). Red tilapia (*Oreochromis* spp.) fish were reared in the RAS. The fish in each tank were fed at a rate corresponding to 1% of their total body weight daily. Insect meal derived from the insects farmed on-site comprised the 10% of the fish feed. The physicochemical parameters of the water in all fish tanks were measured daily; pH, and EC were measured with a portable sensor (HQ40d, Hach, Loveland, CO, USA). Temperature was maintained at 23 (± 0.4) $^o$C. After the conclusion of each experiment, the final fish biomass was determined and the weight gain, the Specific Growth Rate (SGR) and Feed Conversion Efficiency (FCR) indices were calculated. Finally, the production efficiency of the whole system was evaluated by the crop productivity/fish biomass gain index, calculated as the ratio of kg of product resulted from each aquaponics treatment to the fish biomass gain.

*(Continued on next page)*

**Results**

The physicochemical characteristics of the fish water were similar in the cucumber and lettuce experiments, with the exception of phosphorus, potassium and sodium concentrations, which were elevated in the lettuce setup.

The fish biomass gain in cucumber experiment was 42.3 kg, while in lettuce was 17.9 kg due to the shorter cultivation period, with the initial weight being 117.8 kg and 108 kg, respectively. SGR was also similar, reaching 0.4 % $day^{-1}$ in cucumber and 0.44 % $day^{-1}$ in lettuce experiment. The latter showed greater FCR values than cucumber, i.e. 2.12 and 1.56, respectively. Concerning the crop productivity/fish biomass gain index, the differences between the two aquaponics treatments were remarkable. DCAP exhibited greater values in both experiments in comparison with CAP, succeeding a 254% increase in cucumber and 179% higher values in lettuce.

**Discussion and conclusion**

The two reported experiments resulted in similar SGRs, which were low compared to other studies (Tsoumalakou et al. 2022), however the FCR was considerably higher than the values reported in these works. The ratio of crop productivity/fish biomass gain indicates the productivity of crops in comparison to aquaculture subsystems. According to our results, with the production of 1 kg of tilapia fish, 2.7 kg of CAP cucumbers or 9.6 kg of DCAP cucumbers were produced. If lettuce was cultivated only in CAP, 1.6 kg of lettuce would be produced for 1 kg gain for tilapia, while if only DCAP was implemented the result would be 4.5 kg of lettuce per kg tilapia gain. This difference is in accordance with other experiments using the same aquaponics variants (Aslanidou et al., 2024). Other studies calculated a crop productivity/fish biomass gain of 2.94 kg $kg^{-1}$ for lettuce cultivation and tilapia breeding with the supplementation of nutrients (Licamele 2009).

The DCAP variant of aquaponics systems is an effective system that enables the combined production of crops and fish, the latter being fed with sustainably derived insect protein.

**Introduction**
Vaccination has significantly reduced antibiotic reliance in aquaculture; however, oil-adjuvanted injectable vaccines can cause undesirable side effects such as inflammation, peritoneal adhesions, and pigmentation. Dietary nucleotides (NT), essential molecules involved in nucleic acid synthesis, play critical roles in immune modulation, tissue repair, and metabolic regulation. This study investigated the potential benefits of combining a diet enriched with nucleotides alongside vaccination.

**Materials and Methods**
45 fish juveniles (initial weight: 51.54 ± 0.3 g) were assigned into one of four treatments: (N+Vac) Diet with NT + Vaccinated fish; (N) Diet with NT + Unvaccinated fish ; (S+Vac) Standard diet + Vaccinated fish; (S) Standard diet + Unvaccinated fish. After feeding the control or nucleotide (0.05%) supplemented diet for 12 weeks, the fish in treatment N+Vac and S+Vac were injected intraperitoneally with the ICTHIOVAC VR/PD vaccine (0.2 ml/fish). The fish from treatment N and treatment S did not receive any vaccine, but were injected with PBS (0.2ml/fish).

**Results and Discussion**
In 3-month feeding trial, comparing with fish fed standard diet, NT-fed fish showed increased lysozyme activity, total immunoglobulin (Ig), and total antioxidant capacity (T-AOC) in skin mucus, with T-AOC significantly elevated. In the head kidney, dietary NT significantly upregulated the expression of lysozyme (Lyz), immunoglobulin M (IgM), superoxide dismutase (SOD), catalase (CAT) and interleukin-10 (IL-10), while pro-inflammatory markerbinter leukin-1β(IL-1β) was significantly downregulated. Growth hormone (GH) expression was also enhanced, though no significant improvement in growth performance was observed. The addition of nucleotides enhances the fish's basic immunity and antioxidant status, contributing to improved farming resilience and health.

In 1-month vaccination trial, fish were sampled at the 2nd and 4th week post-vaccination. Comparing with S+Vac, N+Vac significantly modulated immune gene expression in the head kidney. Notably, the anti-inflammatory marker IL-10 remained elevated, and IL-1β suppressed at both time points, indicating sustained regulation of inflammatory responses. Expressions of Lyz and IgM were highest in the N+Vac throughout, suggesting prolonged enhancement of both innate and adaptive immunity. Antioxidant genes (SOD, CAT) were consistently upregulated in N+Vac fish, aligning with elevated SOD, peroxidase (POD), and T-AOC activities in skin mucus. Importantly, T-AOC remained significantly higher at 4 weeks post-vaccination, highlighting a prolonged antioxidant response. Bactericidal activity of mucus against *Vibrio harveyi* was also significantly enhanced in the N+Vac. Furthermore, NT supplementation alleviated vaccine-induced side effects such as peritoneal adhesions and pigmentation, particularly evident in week 3 (Fig 1).

**Conclusion**
These findings demonstrate that dietary nucleotides not only prime mucosal and systemic immunity but also extend the duration of immune enhancement post-vaccination, while mitigating inflammatory and oxidative stress responses.

**Introduction**

In the context of global warming, the temperature of global lake systems has shown a climbing trend of 0.34°C per decade. Freshwater aquaculture ponds, being smaller systems than lakes, have slower heat exchange and are likely to experience more pronounced warming. It is reasonable to predict that freshwater aquaculture ponds will show a similar or more extreme warming trend. As most fish are ectotherms, their metabolism and physiology are directly affected by environmental temperature. While increasing temperature within the optimal range (25-30°C for mud carp) can promote fish growth, temperatures exceeding their tolerance threshold place fish under heat stress, threatening their survival and productivity.

Under heat stress, fish metabolism requires significantly more energy. Heat stress induces increased production of reactive oxygen species (ROS) and heat shock proteins, diverting energy away from growth when feed intake remains constant. Consequently, farmers must either use more feed or extend aquaculture time, reducing profitability in commercial operations.

Mud carp, a key member of polyculture systems in South China, has substantial economic value in the Pearl River delta region. Products derived from mud carp, especially canned preparations, are highly favored by consumers. For sustainable mud carp aquaculture under warming conditions, innovative solutions addressing both fish welfare and economic viability are urgently needed. Traditional Chinese medicine (TCM) has long been used in aquaculture to promote growth and enhance immunity while remaining cost-effective with minimal environmental impacts. Recent research indicates that flavonoids and polysaccharides in dandelion (*Taraxacum mongolicum*) can enhance fish growth, antioxidant status, and immune responses. This study investigates whether dandelion can serve as a nature-based solution to mitigate heat stress effects in mud carp aquaculture.

**Method**

To investigate the potential of TCM to mitigate heat stress effects on mud carp growth and metabolism, 96 fish were cultivated at 30°C (control) and 34°C (heat stress). They were reared with or without dandelion extract prepared by mixing dandelion powder (2% w/w, TCM/feed) with distilled water. Each treatment group contained 24 fish. The weight of each fish was recorded every two weeks. After 2 months of dietary treatment, serum and tissues (liver, muscle, and gill) were collected for biochemical analysis to assess oxidative stress markers and antioxidant capacity.

**Result**

Based on the growth performance results, fish fed with dandelion exhibited 62.6% higher relative weight gain and 34.8% better feed conversion ratio under heat stress, reflecting improved growth and feed efficiency compared to those fed without dandelion. Additionally, the analysis of antioxidant enzyme activity in fish serum indicated that fish fed with dandelion had 58.3% higher activity of superoxide dismutase and 17% higher catalase activity compared to those that were not fed dandelion under heat stress. These results showed that dandelion-supplemented mud carp experienced alleviated oxidative stress caused by ROS accumulation. Therefore, dandelion serves as a promising nature-based solution to reduce heat stress effects in mud carp. This project offers a valuable approach for mitigating the impacts of global warming on aquaculture species to promote the sustainable development of the industry in a changing climate.

# NATURAL ANTIOXIDANTS REDUCE OXIDATIVE STRESS AND IMPROVE LARVAL DEVELOPMENT IN ZEBRAFISH (*Danio rerio*)

## Introduction

Resulting from an imbalance between reactive oxygen species (ROS) production and antioxidant defence, oxidative stress is a critical challenge for fish (Hoseinifar et al., 2020). In aquaculture settings, and particularly in hatcheries, oxidative stress is a major concern during the early stages of fish development due to the high metabolic activity of the larvae and environmental challenges (Menon et al., 2023). Excessive ROS production triggers lipid peroxidation, protein misfolding, and DNA damage, leading to reduced growth, impaired immune function, and increased susceptibility to disease (Jia, 2025). To mitigate these adverse effects, natural plant-derived antioxidants are increasingly being used in the aquaculture industry due to their broad-spectrum ROS-scavenging properties, low toxicity, and sustainability compared to synthetic alternatives (Hu et al., 2025). This study investigated the effects of water exposure to natural antioxidants on the larval development of zebrafish (*Danio rerio*), a widely recognised model for developmental and toxicological research, and for studying oxidative stress (Chowdhury and Saikia, 2022). The experimental design focused on three key aspects: survival and hatching rates, morphometric development, and ROS modulation.

## Materials and Methods

Wild-type and transgenic *casper* strains were used. The transparent *casper* strain, which lacks melanocytes and iridophores, was used to allow accurate *in vivo* quantification of ROS without interference from skin pigmentation (Rajpurohit et al., 2023). Fish were exposed to six concentrations of a commercially available natural antioxidant formula (0, 2.5, 5, 10, 25 and 50 mg/L) obtained from Marfeed (NAOX**,** MIAVIT GmbH, Essen, Germany) from 24 to 120 hours post-fertilization (hpf). Each treatment group consisted of 300 fertilised eggs, divided into three replicates. Survival and hatching rates were monitored daily. Morphological characteristics (such as body length, yolk sac area, and swim bladder inflation) and ROS levels were assessed at 120 hpf in 30 and 10 fish per treatment, respectively, according to Camussi et al. (2024). ROS production was assessed using the fluorescent probe carboxy-H2DCFDA, both under basal conditions and after induction of oxidative stress using the pro-oxidant molecule tert-Butyl hydroperoxide (Naef et al., 2021). Statistical analyses were performed using the Mantel-Cox log-rank test for survival rate data and the ordinary one-way ANOVA multiple comparison test for hatching rate, morphology and ROS data.

## Results

The study showed that antioxidant exposure did not affect survival or hatching rates ($p > 0.05$). Treated larvae exhibited significantly increased body length and swim bladder inflation and reduced yolk sac area compared to controls ($p \leq 0.05$) at each tested concentration. Fluorescence-based analysis (Fig. 1) showed a significant reduction in both basal and TBH-induced ROS levels ($p \leq 0.05$) at the 25 and 50 mg/L doses.

## Discussion and conclusions

These findings suggest that the natural antioxidants tested are safe up to concentrations of 50 mg/L. Furthermore, exposure to antioxidants enhances larval development by promoting faster development and higher larval metabolism, in agreement with the literature (El Basuini et al., 2022; Shastak and Pelletier, 2023). The use of the *casper* strain provided clear evidence of ROS reduction, confirming the utility of these natural compounds in oxidative stress management. Given the conserved nature of antioxidant biology across species (Birnie-Gauvin et al., 2017), zebrafish serve as a rapid and cost-effective model for aquaculture research. This study highlights the potential of natural antioxidants as sustainable tools to improve larval growth and health. Further long-term studies are needed to evaluate the effects of water exposure and dietary supplementation with natural antioxidants on growth performance and disease resistance in commercially farmed species.

*(Continued on next page)*

## Introduction

Global production of common carp increased from 1,205,000 t in 1990 to 4,360,000 t in 2020, with aquaculture accounting for the majority (97.2%). Within the European Union, the Czech Rep., Poland, and Hungary contributed 68% of the total common carp output (Shazada et al., 2025). The Czech Republic has maintained a selective breeding program for common carp for over 80 years. Over the past three decades, the program has adopted short-term sperm storage to enable controlled fertilization and preserve genetic diversity. In this context, sperm was collected individually and used at 0.5 to 5 days intervals depending on the breeding and/or testing protocols (Kocour et al., 2005). However, the use of short-term storage of carp sperm greatly reduced sperm fertility. Therefore, during the last five years, we have focused intensively on optimizing the method of sperm short-term storage. Firstly, to enhance the preservation of sperm motility and fertility, and secondly, to verify the potential effect of sperm storage on epigenetic changes in the offspring.

## Materials and methods

Mature males of carp were obtained following fish farm pond harvesting and maintained in a laboratory and hatchery aquatic system. Sperm and egg samples were collected individually after treatment with carp pituitary extract at 21°C. Sperm was diluted with carp extender (Cejko et al., 2018) and stored for 6-14 days at 0-2°C under aerobic conditions. Post-storage, 6 mL sperm suspension was warmed at 20 °C for 2 h, followed by assessment of spermatozoa motility, velocity, and hatchability. To investigate how sperm storage may affect offspring, we integrated DNA methylome, transcriptomic, and proteomic analyses. To standardize the protocol and minimize maternal variation, fertilization for the DNA study was conducted using eggs from a single female.

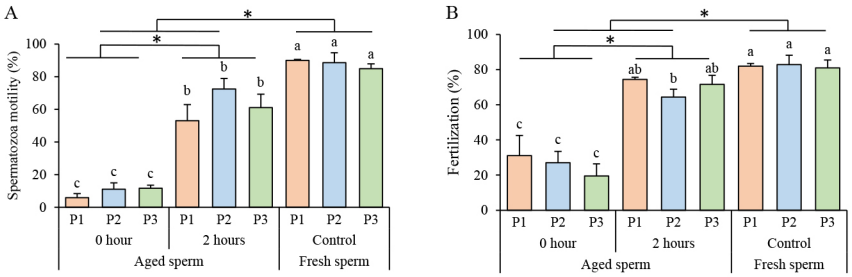

Fig. 1: Effects of warming temperature on motility and hatchability of large-scale short-term stored sperm 8 days at 0-2 °C (n=9; mean±S.D.) in carp under hatchery conditions (Zhang et al., 2023). Sperm from each of three males was pooled (6 mL total volume): males 1-3 (P1), males 4-6 (P2), and males 7-9 (P3) in 50 mL containers and incubated at 20 °C for 0 and 2 h. Fresh sperm was collected from the same males. Fertilization was performed using hatchery water at 30,000 spermatozoa per egg on 50 g eggs for each sperm pool. Values with different lowercase letters were different ($P < 0.05$). Values with asterisks showed significance ($P < 0.05$).

*(Continued on next page)*

**Results and discussion**

Carp sperm is always contaminated to some extent with urine (Billard et al., 1995). Although the level of contamination is low, storing sperm without an extender leads to a significant reduction in sperm motility and fertility within 24h, and sperm become immotile after 3 days post-storage (Cheng et al., 2022, Zhang et al., 2023, 2024). The most effective storage medium is the carp extender (110 mM NaCl, 40 mM KCl, 2 mM $CaCl_2$, 1 mM $MgSO_4$, 20 mM Tris, pH 7.5, and 310 mOsmol/kg) (Cejko et al., 2018). When sperm is used for fertilization within 3h of sperm collection, it is not diluted and cooled to 0-2 °C but instead stored in the incubator at 15-20 °C. This is due to the high sensitivity of carp sperm to temperature (Zhang et al., 2023). Therefore, fertilization within three hours, cooling is avoided. In contrast, sperm intended for later use is diluted 1:1 with pre-cooled extender (Cheng et al, 2022) and stored at 0-2 °C without antibiotics, for up to 14 days (Zhang et al., 2023, 2024). Notably, dilution even after 3h post-collection can still maintain sperm quality, making this practice suitable for hatchery applications (Shazada et al., 2025). Stored and diluted sperm should always be warmed to 20 °C before insemination. A 2-hour warming period significantly improves motility and hatching rates (Fig. 1). Intriguingly, malformation rates increased, especially in fresh sperm compared to those fertilized with stored sperm without warming (Zhang et al., 2023).

Sperm storage negatively affected sperm motility, viability, and DNA integrity, but did not affect the global DNA methylation of sperm or embryos. However, whole-genome bisulfite sequencing revealed altered methylation patterns in differentially methylated regions (DMRs) associated with genes in embryos fertilized with the 6-day-stored sperm. Results provide strong evidence of epigenetic inheritance influencing offspring's performance following fertilization with stored sperm (Cheng et al., 2024). Therefore, in the carp breeding program, we aim to minimize the sperm storage duration.

Limited availability, sustainability issue, and high cost restrict marine-derived ingredients utilization in aquafeed. Plant proteins and land animal fats are cost-effective alternatives but induce many challenges on growth and health. Specific plant oils and land animal fats contain high saturated fatty acids (SFA), which may lead to lipids accumulation. Lysophospholipids (LPLs) enhance nutrient absorption by promoting micelle formation and improving lipid transport. Butyrate, a short-chain fatty acid, supports intestinal health by serving as an energy source for enterocytes and reducing inflammation. Two studies were conducted to address issues posed by high SFA (fish stearin oil) and plant-based diets, offering potential strategies to optimize feed efficiency and mitigate metabolic disorders in fish. The first assessed LPLs' effects on growth and hepatic lipid metabolism-related gene expression, while the second investigated a combined LPL-butyrate approach.

First trial

The present study aimed to investigate the ameliorative effects of three inclusion levels of LPLs on fish stearin oil in largemouth bass. Five diets were formulated in a 68-days study, named WFO (130 g/kg winterized fish oil), FSO (130 g/kg fish stearin oil), LLO (FSO + 0.625 g/kg LPLs), MLO (FSO + 1.875 g/kg LPLs) and HLO (FSO + 3.125 g/kg LPLs), respectively. Largemouth bass fed FSO showed lower apparent digestibility coefficients (ADCs) of nutrients than the WFO. Medium and high doses (0.75, 1.25 g/kg) significantly increased ADCs of nutrients compared with low doses (0.25 g/kg) and FSO. Results showed significant higher FBW, FI, WGR and SGR in diet HLO than FSO, LLO and MLO. Diet MLO significantly decreased lipid and energy in whole-body and lipid retention compared with the FSO, LLO and HLO. In addition, activity and mRNA expression of ATGL significantly increased, while GPAT4 decreased in HLO (Figure 1).

Second trial

This study was conducted to evaluate the effects of lysophospholipids-butyrate (LPB) on a high plant protein diet in Largemouth bass. Three diets were formulated: positive control (PC) with 15.00 % soybean meal (SBM); high-plant-protein diet (HPP) with 28.00 % SBM; LPB diet supplement with 0.1 % LPB in HPP. Fish were fed for 60 days. Results indicated that the HPP group exhibited significantly lower FBW, WGR and SGR compared to the PC group. The HPP diet induced a notable increase in liver collagen fiber and liver lipid content, which was alleviated by LPB. In comparison to the HPP group, the LPB group showed significant decrease in alanine aminotransferase activity ($P < 0.05$). Compared with the PC group, the mRNA levels of ACC-1, DGAT, CPT-1 and TNF-α in HPP group were significantly increased ($P < 0.05$), while ATGL and HSL were significantly down-regulated. The mRNA levels of FAS, ACC-1, PPAR-α, ATGL, IL-1β and TGF-β were up-regulated ($P < 0.05$), while DGAT and TNF-α were down-regulated in the LPB group compared to HPP group ($P < 0.05$). In conclusion, the supplementation of 0.1 % LPB can alleviate liver lipid accumulation and fibrosis caused by high level of soybean meal.

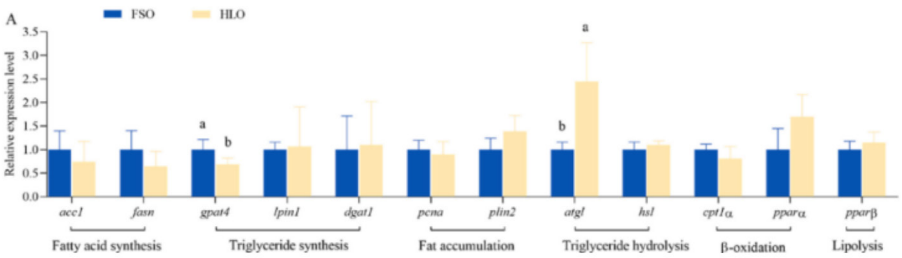

Figure 1, relative mRNA expression of genes involved in lipid metabolism

*(Continued on next page)*

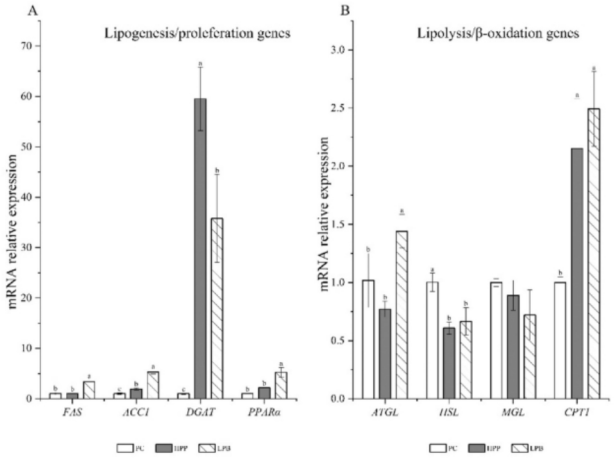

Figure 2, hepatic lipid metabolism gene expression.

Conclusion

The first trial revealed marked alterations in hepatic lipid metabolism-related gene expression between the control group and the lysophospholipids treated group. Notably, in second trial, the group supplemented with lysophospholipids-butyrate exhibited enhanced efficacy, demonstrating more pronounced differential expression of these genes compared to control.

# WITHDRAWAL TIME ESTIMATION AND DIETARY RISK ASSESSMENT OF SULFAMETHOXAZOLE IN GIFT TILAPIA (GIFT *Oreochromis niloticus*) AFTER ORAL ADMINISTRATION

Jianhua Liu, Bo Cheng*, Ruiqi Fan

Center of Ago-product Quality and Safety
Ministry of Agriculture and Rural Affairs of China
No. 223, Chaoyangmenwai Street
Chaoyang District, Beijing, China

Sulfamethoxazole (SMZ), a widely used broad-spectrum antibiotic in aquaculture, lacks comprehensive research on its residual elimination kinetics in tilapia. This study investigated SMZ residue depletion, withdrawal periods, and dietary risks in 1-year-old GIFT tilapia (Genetic Improved Farmed Tilapia *Oreochromis niloticus*) weighing 500 ± 50 g, following oral gavage administration of a loading dose (200 mg/kg BW on day 1) then 100 mg/kg BW daily for 6 more days, at 22±2°C.Tissue samples (plasma, muscle, skin, liver, kidney, gill, and remaining tissues) were collected from 5 fish per time point at intervals from 0.33 to 30 days post-administration, with SMZ residues quantified via HPLC-MS/MS. Results revealed peak SMZ concentrations at 0.33 days (8 h), ordered as liver > skin > plasma > kidney > remaining tissues > gill > muscle. Muscle residues fell below the maximum residue limit (MRL, 100 μg/kg) by day 3, while skin required 10 days. Kidney residues dropped below the limit of detection (LOD) earliest (16 days), followed by muscle, gill, and remaining tissues (25 days), whereas plasma, liver, and skin retained detectable levels until day 30. Elimination equations for SMZ across tissues exhibited first-order kinetics. Based on the specific conditions of this study, a minimum 11-day withdrawal period is recommended for edible tissues (muscle + skin) after SMZ administration. Hazard quotient (HQ) values for all tissues remained below the safety threshold (HQ = 1), indicating low dietary risk. These findings support SMZ use standardization in tilapia aquaculture to ensure food safety compliance.

# INTEGRATING LOW-TROPHIC AQUACULTURE WITHIN OFFSHORE WIND FARMS: ASSESSING ECOLOGICAL IMPACTS THROUGH FOOD WEB MODELING IN THE GERMAN NORTH SEA

Apsara Liyanwala*, Wolf Isbert, Sabine Horn, Bela H. Buck

Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research
Am Handelshafen 12,

Email: thiliniapsara.liyanwalagedon@awi.de

Given the growing competition for marine space, the integration of low-trophic aquaculture (LTA) within offshore wind farms (OWFs) represents a strategic multi-use (MU) solution to enhance ocean productivity while safeguarding ecological integrity. This study examines the ecological impacts of cultivating extractive organisms such as *Mytilus edulis* and *Ulva spp.* within the Meerwind Süd | Ost OWF, located in the German Exclusive Economic Zone of the North Sea. While LTA can contribute to ecosystem services like carbon sequestration and bioremediation, large-scale implementation may also generate ecological trade-offs through nutrient competition, sedimentation, or altered food web dynamics. To investigate these effects, a food web model will be developed using Ecological Network Analysis, incorporating biotic and abiotic data. The model aims to (1) analyze material flows before and after MU implementation, (2) evaluate carrying capacity limits for sustainable LTA expansion, and (3) assess functional shifts in the OWF food web. A systematic literature review is being conducted to inform model structure and parameterization. The outcomes of this research will deliver critical early-stage insights into the feasibility, trade-offs, and ecological thresholds of integrating LTA in offshore energy infrastructures. By providing an ecological perspective, this work aims to inform evidence-based marine spatial planning, guide regulatory frameworks, and support the development of environmentally sound offshore MU initiatives in the North Sea and beyond.

# DIFFERENT SCENARIOS OF PHOTOTHERMAL MANAGEMENT AND ITS IMPACT ON THE OUT-OF-SEASON EGG QUALITY IN PIKEPERC (*Sander lucioperca)*?

U. Ljuboratović[*a], N. Kitanović[b], G. Fazekas[a], J. Stanivuk[a], Z. Marinović[b], N. Vass[a], Z. Nagy[a], Á. Horváth[b]

E-mail: u.ljubobratovic@gmail.com

**Introduction**

The development of protocols for photothermal spawning induction in pikeperch has been a subject of interest for both scientific and commercial purposes during the last few decades (Hermelink et al., 2011; Żarski et al., 2019; Ljubobratović et al., 2025). Accordingly, several protocols have been published, showing their applicability on different levels of reproductive biology indicators. Nevertheless, the advanced gametogenesis cannot guarantee high reproductive performance, which is especially so in the case of eggs, where late stimulation of ovulation may lead to a reduction in gamete quality (Ljubobratović et al., 2022). Therefore, the evaluation of different scenarios of protocols for induction of out-of-season induction and their effect on egg quality upon hormonal stimulation is of importance for establishing indicators of the appropriate maturation stage for the procedure of artificial reproduction.

**Materials and methods**

The study was conducted in one climate chamber over two consecutive years in period from December 2020 to November 2022. In this manner, two photo-thermal spawning protocols were applied: SHORT - 19-week-long, composed of cooling only; LONG - 23-week-long, composed of 19 weeks of cooling with an additional four weeks of chilling. Accordingly, the first reproduction took place in early October 2021, while the second one was performed in early November 2022. For both reproductions, the warming thermal protocol of the artificial reproduction was conducted (Ljubobratović et al., 2021). The SHORT group was composed of 18 pairs of breeders, while the LONG group was composed of 15 pairs of breeders. The ovarian follicle diameter was measured three times during the cooling and chilling period, and egg and sperm quality were examined during the artificial reproduction.

**Results**

Significantly higher ovarian follicle diameters were found at each sampling moment in the LONG group. Latency time was significantly shorter in LONG groups, while main egg quality features were better in the SHORT group, except pseudo-gonadosomatic index, which was higher in the LONG group. On the other hand, better sperm quality was observed in the LONG group.

**Discussion**

Based on the assessed results, it seems that the final chilling phase, composed of a stable minimal temperature, is not required in case of artificial reproduction using external hormones for ovulation stimulation. While this phase appears beneficial for males, it may lead to latency time reduction and, consequently, to egg quality deterioration. Future studies should evaluate whether the low temperatures are necessary for out-of-season artificial reproduction.

**Acknowledgements**

The study was funded by the National Research, Development and Innovation Fund of Hungary (grants PD139053, K138425, FK142933). This work was supported by the Research Excellence Programme and by the Flagship Research Group Programme of the Hungarian University of Agriculture and Life Sciences. The corresponding author was granted the János Bolyai Research Scholarship of the Hungarian Academy of Sciences.

# LINKING CONSISTENT BEHAVIOURS TO PHYSIOLOGICAL STRESS RESPONSE IN ORDER TO UNDERSTAND FISH WELFARE INDICATORS

Sabine Lobligeois*(1,2), Noé Leneveu (3), Maelenn Beillevaire (3), Gabrielle Ladurée (1,2), Marie Delbasty (1), Manuel Gesto (4), David Benhaïm (1)

1) Department of Aquaculture and Fish Biology, Hólar University, Iceland
2) Institute of Life and Environmental Sciences, School of Engineering and Natural Sciences, University of Iceland, Iceland.
3) Institut Agro Rennes-Angers, France
4) DTU AQUA, National Institute of Aquatic Resources, Denmark

I would like to present the preliminary results for boldness/exploration of the fall and the correlation with physiology results: glucose and cortisol. It looks from what we did with Maelenn that boldness and exploration are repeatable but not correlated with glucose (doesn't seem correlated with cortisol either from the couple graphs that I made). I might have time over the summer to do some more stats. If I don't find any correlation, it also opens the debate on: do the stress induced by netting and the boldness test induce a similar response? It also raises the question of repeatability of the cortisol and glucose measurements.

An increasing number of studies are investigating physiological, neural, morphological, or behavioural indicators of welfare in fish. Yet, the links between these traits remain poorly understood. Animal personality refers to consistent individual differences in behaviour across time and contexts. Studies have shown that several behavioural traits in fish, such as boldness and exploration, exhibit such consistency. In some species, these traits have been shown to correlate with fitness, and indicators of welfare. However, few studies have investigated the correlation between these traits. Consequently, the underlying mechanisms shaping fish personality remain unclear. To address this gap, we raised Arctic charr (*Savelinus alpinus*) from an Icelandic aquaculture strain, representing six different families, in either plain tanks or tanks containing a shelter. Tagged individuals were tested for behaviour three times in an open field test and in an emergence test respectively. Following the behavioural trials, the same fish were exposed to a standardized netting stressor, and blood samples were collected either 40 minutes or 2 hours 40 minutes post-stress. We first assessed the consistency of exploration and boldness. Then, we investigated the influence of genetic (family) and environmental (tank condition) factors on personality traits and physiological stress responses. Finally, we explored correlations between traits. This study highlights the relevance of understanding the physiological underpinnings of personality traits in relation to fish welfare. The project and its preliminary results regarding the factors influencing physiology and behaviour, as well as the correlations between these traits will be presented.

# LONG INTESTINES AND STRANGULATING OBSTRUCTION IN FARMED ATLANTIC COD *Gadus morhua*: A RESULT FROM ENVIRONMENTAL FACTORS AND FEEDING STRATEGIES?

G. Løkka[1], F. S. Skedsmo[1], A. Bogevik[2], J. V. Jacobsen[3], K. R. Bakkemo[4], E. Chikwati[1], A. Espenes[1], M. Quagliardi[1,5], T. M. Jonassen[6] and T. M. Kortner[1]

## Introduction

One of the main challenges for the Atlantic cod (*Gadus morhua*) farming industry is a fatal intestinal disorder that compromises animal welfare and causes high mortality. The production of Atlantic cod is experiencing a resurgence to fulfil market demand for a stable fish supply, and ambitions are high in expanding the industry for the future. The pathological gut conditions, undoubtedly painful for the fish, occur from small to large slaughter-size causing high economic losses and is considered a main obstacle for further increase in production. There has until now been a genetic selection process for growth, behaviour and other favourable domestication traits in Atlantic cod, but gut anatomy and gut health have so far not been the focus of the cod breeding programs. The current feeding strategy for cod is moreover based on knowledge and infrastructure from the salmon industry and is probably not yet optimally adapted for cod farming. The gut can show remarkable phenotypic flexibility in response to dietary and other environmental signals. The overall goal of the ongoing research project FôrCod (RCN project no. 337056) is to reduce mortality in cod aquaculture related to intestinal disorders, by increasing our understanding of cod gut anatomy, prevalence and extent of gut disorders, and identifying potential underlying causes of pathological conditions.

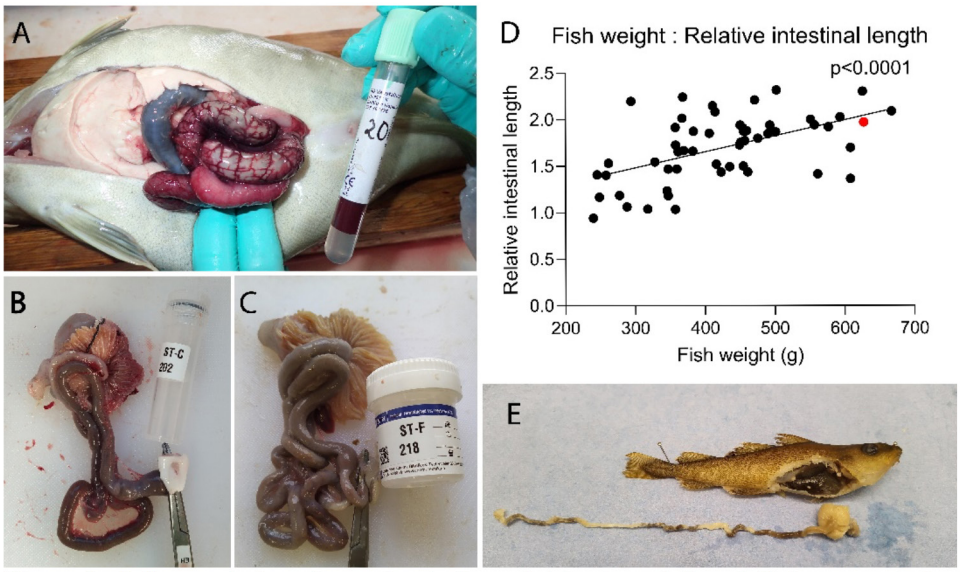

*Figure 1. A) Strangulating obstruction in farmed Atlantic cod. B and C) Large variation in intestinal length and organization in farmed cod. D) Relative intestinal length is linked to fish weight. The red dot illustrates an individual with strangulating obstruction. E) Long intestines in early developmental stages.*

*(Continued on next page)*

**Materials and methods**

Several field surveys and controlled feeding trials have been carried out to study factors to better meet the physiological requirements of Atlantic cod, including improvements of feeding regimes during on-growing stages (meal frequency, underwater feeding) and diet composition (ash and chitin content, moisture, raw material use). Field surveys in cooperation with commercial cod farmers have been performed to investigate the current status of the gastrointestinal system of farmed cod. Inclusion of crab shell meal in the diet have been tested, both in a controlled short-term digestibility trial [1] and in a large-scale feeding trial in practical production. Cod at early developmental stages, obtained from the cod breeding program of Nofima, have moreover been studied. Studies have focused on gastrointestinal anatomy and organization, gut morphology and health, and nutritional status.

**Results**

We recently published the first in-depth pathological description of the intestinal disorder, which is correctly denoted 'strangulating obstruction' [2] (***Fig. 1A***). In affected fish, part of the intestine is permanently entrapped (incarcerated) under fibrous strands in the mesentery. The entrapment interferes with blood flow and physically blocks the flow of the intestinal content, causing a strangulating obstruction with luminal fluid build-up, severe venous congestion causing ischemia of the intestinal wall.

We have observed a large variation in gut morphology observed in today's farmed cod (***Fig. 1B-C***) where relative intestinal length increase with fish size (***Fig. 1D***). Compared to wild cod, the farmed cod has much longer intestine and a more complex organization of the gastrointestinal tract and mesentery. Cod farmers report that intestinal disorders primarily manifest during periods of rapid growth and high feed intake and increase in severity as the fish grow larger. This suggests an association between the long, complicated intestines of the farmed cod and the occurrence of fatal strangulating obstruction. The long and complicated intestine seems to develop during early life stages of farmed cod (***Fig. 1E***) indicating that problems with intestinal strangulation can be rooted in the larval stage. Whether the complicated intestinal system in the farmed cod is related to the environmental conditions such as the feeding regime, a result of genetic breeding, or a combination, is not known. Results from several trials and field surveys performed as part of the project will be presented and discussed at the conference.

# “CONTRASTING MEDIA NARRATIVES ON AQUACULTURE IN SPAIN AND FRANCE”

Raquel López-Martínez[1], Bertrand Le-Gallic[1]

[1] University of Western Brittany
Brest, France

Aquaculture has gained increasing recognition as a key sector contributing to food security, economic development, and environmental sustainability. However, its expansion is influenced by societal perceptions, which are shaped by media representation. This study presents a comparative analysis of media coverage and societal perceptions of aquaculture in Spain and France, with a particular focus on the differing narratives surrounding the trout and salmon industries. By employing content analysis and sentiment classification, we assess how these sectors are portrayed in the media, the key themes associated with them, and the evolution of public discourse over time.

The methodology consists of a systematic media analysis, collecting and categorizing news articles related to aquaculture from national and regional sources. Sentiment classification was conducted to determine the portrayal of aquaculture as positive, neutral, or negative, while thematic content analysis identified key stakeholders, recurring narratives, and dominant concerns in the discourse.

Our findings indicate that in Spain, media coverage of aquaculture has intensified in recent years, with a growing emphasis on sustainability, innovation, and market development. While the perception remains largely positive (48% of articles), there has been an increase in neutral (26%) and negative (27%) portrayals, often linked to environmental concerns and regulatory challenges. In contrast, in France, discussions were more centred on traditional fish farming, particularly trout and salmon production, with a predominance of positive coverage (63%). However, issues such as policy constraints and environmental sustainability were also significant themes.

A notable divergence emerges in the media representation of trout versus salmon. In France, trout farming has been portrayed as a traditional and localized industry, benefiting from strong regional identity and consumer trust. In contrast, salmon aquaculture, particularly in relation to international markets, has faced greater scrutiny regarding environmental impact, disease outbreaks, and regulatory challenges.

In Spain, the commercialization of trout has been positioned as an innovative and growing segment of the market, while salmon remains a dominant but sometimes controversial sector, often linked to broader discussions on global sustainability and competitiveness.

This study highlights the importance of transparent communication and knowledge dissemination in fostering public trust and social acceptability of aquaculture. Understanding how media narratives evolve can inform policy strategies to enhance societal engagement and support the sustainable development of the sector.

# GONADAL SEXUAL DIMORPHISM IN GENOME-WIDE DNA METHYLATION AFTER BACTERIAL IMMUNE CHALLENGE IN EUROPEAN SEA BASS (*Dicentrarchus labrax*)

## Introduction

In the current global population growth and climate change, there is an urgent need to supply the global fish demand while addressing key challenges in aquaculture, particularly those related to the immune response in farmed fish, which affects their vulnerability to infections. The European sea bass (*Dicentrarchus labrax*) is one of the most widely cultured species. According to APROMAR (2023), in 2021, this species ranked as the fifth most farmed in Europe and has shown a steady increase in production, rising from 82,825 tonnes in 2020 to 96,647 tonnes in 2021 across Europe.

Sexual dimorphism has been shown to influence vertebrate immunity through various factors, whose effects are mediated by epigenetic mechanisms, such as DNA methylation, non-coding RNAs, and histone modifications (Sasaki and Matsui, 2008). However, this relationship in fish remains underestimated and poorly studied (Caballero-Huertas et al., 2024). Our study uses cutting-edge techniques to investigate differences in genome-wide
DNA methylation patterns in the context of a sex-related immune response.

## Methodology

Samples from the gonads of European sea bass were collected 48 hours after bacterial infection with *Vibrio anguillarum*. Subsequently, genome-wide DNA methylation analysis was performed using the NEBNext® Enzymatic Methyl-seq Kit (EM-seq™) protocol with triplicate samples of each condition and gonadal tissue. Methylation patterns were assessed at each CpG site. Differentially methylated regions (DMRs) and differentially methylated loci (DMLs) were then identified for each comparison: between treatment conditions within the same sex (INF_F vs CTRL_F and INF_M vs CTRL_M), and between sexes under the same condition (CTRL_F vs CTRL_M and INF_F vs INF_M). After that, the different gene regions that overlapped with the DMRs and DMLs were found. Finally, these genes were annotated using the European sea bass genome as a reference, followed by functional enrichment analyses to identify associated Gene Ontology (GO) terms.

## Results

*Vibrio anguillarum* induced changes in the gonadal DNA methylation pattern across all comparisons. The highest number of differentially methylated CpG sites was observed when comparing sexes under the same condition, specifically in CTRL_F vs CTRL_M and INF_F vs INF_M, with 88,029 and 105,053 hypermethylated CpGs, and 2,829,573 and 2,752,371 hypomethylated CpGs, respectively. Our results suggested that there are more differences in DNA methylation between sexes under basal and infected conditions than after immune activation within the same gonadal tissue. Notably, the highest number of differentially hypermethylated CpGs was found after immune activation when comparing females to males, further highlighting the importance of sexual dimorphism in immune responses. When comparing the infected group against the control group within the same sex, in testes, we observed a higher number of differentially hypomethylated CpGs (53,489) than hypermethylated ones (50,099). In contrast, in ovaries, a higher number of differentially hypermethylated CpGs (94,329) compared to hypomethylated ones (68,876) was observed.

*(Continued on next page)*

## Discussion

These differences in the number of differentially methylated CpG sites suggest that sexual dimorphism plays a significant role in the methylation pattern of European sea bass, with females being hypomethylated compared to males under basal conditions. Furthermore, changes in the methylation pattern after the immune activation show a different tendency in each sex. Overall, in males, immune activation appears to induce a higher number of hypomethylated CpG sites compared to controls. In contrast, females show a tendency towards hypermethylation, which may be associated with gene repression. These findings highlight the importance of sex influencing the methylation status.

## Introduction

To assess fish welfare, physiological stress markers can be measured, with particular emphasis on those related to oxidative status. In this sense, glutathione metabolism plays a central role in cellular redox balance and defense against oxidative stress; however not all organisms respond to stress the same way, there may be differences between species from the same habitat. Moreover, lipid oxidative damage is a crucial indicator of animal welfare, reflecting cellular stress and health status. On the other hand, blood is the most commonly used sample, but to minimize alterations caused by stress from sampling, skin mucus is increasingly being used as an alternative. In addition, there are seasonal changes throughout the year, because of the circannual rhythms, that are to be considered. This study aims to seasonally characterize glutathione metabolism and lipid peroxidation levels in three mangrove teleost species held in captivity and to validate non-invasive sampling alongside oxidative status parameters as welfare markers.

## Materials and methods

*Scatophagus argus*, *Selenotoca multifasciata* and *Terapon jarbua* were maintained at the BioDomo of the Consorcio Parque de las Ciencias de Granada (Spain). Four samplings of mucus tegument of six fish of each fish species were conducted coinciding with seasonal changes: March (spring), June (summer), September (autumn), and December (winter). Six individuals of each species were sampled every season: mucus was collected. After processing, enzyme activities of glutathione peroxidase (GPX), glutathione S-transferase (GST) and glutathione reductase (GR), and levels of lipid oxidative damage (LPO) were determined. Protein concentration was determined by Bradford method. Results are presented as mean ± SEM. Two-way ANOVA was used, with species and season as fixed factors. As in all cases interaction among factors was detected, species and season effects were analyzed by a one-way ANOVA. F values were significant for $P<0.05$ and differences were determined following a post-hoc analysis using Tukey test. Statistical analyses were performed with SPSS v.25.

## Results and Discussion

Results for GPX, GST, GR, and LPO are shown in Figure 1. GPX activity peaked ($P<0.05$) in *T. jarbua* during spring and in *S. multifasciata* during summer, while GST activity was significantly higher in *S. argus* except in summer. Statistically, GR activity was highest in *S. multifasciata* during winter and summer, but in *T. jarbua* during autumn. LPO levels were generally highest in *T. jarbua*, except in spring, when *S. multifasciata* exhibited the greatest lipid peroxidation. No species consistently showed superior or inferior activities for enzymes related to glutathione metabolism, as patterns were season dependent; however, *T. jarbua* tended to display higher oxidative stress, as indicated by LPO values.

*(Continued on next page)*

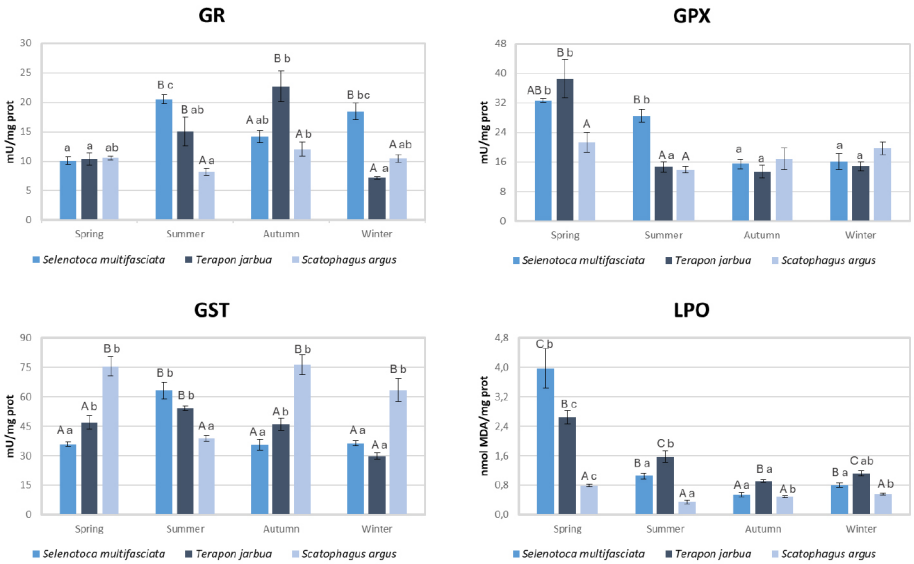

Fig.1. Specific activity for glutathione peroxidase (GPX), glutathione S-transferase (GST), glutathione reductase (GR) and levels of lipid peroxidation (LPO) in mucus of three mangrove fish species. Values are means ± SEM (n=6). Letters present statistical results from one-way ANOVA. Small letters indicate differences ($P<0.05$) among seasons for each fish species. Capital letters indicate differences ($P<0.05$) among fish species in each season.

On the other hand, seasonal trends revealed a circannual cycle for most parameters, with GPX, GST, and GR activities varying by species. So, GPX activity remained stable year-round in *S. argus* but significantly peaked in spring and summer for *T. jarbua* and *S. multifasciata*. For GST and GR, *S. multifasciata* reached maximum activities in summer, whereas *S. argus* recorded the lowest values in this season ($P<0.05$). However, lipid oxidative damage increased in spring across all species, suggesting higher stress during this period.

Overall, the data confirm species and season specific variation, with *T. jarbua* showing the highest stress levels. These oxidative stress parameters can serve as reliable welfare indicators and can be effectively assessed using non-invasive sampling methods.

# PROFILING THE RAINBOW TROUT ERYTHROCYTE EPIGENOME IN FISH EXPOSED TO DIFFERENT IMMUNOLOGICAL STIMULI

Adrian Lopez-Murcia*, Maria Salvador-Mira, Veronica Chico, Maria del Mar Ortega-Villaizan

*Instituto de Investigación, Desarrollo e Innovación en Biotecnología Sanitaria de Elche (IDiBE)

Recent studies in immunology have pointed out a process called trained immunity which is defined as the long-term functional reprogramming of cells of the innate immune system, induced by exogenous or endogenous challenges, leading to an enhanced response to a second challenge after a return to a non-activated state [1]. Trained immunity is known to be mediated by epigenetic reprogramming. In the immune system, epigenomic regulation has been observed during hematopoiesis, T cell memory, and B cell development. Additionally, epigenetic changes in monocytes and NK cells have been shown to imprint a form of innate immune memory [2]. Therefore, the concept of epigenetic imprinting on the immune system has gained particular relevance in the context of vaccination [3].

Fish red blood cells (RBCs) are gaining attention as a model for studying immune responses due to their active gene expression and participation in the innate and adaptive immune responses [4]. In the present work, we evaluated the epigenome of red blood cells (RBCs) from rainbow trout subjected to the viral hemorrhagic septicemia virus (VHSV), a DNA vaccine encoding the glycoprotein G of VHSV (pGVHSV), and an antiviral treatment based on green tea (*Camellia sinensis*). We used single cell Assay for Transposase-Accessible Chromatin sequencing (scATAC-seq), a high-throughput method used to identify open regions of chromatin across the genome, providing insight into the epigenetic landscape.

For this purpose, rainbow trout individuals were injected intramuscularly with the different stimuli mentioned above. After 3 days (or 5 days in the case of those individuals injected with pGVHSV), these individuals were sacrificed and RBCs were purified from blood from each individual. Then, we proceed with the characterization of chromatin accesibility by scATAC-seq.

The results demonstrated that vaccination and viral exposure showed distinct chromatin accessibility profiles, highlighting stimulated epigenomic remodeling of the immune response of RBCs, indicating activation of key regulatory elements.

# IMPACTS OF DIFFERENT LAND-BASED PRODUCTION ENVIRONMENTS ON SKIN HEALTH IN ATLANTIC SALMON

Ana Lourenço[1,3]*, Siri Helene Helland-Riise[1], Linda Andersen[2], Fernando Afonso[3], Carlo C. Lazado[1]

[1] Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 1433 Ås, Norway

E-mail: anacarolinagl12@hotmail.com

**Introduction**

Issues affecting skin health have been a persistent challenge in Norwegian Atlantic salmon (*Salmo salar*) aquaculture. The skin is a multifunctional organ, playing a crucial role in protecting against environmental stressors, pathogens, and physical injury. Beyond serving as a physical barrier, it also performs essential immunological functions, housing complex mucosal layers that contribute to immune surveillance, physiological homeostasis, and protection against harmful agents. As such, skin health is central to the overall robustness and performance of salmon in aquaculture.

The surrounding production environment closely influences the integrity and functionality of the skin barrier. Often regarded as a living sensor, the skin reflects the quality of rearing conditions, making it a key indicator of health in response to environmental factors. Before Atlantic salmon are transferred to sea, they are reared in various land-based systems, with recirculating aquaculture systems (RAS) becoming increasingly common. This shift has largely replaced the previously widespread use of flow-through systems (FTS) and partial-reuse systems (PRS). While RAS offers enhanced control over water quality, they are frequently associated with challenges such as elevated levels of ammonia, nitrite, and organic load, among other factors. These environmental parameters have been linked to compromised skin health, although direct comparisons between these systems remain limited.

This study investigates the effects of different land-based production environments on the skin mucosal barrier of Atlantic salmon, with a focus on immune function, oxidative stress responses, and overall skin physiology.

**Materials and Methods**

A total of 1800 Atlantic salmon parr, with an initial weight of 30-40 g, were reared under three different production regimes: a flow-through system (FTS), a recirculating aquaculture system (RAS) with 95% water recirculation, and a partial-reuse system (PRS) with 40% water reuse. During the first five weeks (Phase I), all fish underwent smoltification, with each system operating in freshwater at 12 °C. In Phase II (post-smolt stage), which lasted three weeks, the salinity in the FTS and PRS systems was increased to 33 ppt, and the water temperature was maintained at 8-10 °C. The RAS group was kept at the same temperature, but the system operated with 17 ppt brackish water. In the final phase (Phase III), all groups were transferred to flow-through systems with a salinity of 33 ppt and a temperature of 8-10 °C to simulate sea transfer conditions.

Skin samples were collected at the end of each phase for molecular and histological evaluations. Mucus was also collected and subjected to proteomic and metabolomic analyses. To simulate exposure to a secondary stressor, scale cultures from fish in Phase III were established and exposed to hydrogen peroxide ($H_2O_2$). Molecular and biochemical assays were then performed on these samples.

**Results and Discussion**

Preliminary histopathological analysis indicated an increase in the severity of pathological changes in the skin in phase III across all groups. Skin morphometric parameters, including epidermis thickness and the number of mucus cells present in the epidermis, did not reveal any significant differences between groups or phases. However, a significant increase in dermis thickness was observed after phase I in the FTS group.

*(Continued on next page)*

Gene expression analysis of skin samples from all production systems across the three phases showed a significant upregulation of immune- and stress-related genes in the PRS group during phase II. Mucin expression was significantly higher in the FTS group than in RAS and PRS groups, and other structural genes also showed a significant upregulation in the FTS and RAS groups in phase III. These findings suggest that production conditions influence skin functions related to barrier integrity and structure.

In the cell culture analysis, while the overall expression patterns of oxidative-stress genes were similar between control and stressed groups, there was a significant increase in the expression of some genes (e.g., *gpx*, *gr*, and *mnsod*) in the PRS group compared to the FTS group upon $H_2O_2$ exposure. In most of the oxidative-stress genes analysed, gene expression was lower in the FTS group than in the RAS and PRS groups, possibly indicating reduced cellular stress in salmon reared in flow-through conditions.

Oxidative stress biomarkers in the cell culture showed that in the FTS group, exposure to $H_2O_2$ led to an increase in total antioxidant capacity and a decrease in reactive oxygen species (ROS) and reactive nitrogen species (RNS), suggesting an efficient antioxidant system, characterized by a dynamic inverse relationship between antioxidant capacity and ROS/RNS levels. The opposite trend was observed in the PRS group.

Preliminary analyses of the mucus revealed differences in the protein and metabolite composition between the production systems, although data are still being analysed. These results will be presented during the meeting.

**Conclusions**

This study demonstrates that each land-based production system has a different impact on the skin barrier functions of Atlantic salmon, with a significant effect on immune and oxidative stress responses. Our findings suggest that the fish group reared in a partial-reuse system exhibited more changes in skin health conditions, exhibited by increased immune and stress responses, along with reduced antioxidant capacity, compared to fish from other rearing systems.

## Introduction

The gonads of sea urchins are a gastronomic delicacy in several regions of the world, which has led to intense harvesting activity. As a result, the sea urchin fishery has become unsustainable. The purple sea urchin *Paracentrotus lividus* is a highly valuable species with a critical ecological role due to its wide distribution. For this and other sea urchin species, aquaculture provides alternative solutions to support wild population restoration as well as stock enhancement initiatives. Aquaculture for restocking purposes and the production of juveniles in controlled environments for further release in areas of over-exploitation helps boost populations and offers promising tools for resource management. However, the production of sea urchin juveniles is still laborious. The complex life cycle, with different stages of development associated with a high mortality rate, especially during the metamorphosis phase, constitutes a major challenge (Mendes et al., 2019). The present study aimed to control the metamorphosis phase and evaluate the feasibility of using 3D-printed clay substrates conditioned with different biofilms to enable the settlement process and improve the survival of juvenile sea urchins.

## Materials and Methods

Adult *P. lividus* urchins (4,20 ± 0,24 cm) were collected by hand on a rocky beach near Peniche and induced to spawn with an injection of potassium chloride. For fertilization, eggs and sperm from different animals were collected and mixed in a beaker in a ratio of 1 egg: 50 spermatocytes, guaranteeing genetic diversity and avoiding polyspermy. The larval rearing experiment was carried out in four 50 L cylinder conical tanks in closed system and maintained in a room with controlled temperature. Larvae were stocked at a density of 4 ind./mL, kept at a salinity of 35, and average temperature of 18 °C and reared in aerated static seawater. Larvae were fed with a mixed microalgal diet (*Chaetoceros calcitrans* and *Rhodomonas lens*) during their exponential growth phase. Larval competence was defined as the number of days post-fertilization (DPF) required for at least 75% of the larvae to reach competence for settlement (Gomes, 2019). To promote settlement, the larvae were transferred to 15 L aquariums containing 3D printed clay substrates conditioned with different biofilms: (a) a biofilm composed of two benthic diatoms, *Skeletonema costatum* and *Nitzschia acicularis*. cultivated in the laboratory - microalgae biofilm: (b) a biofilm composed of natural phytoplankton collected from a rocky beach and cultivated in the laboratory - indoor biofilm: (c) a biofilm naturally grown in the substrates emersed in Peniche harbour – outdoor biofilm. The substrates were conditioned with the different biofilm-forming conditions for eight weeks before sea urchin settlement. Just before the larvae attained competence, all the substrates were immersed in tanks holding adult sea urchins to acquire conspecific molecules. Then, the conditioned 3D-printed substrates were hung in the larvae rearing tanks to allow the competent larvae to metamorphose and settle on the surface of the substrate. Settlement success rate and sea urchin growth were assessed weekly.

*(Continued on next page)*

**Results**

The weekly evaluation of the settling rate between the different biofilm treatments revealed significant differences ($H_{(2)}$ = 23,122, *p-value* < 0,001). The microalgae biofilm treatment differs significantly from the indoor treatment ($Z_{(2)}$ = 24,021; *p-value* 0,005) and outdoor treatment ($Z_{(2)}$ = 40,698; *p-value* 0,001), There was a higher rate of settlement in the substrates conditioned with the outdoor biofilm, and the lowest settlement in the substrates conditioned with the microalgae. The weekly evaluation of the average growth of post-settled juveniles settled in the substrates revealed no significant differences in relation to the nature of the conditioning biofilm. Regardless, these results suggest a non-significant trend towards greater growth in the group settled in the substrates conditioned with the indoor biofilm.

**Discussion**

In marine benthic ecosystems, sea urchins have a substantial effect on the microenvironmental habiting the surface of temperate rocky shores. Juvenile sea urchins move using their spines and ambulatory feet and possess chemosensory abilities that allow them to detect nearby food sources (Solari et al., 2021) and select the most suitable habitats. This experiment demonstrates a preference of post-metamorphosed sea urchins for settling on surfaces conditioned with the outdoor biofilm. This result may have been influenced by biofilm´s closer resemblance to natural conditions. In contrast, the microalgae-based biofilm showed lower settlement success. This may be due to the biofilm not being fully developed, despite the benthic diatom used to form the microalgae biofilm being commonly found in rocky areas covered with macroalgae mats. In future studies, the substrates should be conditioned for a longer period in areas where the natural diet of these organisms is more readily available.

# DAILY EXPRESSION OF CLOCK GENES AND LIPID METABOLISM-RELATED GENES IN *Epinephelus malabaricus* AND THE EFFECTS OF RESTRICTED FEEDING

Siqi Lu*, Rikuto Kuniyoshi, Yafan Zhu, Koudai Fukunaga., Hiroki Takekata, Shingo Udagawa, and Akihiro Takemura

University of the RyukyusNishihara
Nakagami District, Okinawa, Japan 9012213
k248408@eve.u-ryukyu.ac.jp

Biological clock regulates daily rhythms in behavior, physiology, and metabolism. The central clock in the brain is synchronized by the photoperiod, whereas peripheral clocks in peripheral tissues such as the liver may be influenced by other synchronizing factors. This study aimed to elucidate the role of clock genes in the lipid metabolism of the Malabar grouper *Epinephelus malabaricus*. To achieve this, we examined the diurnal expression patterns of clock genes in both diencephalon (central tissues) and liver (peripheral tissues), along with the diurnal expression of genes involved in the liver lipid metabolism.

Juvenile Malabar groupers used in this study were acclimated in a flow-through seawater tank under natural photoperiod conditions (sunrise at 0630 h and sunset at 1800 h). Following acclimation for two weeks, fish (n = 5 per time point) were sampled 4-hour intervals beginning at 0700 h. The diencephalon and liver were collected after anesthesia. RNA was extracted from both tissues, reverse-transcribed into cDNA, and analyzed by the real-time polymerase chain reaction to measure the expression levels of clock genes and lipid metabolism-related genes. Clock genes included brain and muscle ARNT-like (*bmal1* and *bmal2*), period circadian regulator 2 (*per2*), cryptochrome circadian regulator 2 (*cry2*), and circadian locomotor output cycles kaput (*clock*).

Clock genes (*bmal1*, *bmal2*, *cry2*, and *clock*) in the diencephalon and liver peaked during the photophase. In contrast, lipid metabolism-related genes (*cpt1, fas, srebf1*) exhibited daily expression patterns with lower expressions during the photophase and higher expressions during the scotophase. Many of these genes were associated with lipolysis. These results suggest that the expression of lipid metabolism-related genes may be influenced by clock genes expressed in either the central or peripheral tissues.

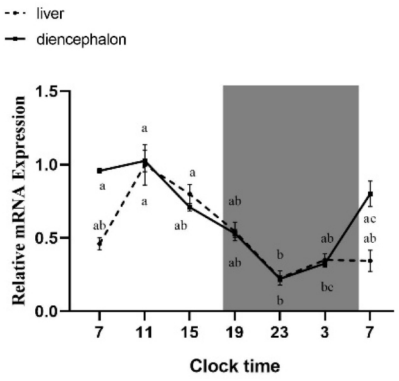

Fig. 1. Daily changes in the transcript levels of clock gene (per2) in the diencephalon and liver of the Malabar grouper. Significant differences between time points are indicated by different lower-case letters. Gray background represents dark period.

# OPERATIONAL MONITORING AT AN AQUACULTURE FACILITY

Alejandro Luna García-Valenzuela[1,*], Carmen Martínez muñoz[2], José Enrique Gutiérrez Romero[3], Pablo Romero Tello[4]

[1] Head Naval and Offshore Technology, CTN, Spain
2 Senior Engineer in Seakeeping and Mooring Systems, CTN, Spain
[3] Department of Applied Physics and Naval Technology, UPCT, Spain
[4] Department of Applied Physics and Naval Technology, UPCT, Spain

**Introduction:**
The advancement of offshore aquaculture has necessitated the development of robust and resilient infrastructures capable of enduring variable and harsh marine environments. Nonetheless, significant concerns persist regarding the efficacy of current conventional system designs, monitoring protocols, and maintenance strategies, primarily due to frequent mooring system failures and structural deformations induced by the synergistic effects of hydrodynamic forces such as currents, wave action, and wind loads.

The AQUAMOORE project, funded by INFO Región de Murcia, seeks to address these challenges through the engineering and deployment of an advanced sensor network integrated with a data analytics framework on a mussel longline platform. This system facilitates continuous real-time monitoring of both structural integrity and environmental parameters, enabling early detection of potential failure modes and risk scenarios. Moreover, it supports the implementation of predictive maintenance strategies grounded in numerical simulations, alongside growth modeling to optimize mussel production.

**Materials and methods:**
A load sensor system with satellite data transmission was installed for continuous monitoring of tensions in production ropes, alongside a current meter to assess sea state conditions.

The working methodology comprised the development of an analytical tool, the execution of seakeeping simulations, and the creation of a machine learning model and digital twin for tension prediction. All results were compared and validated against data collected by the sensor system on two selected days representing storm and calm sea conditions.

This process was initially developed through a simple pilot based on the mooring of a buoy to validate the methodology by studying the correlation between models. Subsequently, the described methodology was applied in a pilot project involving AZTI's mussel raft located in Mutriku (Basque Country, Spain) (Figure 1), aimed at determining tension in three production ropes and assessing the effect of current on these parameters, thereby enabling estimation of biomass at any given time. Two of the ropes were loaded with known deadweights, while the third carried mussels.

**Results:**
The results obtained from the various tools in the buoy pilot validated the implemented methodology. The average stress values (mean tension) from the time series collected by the sensors and numerical simulations were comparable and of the same order of magnitude, with errors below 13%. Additionally, the machine learning model showed a correlation coefficient of $R^2 = 0.834$ relative to the tension measured by the sensors.

Regarding the mussel raft pilot, the conducted study enabled precise characterization of the stresses experienced by three installed production lines. Through analytical, numerical, and experimental methodologies, simulation models were successfully validated against real sensor data. The analytical tool proved effective in estimating tensions under moderate current conditions. However, the machine learning model did not achieve a valid correlation, as current was the sole input variable, which proved insufficiently representative at the raft's location.

The sensor data indicate a progressive increase in load on the mussel line, reflecting the expected biomass growth. In contrast, the lines equipped with deadweights exhibited lower and more consistent load values, potentially attributed to the accumulation of biofouling over time.

*(Continued on next page)*

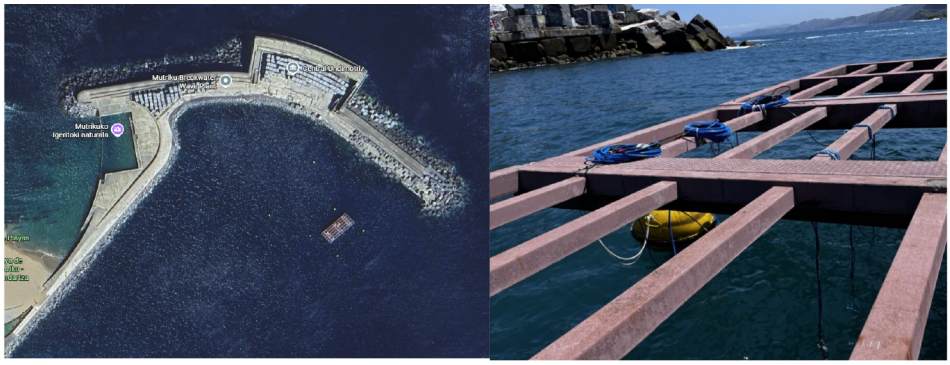

*Figure 1. Mutriku raft and installed sensor system.*

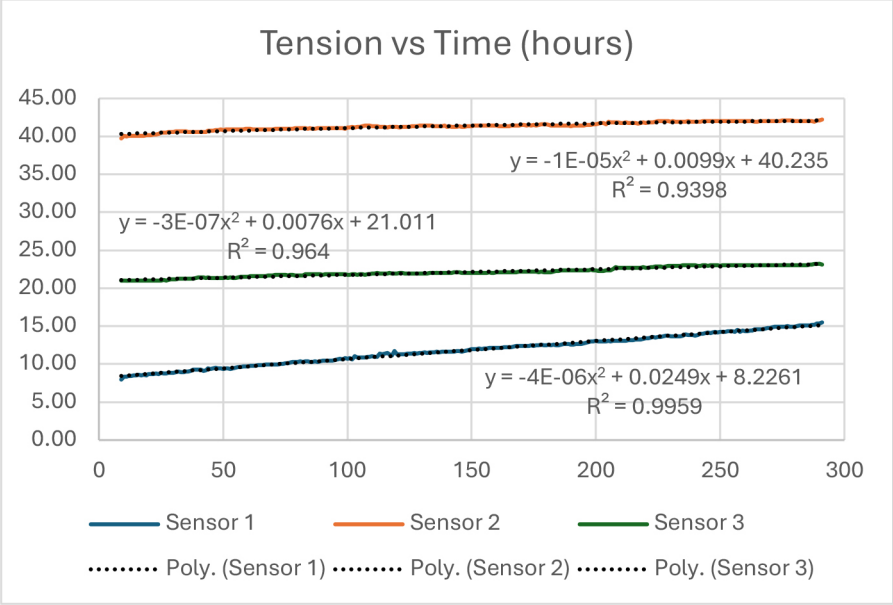

*Figure 2. Pilot raft results*

**Conclusion and future work:**

The results from the buoy pilot validated the working methodology proposed in the project.

The data collected from the mussel raft demonstrated the feasibility of measuring the tension exerted on the production line. Furthermore, the equations derived for each line confirmed the validity of the system, as the extrapolated values at X = 0 closely matched the initial wet weight of each line. The analytical tools and numerical simulations yielded satisfactory results, whereas the machine learning model did not achieve a strong correlation, primarily due to the minimal current observed in the raft's environment, and therefore its lack of representativeness, being the sole variable of the model.

Subsequently, the tension measurement system for weight estimation will be deployed on a longline, where current is expected to have a greater influence on the production lines and additional variables, such as wave loads, will also be monitored.

This new deployment aims to decouple the contribution of current to the measured tension in each line and to estimate the biofouling accumulation rate. Ultimately, this will enable accurate estimation of the biomass present on each line. The resulting data will be compared with a study conducted by AZTI in 2024 [1] on mussel growth in this type of production system.

# RAISING THE BAR ON AQUAFEED SUSTAINABILITY: TRANSPARENCY, EMISSIONS, AND SOCIAL DUE DILIGENCE

Ola Luthman*, Rob Parker, Alexandra Warrington

*Aquaculture Stewardship Council
Daalseplein 101, 3511 SX Utrecht
The Netherlands
ola.luthman@asc-aqua.org

Identifying and addressing climate and social risks in aquaculture calls for a holistic, value chain-wide perspective. The Aquaculture Stewardship Council (ASC) supports this through its robust Farm and Species Standards, which establish best-practice requirements for producers to strengthen environmental and social performance at the farm level. In addition, the ASC Feed Standard extends this responsibility upstream, targeting the significant impacts of feed production, one of the largest contributors to aquaculture's overall footprint. These impacts include greenhouse gas (GHG) emissions, habitat conversion, resource depletion, and labour and human rights risks, many of which arise during the sourcing of feed ingredients, particularly from agriculture associated with land-use change. As climate pressures intensify and competition for land and resources grows, the need for transparent, sustainable, and socially responsible feed systems is more urgent than ever.

ASC's Feed Standard addresses these challenges through a robust, supply chain-wide framework. It sets clear environmental and social requirements for feed mills and their suppliers, including the protection of high conservation value ecosystems, responsible ingredient sourcing, and improved feed efficiency to lower emissions. Socially, the Standard embeds international labour and human rights expectations, requiring due diligence on issues such as child labour, forced labour, and working conditions. It also enhances supply chain transparency through risk-based procurement and traceability requirements.

A key enabler of this transition is the ASC GHG Calculator, a practical tool that allows feed mills and producers to quantify, compare, and report emissions in a consistent and credible way. It helps identify emission hotspots, and combined with the Feed Standard, helps supporting mitigation planning, and facilitating alignment with evolving climate and due diligence regulations. By discouraging the use of high-risk ingredients and enabling informed decision-making, the ASC helps in advancing climate-smart and socially responsible aquaculture.

This presentation explores the rationale, design, and implementation of the ASC Feed Standard and GHG Calculator, and their potential to drive measurable improvements in environmental and social performance across the aquaculture feed sector.

# GUARANTEED BONE FREE? NOVEL INTERMUSCULAR BONE ABNORMALITIES IN CHINOOK SALMON *Oncorhynchus tshawytscha* AND THEIR IMPLICATIONS FOR AQUACULTURE

Brianne A. Lyall*[1,2,3], P. Eckhard Witten[4], Chris G. Carter[1,2], Matthew Perrott[5], Jane E. Symonds[3], Seumas P. Walker[3], Zac Waddington[6], Gianluca Amoroso[1,2]

brianne.lyall@utas.edu.au

## Introduction

Skeletal deformities are a persistent welfare and production issue for salmonid aquaculture, including New Zealand farmed Chinook salmon (*Oncorhynchus tshawytscha*). Research on deformities of the fine bones, such as intermuscular bones (IBs) and ribs, have received much less attention than vertebral deformities in salmon musculoskeletal research[1-3]. IBs, commonly known as pin bones, are small spicule-like bones, present in the muscle fillets of basal teleost species. IBs are removed during fish processing, as they present a human health risk if ingested. IB abnormalities can cause technical difficulties in the automated or manual removal of IBs at processing. Furthermore, the proposed role of IBs in swimming efficiency, emphasises the potential welfare implications of IB abnormalities. However, there are significant knowledge gaps about the function and development of IBs[1]. IB abnormalities were first identified on a significant scale in a population of harvest-size Chinook salmon, during fish processing. The IBs presented as incompletely mineralised at the proximal end, which caused difficulties in removal[1] (Fig. 1). To our knowledge, this is the first account of IB abnormalities in farmed salmonids in the literature. Thus, we aimed to characterise this novel bone abnormality and identify any association with vertebral deformities.

## Materials and methods

A subsample of the affected population (n = 118), (weight = 5081.86 ± 134.69 g, fork length = 679.07 ± 5.5 mm, mean ± SEM) previously stored at -20°C, were weighed, measured, and whole-body and fillets x-rayed. The prevalence and severity of IB abnormalities and vertebral deformities were scored from x-rays. Fish were categorised into two groups: <25% abnormal and >25% abnormal IBs. Normal and abnormal bones (n = 71 normal and 61 abnormal bones from 16 fish, n = 8 fish per group) were selected for: mechanical (breaking load) analyses using a TA.XT texture analyser; calcium and phosphorus content via ICP-MS (n = 12 fish); and osteocyte density by histological examination (n = 6 fish). The significance level was set at $p \leq 0.05$ for Wilcoxon signed-rank tests. For analyses conducted within the Bayesian framework, effects were considered meaningful if the 95% credible interval (CI) of the posterior distribution excluded zero.

## Results and discussion

The individuals assessed had 62 ± 0.18 IBs (31 per fillet). IB abnormalities were present in all fish sampled, with prevalence varying among individuals. Fish with higher prevalence, (>50% of abnormal IBs), were smaller (4773 ± 126 g) than those with lower prevalence (<10%) (5464 ± 178 g). The position of abnormal IBs along the vertebral column was asymmetric. The left fillet had a significantly higher ($p$ <0.001) number of abnormal IBs than the right fillet (9.85 ± 0.58 vs 7.82 ± 0.51). Vertebral deformities were also present in over half of the fish, i.e. compression, fusions or vertical shifts (25%), spinal curvature (14%) or both (15%). There was no association between IB abnormalities and vertebral deformities occurrence (β = -0.06, 95% CI = -0.31, 0.18).

Abnormal IBs had significantly lower (β = -3.43, 95% CI = -5.56, -1.32) breaking load, but only a numerically lower phosphorus content ($p$ = 0.72). IBs of fish with >25% abnormal IBs had significantly lower (β = -2.34, 95% CI = -4.12, -0.51) breaking load for both normal and abnormal bones, relative to the <25% group. No difference in mineral content between normal and abnormal bones suggested the need to compare unaffected fish.

*(Continued on next page)*

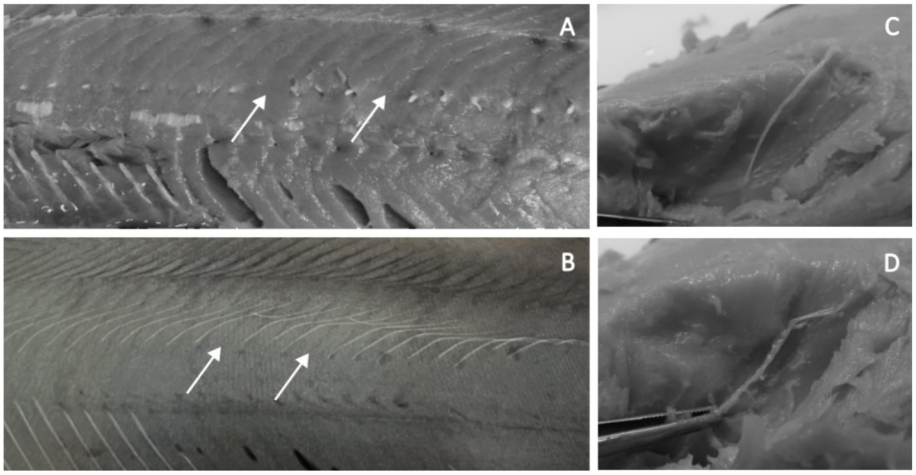

**Fig. 1:** Photograph (A) and radiograph (B) of a harvest-size Chinook salmon fillet, highlighting the missing/radiolucent proximal ends of the abnormal IBs (white arrows). C) Normal IB with a bony proximal end above the fillet surface. D) abnormal IB with a proximal end of non-mineralised collagen matrix, below the fillet surface.

Abnormal IBs had significantly fewer osteocytes than normal bones (preliminary analysis). The reduced number of osteocytes in abnormal IBs may be indicative of variation in bone growth rate and mineralisation. Our findings suggest that the physical and mechanical changes in abnormal IBs are indicative of altered IB development, and possible bone remodelling issues. Moreover, IB abnormalities are independent of vertebral deformities in Chinook salmon. The occurrence of IB abnormalities is a unique example of how musculoskeletal disorders can go by undetected, with unknown consequences on welfare and performance, and until fish are on the plate and it's too late.

## Introduction

The rapidly growing aquaculture sector is recognized as critical to supplying global protein needs, and protein-rich ingredients are required to fill the protein gap in feed production. Single cell proteins (SCPs) such as microalgae, yeast or bacteria are novel ingredients that have all been tested as alternative protein sources for aqua feeds (Glencross et al., 2020). Among the SCPs, bacterial SCPs are some of the most popular and sustainable ingredients, with a high protein content and an amino acid (AA) profile resembling that of fishmeal (Pereira et al., 2022). At the same time, SCPs derived from microorganisms grown on gas offers a sustainable high-quality protein, which can be intensively produced without having a negative impact on the environment (Glencross et al., 2020). The objective of the present study was to assess the digestibility of a bacterial SCP as a viable alternative protein source in the diets of Atlantic salmon (*Salmo Salar*).

## Materials and methods

The diets were formulated based on a 70:30 digestibility model, with the test ingredient, Proton (crude protein = 87.6%), composing 30% of the experimental diet. The control feed was formulated to resemble a commercially available salmon feed for parr to pre-smolt stage. The experimental diets were fed to Atlantic salmon with initial mean weight of 76.18 ± 4.61 g for 49 days in a freshwater recirculating aquaculture system. Before starting the digestibility trial, a random sample of 20 fish were subjected to gross pathology health checks, to ensure a healthy population for the trial. Fish were acclimated to the trial system and fed a commercial diet for 10 days, after which the fish were acclimated to the experimental diet for 6 days, before digestibility collections were initiated. Fish were fed to apparent satiation across three meals per day, and after each feeding round the tanks were cleared for any material (uneaten pellets or faeces). After 15 minutes, the collection of faeces commenced, and continued periodically until no further material was present, or the next feeding round began.

All data was analysed with RStudio, and apparent digestibility coefficient (ADC) was calculated based on the following equation (Zehra et al, 2024):

$$ADCing = \frac{(ADtest \times Nutrtest - (ADbasal \times Nutrbasal \times 0.7))}{(0.3 \times Nutringredient)}$$

Where *ADCing* is the digestibility of the nutrient from the test ingredient (Proton), *ADtest* is the apparent digestibility of the nutrient from the test diet (30% Proton inclusion), *ADbasal* is the apparent digestibility of the nutrient from the basal diet (Control) which makes up 70% of the test diet, and *Nutringredient*, *Nutrtest* and *Nutrbasal* are the levels of the nutrient in the ingredient, test diet and basal diet, respectively.

## Results

There was a statistically significant higher average individual weight gain of the salmon ($p = 0.018$) in the experimental group compared with the control group after 49 days of feeding (53.90 ± 2.72 % and. 45.75 ± 5.95 %, respectively). Additionally, the experimental group had a higher feed intake (2.43 g/day per fish vs. 2.34 g/day per fish) and significantly less faecal matter per tank ($p = 0.015$) compared with the control group (9.55 ± 0.59 g and 12.52 ± 1.73 g DM, respectively). Pairwise comparison of ADC between the diets demonstrated that the average ADC values for protein, GE and AAs were statistically higher for the experimental diet compared to the control diet ($p < 0.003$). Furthermore, Proton demonstrated a protein ADC of 94.1% and average amino acid ADC of 95.6%.

*(Continued on next page)*

**Discussion and conclusion**

Digestibility is a critical factor when evaluating novel protein sources for aquafeeds, particular in juvenile Atlantic salmon that require a high-quality protein for optimal growth. The high protein ADC from Proton demonstrated in this trial suggests a superior nutrient utilisation compared to many alternative protein sources tested in salmonid diets (Øverland et al., 2013; Gong et al., 2018). The high protein ADC is even comparable to other high-quality proteins like fishmeal with ADC values ranging from 80-90% (Øverland et al., 2009). At the same time fishmeal typically provides high digestibility coefficients of essential AAs exceeding 90% (Storebakken et al., 1998), which Proton in the present study could compete with at an average AA digestibility of 95.6%.

Over the duration of the trial, fish receiving the experimental diet had a slightly higher feed intake compared with the control group, which may indicate an improved palatability even at high inclusion levels of Proton. On the other hand, differences in nutrient composition due to the unbalanced diets, must be considered when interpreting the data. The experimental diet had a higher protein content due to a 30% inclusion of Proton, which resulted in not fully reliable growth data. However, the growth results give an indication of how Proton might perform in a dedicated growth trial, and it supports the high digestibility claim. The study indicates that Proton is a highly digestible alternative protein ingredient for juvenile Atlantic salmon, with strong ADC values for protein and AA. The preliminary performance also demonstrates a good palatability of a Proton diet. The findings highlight Proton's potential as a sustainable and effective protein source in salmonid diets.

# BACTERIAL SINGLE-CELL PROTEIN AND ITS HYDROLYSATES AS A PERSPECTIVE FEED ADDITIVES FOR FISH ARTIFICIAL DIETS: A CASE OF PIKE-PERCH (*Sander lucioperca*)

A. Lyutikov [1]*, M. Solovyev [2]

[1] Saint Petersburg Branch of "VNIRO", "GosNIORH" Named After L.S. Berg, St. Petersburg (Russia)
[2] Institute of Systematics and Ecology of Animals of SB RAS, Novosibirsk (Russia)
E-mail: tokmo@mail.ru

## Introduction

The development of industrial pike-perch rearing technology has been limited by the lack of larval artificial diets that can fully meet the nutritional requirements of fish in the early stages of ontogeny. Previous attempts to grow pike-perch on a mono-diet of artificial feed from the start of exogenous feeding have failed. Total larval mortality occurred during the first 2-3 weeks of feeding. To solve this problem, we studied the proximate composition of the natural diet of pike-perch larvae, which consisted mainly of zooplanktonic organisms. We assumed that it should reflect the nutritional requirements of early larvae (Lyutikov et al., 2025).

The obtained results of the proximate compositional analysis of zooplankton allowed us to select the most suitable feed component for the development of artificial starter feed for pike-perch larvae, which was a microbiosynthetic protein - Bacterial Single-Cell Protein (BSCP) based on methane-oxidising bacteria *Methylococcus capsulatus*. BSCP contains similar protein and nucleic acid levels, amino acid composition and molecular weight distribution of peptides as zooplanktonic organisms. The aim of this study was to evaluate the efficacy of BSCP in both intact and hydrolysed forms as part of the initial diet of pike-perch larvae.

## Materials and Methods

The studies were conducted at the "Forvat" LLC fish farm (60°36'14.91"N 30°23'53.54"E). The larvae were obtained from natural spawning of 4-year-old pike-perch, reared from yearlings under industrial conditions in cages on artificial diets only. After becoming horizontal, the larvae were placed in production square tanks (in 3 replicates) with an area of 4 $m^2$ and a water level of 0.25 m. The stocking density of the larvae was 25 individuals $L^{-1}$. The larvae were fed hourly from 8 a.m. to 10 p.m. The photoperiod, lighting and water temperature were natural throughout the experiment; the water temperature increased steadily from 16 to 21°C during the experiment. BSCP ("GIPROBIOSINTEZ" LLC, Russia) and its hydrolysates were added to the diet at the stage of mixing of the diet components, which was then extruded. The extrudate was dried, crushed and dispersed into 0.1 to 0.3 mm fractions. A mixture of fish oil and phospholipids was added to the diet, dried and packed in vacuum bags, which were stored at -18 °C until use.

## Results

After 23 days of rearing, the body weight, SGR and surviving of pike-perch larvae were highest in the group of fish fed diets containing BSCP L (low degree of hydrolysis). The number of non-feeding larvae in this group was less than 1% (Table). Using BSCP H in diets (high degree of hydrolysis) resulted in a decrease in body weight, growth rate, and surviving of pike-perch larvae (Table). The proportion of non-feeding larvae in this group was 57%. The larvae fed with diets containing native BSCP showed intermediate values of estimated characteristics (Table).

Table. Pike-perch larvae fed by diets with BSCP and its hydrolysates. The initial body weight of the larvae was 0.4 mg. Values (mean±SD) in the same row with lower case letters (a, b, c) are significantly different at $P \leq 0.05$.

| Diet | Body weight, mg | SGR, % | Surviving, % | Non feeding larvae, % |
|---|---|---|---|---|
| BSCP | 14,6±0,6$^a$ | 15,6±0,6$^a$ | 12,2±2,2$^a$ | 15,0±2,6 |
| BSCP L | 23,2±0,8$^b$ | 17,6±0,7$^b$ | 25,4±6,1$^b$ | ≤ 1,0 |
| BSCP H | 9,1±0,7$^c$ | 13,5±0,8$^c$ | 5,9±1,4$^c$ | 57,0±4,8 |

*(Continued on next page)*

It is clear that BSCP L has a positive effect on the growth, survival and feeding of pike-perch larvae, due to an increase in the amount of low-molecular-weight peptides (compared to intact BSCP) available for absorption by larvae whose digestive system is immature. On the other hand, BSCP H leads to a sharp increase in the proportion of peptides and amino acids, which has a negative effect on the fish rearing.

**Conclusion**

Obviously, the main direction of industrial farming technology of larvae and juvenile pike-perch will be the development of complete artificial diets capable of satisfying the nutritional needs of fish. For this, the BSCP and its hydrolysates are suitable sources with the necessary amount of peptides and free amino acids, which is especially important during the period of rapid growth of pike-perch.

# CEJKO SOLUTION AND CHILLED CONDITIONS PRESERVE CARP SPERM QUALITY AND FERTILIZATION PERFORMANCE DURING SHORT-TERM STORAGE

Zhijun Ma [1], Songpei Zhang [1], Md. Sabbir Hossain [1], Zuzana Linhartová [1], Nururshopa Eskander Shazada [1], David Gela [1], Otomar Linhart [1], *

Email: zma@frov.jcu.cz

Short-term storage of fish milt is a cost-effective strategy in aquaculture as it enables synchronization of sperm and eggs. However, the optimal handling conditions immediately after milt collection remain unclear. In this study, we evaluated four storage conditions (diluted 1:1 with Cejko solution, undiluted, on ice, and at room temperature) over a 6-hour period in carp (*Cyprinus carpio L.*). Cejko solution–diluted groups exhibited significantly higher sperm kinetics and fertilization ability compared with undiluted groups. Sperm motility, curvilinear velocity (VCL), and straight-line velocity (VSL) decreased significantly during storage in both undiluted groups, with the room-temperature (RT) group showing lower motility than the on-ice (OI) group. Fertilization and hatching rates did not differ significantly between diluted-on-ice and diluted-room-temperature groups but declined markedly in both undiluted groups. These findings indicate that carp sperm maintain the best quality and fertilization capacity when diluted with Cejko solution and stored on ice, and dilution should occur within 6 hours of collection.

## Introduction

Short-term in *vitro* storage of sperm has become a common technique used to support and optimize artificial reproduction in aquaculture (Cejko et al. 2022; Contreras et al. 2017; Shazada et al. 2025). Sperm immediately diluted with Cejko solution show no significant differences in motility, fertilization and hatching rate compared with sperm diluted after 3 hours in carp (Shazada et al. 2025). However, there is currently no reference time threshold to guide fish farmers in performing short-term sperm storage. Raising the temperature to 20 °C before fertilization has been shown to improve sperm kinetic parameters and fertilization potential (Zhang et al. 2023). All current studies have directly used chilled temperature to perform sperm short-term storage in carp (Saad, et al. 1988; Cejko et al. 2019; Dietrich et al. 2021). Nonetheless, the effects of room temperature, which is more convenient for hatchery practice, have not been evaluated.

## Materials and methods

Mature males of carp were obtained following fish farm pond harvesting and maintained in a laboratory and hatchery aquatic system. Sperm and eggs samples were collected individually after treatment with carp pituitary extract at 21°C. Sperm was diluted with carp extender (Cejko et al., 2018) and stored for 6 hours under four different conditions, followed by assessment of spermatozoa motility, velocity and hatchability (Fig. 1).

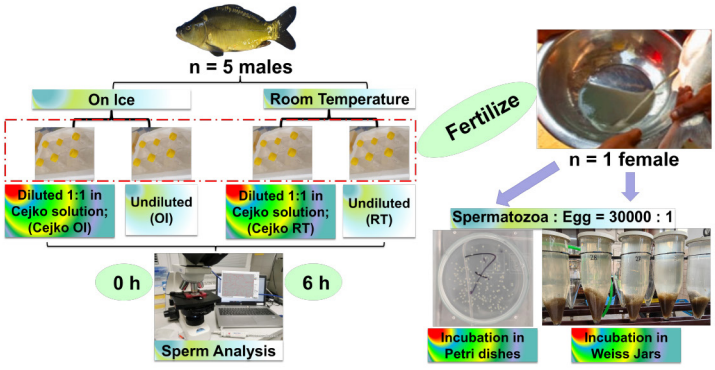

Fig. 1 Schematic figures illustrate the experimental design of the study.

*(Continued on next page)*

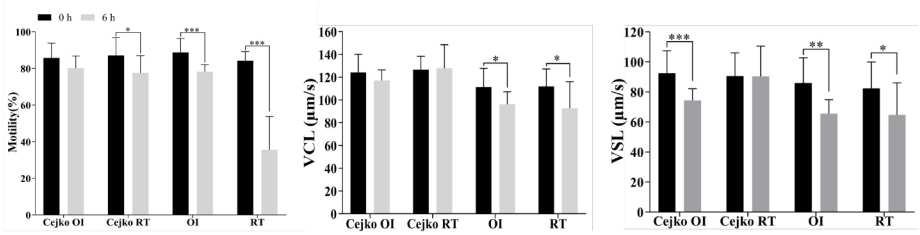

Fig. 2 Sperm kinetic parameters declined in undiluted conditions

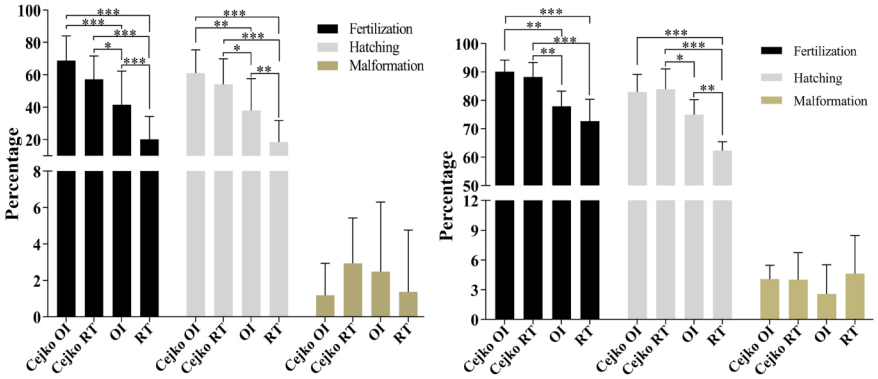

Fig. 4 Cejko solution and stored on ice preserve carp sperm fertilization ability

**Results**

The kinetic parameters of undiluted carp sperm (motility, curvilinear velocity [VCL], and straight-line velocity [VSL]) declined significantly during 6-hour storage, with sperm motility in the room-temperature (RT) group being significantly lower than in the on-ice (OI) group. Sperm diluted 1:1 with Cejko solution and stored on ice (Cejko OI) showed no changes in motility or VCL over 6 hours. Although sperm motility declined significantly in samples diluted 1:1 with Cejko solution and stored at room temperature (Cejko RT), both VCL and VSL remained stable (Fig. 2).

No differences in fertilization or hatching rates were observed between the Cejko OI and Cejko RT groups in either the Petri dish experiment or the Weiss jar experiment. Fertilization and hatching rates in the undiluted groups (OI and RT) were significantly lower than those in the diluted groups (Cejko OI and Cejko RT). Moreover, room temperature significantly reduced fertilization and hatching rates in undiluted samples (RT), whereas no such differences were detected in diluted samples (Cejko RT).

**Conclusion**

- ► Dilution at a 1:1 ratio with Cejko solution and storage on ice is optimal for short-term storage of carp milt in vitro.
- ► Carp sperm should be diluted within 6 hours after collection to maintain quality.

[*]e-mail: dams@ua.pt

## Introduction

Aquaculture systems are critical for global food security. Current cultivation techniques often disrupt the equilibrium of microbial communities, compromising system resilience and harming vital ecosystem services provided by microbes. Some interest in microbial interventions has emerged in the last decade. However, strategies remain focused on the host, the majority of which centred around the gut microbiome. Despite the increasingly obvious benefits of engineering the gut microbiome, the industry and scientific community is overlooking a system-wide strategy, as well as the interactions between fish, water and biofilm communities. The variety of micro-habitats and rich microbial diversity naturally present in aquaculture systems has the potential to improve productivity, health, sustainability and the stability of the system.

## Materials and Methods

This work explores the role of microbial modulators (humic substances [HS] and *Eisenia bicyclis* biomass [EB], and their combination [MIX]) as tools to shape microbial communities across key aquaculture biotopes (water, tank wall biofilms, and fish skin mucus) of a pilot-scale recirculating aquaculture system (RAS), using European seabass (*Dicentrarchus labrax*) as a model organism. To deliver the microbial modulators, this work uses a patent-pending framework that takes advantage of the biodegradable properties of polycaprolactone to release the microbial modulators in a controlled manner.

## Results

Results show an effective modulation of microbial communities across the studied biotopes. Interestingly, community changes were specific both to biotopes and modulators, including the increase of putative beneficial bacteria. As an illustration of how microbial communities have the ability to provide important services to the RAS, nitrification was accelerated by HS, delayed by EB, and all treatments except the control showed a reduced total nitrogen content. These results were possible without adversely affecting water quality, fish health or performance.

## Conclusion

This proof-of-concept provides foundational evidence for an effective early-stage technology that can be used as a complement or alternative to conventional water treatment methods, which has the potential to improve water quality, pathogen resistance and system resilience.

## Background and relevance

Aquaculture research has grown rapidly over the last decades, mirroring the global trend of aquaculture production and demand. The growing complexity of aquaculture research and production, demands more robust data analysis and modelling tools to project, maintain and assess stocks in aquaculture practices. To calculate growth performance and the health status of cultured species, a wide range of zootechnical parameters are routinely used as key performance indicators.

Examples for common key aquaculture performance indicators are, for example, the Feed Conversion Ratio (FCR), Nutrient Use Efficiency (NUE), Specific Growth Rate (SGR), Thermal Growth Coefficient (TGC), and Apparent Digestibility Coefficients (ADC). Interestingly, discussions have repeatedly flared up about how these seemingly trivial indicators should be calculated correctly. For instance, non-standardized metrics, approximations, inconsistencies, and outdated or inadequate references are highly prevalent in aquaculture studies, which resulted in several scientific publications devoted to discussing these metrics, *e.g*. SGR (Crane et al., 2019), FCR (Glencross et al., 2024), or ADC (Bureau and Hua, 2006). However, scientific discussions do not help those who do not have access to the publications in question, nor do they help scientists who are still developing a broad overview of the subject matter. Additionally, the lack of uniformity undermines the quality of the data and harms replicability, reproducibility and cross-study comparability. The increasingly ubiquitous use of artificial intelligence (AI) could further exacerbate the problem. Since large language models predict their responses based on the probability that a certain word or equation follows on the prior output, they might not distinguish between different equations for a metric but rather use the one that occurs more frequently in the underlying data set.

To address this gap, we introduce an open-source R package aiming to standardize and centralize the most commonly used zootechnical equations in aquaculture studies. The package offers a comprehensive bundle that facilitates accurate and consistent calculations, which is easily accessible to students, early career researchers and experts.

## Software description and metadata

"aquacultuR" is an R package that provides functions to compute common indices such as SGR, TGC, and ADC, among others. The use of GitHub as a platform allows for reporting bugs, suggesting changes, and contributing to the existing codebase. Additionally, it can serve both as a discussion hub and knowledge base to support the development of the package and underlying equations. Meanwhile, R as software is open source, free of charge and thus widely accessible for researchers and aquaculturists around the world. In addition, the code can easily be translated into an interactive Shiny app, allowing for user-friendly graphical interfaces.

The "aquacultuR" package implements common indices using standardized objects and functions. The code is based on best practices, following the standards for R software development (Wickham, 2023). Each function is tested for data inconsistencies that may impact or invalidate data analysis. In addition to the standard documentation, the code includes a vignette that elaborates on all functionalities in greater detail, with up-to-date references, and a formulary for quick and easy access to all the main performance indices, and common examples. Version control and an accessible collaboration environment have been ensured by hosting the code repository on GitHub.

## Impact

Currently, AI is an effective tool to conduct data analysis. Meanwhile, the quality of the outcomes depends on the quality of the training data. With widespread adoption, the "aquacultuR" package will contribute to injecting R functionalities of peer-reviewed quality into databases. Well-documented metrics, alongside most relevant literature and formalized equations will provide, for the first time, a comprehensive and collaborative overview that could help with learning and clarifying how common calculations are correctly made and highlight differences between existing equations, while simultaneously making those metrics more accessible for researchers. Additionally, the package offers a citable reference for calculations in scientific publications, making it unnecessary to state equations unless they have been specifically modified, streamlining writing and peer-reviewing.

## Introduction

Consumer behaviour and preferences are key factors for the success of the aquaculture industry in meeting market demands and embracing innovative technologies. To understand and guide purchasing decisions, a synergistic approach has been developed that integrates virtual simulations and real-life experiences.

A central element of this strategy is sensory evaluation, which is crucial for deciphering consumption dynamics and defining effective market strategies. In the initial phase, highly qualified sensory experts conducted a Quantitative Descriptive Analysis (QDA) on various aquatic species (fish and shellfish), profiling their sensory characteristics in terms of taste, aroma, texture, and appearance. Subsequently, over 150 consumers for Italy, Denmark and Slovenia participated in culinary events and guided tasting sessions, expressing their preferences. This phase enabled the collection of valuable data on the most appreciated sensory attributes and identified significant differences among consumer groups with diverse habits and preferences.

Aquaculture faces the dual challenge of meeting the growing global demand and promoting sustainability. In this context, consumer trust is a cornerstone for fostering the adoption of innovations and ensuring the competitiveness of the sector. This study, as part of the FishEUTrust project, aims to strengthen trust in aquatic products through innovative interventions based on advanced sensory analyses and technological solutions.

## Materials and Method

The research was conducted in two distinct phases. Initially, a panel of sensory experts carried out a Quantitative Descriptive Analysis (QDA) on a selection of aquatic products, including fish and shellfish, to define their sensory profiles. The samples were evaluated according to standardised parameters related to taste, aroma, texture, and appearance. Subsequently, over 150 volunteer consumers from the three countries, participated in structured tasting sessions and culinary events, expressing their individual preferences through detailed questionnaires. The data collected were subjected to statistical analysis to identify correlations between sensory preferences and participants' dietary habits.

## Expected Results

The research results provide an in-depth understanding of the sensory characteristics most appreciated by consumers, such as taste, aroma, texture, and appearance, identifying the key attributes that drive their preferences and choices. The analysis highlights significant differences among various population segments influenced by factors such as dietary habits, cultural background, and personal experiences.

Through the analysis of sensory profiles of aquatic products, combined with direct feedback collected during guided tasting sessions, it has been possible to precisely define the characteristics that make products more attractive and desirable. This information is a crucial resource for developing market strategies aimed at effectively communicating sensory qualities and meeting consumer expectations.

*(Continued on next page)*

Furthermore, the integration of this knowledge with innovative technologies, such as virtual experiments and traceability systems, strengthens trust in sustainable aquatic products by promoting supply chain transparency and showcasing the value of responsible aquaculture practices. This synergistic approach seeks to encourage consumers to choose more sustainable options, driven not only by ethical principles but also by the high sensory quality of the products offered.

This research was conducted as part of the FishEUTrust project, which has received funding from the European Union's Horizon Europe programme under grant agreement no. 101060712.

# DEVELOPMENT OF A SENSORY PROFILE FOR DIPLOID MUSSELS FROM DIFFERENT EUROPEAN REGIONS: A COMPARATIVE STUDY USING QDA®

Magnani M.[1]*, De Marco A.[1], Benini E.[1], Cella M.,[1] Nordio D.[1], Urbini R.[1], Bonaldo A.[1]

[1]Department of Veterinary Medical Sciences

* martina.magnani20@unibo.it

## Introduction

Mussels represent a cornerstone of European aquaculture, appreciated not only for their nutritional value and sustainability but also for their distinctive sensory qualities, which are shaped by local farming practices and environmental conditions. This study aims to establish an objective and standardized sensory profile for diploid mussels from three major European production areas: Italy, Norway, and Ireland. The goal is to highlight region-specific organoleptic characteristics that can support product differentiation, enhance consumer perception, and strengthen market positioning.

## Materials and Methods

A Quantitative Descriptive Analysis (QDA®) approach was adopted, involving a trained panel of sensory assessors who evaluated key attributes (appearance, odour, flavour, and texture) based on a rigorously developed lexicon. Mussels were assessed in their fresh state shortly after arrival, and all panellists underwent specific training over several weeks to ensure consistent and reliable evaluations. Sensory assessments were performed under controlled laboratory conditions.

## Results

Preliminary findings reveal significant inter-regional differences in sensory profiles, particularly in terms of flavour complexity, colour intensity, and textural firmness. These differences appear to be strongly correlated with farming methods, feed availability, and environmental variables such as water temperature and salinity. By objectively characterizing the sensory identity of mussels from different European regions, this research offers valuable implications for quality control, product certification, and marketing strategies. Emphasizing the unique sensory attributes of mussels can play a pivotal role in increasing their appeal in high-value markets and fostering consumer trust in European aquaculture products.

# THE INFLUENCE OF 5-HTR AND NR3C1 POLYMORPHISMS ON THE AGGRESSIVE BEHAVIOR OF GILTHEAD SEABREAM (*Sparus aurata*)

E. Malandrakis, A. Rekleiti, O. Ntantali and C. Zantioti

## Introduction

Gilthead seabream (*Sparus aurata*) is an important species for the Mediterranean aquaculture. Social structure significantly impacts animal welfare and productivity in intensive farming, underscoring the need to understand the genetic and neuroendocrine mechanisms behind these traits. Stress responses, aggression, and social hierarchy directly affect fish welfare and productivity, yet their genetic basis remains poorly understood. Studies in many animal models suggest that genetic variations (SNPs) in serotonin receptors (*5-htr1a, 5-htr2b*) and the glucocorticoid receptor (*nr3c1*) influence stress response. This study explored the genetic background of aggressive behavior in *Sparus aurata* (gilthead sea bream) by investigating SNPs in the *nr3c1*, *htr1a*, and *htr2b* genes using high-resolution melting (HRM) analysis. Seven primers were tested, all of which correlated with aggressive responses measured as total attack frequency, attacks before feeding and attacks post-feeding, as well as subordinate behavior in the tanks. Some SNPs were associated with aggression, underlining their potential role in stress response and social behavior regulation. These findings highlight the utility of HRM as a screening tool to identify molecular markers related with aggression.

## Materials and methods

Forty fish with an average body weight of 113.34 ± 18.19 gr and an average standard length of 15.92 ± 2.58 cm were kept in four tanks in a RAS system, and all water parameters were recorded daily. The average water parameters were: DO: 7.52 ± 0.30 mg/L, pH: 7.53 ± 0.45, salinity: 30.7 ± 2.3psu, water temperature: 23 ± 1.8 °C, and ORP: 226.5 ± 18.3mV. Fish were recorded with a video camera (1080p, 60fps) daily (5min) for seven days before and after feeding, and their behavior was assessed as follows: aggression, subordination, attacks before feeding, and attacks after feeding. Fin clips were used for DNA extraction according to standard protocols (Macherey-Nagel NucleoSpin Tissue kit). Sequences from chromosomes 5, 11, and 13 of the *Sparus aurata* genome (fSpaAur1.1 assembly), which contained 5HT2b, nr3c1, and 5HT1a gene sequences, respectively, were obtained from NCBI (NC_044191.1, NC_044197.1, NC_044199.1) and indexed with bwa index. For *in silico* SNP discovery, 22 fastq files ERR5296642-4, SRR9615483-4, SRR9615489-95, SRR9615501-3, SRR9615517-24 were acquired. Following quality filtering and annotation of the candidate polymorphisms, six HRM primers were designed. PCR reactions were carried out in a BIO-RAD CFX96 real-time cycler using the QIAGEN Type-it HRM PCR Kit. Genotypes were discriminated with a high-resolution melting analysis from 60 to 90°C with an increment of 0.2°C and confirmed with Sanger sequencing. GLM was used to examine the relationship between behavioral traits and genotypes.

## Results

After observing the aggressive behaviors between individuals, the attacks were analyzed, and most of the fish were categorized as aggressive and semi-aggressive, as in both tanks were observed fish with more aggressive tendencies than others were observed. There were on average 3,8 and 1,9 attacks before and after feeding, respectively. Around 26% of fish exhibited no aggression and remained completely inactive during the trials. A greater percentage of the population showed less aggression, with 37% (1-3 attacks), while 21% were considered very aggressive (more than 5 attacks), mostly in the prefeeding phase. The remaining 16% had responses that varied and did not easily fit into any category. HRM analysis revealed the different genotypes, which are presented in Figure 1.

*(Continued on next page)*

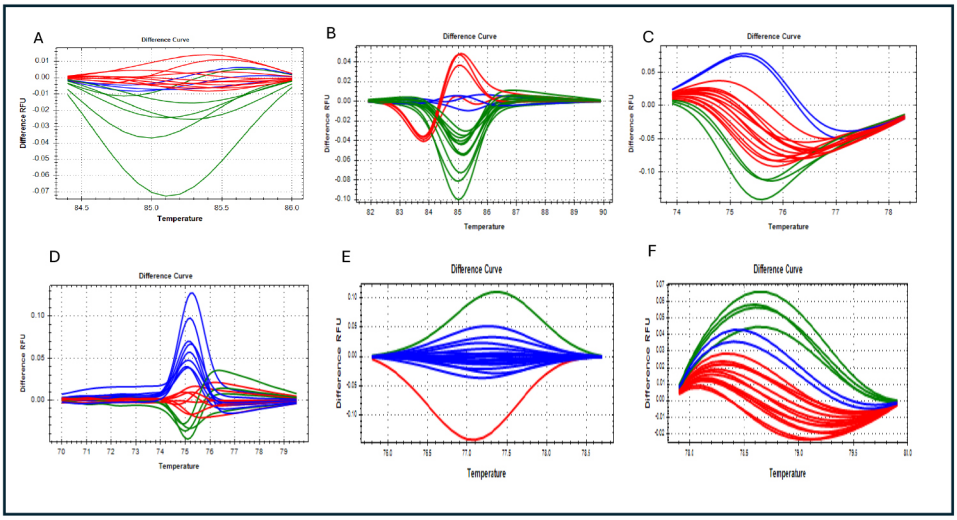

*Figure 1 HRM analysis depicting SNPs at genes nr3c1 (A,B), 5-htr1b (C,D) and 5htr2a (E,F)*

## Discussion

This study analyzed six SNPs in the *nr3c1*, *htr1a*, and *htr2b* genes in *Sparus aurata* using HRM and behavioral assays, revealing genotype-behavior correlations. Distinct aggression patterns matched stress-coping styles mediated by serotonin and cortisol pathways. *htr2b* polymorphisms showed linear aggression increases, while *htr1a* AG genotypes exhibited peak aggression, suggesting receptor sensitivity effects. In fish, aggression is correlated with serotonergic activity (Silva et al., 2012). Aggression was related to glucocorticoid receptor (*nr3c1*) variants, a gene that is regulated during physical stress (Malandrakis et al., 2016). HRM confirmed genotype-behavior links, with *htr2b* GG homozygotes exhibiting the highest aggression. htr2b polymorphism may have a functional role in regulating serotonergic signaling, which is known to affect vertebrate aggression (Delprato et al., 2018). These findings enabled the discovery of biomarkers for reduced aggression and improved welfare in aquaculture. The combined HRM-genotype-behavior approach advances precision in fish behavioral genomics.

E-mail: malene.m.fosse@ntnu.no

## Introduction

Moderate levels of intestinal damage and inflammation are often seen in intensive fish aquaculture. This can be caused by stress, sub-optimal farming conditions or antinutritional factors present in plant meals. There is currently a lack of good models to explore these effects and how to mitigate the consequences. Thus, the aim of the present study was to develop a low-intestinal inflammation model using HP48, derived from solvent-extracted peeled soybeans and to test whether of the probiotic *Pediococcus acidilactici* CNCM I-4622 – MA 18/5 M (Bactocell) could diminish this effect.

## Materials and methods

Atlantic salmon (*Salmo salar*) post-smolts (averaging 106.8 ± 5.8 g) were assigned three feeding groups. The Control diet contained 18.08% soy protein concentrate (SPC) and for the HP48 diets, most of the SPC were exchanged with HP48 to induce low intestinal inflammation. The Bactocell diet was identical to the HP48 diet but was supplemented with 0.03% Bactocell (Lallemand Animal Nutrition, Blagnac, France). The fish were fed to excess over ~ two months and weight were recorded at the start, mid and end of the experiment. At the end sampling, mid- and hind-intestine were collected for analysis of histology, Ussing chamber and RNA sequencing.

## Results

Results revealed that fish fed the HP48 diet showed a reduced SGR (1.55 ± 0.04) compared to the Control diet (1.66 ± 0.03) ($p < 0.05$). The difference in SGR was greater in the first half of the experiment. The Bactocell diet showed intermediate growth (1.58 ± 0.03) which did not differ from the other groups. Histological assessment of the mid-intestine revealed few differences, except for wider lamina propria in the HP48 group, but transcriptomic and integrity data suggest that HP48 led to a disturbed mid-intestinal homeostasis with impaired cellular integrity and increased inflammation and cell turnover. Most of the transcriptomics effect were reversed with Bactocell. In the hind-intestine, HP48 led to several morphological changes, i.e., reduced vacuolisation and disrupted mucosal folds (Fig. 1) and upregulated immune related genes like CD99 and IL-17F. Bactocell alleviated several of the morphological changes, but did not reverse the gene expression.

## Discussion

Plant-based ingredients like soybean meal (SBM) are commonly used to study intestinal inflammation in Atlantic salmon (*S. salar*), but the resulting damage may be too severe for functional ingredients to mitigate (Krogdahl et al., 2003, Booman et al., 2018). In this study, a milder inflammatory model was developed using HP48 to better assess probiotic supplementation. Feeding HP48 led to lower SGR, especially early on, but recovery towards the end indicated mild and reversible damage (Ali et al., 2003). Bactocell supplementation improved SGR, suggesting a protective effect. HP48 caused impaired epithelial barrier function and low-level inflammation in the mid-intestine (Bakke-McKellep et al., 2007, Booman et al., 2018, Wu et al., 2018). Bactocell restored collagen and immune-related gene expression in this intestinal segment. In the hind-intestine, HP48 induced inflammation, including morphological changes and increased expression of in CD99 and IL-17F (Knudsen et al., 2007, Marjara et al., 2012). Bactocell supplementation mitigated the morphological effects but was not able to reverse the transcriptional effects. This could indicate that Bactocell increased colonisation of probiotic bacteria in the mid-intestinal segment compared to the hind-intestine. A dose-response trial would be interesting to investigate whether a higher inclusion of Bactocell would lead to more effects lower down in the intestine.

*(Continued on next page)*

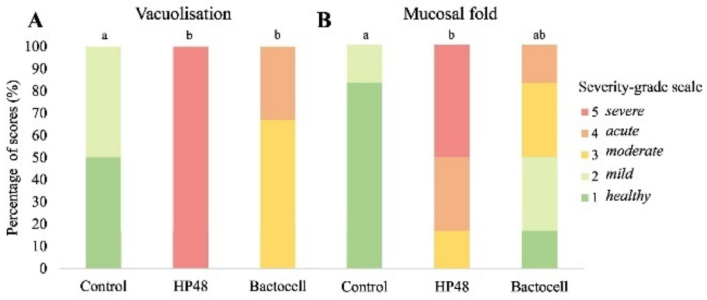

Fig. 1. Relative frequency distribution of A) visualization and B) mucosal fold scores in the hind-intestine per diet group (n=6 with 6 folds assessed per fish). Score 1 (green) represents large supranuclear vacuoles and thin, long folds, whereas score 5 (red) represents tissue disruption with fused mucosal folds.

## Conclusion

Overall, HP48 successfully induced mild intestinal inflammation, providing a better evaluation platform for functional feed ingredients. Probiotic supplementation with *Pediococcus acidilactici* (Bactocell) mitigated several of the negative effects, particularly in the mid-intestine.

# COMPARATIVE ANALYSIS OF SWIMMING PERFORMANCE IN PIKEPERCH (*Sander lucioperca*) FROM RECIRCULATING AQUACULTURE SYSTEMS AND TRADITIONAL POND CULTURE

Malinovskyi Oleksandr, Jan Kubec

[1]University of South Bohemia in České Budějovice
Faculty of Fisheries and Protection of Waters
Vodňany, Czech Republic
Email: omalinovskyi@jcu.cz

**Introduction**

Pikeperch (*Sander lucioperca*) is a valuable aquaculture species with a steadily increasing market demand (Policar et al. 2016) frequency of fin erosion, skeletal and gill covers deformities, proximal composition of fish body with special emphasis on fatty acid contents in liver and muscle, oxidative stress and antioxidant response in gill, liver, muscle and intestine were analyzed and compared in exclusively RAS- and POND-cultured juveniles and juveniles produced with the combination of POND and RAS aquaculture in pikeperch (Sander lucioperca L.. Most pikeperch originating from intensive culture are intended for market-size production. Nevertheless, pond aquaculture is becoming increasingly interested in stocking material produced in recirculating aquaculture systems (RAS), mainly due to predictable production and logistical advantages. However, differences in rearing environments, such as RAS versus traditional pond culture, may significantly impact swimming capabilities and behavior in general, which are critical as a foundation for predatory efficiency and effective escape responses (Khendek et al. 2017). These traits are important for survival, influencing both pond aquaculture success and the effectiveness of restocking programs into natural habitats as in both scenarios fish is exposed to natural complex environment and conditions close to them (Juza et al. 2024). This study investigates how distinct rearing conditions influence the swimming performance of pikeperch, with particular emphasis on traits supporting predatory capacity and escape reflexes.

**Material and methods**

Pikeperch with an average body weight of 30 g, originating from two different rearing systems — recirculating aquaculture systems (RAS) and traditional pond culture — were used for the study. Prior to the swimming performance trials, fish were acclimated for two days to the experimental environment under controlled conditions. Swimming activity was assessed over a three-day period for each repetition. The trials were conducted in three identical flow arenas, allowing simultaneous testing of multiple individuals. Each experimental set consisted of three repetitions. Fish swimming behaviour was continuously recorded using infrared cameras, enabling observation during both day and night without disturbing the fish. The recorded footage was analysed using EthoVision XT software (Noldus Information Technology), providing detailed quantification of swimming parameters such as velocity, distance travelled, and activity patterns.

**Results and discussion**

Significant differences in swimming performance were observed between the two groups of pikeperch. Fish differed in average velocity, total distance travelled, and overall activity levels throughout the recording periods. These differences were consistent across all repetitions and were evident during both daytime and nighttime observations.

The variation in swimming performance likely reflects the impact of rearing conditions. Environmental factors such as water movement and habitat complexity during the early stages of development can influence muscular development, stamina, and behavioral patterns. Fish reared under more dynamic conditions may develop enhanced swimming abilities, which can be advantageous for survival after release. These results highlight the importance of considering environmental conditioning in aquaculture practices, particularly for species intended for stocking into natural or semi-natural environments.

**Introduction**

This project aims to formulate a broad-spectrum subunit vaccine against A. salmonicida, focusing on two high-value species: turbot (Scophthalmus maximus) and sole (Solea senegalensis). To this end, candidate immunogenic proteins were identified using two complementary approaches: (1) a proteomic analysis based on the shaving technique applied to seven strains isolated from both host species, and (2) a bioinformatic screening based on published proteins of A. salmonicida subsp. salmonicida. These results were complemented by a review of recent literature on proteins with immunogenic potential. The selected proteins were expressed in two different experimental formulations, which were evaluated through immunisation trials.

**Materials and methods**

Seven different strains of A. salmonicida were used, each isolated from different individuals of turbot and sole (see Table 1). The shaving technique was applied to each bacterial sample, adding trypsin at 5 $\mu$g/mL (Olaya-Abril et al., 2014). Finally, the samples were completely dried in a SpeedVac concentrator. The peptides generated were analysed by ultra-high-pressure liquid chromatography (nanoElute, Bruker) coupled to a high-resolution timsTOF PRO mass spectrometer (Bruker). The proteins were detected using the UP000000225 database. The detected proteins were analysed using bioinformatic tools, with the aim of predicting their subcellular location, presence of signal peptide, and immunogenic potential (Razali et al., 2023). This screening allowed us to prioritise candidate proteins with the highest probability of exposure and recognition by the host immune system.

Finally, ExeD was selected as the main candidate. Its sequence was cloned into a pet20b plasmid and introduced into the E. coli BL21(DE3) strain. The recombinant protein was expressed from a culture in LB medium (50 mL) and isolated using an inclusion body extraction protocol (Novagen, pET System Manual, 11th edition). In addition, the VapA protein was considered due to its relevance described in the literature, despite having been excluded from the pool of candidate proteins after searching using both approaches. For its purification, strains B, D, E, F, and G of A. salmonicida were used in a glycin solubilization based method (Bjørnsdottir et al., 1992). Three infection challenges were performed 1 and 3 months after vaccination with vapA, as detailed in Table 2, and administered intraperitoneally, while exeD is pending validation.

**Results**

ExeD was the protein chosen after shaving and bioinformatic screening. Although no challenge has been performed for exeD, it should be noted that this is an interesting protein involved in the type II secretion system, which is important in the secretion of virulence substances in Gram-negative bacteria. This protein forms an important multimeric channel in this task.

In the challenge 1 month after vaccination, the first group showed an RPS of 30% and a mortality rate of 48%, compared to an 80% mortality rate in the control group. The second and third groups showed an RPS of 50% and 33.33%, and a mortality rate of 12% and 16%, compared to the 24% mortality rate of their control group. In the challenge 3 months after vaccination, the first group showed an RPS of 50% and a mortality rate of 16%, compared to the 80% mortality rate of its control group.

*(Continued on next page)*

**Table I: Strains of *A. salmonicida* used to search for immunogenic proteins using the shaving technique**

| ID cepa | Subspecies | Host |
|---|---|---|
| A | *A. salmonicida subsp. achromogenes* | Turbot |
| B | *A. salmonicida subsp. achromogenes* | Turbot |
| C | *A. salmonicida subsp. salmonicida* | Turbot |
| D | *A. salmonicida subsp. achromogenes* | Sole |
| E | *A. salmonicida subsp. achromogenes* | Sole |
| F | *A. salmonicida subsp. achromogenes* | Turbot |
| G | *A. salmonicida subsp. achromogenes* | Turbot |

**Table II: Groups used in vaccination challenges**

| | Host | *A. salmonicida* strains | Number of fishes | Weight per fish(g) | ug of protein per fish |
|---|---|---|---|---|---|
| **1st group** | Sole | D, E | 150 | 15 | 24 |
| **2nd group** | Turbot | F | 175 | 60 | 25 |
| **3rth group** | Turbot | B, G | 175 | 60 | 50 (25 each strain) |
| **Control 1st group** | Sole | - | 250 | 15 | - |
| **Control 2nd and 3rth group** | Turbot | - | 250 | 60 | - |

## Conclusion

The results obtained in trials with the VapA protein indicate a significant protective immune response in sole and turbot, with notable reductions in mortality (up to 64% in some groups) and RPS values reaching 50% even three months after vaccination. These data suggest that VapA is a promising candidate for the development of subunit vaccines against A. salmonicida in species of high commercial value. Although the trial with the ExeD protein is pending, its role in the type II secretion system and its exposure on the bacterial surface make it a target of high interest for future evaluations. The combination of proteomic and bioinformatic approaches has proven effective for the identification of candidate antigens, and their validation in field trials could contribute to improving health and productivity in aquaculture, reducing dependence on antibiotic treatments.

## Introduction

Seaweeds have a longstanding tradition in their use for human consumption in many Asian countries. In the western world, their use has for long been limited to limited coastal areas and has been associated for a long time with episodes of hunger and war. This view has been changing drastically as the need for new prime matter for human food production is has been growing. Seaweeds are now also in the western world increasingly being considered as a more sustainable, high quality food source.

Against this background, several R&D projects have been executed in the last 5 years, focusing on cultivation of seaweeds and their use in human food production, such as the Spanish INNOVALGA project (2020-2023) and the EU Horizon Europe project NOVAFODIES (2023-2026) that both aimed to stimulate diversification, efficiency, innovation, and upscaling of European micro- and macroalgae solution.

In this contribution we will present an integral overview of a potential production chain based on the green seaweed *Codium*, from line-seeding to biomass composition and production of a food prototype. The genus *Codium* has a worldwide distribution and a traditional use in various countries both within and outside Europe and various interesting functional properties. Its taste is generally considered subtle, reminiscent of crustaceans. It is therefore considered to be promising ingredient for the food of the (near) future.

## Material and Methods

Locally collected specimens of the species *Codium taylorii* were maintained in a climate room (20 °C) in plastic containers in fresh seawater (weekly renovation) at minimum light (< 20 µmol photons $m^{-2}$ $s^{-1}$) and under constant aeration. Biomass samples were analysed for their nutritional composition, antioxidant properties and antimicrobial properties. To optimize low-cost cultivation of *Codium*, seeding trials were carried out, studying the effects of temperature, irradiance, and substrate type for biomass seeding on lines. A fully factorial experiment has been carried out considering two light intensities (60 and 100 µmol photons $m^{-2}$ $s^{-1}$) and two temperatures (15 and 20 °C) and three substrate types (cotton, hemp and polypropylene ropes). Seeded lines were deployed in earthen ponds to study outgrowth. The seaweed was subjected to shelf-life trials in which fresh biomass stored directly or in vacuum packaging in the refrigerator. Organoleptic properties and food microbial analyses were carried out at different time intervals to determine shelf-life. Finally, a food prototype product was developed in the form of fish-filled ravioli-type pasta. Freshly harvested algae were added to the pasta-dough in differ recipe formulations and products were subjected to organoleptic and biosecurity tests.

## Results and discussion

Freshly harvested *Codium* biomass can be maintained for more than 6 months with minimal maintenance effort as described. With respect to composition, compared to other macroalgae, *C. taylorii* had a relatively high water content (92% DW), whereas protein content was relatively low (8-10% DW). However, literature values for the species list values up to 18% and therefore claim to be high fibre and high protein biomass according EU regulations (EC Regulation No. 1924/2006). The percentage of essential amino acids for all samples was approximately 40% and generally favourable for human nutritional needs.

Mean antioxidant capacity of *Codium* was comparable to reported values of other green seaweeds and consistent across TEAC and ORAC test methods. No antimicrobial properties of the algae were detected were detected using the agar well diffusion method, however, watery extracts from *Codium* presented significant antimicrobial activity against the food pathogen *Staphylococcus aureus*.

*(Continued on next page)*

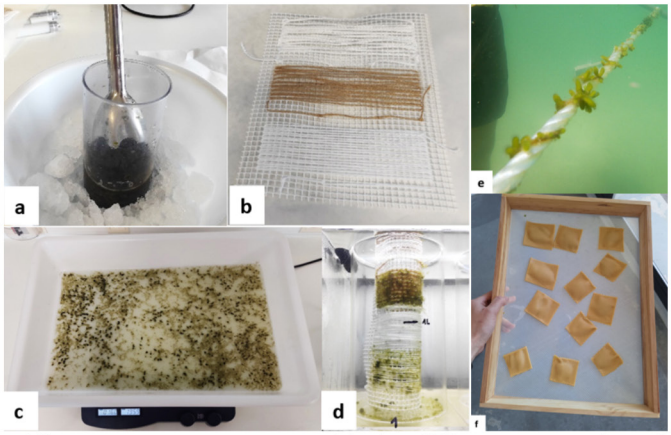

Figure 1: Shredding process (a), support with the different types of seeding yarns (b), shredded mixture sieved and ready to incubate the support with the yarns (c), aquarium with the yarns arranged cylindrically (d) seeded line deployed for outgrow (e), and ravioli-type pasta prototype product (f).

With respect to the cultivation trials, successful seeding of the lines was obtained. Both temperature and substrate significantly affected appearance of *Codium* Forming Units (CFU) on lines, whereas irradiance was significant in second-order interactions. The highest number of CFUs (11 units/cm) occurred in the high-temperature, low-irradiance treatment for hemp yarn. It was concluded that substrate was the main factor determining fixation success, moderated by temperature and light interactions. Outgrowth in earthen ponds proved successful initially, although modifications had to me made to the seeding lines.

Shelf-life tests indicated limited storage time (1 week) of fresh *Codium* under refrigerated conditions, although vacuum packaging seemed to slightly prolong shelf life. Although counts of major food pathogens were well below legal limits, general count of aerobic bacteria was too high and organoleptic properties decreased drastically after 1 week. First pasta dough prototype products elaborated with *Codium* produced satisfactory results with respect to product structural and organoleptic qualities. The final product was slightly orange coloured, probably due to relatively high β-carotene contents of the *Codium*.

It is concluded that *Codium* shows considerable promise for cultivation as prime matter for human food ingredients with prospects of efficient cultivation. Future studies should concentrate on the outgrow phase. Regarding biomass processing, further studies on the effects of storage methods on nutritional qualities and alternative storage methods to ensure longer shelf life are required.

# EFFECTS OF SUBSTRATE TYPE AND DIETARY ENRICHMENT ON THE GROWTH PERFORMANCE OF THE SEA CUCUMBER *Holothuria arguinensis* (Koehler & Vaney, 1906) IN RECIRCULATING AQUACULTURE SYSTEMS

M. Galindo, Y. Pascual, S. Aranda and E.-j. Malta*

Aquaculture Technology Centre (CTAQUA)
Muelle comercial s/n
11500 El Puerto de Santa María
Cádiz, Spain
E-mail: m.galindo@ctaqua.es

Sea cucumbers are experiencing increasing demand, particularly in Asian markets, which has led to their high economic value (Purcell,*et al.,* 2023). As a result, many species are subject to overexploitation, often through illegal, unreported, and unregulated (IUU) fishing practices and/or poor fishery management. Aquaculture represents a sustainable alternative to prevent further depletion of wild sea cucumber populations (Sousa *et al*., 2023; Domínguez-Godino and González-Wangüemert, 2019; Félix *et al.,* 2018).

Recent advances in culture techniques for the genus *Holothuria* have improved methods for reproduction and captive rearing. Key developments include spawning induction (Venancio et al., 2021), larval and juvenile management (Madruga et al., 2023; Sousa et al., 2023) and specialized feeding strategies (Domínguez-Godino and González-Wangüemert, 2019a; Rodrigues et al., 2023), which have led to optimized survival and growth rates. Factors such as substrate conditions, diet supply and stocking density are determinants of culture success (Domínguez-Godino et al., 2015). To date, no commercial feed has been patented for sea cucumbers, and the development of effective diets remains an active area of research.The study aimed to evaluate the impact of different substrate and diet combinations on the growth performance of *H. arguinensis* cultured in a recirculating aquaculture system (RAS).

Individuals of *H.arguinensis* (n=24) were collected from the wild and acclimated in indoors tanks for 48h without diet enrichment. The experiment was divided into two phases: i) assessment of three types of substrates (sand, mud and a mixture of both) on growth and survival; ii) evaluation of three feeding regimes were evaluated: T1 (no enrichment), T2 (50:50 mixture of *Ulva* sp. and commercial feed), and T3 (replacement of *Ulva sp*. with *Chaetomorpha sp*.). Experimental tests were carried out with the main objective of determining the optimal substrate and diet combinations to maximize growth performance in a RAS system.

In both cases, the Specific growth rate (SGR) (Ricker, 1979) and the mortality rate (%) were analyzed and evaluated to determine the culture feasibility. Organic matter content in substrate was determined using the loss on ignition (LOI) method (%). Statistical analysis was performed using R-Studio (R version 4.2.1). Differences among treatments were evaluated using one-way ANOVA followed by post-hoc tests, with significance set at $P < 0.05$. Substrate type did not significantly affect growth, however the sand treatment showed greater variability in SGR. The lowest growth was recorded in the control (no substrate), with a mean SGR of -0.10 ± 0.11 %/day, indicating limited development in the absence of substrate (Fig. 1). The Overall mortality rate was low (one individual only). LOI analysis revealed higher organic matter content in mud sediments (1.2971% and 1.1522%) compared to sand (0.1554%). This, along with the average SGR for mud (0.29 ± 0.35 %/day), led to the selection of mud as the substrate for the second experimental phase, testing diet supply only.

Among the three dietary regimes tested, the treatment containing *Chaetomorpha* sp. and commercial feed (T3) yielded the highest growth rate (0.56 ± 0.65 %/day), with statistically significant differences compared to the control group (Fig. 2). No mortality was recorded during this phase.

*(Continued on next page)*

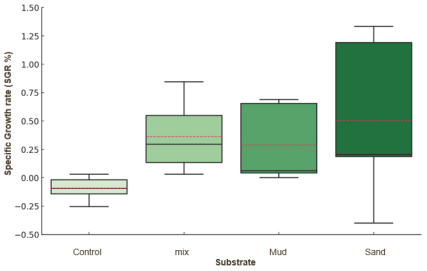

**Fig 1.** Specific Growth rate (%/d) of *H. arguinensis* under four culture conditions varying types of substrates (sand, mud, and 50:50 sand & mud)

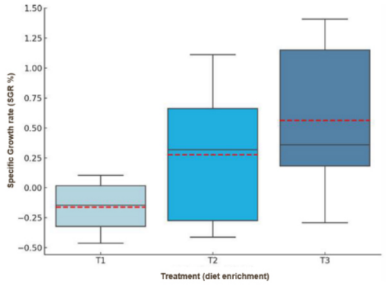

**Fig 2.** Specific Growth rate (%/d) of *H. arguinensis* under three feeding regimes: T1 (no enrichment), T2 (50:50 mixture of *Ulva sp.* and commercial feed), and T3 (replacement of Ulva sp. with *Chaetomorpha sp.*

The results emphasized the importance of the presence of sediment in the cultivation systems of *H. arguinensis*. Both muddy and sandy sediments and their mixture proved to be suitable substrates for animal growth, without rendering significant differences between them. Both have their advantages; mud provided a higher organic matter content, offering a potential nutritional benefit, while sand contributed favorable physical conditions for development. Dietary enrichment demonstrated to be a key factor in enhancing growth of *H. arguinensis*. The combination of *Chaetomorpha sp*. and commercial feed (T3), particularly when used with a muddy substrate, significantly improved growth compared to the control.The requirement for substrates to support optimal growth presents challenges for indoor tank-based systems. Consequently, alternative culture environments such as earthen ponds should be explored to facilitate scaling and improve operational efficiency in the cultivation of this species.

## Introduction

Landlocked regions such as Czechia exhibit critically low omega-3 indices, correlating with high cardiovascular mortality and ageing related disorders. There is an import dependency on long-chain omega-3 polyunsaturated fatty acids (LC-PUFAs), essential for cardiovascular and cognitive health, from overexploited marine resources. While microalgae and genetically modified vegetable oils present potential solutions, their scalability and regulatory limitations hinder widespread adoption. In contrast, Central European semi-intensive fishponds—regulated under EU water directives—harbor abundant plankton-derived LC-PUFAs (800-1600 mg EPA+DHA 100 g dry matter$^{-1}$), yet their trophic transfer to farmed fish remains inefficient. Common carp (*Cyprinus carpio*), predominantly fed cereal-based diets deficient in PUFAs, exhibit poor retention of LC-PUFAs in fillets, despite plankton availability. Also, application of any farming solution to improve LC-PUFA transfers from pond food web to pond fish is discouraged by nuanced arguments such as '*each year is different*'' or '*each pond is different*'. In this research, we explored whether such arguments are true or unfounded.

This study investigates the interannual as well as seasonal dynamics of dry matter, lipids and fatty acids in common carp gill filterable (>200 $\mu$m) plankton consortia in relation to physicochemical parameters, fishgrazing pressure, and human intervention such as supplementary feeding. By assessing these dynamics, we evaluate plankton nutritional quality to develop pond feeding strategies, improve LC-PUFA retention and sustainable land-locked mining of LC-PUFA from the pond farmed fish. In a way, to develop nature-based solutions one first have to understand the nature itself.

## Material and method

A study was conducted in nine uniform (0.2 ha, 1 m deep) experimental ponds in Vodňany, Czechia (49°09'24.9"N, 14°09'54.2"E; 404 m a.s.l.), stocked with Cyprinus carpio (471.3 kg ha$^{-1}$) and differentially fed (control ponds: 563 kg wheat pond$^{-1}$ throughout season, n=3 replicates; treatment ponds: 123 kg wheat pond$^{-1}$ during April-June + 432 kg plant-based pellet pond$^{-1}$ during July-October, n=6 replicates, half hand-fed and other half by demand feeder). The plant pellets were non-refined and agri-food by-products based, with protein content ~28% and lipid ~3.5%. From April to October 2024, monthly sampling included water quality, climatic variables, submerged temperature loggers, fish biometrics, and net plankton consortia (>200 $\mu$m) was collected that pond carp generally acquires by gill filtration while predominantly grazing on the pond pelagic food web (that is the larger feeding area/ surface area, compared to feeding surface area of pond bottom or margin). Lyophilized (14 hours main drying + 10 hours final drying) plankton consortia (May–October) were analyzed for dry matter (DM), lipid composition, and fatty acids. Comparative analysis with 2022 data was performed, followed by seasonal trend visualization and Pearson's two-tailed correlation (OpenAI Data Analyst 4o, R).

## Results

Between 2022 and 2024, the annual mean lipid concentration (% DM) of gill-filterable plankton consortia differed significantly ($p<0.05$), but the monthly trend or seasonal progression remained consistent (Month × Year: p = 0.998) between years. Despite different feed formulations applied to pond groups, plankton lipid and dry matter content showed no statistically significant difference. Both DM (mg l$^{-1}$) and lipid ($\mu$g l$^{-1}$) concentrations peaked in June–July, reaching minima in August–October, a pattern congruent with Cladocera abundance (a good marker) and exhibiting moderate positive correlation ($r$= 0.30-0.42, $p<0.01$). Chlorophyll-a (a eutrophication proxy) and temperature displayed a moderate inverse correlation with

*(Continued on next page)*

lipid quality and availability. An inverse trend was observed between storage lipids (e.g., triacyclglycerols) and structural lipids (e.g., phospholipids) over the season. As the season progressed, the pelagic food web seemed to deteriorate in storage lipid classes and preserve the critical structural lipids; and a strict homeostasis on cholesterol throughout season. LC-PUFAs like eicosapentaenoic acid (EPA, 20:5n-3), docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (ARA, 20:4n-6) exhibited similar trends in the pond pelagic food base (gill-filterable). They were abundant (mean±standard error) during the beginning of season (May-July;2.62 ± 0.36 $\mu$g EPA $l^{-1}$, 24.35 ± 4.21 $\mu$g DHA $l^{-1}$, 17.41 ± 2.29 $\mu$g ARA $l^{-1}$), but declined during end of season (August-October; 1.3 ± 0.24 EPA $\mu$g $l^{-1}$, 12.35 ± 2.37 $\mu$g DHA $l^{-1}$, 4.91 ± 0.98 DHA $\mu$g $l^{-1}$ ). Additionally, the alpha-linolenic acid (ALA, 18:3n-3) requirement for pond carp is not fulfilled during August-September (modelled on a system or pond-wide scale). Which means during these months carp may not have the luxury to endogenously fortify LC-PUFA from an excess of ALA pre-cursor. The (SFA+MUFA): PUFA ratio (PUFA sparing proxy) was elevated in beginning of season (May–July) and declined thereafter, implying PUFA or omega-3 sparing effect may be compromised too in second half of the season (if no non-protein energy is fed to ponds). Concurrently, the n-3: n-6 PUFA ratio decreased progressively from May, reaching minimum in July–August before rebounding in September–October. Overall results suggest that the period of late July to September is a critical period, when both the supply and endogenous fortification of LC-PUFA is quite constrained in temperate European fishponds.

**Discussion**

Based on 2022 and 2024 observations, we rebut the nuanced arguments mentioned in the introduction. Results suggest both lipid quantity and quality in the carp gill-filterable pond pelagic food web predictably deteriorate mid-season– typically during late July to early September. It happens irrespective of the year or ponds with different supplementary feed choice. The lipid and fatty acids dynamics in temperate European semi-intensive fishponds exhibit a signature trend that can be used to plan feeding solutions in the temperate Central Eastern European region. Cladocerans, a reliable marker of lipid and LC-PUFA availability in ponds, decline seasonally (Aug–Oct) due to intensified fish predation and eutrophication-induced shifts in food resources, whereas copepod abundance remains stable (although it does not cover the missing lipids in food web due to missing cladocerans). Coupled with diminished lipid availability and LC-PUFA constraints during pre-harvest (Aug-Oct), this obviously results in low LC-PUFA concentration in carp fillets harvested during November (100-150 mg EPA+DHA 100 $g^{-1}$). These findings underscore the necessity to prolong Cladocera abundance by promoting submergent vegetation as forage for zooplankton, and end-of-season supplementary feeding with energy-dense (lipid energy) formulations to mitigate LC-PUFA catabolism. Late July to September is identified as a critical window for balanced nutritional interventions in ponds in terms of lipids or finishing feeding strategies.

# AQUAVAX PROJECT "STANDARDISATION, DISTRIBUTION AND EVALUATION OF THE EFFICACY OF AUTOGENOUS VACCINES IN THE FISH SECTOR AS A SUPPLY CHAIN STRATEGY FOR THE CONTAINMENT OF BACTERIAL DISEASES AND THE REDUCTION OF ANTIMICROBIAL USE"

A. Manfrin[1*], S. Catania[1], D. Volpatti[2], A. Fabris[3]

[1] Istituto Zooprofilattico Sperimentale delle Venezie
[2] Department of Agri-Food, Environmental, and Animal Sciences, University of Udine
[3] Italian Fish Farmers Association
*amanfrin@izsvenezie.it

Aquaculture has rapidly become one of the fastest-growing food industries and represents a vital source of protein for populations worldwide. The expansion of finfish aquaculture is closely associated with the development of intensive farming systems. In these facilities, fish are reared in different tanks/net cages, which can under certain conditions facilitate the rapid transmission of infectious agents and can lead to significant economic losses. Antimicrobials play a crucial role in the treatment of symptomatic bacterial fish diseases. However, their incorrect use in the past has contributed to the emergence of antimicrobial-resistant pathogens, posing potential risks to both human health and environmental sustainability. Vaccination strategies have demonstrated a positive impact in reducing the risk of antibiotic-resistant bacterial strains. However, compared to other livestock sectors, the availability of commercial vaccines for aquaculture remains limited. Istituto Zooprofilattico Sperimentale delle Venezie (IZSVe), a public institute belonging to the Italian Ministry of Health, has established a certified vaccine production laboratory dedicated to autogenous vaccines, and leads the AquaVax project funded by the Italian Ministry of Agriculture and Forestry (MASAF).

AquaVax is structured into four operational phases, involving specific Operating Units (O.U.s).

**Phase 1: Enhancement of Production Performance and Standardization of Antigen and Autogenous Vaccine Production Processes for Fish**
This phase focuses on implementing and standardizing production protocols mainly for *Yersinia ruckeri* biotype 2 and *Lactococcus garvieae* formulations, laying the foundation for developing monovalent vaccines (*e.g.,* an autogenous vaccine for lactococcosis in marine species) as well as a bivalent formulation, which is in high demand among trout farmers. To improve both the quality and quantity of vaccine provision, a series of trials will be conducted to ensure standardized protocols. Furthermore, new chemical agents for pathogen inactivation and plant-based oil adjuvants will be tested. The "water-in-oil" emulsion process will also be standardized. All formulations will undergo both *in vitro* and *in vivo* testing to ensure they are completely non-toxic to fish.

**Phase 2: Production of Autogenous Vaccines Targeting Major Bacterial Diseases**
Building on the outcomes of Phase 1, priority will be given to developing innovative vaccine prototypes based on the needs of fish farmers and on the prevalence of bacterial diseases for which no commercial vaccines are currently available.

**Phase 3: Training of Technical Staff for the Standardization of Vaccination Protocols and Administration Procedures**
Theoretical sessions will be complemented by on-site, hands-on and / "on-the-job" training at selected farms, involving all relevant staff. These activities will be carried out in collaboration with industry experts and/or fish farmers association to identify suitable training sites and coordinate the implementation process. This phase is essential to the success of the project, as field vaccination practices are influenced by several variables, including farm management, disease seasonality, staff availability and staff experience.

**Phase 4: Evaluation of the Immune Response in Vaccinated Fish Populations According to the Developed Protocols**
The Department of Agri-Food, Environmental, and Animal Sciences (University of Udine) with a long expertise on farmed fish immunology will assess the effectiveness of the vaccination protocols developed in the above metioned phases. These evaluations will take place at selected farms, in close collaboration with farm veterinarians and fish farmers.

**Conclusion**
The development of fish vaccines requires strong collaboration between research institutions, pharmaceutical industry, fish farmers and regulatory authorities. An effective vaccination strategy has proven to significantly reduce the impact of major bacterial diseases and to lower the risk of antibiotic-resistant in aquaculture.

# PRELIMINARY STUDIES ON THE EFFECTIVENESS OF ESSENTIAL OILS AGAINST *Lactoccoccus garvieae* ISOLATED FROM MARINE FISH SPECIES IN ITALY

**Introduction**

Since their discovery, antibiotics have been used to treat infections caused by bacteria, in human medicine to heal people, but also to save both pets and farm animals in the veterinary field. Unfortunately, in recent years, their excessive and often inappropriate use has led to the development of antibiotic resistance, meaning that certain antibacterial molecules are no longer effective because the bacteria have been able to develop and/or acquire genes that can render the mechanism of action with which those specific molecules were able to act on the target ineffective.

Aquaculture farmed fish are no exception. In the event of disease outbreaks, they can be treated with antimicrobials, and this sector is also experiencing antibiotic resistance and treatment ineffectiveness, resulting in animal losses and significant economic damage to the production sector.

Currently, in addition to vaccination, probiotic microorganisms and new, more natural molecules are being sought to help fightening bacterial infections while reducing the use of antibiotics. Among these substances, essential oils seem to have emerged in recent years as a valuable tool in the fight against the spread of bacterial diseases.

**Materials and methods**

Various essential oils (oregano, lavender, thyme, melaleuca alternifolia, cajeput, lemongrass, cinnamon) or mixtures thereof were tested to assess whether these substances could have a bacteriostatic and/or bactericidal effect against *L. garvieae* isolated from marine fish species farmed in Italy.

The study was conducted following the guidelines of the Clinical & Laboratory Standards Institute (CLSI) by bringing a suspension of the microorganism under examination into contact with different concentrations of essential oil to find the MIC (Minimal Inhibitory Concentration) and MBC (Minimal Bactericidal Concentration). The MICs of the different strains under examination were also established with the antibiotic molecules currently used in aquaculture.

**Results**

The initial results show that *L. garvieae* is resistant to individual essential oils. In fact, at high concentrations of oil, the strains under examination were found to be viable and it was not possible to determine the MIC and MBC. Cinnamon and a mixture of oils, on the other hand, proved to be more effective in treating *L. garvieae*, as it was possible to establish the MIC and, in some cases, the MBC.

These are preliminary results. In the future, other essential oils and mixtures will be tested on *L. garvieae*, an emerging pathogen in Italian marine aquaculture, and the sensitivity to essential oils will be analysed on other pathogenic strains isolated from marine species such as *V. anguillarum*, *V. harveyi*, *T. maritimum* and *P. damselae*.

**Introdução**

Streptococcosis, caused by *Streptococcus agalactiae* (serotypes Ib and III), poses a serious threat to tilapia farming, causing significant economic losses (Delphino et al., 2019). Currently, the main therapeutic measure used during bacterial outbreaks is antibiotics, which can lead to bacterial resistance and even antimicrobial residues in fish when used indiscriminately (Milijasevic et al., 2024). An alternative to antibiotics for preventing infections is fish vaccination, which induces specific antibodies, conferring protection and safety to the immunized host, as well as economic benefits (Rivas et al., 2023). This study evaluated the efficacy of the CampVac® Streptomune vaccine in preventing experimental infection, conferred immunity, and production performance of Nile tilapia (*Oreochromis niloticus*) using highly virulent Brazilian strains.

**Materials and Methods**

Six hundred seronegative juveniles (30 ± 0.1 g) for *S. agalactiae* were used, distributed into 15 tanks (40 fish/tank). Experimental groups included: GCN1 (unchallenged negative control), GCP2 (serotype Ib-challenged positive control), GCP3 (serotype III-challenged positive control), GV4 (vaccinated/challenged with serotype Ib), and GV5 (vaccinated/challenged with serotype III). Vaccination (Day 0) was administered intraperitoneally (0.05 mL/fish). Challenge (Day 30) used established LD50: $4.6\times10^7$ CFU/fish (serotype Ib) and $1.6\times10^7$ CFU/fish (serotype III), administered via intracelomic (50%) and intramuscular (50%) routes. Water quality parameters (pH: 7.8±0.2; $O_2$: 7.1±1.5 mg/L; ammonia: 0.1±0.01 mg/L; temperature: 25.1±0.6°C) were monitored daily, maintaining optimal conditions. Mortality and clinical signs were assessed for 30 days post-challenge. Liver, spleen, and brain samples were collected for bacterial count and molecular confirmation by PCR and sequencing. Relative Percent Survival (RPS) was calculated as RPS = [1 - (% mortality treatment / % mortality control)] × 100. Data were analyzed using SAS (ANOVA, Fisher's exact test; Student's T-test; $p<0.05$).

**Results**

The vaccine demonstrated high protective efficacy: Survival in vaccinated groups (GV4: 97.5±2.5%; GV5: 94.2±6.3%) was significantly higher ($p<0.001$) than in positive controls (GCP2: 61.7±1.4%; GCP3: 53.3±8.0%) (Table 1). RPS was 93.6±3.6% (serotype Ib) and 88.5±7.3% (serotype III). A significant reduction ($p<0.001$) in bacterial load was observed in tissues of vaccinated fish, notably in the liver of GV4 ($2.16\times10^2$ CFU) compared to GCP2 ($5.51\times10^5$ CFU). GV5 showed absence of bacteria in the brain and spleen. Regarding production performance (Day 60), vaccinated fish exhibited higher weight gain (GV4: 67.9±8.5 g; GV5: 54.5±1.8 g) versus non-vaccinated challenged groups (GCP2: 38.1±4.4 g; GCP3: 31.7±3.1 g) and better feed conversion ratio (GV4: 1.70±0.14; GV5: 1.93±0.26 vs. GCP2: 3.33±0.48; GCP3: 3.85±0.22).

**Discussion**

Robust protection (>88% RPS) against both serotypes was accompanied by a drastic reduction in bacterial load in key organs, with the notable absence of bacteria in the brain of vaccinated fish suggesting blockage of neural dissemination. This RPS value is higher than the 59.14% reported by Rivas et al. (2023). The superior production performance of vaccinated groups (72-78% higher weight gain than infected controls) indicates that immunization minimizes energy diversion towards inflammatory responses, optimizing growth (Delphino et al., 2019). Despite the higher virulence of serotype III ($LD_{50}$ threefold lower than Ib), the vaccine-maintained survival >94%, demonstrating efficacy against Brazilian strains.

## Conclusions

CampVac® Streptomune is highly effective against *S. agalactiae* serotypes Ib and III in Nile tilapia, demonstrating: (1) >35% reduction in mortality compared to infected controls; (2) Significant tissue protection (bacterial load ≤$10^2$ CFU in vital organs); (3) Maintenance of production performance (FCR <1.93 vs. >3.33 in infected groups); (4) Proven efficacy against highly virulent native strains. This vaccine represents a strategic tool for the sustainable management of streptococcosis in tilapia farming, offering both economic and health benefits.

# MODELING PRODUCTIVITY AND PROFITABILITY FOR SMALLHOLDER TILAPIA AND SHRIMP POLYCULTURE IN JAVA

Meilisa L. Margarita[1,2]*, Miranda P.M. Meuwissen[2], Sander W.K. van den Burg[3], Hans Komen[1], John W.M. Bastiaansen[1]

E-mail: meilisa1.margarita@wur.nl

## Introduction

Aquatic polyculture is re-emerging globally as a promising system to optimize yield and profit (Knowler et al., 2020), including in Java, Indonesia. Among smallholder farmers in Java, tilapia-shrimp polyculture is one of the chosen species combinations (Setyawan et al., 2022a). However, optimizing profit in tilapia-shrimp polyculture systems remains a challenge due to the underexplored effects of management decisions on species interactions, which influence productivity and profitability. The objectives of this study are to (1) develop a multispecies bioeconomic model for pond production of tilapia and shrimp that incorporates species interactions and (2) validate the model outputs.

## Materials and methods

The multispecies bioeconomic model was developed through a literature review and insights from a scoping visit in Java. Model inputs are based on management parameters that farmers can influence: feed, stocking density, stocking weight, and culture duration. The model operates on two levels: (1) the individual species level which produces daily weight gain as output, and (2) the pond level which incorporates interaction effects from the other species and produces biomass, daily mortality, and cumulative mortality for each species as outputs. The final outputs are total production and operating profit expressed in USD/$m^2$/year. The model was programmed in R software version 4.3.2 (R Core Team, 2023) as a simulation tool. Expert validation of model projection was conducted for six scenarios (Table 1). Four scenarios with average feeding rate and (1) low tilapia and low shrimp density (LT-LS), (2) low tilapia and high shrimp density (LT-HS), (3) high tilapia and low shrimp density (HT-LS), or (4) high tilapia and high shrimp density (HT-HS), and 2 scenarios with average stocking density and (5) low feeding rate (LFR), or (6) high feeding rate (HFR).

## Results

In the stocking density scenarios, higher tilapia stocking density led to lower tilapia harvest weights, regardless of shrimp density (Table 2). For shrimp, higher tilapia density or lower shrimp density increased harvest weights due to greater feed availability. Experts validated tilapia harvest weights as realistic across all scenarios but noted that shrimp harvest weights in LT-HS and HT-HS appear to be underestimated. Higher stocking density raised the cumulative mortality of the same species. Higher shrimp densities slightly reduced tilapia mortality (Table 2). But higher tilapia density slightly increased shrimp mortality. Experts remarked that tilapia cumulative mortality appeared to be overestimated at high densities, while shrimp mortality was within a realistic ranges.

Under the HFR scenario, tilapia growth was 2.7 times faster to a harvest weight of 205 grams (Table 2), and shrimp harvest weights were 3.8 times higher than under LFR. Experts agreed with the faster tilapia growth at higher feeding rates but pointed out that shrimp harvest weights under LFR appear to be underestimated. Operating profit under HFR was USD 1.54 higher than under LFR (Table 2), though experts cautioned that this large difference may indicate model overestimation.

## Discussion

The lower than expected shrimp harvest weights can be attributed to a lower realized feeding rate from uneaten tilapia feed, a low and constant natural feed availability assumed by the model, and potentially unrealistic estimates for the effect of stocking density and FCR used to calculate economic FCR. Experts expected tilapia cumulative mortality of around 30% in the HT-LS and HT-HS scenarios. The discrepancy arises because the daily mortality model links higher biomass to higher daily mortality rates. Experts also noted that mortality is typically higher in the early weeks after stocking for both species due to biological vulnerability. The annual operating profit projected under the HFR scenario appears high. The model focuses on the effects

| Operating cost (USD/$m^2$/$year^1$) | 0.49 | 0.59 | 1.18 | 1.28 | 0.46 | 1.46 |

LT: Low tilapia, LS: Low shrimp, HT: High tilapia, HS: High shrimp, LFR: Low feeding rate, HFR: High feeding rate.

of species interactions on the total economic performance, and does not account for the effects of disease and other risks which will likely reduce the annual profit when they affect the pond. The main aim for the model is to assess the effects of management choices on the technical and economic performance. Availability of the data on the performance of polyculture ponds is limited which, when available, will allow finetuning of the model parameters, especially for growth on natural feed and for the interaction effects on mortality.

**Conclusions**

The model performs well to predict the effects of management choices on tilapia growth. Shrimp growth appears to be underestimated in some scenarios, especially with low feeding rate. Projections of mortality appear realistic in most cases, but mortality under high tilapia stocking densities tends to be overestimated. Currently, the model could serve as a tool for assessing the tilapia-shrimp polyculture, supporting food production and economic stability for smallholder farmers.

Developing sustainable aquafeeds and diversifying farmed fish species, with focus on that with a low dependency on marine-derived ingredients, is crucial for the modern aquaculture. In the present study, for the first time, low-fish meal diets, in which black soldier fly (*Hermetia illucens*) meal was used to partially replace conventional ingredients, were formulated to assess the effect on growth, gut health and transcriptomic profile of flathead grey mullet (*Mugil cephalus*). Four, iso-proteic, iso-lipidic and iso-energetic diets were formulated to replace the conventional protein sources of a control diet (H0) with 10, 15 and 20 % black soldier fly (*Hermetia illucens*) meal (H10, H15 and H20, respectively). For the feeding trial, 360 juvenile grey mullets (weight = 40.2±0.5 g), obtained by the International Marine Center (IMC, Oristano, IT), were transferred to the Institute of Marine Biological Resources and Biotechnologies, National Research Council (IRBIM-CNR, Messina, IT). After acclimatation, fish were randomly divided in 12 experimental tanks, connected to an open recirculating system located on the Sicilian coast of the Strait of Messina (Temperature, 22,05±9,12 °C; $O_2$, 66.5±8.1 mg $L^{-1}$; Salinity=, 39.07±0.41 PSU; pH, 8.62±0.42). Fish were assigned to the four dietary treatments, in triplicate and fed the experimental diets (1-3% body weight, according to the water temperature) for 138 days. At the end of the experiment, after euthanasia (MS-222 500 mg $L^{-1}$), fish were individually weighted and gut, liver and spleen were sampled and processed for histological and immunohistochemical analyses.

At the end of the experiment, fish fed H15 and H20 diets showed a significantly lower final weight compared to those fed H0 and H10 diets. Moreover, fish fed diet H20 showed a significantly lower Fulton condition factor compared to the other groups. Gut histology was marginally affected by the experimental diets (fig.1 a); however, a significant increase in villi thickness and mucous cells abundance was evidenced in group H15. No alterations in liver and spleen histology were observed within the experimental groups. Transcriptomic analyses of intestine revealed changes in expression of genes involved in inflammation, cell recognition patterns and lipid uptake in response to *Hermetia illucens* meal inclusion. According to the results obtained in the present study, the tolerance of *M. cephalus* to dietary *H. illucens* meal is lower compared to other, strictly carnivorous farmed fish species. However, replacing conventional protein sources with 10% *H. illucens* meal can play a role in improving fish gut health as also suggested for the first time in this species by the transcriptomic analyses, suggesting a role of this ingredient in improving fish immune defenses, without affecting fish zootechnical performances.

# DIETARY ADMINISTRATION OF THE HOST DEFENSE PEPTIDE PISCIDIN 1: IMMUNE AND TEXTURAL EFFECTS IN GILTHEAD SEABREAM (*Sparus aurata*)

C. Marín-Parra[1*], A. Reboredo-González[2], E. Valero-Cases[2], C. Espinosa-Ruiz[3] & M.Á. Esteban[1]

**Introduction**
Host defense peptides (HDPs) have garnered significant attention as innovative alternatives to conventional antibiotics. These peptides are notable not only for their antimicrobial properties but also for their capacity to modulate immune responses. Piscidins are amphiphilic, cationic peptides characterized by an α-helical secondary structure, potent antimicrobial activity against a broad spectrum of pathogens, and notable immunomodulatory properties [1]. However, their oral administration is constrained by limited stability and vulnerability to enzymatic degradation [2].

**Methodology**
To address these limitations, we encapsulated piscidin 1 (P1) within carrageenan and pectin microparticles, thereby developing an oral delivery system. P1 is an HDP of gilthead seabream (*Sparus aurata)*. Gilthead seabream specimens were fed for 17 days a commercial diet (Skretting) supplemented with 0%, 0.05%, or 0.1% encapsulated P1. The scanning electron microscope was used to determine the size of the microparticles. Serum and head-kidney leucocytes were collected on days 4 and 17 to assess humoral and innate immune parameters (peroxidase, anti-protease, lysozyme, and respiratory burst activities and phagocytosis). Additionally, muscle samples were collected on day 17 for texture profile analysis (TPA; hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness, and resilience) and proximate composition analysis (carbohydrates, protein, fat, ash, fiber, water).

**Results**
The results indicated that serum peroxidase activity significantly increased on day 4 in fish fed the 0.05% encapsulated P1 diet. Respiratory burst activity decreased in fish fed with encapsulated P1 at both day 4 and day 17. Phagocytic ability increased in fish fed the 0.1% diet at both sampling points, while only the 0.05% diet group exhibited an increase in phagocytosis capability on day 4. TPA results demonstrated that adhesiveness decreased in fish fed the 0.1% encapsulated P1 diet, while resilience increased in both groups receiving encapsulated P1. The diet had no effect on the proximate composition of the fish.

**Conclusion**
Therefore, this study suggests that encapsulated peptides may hold potential as an oral delivery system to stimulate the immune system and enhance muscle quality in aquaculture.

## Introduction

Salinity gradients play a crucial role in coastal ecosystems by supporting biodiversity, regulating nutrient cycling, and contributing to overall ecosystem resilience. Marine organisms depend on specific salinity ranges for optimal physiological function, and deviations from these ranges can impair organism health and trigger cascading effects on population dynamics and ecosystem stability. Understanding how salinity variation influences marine organisms and how it relates to biological features such as sex is essential, as it directly impacts key cellular processes, such as lipid metabolism and the structural integrity of cell membranes. Assessing the factors that shape the lipid composition of marine organisms is key for aquaculture species, as optimizing lipid profiles can enhance their nutritional value and improve survival rates during early life stages. At a production level, such insights can improve species selection, refine rearing protocols, and support effective water quality management. In this study, we investigated whether the fatty acid (FA) composition of two gammarid amphipod species, *Melita palmata* and *Gammarus locusta*, differs between males and females, as well as in response to salinity variations along a natural gradient in Ria de Aveiro coastal lagoon (Portugal). Special emphasis was placed on eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), given their essential roles in cellular homeostasis and nutritional value for marine species.

## Materials and methods

Three sampling sites were selected along Mira channel (Ria de Aveiro, Portugal), encompassing a natural salinity gradient from marine to freshwater conditions: S35 (~35 salinity), S30 (~30 salinity), and S3 (~3 salinity). Fatty acid methyl esters were individually extracted from *M. palmata* and *G. locusta* adult amphipods using gas chromatography-mass spectrometry (GC-MS). The overall abundance of the most important FA (measured as μg of FA per mg of amphipod dry weight), including EPA and DHA, was compared separately for each species between salinities and sexes using a multivariate approach. Differences in the abundance of each FA between the same factors were assessed through univariate linear models.

## Results

The overall FA composition of *M. palmata* varied significantly with both salinity and sex (Fig. 1a). Regardless of the salinity level, females showed a higher FA abundance than males (females: 14.3 $\mu g.mg^{-1}$; males: 11.1 $\mu g.mg^{-1}$). Additionally, amphipods from the high-salinity site exhibited greater total FA content compared to those from the low-salinity site (S30: 14.6 $\mu g.mg^{-1}$; S3: 10.8 $\mu g.mg^{-1}$). In contrast, the overall FA composition of *G. locusta* differed according to sex (females: 17.2 $\mu g.mg^{-1}$; males: 7.5 $\mu g.mg^{-1}$) but not between salinity levels (S35: 24.45 $\mu g.mg^{-1}$; S30: 24.85 $\mu g.mg^{-1}$), with higher content for females than males (Fig. 1b). Salinity gradients significantly influenced the FA composition of *M. palmata*, with high-salinity conditions promoting the accumulation of EPA and DHA, regardless of sex. In contrast, while salinity had no measurable effect on the FA composition of *G. locusta*, females consistently exhibited nearly three times higher levels of EPA and DHA, when compared to males.

*(Continued on next page)*

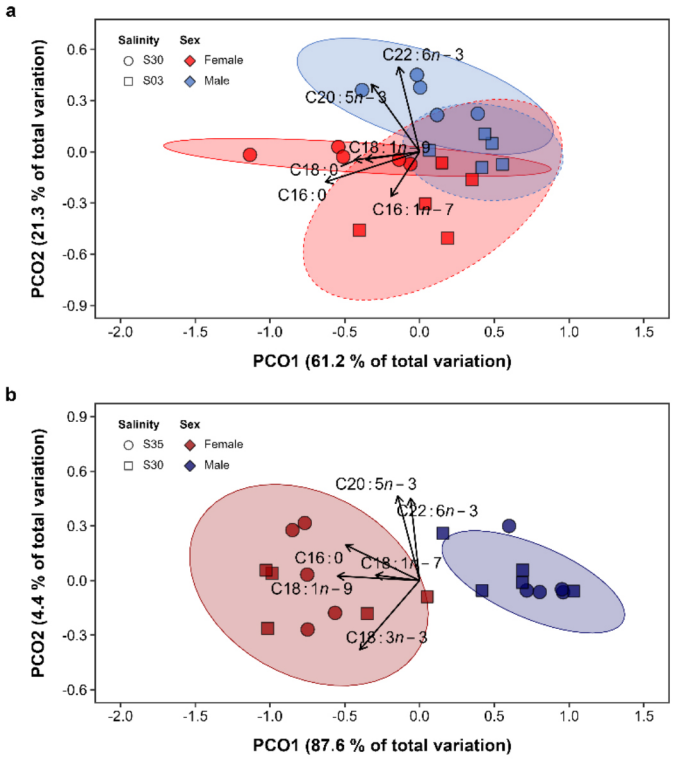

**Figure 1.** Principal Coordinate Analysis (PCO) illustrating the variation of the fatty acid (FA) composition of the amphipods a) *Melita palmata* and b) *Gammarus locusta* according to different salinity levels (Salinity 35 - S35; Salinity 30 – S30; Salinity 3 – S3) and the sex (female and male) of the individuals. Analyses were restricted to FA accounting for more than >1% of total FA abundance. Vector loadings were represented only by the FAs that contributed the most to the differences between factor levels.

## Discussion

The observed differences in FA composition suggest that each species employs distinct strategies to cope with environmental salinity stress. In both gammarid amphipod species, females exhibited higher FA content than males, likely reflecting the greater energy demands associated with reproduction. *Melita palmata* showed high plasticity along the salinity gradient, with significant variation in FA composition being linked to both salinity and sex. This indicates that *M. palmata* is well-adapted to dynamic estuarine conditions and may possess a flexible metabolic strategy beneficial for survival and potentially valuable for aquaculture in environments with variable salinity. In contrast, *G. locusta* exhibited a strong sex-related difference in FA composition, but no significant response to salinity, probably due to the limited salinity variation between the sampled locations. Nevertheless, these results suggest that in aquaculture settings, favouring an all-female population, whether through selective rearing or sex-inducing technologies, can enhance biomass yield and profitability, owing to females' superior FA composition.

## Conclusion

Salinity- and sex-specific patterns in *M. palmata* and *G. locusta* revealed that salinity conditions can shape the FA composition of each species, affecting males and females differently. These patterns highlight the species' capacity to tolerate moderate salinity fluctuations, reflecting their adaptability to dynamic coastal environments. Beyond advancing our understanding of salinity-driven physiological adaptations in marine and estuarine amphipods, this study offers valuable insights for improving aquaculture practices. By examining how salinity influences FA composition, particularly the levels of EPA and DHA, our findings can support more informed decisions on species selection and salinity management to enhance the nutritional value of cultured organisms.

# OPTIMISING VITAMIN E PRODUCTION IN THE MICROALGA *Phaeodactylum tricornutum* FOR SUSTAINABLE AQUAFEED FORMULATIONS

C. Marrero-Alemán[12*], E. Cabrita[1], H. Pereira[2]

[1] CCMAR/CIMAR.LA-Centre of Marine Sciences, University of Algarve, Campus Gambelas, 8005-139 Faro, Portugal

*E-mail: cmaleman@ualg.pt

## Introduction

Microalgae are increasingly recognised as a promising resource for sustainable aquaculture, not only due to their protein and lipid profiles but also because of their richness in bioactive compounds with antioxidant proprieties (Dineshbabu et al., 2019). Among these, vitamins such as C and E play a significant role in maintaining cellular homeostasis and mitigating oxidative stress in aquatic organisms. The presence and concentration of these compounds can vary significantly depending on the microalgal species, cultivation parameters, and biomass processing techniques (Goiris et al., 2012; Mavrommatis et al., 2023). As such, the strategic cultivation and harvesting of microalgae have become an area of interest for enhancing their functional value in supporting reproductive health and performance in aquaculture species (Shastak and Pelletier, 2023).

Vitamin E (α-tocopherol) is a fat-soluble antioxidant essential for the health and reproductive performance of farmed fish. It contributes to membrane stability, supports reproductive function, particularly by protecting gametes from oxidative stress and aids immune response, making it a critical micronutrient in aquafeed formulations aimed at enhancing breeding success. While traditionally supplied in synthetic form, there is growing demand for natural, sustainable alternatives. *Phaeodactylum tricornutum*, a model marine diatom, stands out due to its established cultivation protocols, rapid growth, and genetic tractability. Recent efforts have focused on optimising culture conditions to stimulate the biosynthetic pathways responsible for vitamin E production in this species. Increasing the endogenous levels of α-tocopherol within *P. tricornutum* biomass could reduce the total quantity of microalgae required to achieve the desired reproductive support in aquaculture broodstock diets. This biofortification approach offers multiple benefits, including lower production costs, enhanced sustainability, and reduced reliance on external synthetic inputs, aligning with current trends in the development of environmentally responsible aquaculture systems.

## Materials and Methods

This study evaluated the effects of exogenous vitamin supplementation on the growth and antioxidant potential of the marine diatom *Phaeodactylum tricornutum*. Cultures were obtained from GreenCoLab (University of Algarve) and maintained in a sterile 800 mL photobioreactor containing either standard algal growth medium (control) or medium supplemented with α-tocopherol acetate (vitamin E) in concentrations ranging from 2 to 10 mg·L$^{-1}$. The vitamin solution was sterilised via 0.22 µm Millipore membrane filtration before use. Cultures were incubated in triplicate for each treatment for 10 days at 25 ± 2 °C under white light illumination (2,500 lux) and constant aeration. Biomass was harvested at predefined time points, freeze-dried, and stored until further analysis. Vitamin content was quantified using chromatographic techniques to assess the intracellular accumulation of supplemented compounds. Additional parameters such as culture density and biomass yield were also monitored throughout the experiment.

## Results and Discussion

Specific supplementation strategies with α-tocopherol are expected to enhance intracellular vitamin E accumulation in *Phaeodactylum tricornutum* without compromising biomass productivity, offering an effective means of producing antioxidant-enriched microalgal biomass for targeted applications. In the present study, α-tocopherol acetate supplementation at 2, 4, 6, 8, and 10 mg·L$^{-1}$ yielded vitamin E contents of 36.85, 96.62, 171.99, 64.25, and 38.51 mg per 100 g DW of sample, respectively, compared with only 8.88 mg per 100 g DW in the control, clearly demonstrating a concentration-dependent response. Cultures grown under optimised conditions thus exhibited markedly improved antioxidant profiles, with the highest intracellular vitamin E accumulation observed at 6 mg·L$^{-1}$, suggesting this concentration as a potential optimum for enrichment purposes, whereas excessive supplementation (≥8 mg·L$^{-1}$) led to a pronounced decline in vitamin E content, possibly due to metabolic regulation or feedback inhibition mechanisms.

*(Continued on next page)*

The production of vitamin E-enriched *P. tricornutum* biomass represents a promising strategy to improve male reproductive performance in fish. Vitamin E plays a critical role in protecting spermatozoa from oxidative damage, preserving membrane integrity, motility, and fertilisation capacity. By reducing oxidative stress during spermatogenesis, particularly under periods of high metabolic demand, α-tocopherol-rich microalgal supplementation may enhance sperm quality parameters and increase successful fertilisation rates. These findings underline the potential of targeted vitamin E enrichment in microalgal biomass as a functional approach to boosting broodstock reproductive efficiency in aquaculture breeding programs.

## Introduction and background

The Strategic guidelines for a more sustainable and competitive European aquaculture sector address challenges and opportunities in line with the European Green Deal and related strategies. A key priority is to reduce the environmental impact of aquaculture products by promoting the use of more sustainable technical and biological inputs under the call of the circular economy (COM, 2019).

Mussel farming, one of the most important sub-sectors in Europe, is facing new challenges as it has been identified as a significant source of marine pollution (Tudini & Forgione, 2024). Indeed, the sector extensively uses plastic materials for production and packaging (Fortibuoni et al., 2021; Bottari et al., 2024). It is estimated that approximately 20 grams of plastic are used for each kilogram of mussels marketed (Pietrelli, 2022).

As part of the outcomes of the "LIFE MUSCLES" project (LIFE20 ENV/IT/000570), this study aims to investigate the economic viability of using biodegradable or recycled nets in Italian mussel farming. Specific objectives include (i) identifying the main barriers to adoption, (ii) exploring the perspectives of Italian mussel farmers, and (iii) offering policy recommendations in line with European strategies.

## Methodology

Interviews with Italian mussel farmers were conducted to identify the main cost factors of sustainable alternatives to conventional nets. A contingent valuation model (Carson, 2005) was used to estimate willingness to pay (WTP) based on (1) farmers' subjective knowledge and (2) objective information provided during the study on the characteristics of recycled and biodegradable nets. Economic data were also analyzed to assess costs and benefits.

## Results and conclusions

While mussel farmers acknowledge the environmental advantages of alternative nets, widespread adoption remains limited due to key challenges such as high initial costs, doubts about performance, lack of institutional backing, and uncertainty surrounding consumer acceptance. These findings highlight the urgent need for coordinated institutional support, including financial incentives, a robust regulatory framework, and targeted awareness campaigns.

A comprehensive policy approach - integrating funding, training, research, and consumer engagement - is essential to driving the transition toward sustainable practices in the mussel farming sector.

# DO PHOSPHOLIPIDS AND BILE SALTS SHAPE LARVAL GROWTH, SURVIVAL AND DEVELOPMENT IN ATLANTIC COD *Gadus morhua*?

J.L. Marthinsen[1]*, K.I. Reitan[1], R.E. Olsen[1], K. Li[2], B. Nunes[1], R.H. Bjørklund[1], T. Bardal[1], E. Kjørsvik[1]

## Introduction

Atlantic cod (*Gadus morhua*) farming has recently resurged in Norway, but larval nutrition remains a major challenge (Nardi et al., 2021), and no commercial diets are specifically tailored to cod larvae. Lipids are a key dietary component, providing both energy and essential fatty acids (Hamre et al., 2013). Cod larvae are thought to have limited ability to digest dietary lipids due to low endogenous bile salt (BS) levels (Olsen et al., 1991). Adding BS to the diet could improve lipid digestion, as seen in other fish species (Wang et al., 2023). After absorption in enterocytes, lipids are transported to peripheral tissues in lipoproteins, but this process may be restricted in larvae due to low *de novo* synthesis of phospholipids (PLs) (Teshima et al., 1987), an essential component of lipoproteins. Fish larvae therefore need more dietary PL than juvenile and adult fish (Tocher et al. 2008), yet the specific requirements in cod larvae remain unclear.

This study aimed to assess how dietary PL level, BS supplementation, and their interaction (PL×BS) affect growth, survival, and development in cod larvae. We hypothesized that larval performance would be improved by (1) a higher dietary PL level and (2) BS supplementation, and (3) that the effect of BS would be more pronounced at low PL levels, where the diets contained more neutral lipids to maintain an isolipidic formulation.

## Materials and methods

Atlantic cod larvae were reared in 200 L tanks and fed one of four formulated diets from 17 to 61 days post-hatching (dph), using a 2×2 factorial design with $n = 3$ tanks per group. The diets differed in PL level – high (7 % dry matter, dm) or low (6 % dm) – and BS supplementation – 0.04 % dm or 0 % dm – yielding the following treatment groups: HPL (high PL), HPL-BS (high PL with BS), LPL (low PL), and LPL-BS (low PL with BS).

Larvae were sampled throughout the experiment to measure dry weight (DW) and standard length (SL), and for histological analysis of the liver. At 61 dph, samples were taken for bone staining to assess skeletal ossification and anomalies, as well as biochemical analyses of proximate composition, lipid classes, and fatty acid composition. Survival from 20 to 60 dph was calculated by daily counts of dead larvae.

## Results

No significant differences in larval growth (DW and SL) were observed among the groups at the end of the experiment. Nonetheless, the HPL group had significantly higher DW compared to the LPL-BS and LPL groups at 38 and 45 dph, respectively. Larvae receiving high-PL diets also showed a modest but significant increase (6 %) in specific growth rate (SGR) compared to larvae receiving low-PL diets between 15 and 52 dph. Survival at 60 dph ranged from 42 to 60 % across the treatment groups, with no significant differences.

Liver histology showed a decrease in hepatocyte nucleus size following 15 dph, with a subsequent increase towards 61 dph. Notably, LPL-BS larvae maintained significantly smaller nuclei at the end of the trial. Hepatic energy storage increased markedly between 45 and 61 dph, with a tendency for higher storage in high-PL groups (22%) compared to low-PL groups (12%) at 52 dph. Energy storage was closely associated with larval size and followed a Gompertz growth model (sigmoid curve), with no differences between the dietary treatments.

Bone staining revealed significantly more ossified dorsal and anal fins in the HPL and HPL-BS groups compared to the LPL-BS group. Additionally, larvae fed the HPL-BS diet showed a greater number of fully ossified vertebrae compared to the LPL group. Model comparisons using Akaike's Information Criterion (AIC) indicated that these differences in skeletal development were associated with dietary PL level rather than larval size. The diets showed no consistent effects on skeletal anomalies, though the frequency of kyphosis was significantly higher in the LPL group (15 %) than in the HPL group (1 %).

*(Continued on next page)*

No significant diet effects were observed in larval proximate and lipid class compositions. The fatty acid composition of the PL fraction also showed no differences across diets. In contrast, the level of n-3 polyunsaturated fatty acids (PUFAs) in the triacylglycerol (TAG) fraction was significantly higher among larvae fed low-PL diets (13 %) compared to high-PL diets (9 %).

**Conclusions**

Our findings suggest that increasing dietary PL levels enhances skeletal development and, to a lesser extent, supports larval growth in Atlantic cod. These benefits may be linked to more efficient utilization of n-3 PUFAs when supplied through the dietary PL fraction rather than the TAG fraction. BS supplementation did not improve larval performance, suggesting that endogenous BS levels were sufficient to ensure effective lipid digestion under the tested dietary conditions.

## Introduction

The recent advances in the aquaculture of the cephalopod *Octopus vulgaris* warrant further research into specific topics about the feeding, growth, and welfare of this species in captivity. *In vitro* models of digestion have been applied to terrestrial and fish species of commercial interest to explore the potential digestibility of dietary ingredients with a reduced cost in terms of time and resources (Moyano et al., 2015). However, the application of *in vitro* techniques to the digestion of cephalopods is very infrequent (Domingues et al., 2020; Hamdan et al., 2014). The present work describes the application of a two-step *in vitro* model for the digestion of different fresh prey with the enzymatic extracts of posterior salivary glands and digestive glands from the common octopus.

## Materials and methods

Protein sources comprise the freeze-dried muscle of fish (*Hippoglossus hippoglossus*), crab (*Callinectes sapidus*), or squid (*Loligo vulgaris*). Digestive crude extracts were prepared by mixing the tissue of posterior salivary glands (PSG), or the digestive gland (DG), with distilled water in a proportion of 1:10 (w/v), homogenizing the mixture, centrifuging at 12000 g for 30 min at 4 ºC, and retaining the supernatant as the source of enzymes. Total alkaline and acid protease activities of the crude extracts were measured according to the protocol of Anson (1938). One unit (U) of activity was defined as the amount of enzyme liberating 1 µmol of product per min. under the conditions described. *In vitro* digestions were conducted in 15 mL Falcon tubes at 25 ºC under shaking, and consisted of two phases: a phase with PSG extract acting at pH 8.0 for 60 min, and a second phase with DG extract acting at pH 3.0 for 120 min. Each substrate (halibut, crab, and squid muscle) was tested three times with active extracts, and another three times with inactivated (by heating at 100ºC) extracts (blank assays). Each reactor was charged with 25 mg of crude protein, and the ratios protease: protein were 5 and 25 protease units per mg protein for the first and second phases, respectively. The reaction started with the addition of the PSG extract. After 60 minutes, the pH was reduced with HCl and the DG extract was added. The reaction medium was sampled after 5, 60, 65 and 180 minutes of digestion. Samples were stored at -80ºC until being analyzed for the quantity of amino groups according to the OPA spectrophotometric method (Zahir et al., 2018). Data on the released amino acids at each sampling time (calculated as the soluble amino groups in the reactor with active extracts minus the same variable in the reactors with inactivated extracts) were analyzed using a repeated-measures ANOVA with time as the repetition variable, and prey as the among-subjects factor. Statistical significance was set at $p < 0.05$.

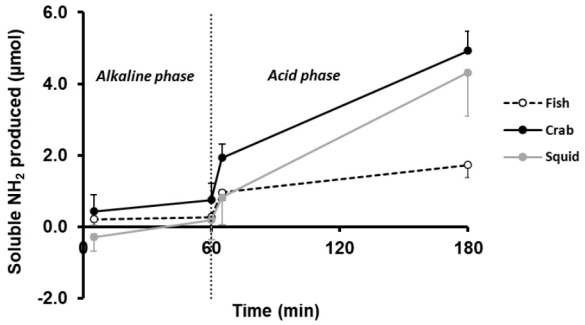

Fig. 1. Production of amino groups in a two-step *in vitro* model of the digestion of fresh muscles from fish, crab, and squid with digestive enzymes from *O. vulgaris*.

*(Continued on next page)*

## Results

The release of amino acids was clearly affected by time ($p < 0.001$). The production of amino acids was very low at the end of the alkaline phase, but increased rapidly after the pH was lowered to 3.0, at the beginning of the acid phase of digestion. This increase in amino acid release continued throughout the acid phase. The effect of the type of protein source on the amino acid production was marginally significant ($p = 0.062$), with higher production observed when the substrate was crab or squid muscle. The effect of the interaction term (time x prey) was highly significant ($p < 0.001$), indicating a faster release of amino acids from crab and squid muscles compared to fish muscles.

## Discussion

The *in vitro* model described herein reveals differences in the release of amino acids from different prey when digested with digestive extracts of *O. vulgaris*. Proteins from preferred prey, such as decapod crustaceans, seem to be more easily hydrolyzed by octopus' digestive extracts. The first phase of the digestion carried out with enzymes from the posterior salivary glands at an alkaline pH, was nearly ineffective to release amino groups. It is possible that this phase mainly consisted in the production of large polypeptides instead of free amino acids or small oligopeptides, as it occurs when simulating the gastric phase of digestion in fish (Grabner and Hofer, 1989). Further research is necessary to clarify this point. In contrast, Hamdan et al. (2014) reported that proteins from fish-based ingredients (fish meal) were more easily hydrolyzed by octopus digestive enzymes than proteins from a crustacean-based ingredient (krill meal). However, those ingredients were subjected to heating processes, and it is known that the thermic treatment of fresh preys depresses the assimilation of nutrients by living cephalopods (Domingues et al., 2009). The intensity of this phenomenon is not only related to the temperature of the heating process but, possibly, to the source of protein. Domingues et al., (2020), applied a one-phase *in vitro* digestion model (only the acidic phase) to digest different fresh or heated prey, measured the degree of hydrolysis (DH) by the pH-Stat method, and reported a higher DH for marine crabs and squids than for terrestrial crabs and marine fish when this prey was freeze-dried. In general, our results indicate that *in vitro* digestion models can be applied to cephalopods species but, in the future, it will be important to unify protocols and techniques to compare the results obtained by different authors.

# DIFFERENTIATION BETWEEN *Neobenedenia spp.* AND *Benedenia seriolae* USING A PCR-RFLP ASSAY

Carla Ferri, Salvador Jerez, Diego Garrido, Daniel Hernández-Pereza, M. Virginia Martín*

Centro Oceanográfico de Canarias (COC-IEO), CSIC
Santa Cruz de Tenerife, Spain
Email: virginia.martin@ieo.csic.es

## Introduction

Monogenean parasites, particularly skin ectoparasites *Neobenedenia spp.* and *Benedenia seriolae*, represent a significant threat to marine aquaculture species such as *Seriola dumerili*. Specifically, *Neobenedenia spp* has been identified in major outbreaks causing losses in both in juveniles and broodstock of *S. dumerili* in the Atlantic Sea. The broad host specificity reported for *Neobenedenia* is atypical for monogeneans, where it is considered that approximately 80% of all monogenean species only infect one host species and usually only in a single ocean (Brazenor et al., 2018). Both parasite species possess very similar morphological characteristics, which complicates their differentiation by traditional methods. Therefore, molecular tools can be very useful to differentiate them. This study aimed to distinguish *Neobenedenia spp.* from *Benedenia seriolae* through PCR amplification and restriction fragment length polymorphism (PCR-RFLP) analysis of the *cox1* gene.

## Materials and methods

Adult skin flukes were collected from cultured fish at the culture facilities of Canary Island Oceanographic Center (IEO-CSIC). Samples were collected by removing live parasites from the skin of their hosts using a scalpel blade. Parasites were fixed and stored in 70% analytical grade ethanol. Parasite DNA was isolated by proteinase K digestion followed by phenol-chloroform purification. The *cox1* gene was amplified by PCR following the protocol described by Kobayashi et al., 2018. Two independent digestion reactions were performed on the PCR products using the restriction enzymes EcoRI (recognizes G^AATTC sites) (Kobayashi et al., 2018) and RsaI (recognizes GT^AC sites) (Fig. 1). Digestion products were analyzed by agarose gel electrophoresis.

## Results

No digestion was observed with EcoRI, which is consistent with the restriction pattern of *Neobenedenia spp*. The independent digestion with RsaI produced two visible fragments (~700 bp and ~250 bp), as predicted in silico for *Neobenedenia spp*. A third smaller fragment (~70 bp) was expected but only faintly visible.

## Conclusions

The digestion profile obtained with RsaI supports the identification of the samples as *Neobenedenia spp*. The absence of EcoRI digestion is also compatible with this identification. PCR-RFLP provides a reliable method for differentiating monogenean parasites affecting aquaculture species.

## Introduction

Taste perception is crucial for animals to detect nutrients and provide essential dietary information for growth and survival. In rainbow trout (*Oncorhynchus mykiss*) alevins, early growth performance can be influenced by food intake, particularly when fed terrestrial ingredients that exclude fish meal and fish oil. Our study aimed to investigate the role of taste receptors in nutrient detection and the associated signaling pathways leading to central nervous system activation in the regulation of feeding behavior.

## Material and Methods

We conducted a nutritional experiment from the first feeding through 30 days, comparing the performance of fish fed a commercial-like diet (C diet: a blend of fish meal, fish oil, and plant ingredients) with those on a 100% plant-based diet (V diet). After 5 and 30 days of feeding, fish were fasted for 16 hours and then re-fed with either the C or V diet, with sampling conducted at two time points: 20 minutes and 6 hours post-meal. We assessed the expression of nutrient-sensing genes related to fatty acids, amino acids, and sweetness, as well as taste receptor genes for different flavors. Additionally, we examined calcium signaling pathways in the tongue, focusing on indolamine and catecholamine pathways, alongside appetite-regulating neuropeptides in the brain and gut hormones in the intestinal system of the alevins.

## Results

Results revealed that fish on the V diet experienced a decrease in body weight gain starting from day 10, which continued through to day 30. Changes in feed intake were also observed between days 0–10 and 21–30 after the first meal. In tongue tissue, after 5 days of feeding, fish on the C diet showed a slight upregulation of nutrient taste receptors, but not those related to flavor, along with a clear activation of the calcium signaling pathway. By day 30, there was a general upregulation of both nutrient and flavor taste receptors, although calcium signaling appeared less distinct in regulation. A significant dysregulation of the serotonin pathway, along with its degradation, was observed in the tongues of fish fed the V diet at both 5 and 30 days. Notably, for the first time in fish, catecholamine quantification levels in the tongue were identified as a potential marker for nutrient detection. Fish on the V diet showed a high quantification of L-DOPA after 5 days, which was markedly reduced by day 30. This impaired turnover of monoamines and catecholamines in the tongue may disrupt the tongue-brain axis, potentially contributing to the reduced food intake observed. This hypothesis was further supported by poorly regulated brain neuropeptides and intestinal hormones in fish fed the V diet after 30 days.

## Conclusions

Together, these findings demonstrate that a plant-based diet disrupts the feeding response at an early stage, highlighting the heightened sensitivity of rainbow trout alevins' tongue sensory systems to novel food sources during critical stages of development. Our study underscores the importance of early dietary influences on taste perception and the central regulation of feeding behavior in fish.

## Introduction

Matrix metalloproteinases (MMPs) are enzymes that play pivotal roles in various biological processes, including tissue remodeling and inflammatory responses across multiple organs. Certain bioactive compounds found in macroalgae—such as sulfated polysaccharides and phlorotannins—have attracted increasing attention due to their capacity to act as matrix metalloproteinase inhibitors (MMPIs), thereby modulating extracellular matrix (ECM) turnover and attenuating inflammation (Jayawardhana *et al*., 2023). In several teleost fish species, intestinal inflammation—sharing pathophysiological similarities with human inflammatory bowel disease—can be induced by diets containing plant-based ingredients (Krogdahl *et al*., 2015). However, to date, no studies have explored the potential of algal-derived MMPIs to mitigate such diet-induced enteropathies. This preliminary study aimed to: (a) determine the presence of MMPI activity in a concentrated extract obtained from the green macroalga *Ulva spp*; (b) evaluate the compound's stability under *in vitro* conditions simulating gastrointestinal digestion in *Sparus aurata* (gilthead seabream); and (c) assess its effects on intestinal function in this species when included in experimental diets.

## Materials and methods

A protein-enriched concentrated extract was obtained from the green macroalga *Ulva* spp. through a multi-step extraction process conducted at ANFACO-CECOPESCA (Vigo, Spain). The extract's potential to inhibit matrix metalloproteinases (MMPs) from *Clostridium histolyticum* was evaluated using the EnzChek™ Gelatinase/Collagenase Assay Kit (Thermo Fisher Scientific). Upon confirmation of inhibitory activity, the extract was incorporated at 12% (w/w) into an experimental diet containing 50% plant-derived ingredients, including 10% soybean-based products. This formulation was subjected to an *in vitro* digestion assay simulating seabream (*Sparus aurata*) gastrointestinal conditions, following the methodology described by Martínez-Antequera *et al.* (2023). A control diet, identical in composition but lacking the algal concentrate, was used for comparison. Both diets were subsequently administered to juvenile seabream (68.7 ± 0.1 g) over a 6-week feeding trial. At the end of the trial, fish were sampled and intestinal functionality was assessed by measuring epithelial electrical resistance and paracellular permeability using Ussing chamber techniques, following the procedure outlined by Gregorio and Fuentes (2018).

## Results and discussion

The concentrated *U. lactuca* extract exhibited strong inhibitory activity against *C. histolyticum* MMPs, achieving nearly complete inhibition (~100%) at a concentration of 50 mg/mL. This result is consistent with previously reported values for other algal products (Martínez-Antequera *et al.,* 2025). The simulated digestion of the diets demonstrated that a substantial MMP inhibitory effect was retained in the digestate following sequential exposure to gastric and intestinal enzymes (Table 1). These observations support the hypothesis that, under *in vivo* conditions, the extract may exert modulatory effects on intestinal MMP activity, potentially reflected in altered intestinal barrier functionality.

*(Continued on next page)*

Table 1. Inhibitory capacity on MMP of *C. hystolitycum* retained after simulated digestion of the feed including or not 12% of algal extract. Values are presented as mean ± SD for n = 3. Values not sharing a common superscript are significantly different with $p<0.05$

| **Experimental feed** | **% inhibition MMP *C. hystolyticum*** |
|---|---|
| Including *Ulva* extract | $16.21 \pm 7.48^{b}$ |
| Control | $0.00 \pm 4.33^{a}$ |

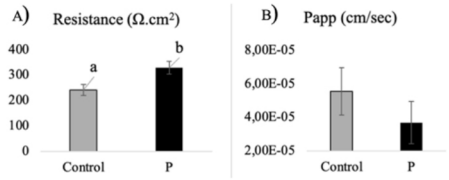

Figure 1. The effect of feeding with different experimental diets on A) Trans-epithelial electrical resistance (Rt, Ω $cm^2$) and B) Apparent permeability (Papp, cm/sec) in the anterior intestine of gilthead seabream measured *in vitro* in Ussing chambers. Values are presented as mean ± SEM. Values with $p < 0.05$ (One-way ANOVA) differ significantly.

The inclusion of the algal extract in the diet significantly increased tissue resistance (Rt) in the anterior intestine of gilthead seabream from values of 241 in the control diet to 330 Ω·$cm^2$, indicating enhanced epithelial barrier integrity. Although apparent permeability to Lucifer Yellow showed a trend toward lower values in fish fed the algal-supplemented diet, the differences were not statistically significant (Fig. 1).

The significant increase in epithelial resistance strongly suggests that bioactive compounds delivered through the algal extract played a pivotal role in enhancing intestinal tissue integrity compared to fish fed the control diet. This positive response may be attributed to either an alteration in tissue repair mechanisms or a reduction in inflammatory activity, potentially mediated by the MMP-inhibitory properties of the algal compounds. This finding may provide additional support for the incorporation of algal-derived bioactives as functional ingredients in aquaculture nutrition strategies.

**Introduction**

The European native oyster (*Ostrea edulis*) is a keystone species once abundant across European seas, forming extensive biogenic reefs, but it is currently considered as threatened and/or declining due to overfishing, habitat degradation, pollution, and disease (OSPAR, 2013).

Conservation and restoration efforts are now essential, not only to conserve the species but also to reinstate the ecosystem services oysters provide, such as enhancing biodiversity, improving water quality, and contributing to coastal resilience (Pogoda et al., 2020).

A critical component of effective restoration is understanding larval dispersal and recruitment, which informs the optimal placement and design of restoration sites and protected areas (Korringa, 1946). This study simulates larval dispersal and settlement potential of *O. edulis* to support targeted restoration strategies in Northern Ireland's coastal marine area.

**Modelling approach**

We applied the OpenDrift particle-tracking framework (opendrift.github.io), using its LarvalFish module to simulate the dispersion of native oyster larvae in three Northern Ireland's sea loughs: Belfast, Larne and Carlingford. Opendrift benefits from being highly customizable in terms of larval behaviour, agnostic with regard to the underlying hydrodynamic model and from allowing for a cross-domain/cross-model calculation of dispersion. It also allows for backward tracing of the dispersion paths, the introduction of pseudo-random stochastic variability and for a customizable coastline detection behaviour.

A Delft3D-Flow hydrodynamic model with a domain covering from the Larne to Carlingford Lough was used as the main source of time-varying 3-dimensional velocity fields for the Opendrift model.

A dedicated *O. edulis* larvae dispersion model was developed for the Opendrift platform (OedulisLarvaeDrift) that implements the current state-of-the-art knowledge on the early life-cycle of the native oysters. In addition to the physical behaviour of neutrally-buoyant particle, the following high-level responses were included to simulate the growth, motility, mortality and settling of the *O. edulis* larvae:

1. Time-dependent growth rates that increase the diameter of the larvae from its size at swarming time to its maximum know size before settling;
2. Size-dependent stage switching between the umbo, veliger and pediveliger stages
3. Stage-dependent vertical swimming behaviour
4. Prescribable stochastic mortality
5. Mortality due to environmental limits (salinity and temperature)
6. Stage maturity for settling, ensuring that only larvae at the pediveliger stage settles
7. Settling behaviour, including seafloor detection and viable habitat detection that ensures the settling of only the matured larvae that reach the bottom at a viable habitat
8. Exclusion of the settled larvae from the calculation to prevent their aging, growing, mortality and movement.

*(Continued on next page)*

As the availability of suitable settlement substrate is one of the main factors governing recruitment success of oyster populations (Rodriguez-Perez et al. 2021), our dispersal model integrates benthic habitat maps to evaluate the settlement success in the three loughs.

Larval sampling was conducted early in the seedling collection season to calibrate the horizontal distribution of hatched larvae to be used as the initial distribution for particle tracking. A sensitivity analysis explored how variation in uncertain parameters—such as pediveliger stage duration, swimming speed, and survival rates—affected dispersal and settlement outcomes.

## Introduction

The implementation of genetic breeding programmes (GBPs) in the *Penaeus vannamei* production sector has reduced generation intervals and demonstrated significant genetic gains for traits related to growth and survival (Castillo-Juárez *et al.,* 2015; Martínez Soler *et al.,* 2024). External morphometric traits—reflecting the species' health status under specific culture conditions (Singh *et al.,* 2017)—have emerged as valuable alternative to traditional body weight measurements for improving shrimp performance. These traits exhibit high heritability ($h^2$), strong positive genetic correlations ($r_g$) with both weight and product quality traits and offer high measurement precision (Shin *et al.,* 2023; Martínez Soler *et al.,* 2024). Moreover, they can be measured non-invasively through image analysis technologies. The objective of the present study is to integrate the IMASHRIMP system—which combines deep learning and computer vision—as an advanced tool to enhance genetic selection of *P. vannamei* within the PMG-BIOGEMAR© GBP at commercial scale.

## Materials and methods

588 shrimp from the sixth generation ($G_6$) of the PMG-BIOGEMAR© GBP—genetically selected for growth traits and reared under commercial conditions—were photographed at harvest size using an Intel® RealSense™ D435 depth camera. Each shrimp was imaged from both lateral (right and left) and dorsal views, with four different angles captured per view, resulting in twelve images per individual. The initial module of the IMASHRIMP system uses pose estimation algorithms to automatically identify the shrimp's orientation (lateral or dorsal view; right or left side) and detect the presence or absence of the rostrum. Based on this information, the system applies one of two customized skeletal key point models—depending on the detected view and rostrum presence—to extract morphometric traits in pixels. A second module then converts the pixel-based measurements into centimetres using a Support Vector Machine (SVM) regression model. The resulting traits are classified as non-invasive morphometric traits (mNiT). To validate the IMASHRIMP system, the 588 shrimp were manually measured for the same 22 morphometric traits—designated as invasive morphometric traits (miT)—as well as for body weight. These traits, related to length, width, and height, were previously defined and validated by Shin *et al.* (2023) and Martínez Soler *et al.* (2024). All shrimp were genotyped using the AQUAarray LD™ SNP-chip at the Center for Aquaculture Technologies (California, USA). Additive genetic components for all morphometric traits were estimated using the Restricted Maximum Likelihood (REML) method. Best Linear Unbiased Prediction (BLUP) evaluation was performed using VCE (version 6.0) and supporting software.

## Results

At 103 days after hatching (DAH), the weight and total length (TL) of shrimp were 23.74 g and 14.35 cm, respectively, following five generations of genetic selection. Shrimp analysed were assigned to 135 full-sib and 25 half-sib families. $h^2$ for weight was 0.37. For miT, $h^2$ values ranged from 0.05 to 0.40 for length traits, while for mNiT, they ranged from 0.14 to 0.36. The lowest $h^2$ was observed for first segment length (SL1), and the highest for cephalothorax length (CL) and sixth segment length (SL6) in both miT and mNiT. For height traits, $h^2$ ranged from 0.13 to 0.30 for miT and from 0.21 to 0.41 for mNiT. When shrimp were measured using IMASHRIMP system from a lateral view, all morphometric traits—except CL—showed

*(Continued on next page)*

increased $h^2$. The average increase for length traits was 90%, while the average increase for height traits was 37.40%. When mNiT measurements were taken from a superior view, $h^2$ values for length ranged from 0.13 to 0.45, with the highest value found for abdominal length (AL). In this case, $h^2$ increased by an average of 95% compared to miT. Regarding width traits measured from a superior view, $h^2$ ranged from 0.08 to 0.40 for miT and from 0.10 to 0.33 for mNiT. $r_g$ between miT and mNiT ranged from 0.81 to 1.00 for lengths (lateral view in mNiT), from 0.53 to 1.00 for heights, from 0.72 to 0.98 for lengths (superior view in mNiT), and from 0.98 to 1.00 for widths. $r_g$ between mNiT and weight ranged from 0.82 to 1.00.

**Discussion**

Shrimp from $G_6$ exhibited 30% higher body weight 27 days earlier in commercial estuaries compared to second generation ($G_2$) (Shin *et al.,* 2023), demonstrating that genetic selection is significantly accelerating growth under farming conditions. However, increases in length were less pronounced (8%) compared to width (15%) and height (16%). The inclusion of morphometric traits as selection criteria is particularly relevant for shrimp markets in the USA and Europe, where whole animals are marketed and consumers place high value on exoskeletal integrity. But comprehensive morphometric assessments in animal production are typically labour-intensive, time-consuming, and costly. Recent advances in deep learning and computer vision (Chai *et al.,* 2021) offer new opportunities for aquaculture by enabling high-throughput, cost-effective measurement of traits that were previously difficult to assess. The IMASHRIMP system represents a robust technological tool for integration into the sampling workflows of shrimp GBPs. To the best of our knowledge, this is the first application of pose estimation in the shrimp aquaculture sector. IMASHRIMP significantly reduces sampling time, minimizes measurement error, and increases the $h^2$ of key morphological traits in *P. vannamei*. Successfully integrated into the PMG-BIOGEMAR© GBP, this system enhances selection accuracy and supports long-term genetic improvement.

## Introduction

In aquaculture, fasting is a management strategy implemented before routine operations to optimize efficiency, enhance flesh quality and support animal welfare. However, its benefits depend on the duration of food deprivation and environmental conditions, as fasting is influenced by water temperature and, therefore, the increasing impact of global warming on aquatic environments. Studies suggest that fasting for approximately 55-58 degree days (°C d) minimizes the impact on stress response while enhancing muscle structure, biochemical processes and overall quality. However, seasonal temperature variations lead to shorter fasting periods in summer and longer ones in winter. Given that rainbow trout are a cold-water species with an optimal temperature range of 12 to 18°C, analyzing the effects of fasting across different temperature would be particularly valuable. This is especially crucial in light of the increasing risk of heat stress in rainbow trout farming due to global warming.

## Material and methods

A total of 495 rainbow trout were distributed across nine cages with an average water temperature of 22.0 ± 0.06 °C in summer and 8.8 ± 1.79 °C in winter. After a two-week acclimation period with daily feeding, fish were subjected to different pre-slaughter fasting durations: no fasting (0D), 3 days (65.49 ± 0.22°C d) in summer and 6 days (58.7 ± 2.21°C d) in winter (50D), 6 days (131.34 ± 0.07°C d) in summer and 13 days (114.5 ± 1.86°C d) in winter (100D). Blood samples were collected to analyze plasma cortisol levels, liver and muscle samples were taken to assess glycogen concentration. Additionally, muscle samples were analyzed for pH, *rigor mortis* and acetylcholinesterase activity. The color of the liver and skin was also measured using the CIELAB system.

## Results and discussion

In winter, plasma cortisol levels were higher in the 50D group compared to 0D, likely due to the acute stress response triggered by sudden food deprivation. However, cortisol levels in the 100D and 0D groups remained similar across both seasons, which could indicate metabolic adaptation or hypothalamic-pituitary-interrenal axis exhaustion. Additionally, higher cortisol levels in the 50D winter group compared to 50D summer suggest that prior acclimation to elevated temperatures might limit stress responses to additional stressors. Hepatic glycogen levels were lower in summer than in winter, where a progressive decline was observed with prolonged fasting. The 100D group in winter showed values comparable to the 0D summer group, likely due to glycogenolysis maintaining blood glucose as an energy source. Muscle glycogen levels remained relatively stable across fasting durations, but they were higher in summer, possibly due to reduced swimming activity in warmer water. Glycogen directly affects post-mortem pH, with a significant negative correlation between glycogen levels and pH decline, influencing *rigor mortis*. In summer, higher glycogen levels led to greater lactic acid production and a less pronounced pH drop compared to winter. Fasted fish in winter showed higher pH, possibly due to increased pre-slaughter activity. Higher temperatures generally accelerate *rigor mortis* due to faster pH decline, but in this study, summer trout exhibited lower *rigor* at 0 h, suggesting additional influencing factors. During winter, AChE activity increased significantly with fasting duration, suggesting that AChE levels rise in catabolic tissues during prolonged starvation, contributing to muscle degradation and heightened food-seeking behavior. Unfasted fish in summer exhibited higher AChE activity than those in winter, remained elevated across fasting groups. This could be due to greater sensitivity to temperature stress. Regarding skin color, no significant variations were

S: summer, W: winter, Se: season and F fasting.

observed between fasting groups in summer, suggesting acclimation to higher temperatures. However, chroma values were higher in summer than in winter, with 100D groups in both seasons reaching similar levels, possibly linked to stress responses. Additionally, 100D winter group showed lower lightness (L*), likely due to the dispersing effect of adrenocorticotropic hormone on chromatophores. Similarly, liver color in summer remained unchanged across fasting groups. L* and redness were not affected by fasting but were influenced by seasonality, whereas chroma and hue were higher in winter. These changes are likely due to metabolic responses, mobilizing hepatic reserves and altering lipid composition. Overall, when fasting is the primary stressor, an initial acute stress response is followed by gradual metabolic adaptation, reducing stress over time. However, in summer, prior acclimation to higher temperatures lessens the response to additional stressors

**Aim of research**

Sustainable aquafeed development is a growing priority in European seabass (*Dicentrarchus labrax*) farming. The incorporation of functional ingredients with antimicrobial or immunomodulatory potential must be validated to ensure optimal growth, welfare, and health status of farmed fish. In this context, organosulfur compounds from *Allium* spp., such as propyl propane thiosulfonate (PTS) and propyl propane thiosulfinate oxide (PTSO), have shown promising bioactivity. This study aimed to evaluate the protective and functional effects of PTS/PTSO using a dual approach: first, by assessing their anti-infective potential in an in vivo surrogate model (*Caenorhabditis elegans* infected with *Vibrio harveyi* and *V. anguillarum*), and second, through a 12-week nutritional trial in seabass juveniles reared in a recirculating aquaculture system, including evaluation of innate immune parameters and survival following *V. anguillarum* challenge.

**Materials and Methods**

The effect of pathogen exposure on *C. elegans* survival with and without PTSO was evaluated. Synchronous L4-stage nematodes were fed with *E. coli* OP50 (control), *V. anguillarum* LMG/1086, or *V. harveyi* 16/00. Three replicates were used per dietary condition (10 nematodes each). Each diet was tested with or without PTSO at 27.5 $\mu$M. Survival was analyzed using Kaplan–Meier and log-rank tests.

**RNA Extraction and RNASequencing.** Total RNA was extracted using TRIzol (Invitrogen, USA). RNA sequencing was performed on the NOVOGENE platform (UK). Differentially expressed genes (DEGs) were annotated with Gene Ontology (GO).

**Feeding Trial in European Seabass.** A 12-week feeding trial was conducted with 300 seabass juveniles (initial body weight: 3.25 ± 0.33 g) randomly distributed across 18 tanks (100 L) in a RAS. Two diets were tested in triplicate: (1) control diet (standard commercial feed), and (2) diet with *Allium*-derived extract blend. All feeds were isoproteic, isolipidic and isoenergetic. Zootechnical parameters and immune endpoints were monitored. After feeding, innate immune parameters (protease, antiprotease, lysozyme activity, total proteins) were assessed using commercial kits based on biochemical and enzymatic reactions. Fish were then challenged with *V. anguillarum* ($1\times10^4$ CFU/mL, immersion), and mortality was recorded for 14 days. Survival was analyzed by log-rank test.

**Results**

**Effect of *Vibrio* sp on *C. elegans* Lifespan.** Log-Rank test (OASIS2) showed significant survival differences. *V. anguillarum*- and *V. harveyi*-fed nematodes had reduced survival vs. *E. coli* OP50 (Bonferroni-adjusted $p < 0.05$).

With PTSO, *C. elegans* survival improved across treatments. Lifespan in *E. coli* + PTSO (18.84 days) was similar to control (19.72 days), suggesting no toxicity. Survival increased significantly in nematodes fed with *V. anguillarum* and *V. harveyi* + PTSO (16.91 and 15.32 days) vs. without PTSO (9.37 and 5.96 days).

**RNAseq Analysis.** NMDS analysis showed that PTSO altered transcriptomic profiles, reducing divergence among worms exposed to *E. coli*, *V. anguillarum*, and *V. harveyi*.

*(Continued on next page)*

Transcriptomic data showed downregulation of genes linked to epithelial defense, stress response and immune effectors (C-type lectins), and upregulation of genes involved in intracellular signalling, lysosomal metabolism, energy regulation and detoxification (e.g., cytochrome P450s). These data support a role for PTSO in modulating pathogen-induced stress and enhancing adaptative responses.

**Seabass Trial.** Although no significant differences were found in growth or immune parameters, fish fed the *Allium*-supplemented diet showed significantly higher survival after *V. anguillarum* challenge ($p < 0.05$), indicating enhanced disease resistance.

**Conclusion**

This study demonstrates that organosulfur compounds derived from *Allium* spp. exert protective effects against bacterial infection in a *C. elegans–Vibrio* model. Furthermore, their inclusion in pre-growing diets for European seabass has proven to be safe, with no negative impact on zootechnical performance. Compounds such as PTS and PTSO represent a promising functional strategy for aquafeeds, as they help maintain growth performance in European seabass while enhancing resistance to pathogenic infections in surrogate models. These findings also support the protective effects of these compounds in seabass, as evidenced by improved survival after *V. anguillarum* infection.

**Introduction**

In recent years, the study of commensal microbiota has gained increasing relevance, as endogenous microbial communities are now recognized as key modulators of disease progression, including viral infections. These microbiota-host interactions play a complex, bidirectional role in the establishment and outcome of infections. In particular, the gut microbiota and its metabolites have been shown to influence the host's immune response and antiviral defenses (Mizutani et al., 2022).

Turbot (*Scophthalmus maximus*), a commercially important flatfish species, holds significant economic value in Spain, one of the world's leading producers alongside China. The intestinal microbiota of turbot comprises a diverse community of microorganisms, including both non-pathogenic and potentially pathogenic *Vibrio* spp., which under specific conditions can cause vibriosis—a major bacterial disease in aquaculture responsible for considerable economic losses.

Oxytetracycline (OTC), a broad-spectrum antibiotic, is widely used in aquaculture to treat vibriosis. It remains one of the most commonly administered antibiotics for both prophylactic and therapeutic purposes and is often readily available to aquaculture operations (Sanches-Fernandes et al., 2022). However, the overuse of OTC has been linked to the emergence of drug-resistant *Vibrio* strains (Ji et al., 2020), raising concerns about the long-term sustainability of current disease management practices. In addition to fostering resistance, antibiotics like OTC may have unintended consequences on the host by disrupting the composition and function of the gut microbiota.

**Materials and methods**

In this study, we aimed to investigate the impact of OTC treatment—administered under routine aquaculture conditions via immersion (0.1 g/L for 1 hour over four consecutive days)—on the gut microbiota of turbot. Additionally, we assessed whether the resulting alterations in microbiota composition influence the host's immune response and survival following infection with viral hemorrhagic septicemia virus (VHSV). Viral infections were conducted either one day after the final OTC treatment or 30 days later, to determine whether the effects of the antibiotic were transient or sustained over time. The intestinal bacterial microbiota was also analyzed at the one-month time point to evaluate the recovery of the normal microbial community. Changes in gut bacterial composition were characterized using 16S rRNA amplicon sequencing. To further assess the systemic effects of OTC, transcriptomic profiles of intestine and head kidney samples from both uninfected and VHSV-infected fish (24 hours post-infection) were analyzed using RNA-Seq.

**Results**

The results revealed a significant reduction in *Vibrio* spp. abundance across all OTC-treated individuals, with no detection of drug-resistant strains. The ecological niche vacated by *Vibrio* spp. was subsequently occupied by bacteria from various other taxonomic classes. This antibiotic-induced disruption of the gut microbiota had a marked effect on turbot survival following VHSV challenge: fish infected immediately after OTC treatment exhibited significantly reduced survival compared to untreated controls. In contrast, when infection was performed 30 days post-treatment, survival rates were comparable between treated and untreated groups, which is supported by a recovery of the gut microbiota and its associated protective functions over time.

At the transcriptomic level, RNA-Seq analyses revealed notable alterations in the expression of key immune-related genes in OTC-treated fish, which most likely contributed to their reduced survival following VHSV infection. These findings underscore the critical importance of maintaining microbiota integrity in aquaculture species. Beyond promoting antimicrobial resistance, the misuse or overuse of antibiotics can impair host immune defenses and increase susceptibility to viral infections.

# ADVANCING *EX SITU* CONSERVATION METHODS FOR THE CRITICALLY ENDANGERED *Pinna nobilis*

Martínez-Martínez, P.[a,b,*]; Giménez Casalduero, F.[a,b]; Vera Inglés, J.[c]; Sánchez M.A.[c]; Crespo Montalt, A.[c]; Fernández-Torquemada, Y.[a]; Martínez Ortega, E.[c]; Cortés-Melendreras, E.[c]

## Introduction

*Pinna nobilis* Linnaeus, 1758, is a critically endangered bivalve mollusk endemic to the Mediterranean Sea. Since the mass mortality event (MME) detected in 2016, the species has experienced drastic declines. Today, the only known surviving populations are restricted to areas where environmental conditions exceed the survival limits of the main parasite responsible for this mortality: *Haplosporidium pinnae* (Catanese et al., 2018). On the Spanish coast, one of the two remaining populations exists in the Mar Menor coastal lagoon (Murcia, SE Spain). However, this population has also suffered a sharp decline due to repeated episodes of eutrophication (Cortés-Melendreras et al., 2022). *Ex situ* maintenance of the species plays a key role in its conservation. However, this task has proven more difficult than initially expected, with no records to date of long-term maintenance or clearly defined optimal conditions. The objective of this study was to improve understanding of the optimal conditions for the *ex situ* maintenance of *P. nobilis* from the Mar Menor, at the Aquarium of the University of Murcia, from 2019 to 2023.

## Methodology

A total of 43 adult *P. nobilis* specimens were collected from the Mar Menor and transferred to the University of Murcia's Aquarium facilities from 2019 to 2023. The *ex situ* system consisted of four large-volume tanks filled with artificial seawater. Closed-loop maintenance tanks were equipped with a comprehensive filtration system combining mechanical, chemical, and biological filters, as well as UV germicidal sterilization and integrated temperature control. The optimal volume was about 200–300 liters of water per specimen in the tank. Individuals were kept in a vertical position within perforated mesh baskets. Environmental parameters from their natural habitat were replicated, including photoperiod, salinity, temperature, pH, and saturated dissolved oxygen levels. Alkalinity, calcium (450 mg/L), magnesium (1370 mg/mL), iodine (0.07 mg/L) were carefully monitored. Nutrient levels were maintained below 20 mg/L for nitrates and 1.5 mg/L for phosphates; values above these thresholds triggered complete water replacement. Seasonal temperature fluctuations from the Mar Menor were reproduced without exceeding stress thresholds (<14°C or >28°C). Environmental parameters were recorded daily between May 2019 and May 2023. Feeding protocols included a mix of three microalgae species cultivated in the lab: *Tisochrysis lutea* ($6\times10^3$ cells/µL), *Tetraselmis chuii* ($2\times10^3$ cells/µL), and either *Chaetoceros gracilis* or *Phaeodactylum tricornutum* ($7\times10^3$ cells/µL), combined in a 3:3 ratio. Additionally, zooplankton (*Brachionus rotundiformis* and *Acartia tonsa* nauplii at 0.5 units/mL) were provided. Of the 43 individuals, survival monitoring was performed for 22. Average survival times were calculated and monthly survival rates were also estimated based on the expected stay duration.

## Results

The average maintenance conditions from 2019 to 2023 are shown in Table 1. The recorded salinity values reflect those of the Mar Menor, remaining below the species' maximum tolerance (45 psu), but above the optimal level for *H. pinnae* infection (39 psu). The survival rate remained above 80% during the first 15 months, followed by a significant decline in the subsequent months (Fig. 1). However, from months 19 to 33, the number of surviving specimens remained stable until month 35, when another drop in survival was observed (Fig. 1). The average survival time was 19.43 ± 2.84 months, with one exceptional individual, collected in 2019, surviving for over 48 months.

*(Continued on next page)*

**Table 1.** Mean and maximum/minimum values of each parameter in the four systems between 2019 and 2023. Conversion of density to salinity based on temperature.

| | Density ($kg/m^3$) | Salinity (psu) | Temperature (°C) | Alkalinity (meq/l) | pH |
|---|---|---|---|---|---|
| **Mean** | 1031.04 ± 1.38 | 42-43 | 19.17 ± 2.06 | 3.10 ± 0.27 | 8.12 ± 0.07 |
| **Max.** | 1034.00 | >44 | 22.90 | 4.00 | 8.33 |
| **Min.** | 1028.00 | 39 | 15.36 | 2.20 | 7.84 |

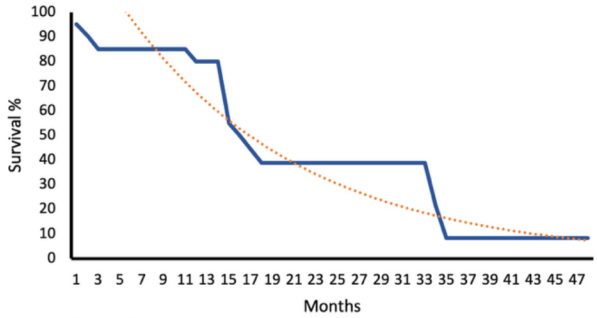

**Figure 1.** Monthly survival rate of maintained *P. nobilis* specimens.

## Discussion

The programmed and observed environmental parameters in the tanks are considered the most suitable for maintaining *P. nobilis* specimens from Mar Menor. Given the critical status of the population, minimizing stress on the individuals was a priority. Therefore, the natural environmental conditions in which the species completes its life cycle were carefully replicated in the *ex situ* system. Additionally, it is important to emphasize that environmental parameters should be tailored according to the origin of individuals. *Ex situ* conservation of *P. nobilis* has been marked by high mortality, primarily due to challenges in feeding and infections by pathogens like *H. pinnae* and *Vibrio mediterranei* (Prado et al., 2020). Infections by *Vibrio* spp. have been a major cause of mortality, especially under immunosuppressive conditions such as stress, wounding, or elevated temperatures. Nevertheless, in this study survival rates remain relatively high, and tank maintenance protocols for the species are gradually being optimized.

# AUTOMATIC SIZE ESTIMATION OF SEA BREAM IN THEIR NATURAL UNDERWATER ENVIRONMENT USING DEEP LEARNING (DL)

J. Martinez-Peiró[1*]; P. Muñoz-Benavent[1]; G. Andreu-García[1]; P. George Holhorea[2]; A. Belenguer[2]; J. Pérez-Sánchez[2]

[1]Automatics and Industrial Informatics Institute (AI2), Universitat Politècnica València
[2] Nutrigenomics and Fish Growth Endocrinology of Institute of Aquaculture Torre de la Sal (IATS-CSIC)
*Email: joama14j@upv.es

## 1. Introduction

This study leverages Deep Learning (DL) models and stereoscopic vision techniques to develop tools that automatically estimate fish size in near real-time, using a non-intrusive approach. Accurate and efficient length measurement in intensive aquaculture systems requires advanced object detection algorithms capable of extracting highly discriminative features specific to fish. However, practical fish detection still presents challenges, such as complex underwater backgrounds, varied fish orientations, and a lack of large-scale annotated datasets.

Monitoring fish growth is essential in aquaculture for optimizing feed quantity, oxygen supply, and overall animal welfare. Typically, length estimation relies on manual sample collection, a process that can induce stress, negatively affect fish growth and, in some cases, result in mortality. This highlights the urgent need for automated, non-invasive alternatives to manual handling. Stereoscopic vision techniques in computer vision have proven effective for estimating the size of freely swimming fish.

The primary objective of this work is to automatically process underwater stereo videos of freely swimming fish to obtain accurate measurements of many individuals in near real-time. The main contributions of the proposed approach are as follows:

- An encapsulated stereoscopic camera system was designed and prototyped to support long-term monitoring in underwater environments.
- A ground-truth dataset was developed, consisting of real images annotated with keypoints required for accurate analysis.
- A Convolutional Neural Network (CNN) was trained to automatically detect keypoints in the images, and this output was subsequently combined with stereoscopic vision to estimate fish length.
- Automatic measurements were validated through comparison with manual measurements.

## 2. Stereoscopic vision system and video acquisition

A stereoscopic camera system was prototyped using a watertight enclosure with sealed wiring, ensuring durability in aquatic environments. Its design required careful consideration of parameters such as focal length, inter-camera distance, shutter speed, and other optical and mechanical factors. Video recordings of sea bream at different growth stages were conducted at the Instituto de Acuicultura Torre de la Sal (IATS-CSIC) facilities, resulting in six hours of footage at varying resolutions and frame rates.

## 3. Results: Applying DL models to automatic fish length estimation

A dataset was generated by manually annotating the snout and tail keypoints of individual fish, resulting in 250 images and 700 annotated individuals. Two DL-based object detection models were trained: Keypoint R-CNN and YOLO. Keypoint R-CNN extends the Mask R-CNN architecture for keypoint detection. It first uses a Region Proposal Network (RPN) to generate candidate regions and then refines these proposals with a CNN-based object detection head. YOLO (You Only Look Once) is a fast, single-stage object detection algorithm that treats detection as a regression problem. It divides an image into a grid and simultaneously predicts bounding boxes and keypoints per cell in a single pass through the network, making it well-suited for real-time applications.

*(Continued on next page)*

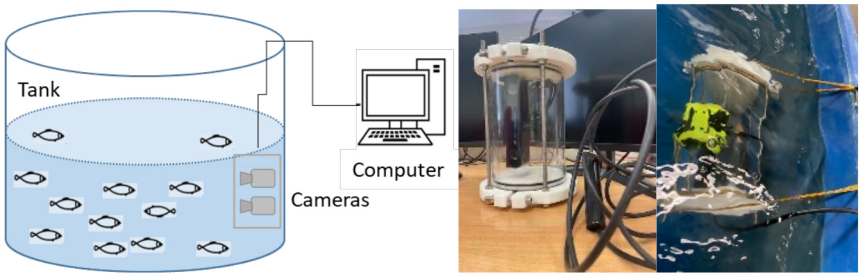

Figure 1. On-site data acquisition system.

| Tank Number | 25 | 27 | 15 | 25 |
|---|---|---|---|---|
| Date | 5/6/2023 | 27/9/2023 | 6/10/2023 | 6/10/2023 |
| Average Length (Manual) | 23.67 | 30.41 | 18.35 | 38.12 |
| Average Length (Keypoint-RCNN) | 23.91 | 30.00 | 18.15 | 36.18 |
| Average Length (YOLO) | 23.90 | 30.12 | 18.17 | 37.43 |

Table 1. Comparison of manual and automatic average fish lengths (in cm).

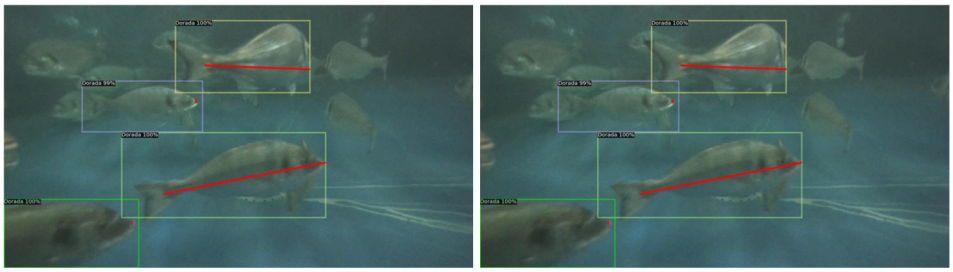

Figure 2. Automatic detection of sea bream lengths using Deep Learning and stereoscopic vision techniques.

Table 1 compares the average fish lengths obtained from manual measurements and the two DL models. Both models yielded accurate results, with YOLO performing slightly better, particularly in tank 25. The average processing times per frame were 0.347 ms for Keypoint R-CNN and 0.068 ms for YOLO. An example of automatic fish detection and length estimation is shown in Figure 2.

**4. Conclusion**

A dataset of sea bream was developed with manually annotated snout and tail keypoints to train Keypoint R-CNN and YOLO networks for automatic fish length estimation. Both models demonstrated high accuracy across different growth stages when compared to manual measurements. These results support the potential of Deep Learning and stereoscopic vision as a robust, non-invasive, and automated method for fish length estimation in aquaculture.

# ENVIRONMENTAL PERFORMANCE OF FARMED STURGEON CAVIAR PRODUCTION: AN LCA STUDY ON LUXURY FOOD

Arianna Martini[1*], Riccardo Napolitano[12], Marco Martinoli[1], Richard Newton[2], Domitilla Pulcini[1], Nicolò Tonachella[1], Fabrizio Capoccioni[1]

* Corresponding Author: arianna.martini@crea.gov.it

## Introduction

Aquaculture is generally regarded as one of the most sustainable sources of animal-derived food (Gephart et al., 2021). Nevertheless, the variety of farmed species, technologies, and practices across regions requires product-tailored evaluations, especially for poorly studied luxury foods, such as caviar. Traditionally derived from wild female sturgeons, caviar is now primarily obtained through aquaculture due to the depletion of wild stocks (Bronzi et al., 2019). With 65 tons produced in 2023 (EUROSTAT, 2023), Italy ranks third in global caviar production, following China and Russia (EUMOFA, 2021). This study aims at (1) assessing for the first time the environmental performances of caviar production, including its co-products (i.e., meat), from different sturgeon species reared in a representative Italian farm, using the *Life Cycle Assessment* (LCA) methodology, and (2) evaluating, through scenario analysis, the effects of potential impact mitigation strategies.

## Materials and methods

The enterprise in northern Italy produces caviar from four sturgeon species: *H. huso*, *A. baerii*, *A. transmontanus*, and *A. gueldenstaedtii.* The production chain includes sturgeon farming and caviar/meat processing. Farming involves four sub-phases: nursery, on-growing, mixed males and females fattening, and females fattening. Sturgeons are raised in indoor recirculating aquaculture systems (RAS) and outdoor raceways. The water that feeds all the systems comes from a nearby freshwater channel. A sedimentation and biological filtration system is in place. The facility meets its energy needs using electricity from the grid and an in-house photovoltaic system (PV). As soon as males are identified (at 3-8 years, depending on the species), they are processed for meat, while females are raised until sexual maturity (8-20 years, depending on the species) for egg collection and meat processing. Eggs are processed, salted, and packed in tins or jars for sale.

The analysis used the Life Cycle Assessment (LCA) methodology (ISO 14040 and 14044), with a cradle-to-gate approach. The functional unit (FU) was defined as 1 kg of caviar (reference flow: 1 kg of caviar and 5.9 kg of marketable meat), with economic allocation applied. Primary data were gathered via questionnaires and site visits (reference production year: 2022–2023), while background data were sourced from Ecoinvent 3 and Agri-footprint 6.3. Calculations were performed using SimaPro 9.5, adopting ReCiPe 2016 Midpoint (H), Cumulative Energy Demand and CML-IA baseline methods. LCA's output allowed the identification of critical hotspots along the caviar production chain, which were also used to forecast two impact mitigation scenarios: 1) optimization of feed use by hypothesizing the application of a genetic early sex determination strategy (Kuhl et al., 2021), and 2) energy transition, i.e., by increasing the in-house PV power supply up to 50% of the energy needs.

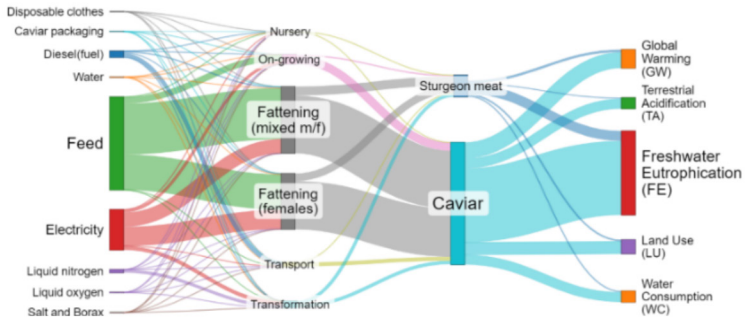

*Figure 1 Contribution analysis at the sub-phase, inputs and products levels for A. baerii*

*(Continued on next page)*

## Results

LCA results showed high variability depending on the species, e.g., Global Warming (GW) ranged between 53 and 83 kg $CO_2$ eq/kg of caviar, Terrestrial Acidification (TA) between 0.18 and 0.29 kg $SO_2$ eq/kg of caviar, Freshwater Eutrophication (FE) from 0.02 to 0.05 kg N eq./kg of caviar, Land Use (LU) from 43 to 93 $m^2$/kg caviar, and Cumulative Energy Demand (CED) from 714 to 1153 MJ/kg of caviar. For all the species, the fattening phases had the highest impact contribution, ranging from 80% in GW for *A. gueldenstaedtii* to 94% in FE and 99% in LU for *H. huso*. In all cases, the inputs that collectively accounted for >95% of the impacts were feed, electricity and transportation. Figure 1 depicts the contribution analysis at the sub-phase, inputs and products levels for *A. baerii*. The scenario analysis showed that: i) an early genetic sex determination allows a significant reduction in the feed used with consequent decrease in impacts (e.g., up to -21% of the impacts related to Freshwater Eutrophication-FE); ii) increasing the supply of renewable energy at the farm level is effective, but to a different extent depending on the species considered (from -2% to -19 % for GW).

## Discussion and Conclusions

Caviar production comes with significant environmental impacts, although mitigation strategies could improve its sustainability. Species-specific differences are mainly driven by farming cycle duration, feed requirements, and production efficiency. The fattening phase emerged as the primary contributor to impacts due to its length and resource intensity, with feed identified as a key hotspot, as also reported by Bohnes et al., 2019 and Gephart et al., 2021. Electricity was the second major hotspot: substituting grid electricity with solar energy reduced GHG emissions but increased abiotic resource depletion. Despite this burden shift, renewable energy remains essential for decarbonising the sector (De Vet et al., 2024). This study also underscores the methodological challenges in assessing complex systems through LCA, such as, for example, the choice of the appropriate FU, system boundaries, and temporal coverage for data collection.

Introduction

Due to an increasing consciousness to provide more adequate production conditions, thereby ensuring animal welfare and high protein quality for the consumer, one of the biggest challenges is to assure the availability, sustainability and lowest costs of conventional feeds, mostly for carnivorous species as greater amberjack (*Seriola dumerili*). Despite recent advances in feed formulations, a significant gap remains in the ability to drive farmed fish development toward desired phenotypes. In particular, there is currently no protocol to prepare the intestinal physiology of fish from larval stages to the successful introduction of vegetable ingredients during the production cycle. However, some improvements related to developmental programming have been recently achieved. Thus, the use of several vegetable sources and their physiological implications in the early-life stages has been evaluated in the gilthead sea bream by using a high content of soybean meal as an epigenetic trigger (Perera and Yúfera, 2017), but the later consequences along the production cycle in juvenile/adult fish remain unknown. The present study evaluates the effects of dietary incorporation of a multibiotic nutraceutical extracted from algae during first-feeding of *S. dumerili*, and their lasting effects on growth and intermediary metabolism after being fed with a plant-based diet during the on-growing cycle.

Materials and methods

Fry specimens (~0.3 g of initial mean body mass) of *S. dumerilli* were obtained from commercial sources (Futuna Blue S.L., El Puerto de Santa María, Spain) and maintained at the indoor facilities of the *Instituto de Ciencias Marinas de Andalucía* (ICMAN-CSIC, Puerto Real, Spain) by feeding fish (90 days) as follow: i) a control group fed enriched artemia with *Tetraselmis chuii* (10 days) + a commercial formulations (CT), or ii) this same protocol with enriched artemia and aquafeed supplementation (1 %, BP) with the multibiotic extract from algae *Prebiodo II* (Biotechnology Biopolym S.A.). After that, fish were pit-tagged to be maintained in a common garden and fed with a commercial diet for 6 months, and then 1) nutritionally challenged with a plant-based diet (PP) or 2) fed with the same commercial diet (COM) for an extra 3-month feeding period. Growth and somatic indices were analysed along with plasma, muscle and hepatic metabolites (glucose, glycogen, lactate, triglycerides, cholesterol and proteins).

Results and discussion

Fish fed with *Prebiodo II* during first feeding (BP group) exhibited higher specific growth rates (SGR) 9 months after early-nutritional interventions, regardless of the experimental diet (COM or PP) fed during the on-growing cycle. BP-COM group showed the highest growth performance, followed by the same pattern by both CT-COM and BP-PP, being the lowest SGR registered for CT-PP fish. Regarding somatic indices, mesenteric fat (MSI) was very low (up to 0.35 %) and did not show significant differences among experimental groups, although those fish fed with BP diet (BP-COM and BP-PP) presented the lowest levels. Moreover, hepatosomatic index (HSI) and the intestine length index (ILI) revealed a significant increase in fish from the CT-PP group. This effect on ILI was accompanied by a constant epithelial resistance (Rt, W.cm$^2$) and higher apparent permeability in the anterior intestine of fish fed *Prebiodo II* during early nutritional interventions.

*(Continued on next page)*

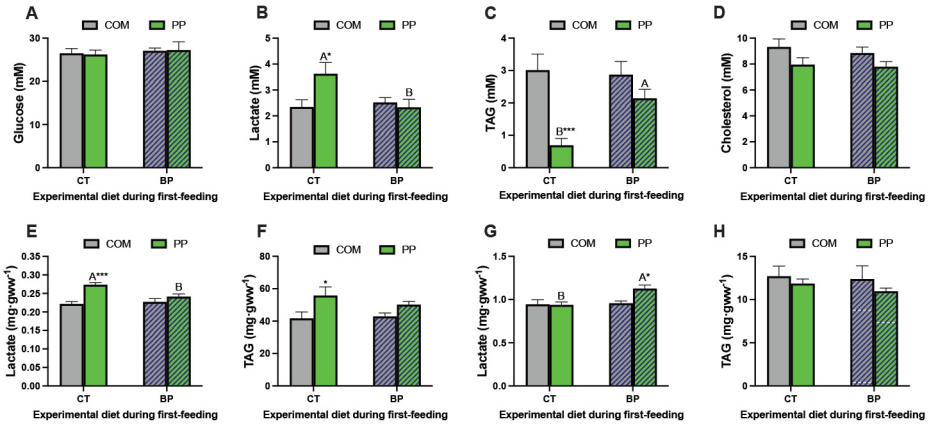

**Figure 1.** Plasma (A, B, C, D), hepatic (E, F), and muscular (G, H) metabolites of *S. dumerili* juveniles fed different experimental diets (COM and PP) after being fed during first-feeding without (CT) or with (BP) nutraceutics. Data are the mean ± SEM of 10 fish. Different superscript letters indicate significant differences among first-feeding dietary treatments (CT vs BP) for the same experimental diet (COM or PP). Asterisks represent differences between experimental diets (COM vs PP) for the same first-feeding dietary treatments (CT or BP) based on two-way ANOVA and Tukey's test (*p < 0.05; ***p < 0.001).

Attending to metabolic orchestration, plasma glucose maintains a homeostatic state along the four experimental sub-groups (Fig. 1A), whereas higher lactate (Fig. 1B) levels can also result from carbohydrate-enriched diets that contribute to increased glycogen stores throughout the formation of pyruvate from lactate by lactate dehydrogenase (LDH) at hepatic level (i.e. Cori cycle; Fig. 1E) and preferential glycogen degradation for energy requirements, as also shown herein. Our results also suggest that these observations can be found only in fish non-previously fed with *Prebiodo II*, where this compound appears to differentially regulate this metabolite in muscle (Fig. 1G). In addition, the contrasting trends for plasma TAG and cholesterol concerning lactate levels further indicate a shift in the energy substrate preferentially used, and thus an overall change in the relative contribution of anaerobic metabolism and TAG oxidation clearly ameliorated by early nutritional interventions (Fig. 1C and 1D). Moreover, our results suggest that plasma TAG depletion is the cause or the consequence of a preferential accumulation of this metabolite in the liver (Fig. 1F), but not in muscle (Fig. 1H) in fish fed PP-based diets and not supplemented with the nutraceutical compound during early stages.

## Conclusions

Our preliminary results demonstrate that carnivorous fish, genetically- and physiologically-adapted to high content of animal proteins in the diet, can be programmed by nutritional interventions, as that produced by the inclusion of a blend of different algae extracts biotechnologically obtained (*Prebiodo II*), and included in live crops and first microdiets during early development to better use vegetal proteins in later life during the on-growing cycle.

# THERMAL AND CHEMICAL PRIMING FOR RESILIENCE: A MITIGATION STRATEGY AGAINST MARINE HEATWAVES

Chiara Mascitelli*, Giovanna Monticelli, Giulia Dalla Rovere, Ilaria Bernardini, Luca Peruzza, Luca Bargelloni, Massimo Milan

Department of Comparative Biomedicine and Food Science
University of Padova
Galilean School of Higher Education

The Manila clam (*Ruditapes philippinarum*) is a bivalve species with a broad native and introduced distribution holding significant economic and ecological importance. It is one of the most valuable species in global seafood markets and is widely used as a sentinel organism for environmental monitoring.

Climate change, characterized by a rise in average global temperatures, is one of the major global issues and has increasingly adverse effects on marine life. In particular, marine heatwaves — defined as prolonged periods of abnormally high seawater temperatures and closely linked to anthropogenic climate change — have been shown to impact marine life at multiple biological scales, including individual organisms, species, populations, and ecosystem services. These extreme events have been linked to alarming mass mortality events in bivalve populations. In this context, the development of effective mitigation strategies is urgently needed.

One promising approach is priming, described as the controlled exposure to a sublethal stress to enhance an organism's ability to cope with future environmental challenges.

This study focuses on testing different priming strategies on Manila clam. Both thermal and chemical sub-lethal stresses were used as priming agents.

Clams were divided into four groups that underwent the following treatments, with a duration of 7 days: no treatment (control), heat priming, chemical priming (hydrogen peroxide), and the combination of the two. After a period of resting (7 days), clams experienced a 7 days challenge during which they were exposed to daily 34°C heatwaves. The clams' digestive glands were sampled prior to priming, after priming, and after challenge.

Clam performance was evaluated using the following methods: survival monitoring over the following 14 days, hepatosomatic index (HSI) and condition index (CI), burrowing test, and transcriptional/biomarker analysis of samples.

To evaluate the effectiveness of priming as a mitigation strategy, the same treatment was applied to a second batch of clams for field testing. This approach aimed to assess the animals' responses to summer heatwaves under natural environmental conditions, thereby validating the potential of priming in realistic settings.

# EXPLORING GONADAL FACTORS IN EARLY GAMETOGENESIS AND PUBERTY: INSIGHTS FROM THE EUROPEAN SEA BASS

## Introduction

Effective control of reproduction is fundamental for sustainable aquaculture of farmed species, and understanding in-depth the molecular regulatory systems governing gametogenesis becomes essential. In vertebrates, the brain-pituitary-gonad (BPG) axis regulates reproduction though gonadotropins, sex steroids, and local gonadal factors, the latter being largely unknown in fish. Among these, some members of the transforming growth factor β (TGF-β) family, including the Anti-Müllerian Hormone (Amh) and the Gonadal Soma-Derived Factor (Gsdf), are emerging as key regulators of early stages of gametogenesis and sex determination and differentiation [1]. To date, their characterization links them to male sex differentiation [2,3] and to the proliferation of type A spermatogonia (SgA) [4,5], while their regulatory roles in male and female adult gonads remains to be clarified. The European sea bass (*Dicentrarchus labrax*), an economically important species in Mediterranean aquaculture, provides a robust experimental model for this research based on the good number of tools available for reproductive physiology studies. Based on our previous knowledge and developed tools (sea bass recombinant proteins and specific antibodies) [6,7], the aim of this work is the functional characterization of Amh and Gsdf in male and female sea bass during puberty and adult gametogenesis.

## Materials and methods

To further investigate on these gonadal factors, a multidisciplinary approach including molecular, biochemical and physiological analysis was performed. Recombinant sea bass Amh and Gsdf produced in CHO cells were used to treat *in vitro* cultured testes and ovaries to assess their direct effects on the gonads. Specific antibodies allowed protein detection in gonadal extracts and their localization in histological sections to disclose the role of these proteins in the local control of gametogenesis. *In vivo* administration of hormone-coding plasmids were conducted in the pre-meiotic stage animals to analyse their action at the organism level. Finally, transactivation assays were done in Cos7 cells for studying Amh and Gsdf intracellular signalling pathways, and to identify the specific receptor for Gsdf, which remains unknown.

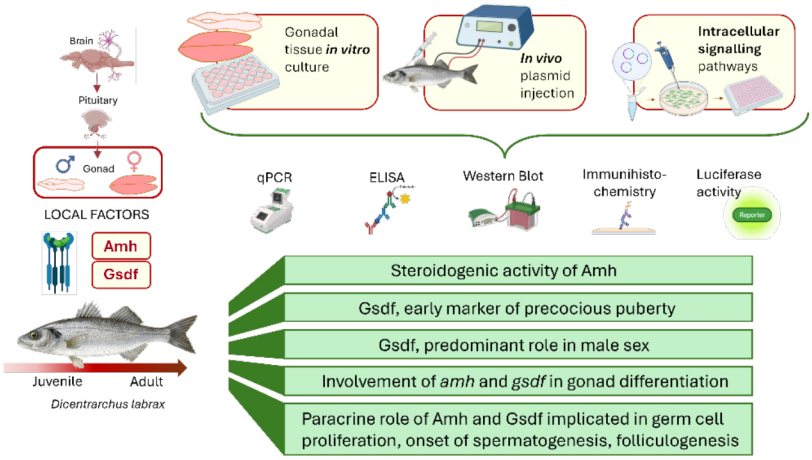

**Figure 1.** Graphical summary of the main outcomes of this study. Created in https://BioRender.com.

*(Continued on next page)*

**Results**

*Gene expression:* During juvenile gonadal differentiation, expression levels of *amh*, *amhr2*, *gsdf1* and *gsdf2* peaked at 250 days post-hatch. In testis of 1-year-old males that enter precocious puberty, the expression of *gsdf1* and *gsdf2* decreased compared with their siblings that remained immature. In adult males, *gsdf1*, and to a lesser extent *gsdf2*, showed maximum expression levels in premeiotic testis, while in adult females, the expression levels of *gsdf* genes were lower than in testis, and *gsdf2* mRNA predominated in post-ovulatory ovaries and in isolated follicular cells.

*Protein localization*: In adult testis, Amh was immunodetected in Sertoli cells surrounding early germ cell generations, whereas Gsdf was localized in Sertoli cells surrounding SgA but exclusively in the central region of each lobule. In ovaries, Amh was present in follicular cells of both early and late-vitellogenic stages, while Gsdf presence was confined to pre-vitellogenic follicular cells. In addition, Amhr2 was detected in SgA of post-spawning and pre-meiotic testis and in follicular cells of pre-/vitellogenic ovaries.

*Functional analysis*: *In vitro* cultured pre-meiotic testis or pre-/early-vitellogenic ovaries treated with recombinant Amh revealed its steroidogenic activity, resulting in an increase of steroid production. In the same vein, *in vivo* intramuscular injection of Amh expression plasmid caused an increase of circulating sexual steroids. Transactivation experiments in Cos7 cells confirmed that, in addition to the canonical Smad pathway, the sea bass Amh/Amhr2 pair was able to signal through the main steroidogenic cAMP pathway and its action was inhibited by the cAMP antagonist Rp-cAMPS. Finally, all the sea bass TGF-β type I receptor genes were cloned and functionally tested in Cos7 cells in combination with type II receptors to define the precise intracellular mechanism of action of Amh and to find the specific Gsdf receptor.

**Discussion and Conclusion**

The novel steroidogenic activity of Amh found in our experiments in sea bass indicates that fish Amh may act differently from mammalian Amh, which inhibit Fsh-induced on steroidogenesis. Gene expression analysis indicates that Gsdf1/2 and Amh have a clear function in male gonad differentiation. Moreover, the gonadal expression of *gsdf* genes during the adult reproductive cycle suggests a predominant role in adult males rather than females. The *gsdf1* downregulation in precociously maturing males suggests its potential as an early marker and target for puberty regulation. Protein detection and cellular localization demonstrated a paracrine role of both factors in germ cell proliferation, in the onset of spermatogenesis before meiosis, in folliculogenesis, and during vitellogenesis. Finally, the description of the specific interactions between type II and type I receptors, and their particular signaling trough phosphorylation of Smad 2/3 or Smad 1/5/8 proteins contributes valuable insights into the TGFβ signalling network in teleost gonadal function.

# ITALIAN POLICY PERSPECTIVES ON CURRENT CHALLENGES IN FISHERIES AND AQUACULTURE

M. Masi*, R. De Nicolò, Y. Vecchio, E. Dolfi, G. Yeter, E. S. Marrocco, F. Adinolfi

Department of Veterinary Medical Science
Alma Mater Studiorum - University of Bologna
Via Tolara di Sopra 50

Email: margherita.masi4@unibo.it

## Introduction and background

The growing demand for seafood and the pressing need to reduce the ecological impact of blue sectors have elevated the sustainability of fishing and aquaculture industries to the forefront of European and international policymaking agendas in the last decades (FAO, 2024). This shift reflects a broader commitment to balancing economic growth with environmental sustainability, driving comprehensive policy initiatives across the blue economy.

In line with the United Nations 2030 Agenda, European institutions have aimed to ensure the blue sectors' sustainable development by promoting innovative practices and improving the management of aquatic resources, a transformative process known as the "blue transition". In this context, the European Maritime, Fisheries and Aquaculture Fund (EMFAF) aims to promote innovative projects and more effective governance strategies, backed by a financial allocation of €6.108 billion for the 2021-2027 period to support four key priorities: (i) sustainability of the fisheries sector, (ii) sustainability of aquaculture, (iii) development of maritime communities, and (iv) ocean surveillance.

The effectiveness of this instrument largely depends on its ability to address the actual needs of the sector's stakeholders (Vecchio et al., 2024) and bridge existing gaps between people and policy (Krause et al., 2015; Brugere et al., 2021).

In line with the abovementioned information, this study aims to analyze the blue sector stakeholders' perspectives on EMFAF 21-27's priorities in Italy to assess their views and alignment with current policies.

## Methodology

As an effective way to detect the viewpoints, the Q-methodology approach was applied, a quali-quantitative analysis aimed to identify the different perspectives within a group of participants, also known as discourses (Brown, 1980).

Following the steps of methodology (see McKeown and Thomas, 2013), 36 statements (Concourse) related to each priority of Italy's National EMFAF Plan (European Commission, 2021) have been designed. Afterwards, 18 respondents (P-sample) are called to rank the statements based on a predefined scale ranging from -5 to +5 (Q-set) based on their level of agreement or disagreement, arranging them within a normally distributed grid (Q-sorting) (Watts and Stenner, 2012).

The chosen participants are stakeholders who cover different roles in the supply chain - producers, cooperatives, public institutions, trade associations, academics, and consultants - to capture the different views on the relevance of different strategies proposed within EMFAF priorities. Lastly, a principal component analysis was performed to identify shared opinion patterns.

## Results

The Q-methodology analysis reveals five distinct perspectives, each emphasizing different opinions towards their alignment with current policies.

*(Continued on next page)*

The first discourse, "Cooperation and control", emphasizes the importance of regulation and marine area monitoring.

The second discourse, "Innovation, entrepreneurship, and a circular approach to aquaculture", demonstrates a strong interest in adopting innovative technologies and fostering new entrepreneurial opportunities in blue-farmed sectors.

The third discourse, or "Systemic vision and openness of mind", underlines the importance of an integrated approach involving all supply chain actors and promoting sustainable and collaborative marine resource management.

The fourth discourse is named "Local promotion and collaboration" since it highlights the significance of the statements falling into the second and third priority.

The last viewpoint, called "Sustainable fishing development", prioritizes the development of the fishing sector through fleet modernization, port infrastructure improvements, workforce training, and adopting more sustainable fishing practices

From a policy perspective, the present study reveals a significant divergence between stakeholders' perceived priorities, highlighting the potential need to revisit the allocation of financial resources for the blue transition of Italy's fisheries and aquaculture sectors.

# EVALUATION OF THE POTENTIAL FOR ANTI-PREDATOR STOCKING TO REDUCE CROP LOSSES DUE TO FISH PREDATION IN GREENSHELL™ MUSSEL (*Perna canaliculus*) FARMS

Thomas C. Mason*, Andrew Jeffs, and Brad Skelton

Institute of Marine Science
University of Auckland
Private Bag 92019
Auckland, New Zealand
Email: tmas707@aucklanduni.ac.nz

Enormous losses of juvenile mussels are commonplace in mussel aquaculture worldwide. Fish predation is one important contributor to these losses in many mussel growing regions. The Greenshell™ mussel industry in New Zealand is particularly susceptible to fish predation, where farmers have reported losses of seed mussels of up to 100%. The current practice for seeding juvenile Greenshell™ mussels onto coastal farms is to deploy the mussels alongside a continuous longline growing rope enclosed in a cotton stocking which holds the mussels against the rope. The mussels subsequently attach to the rope with byssus threads before the cotton degrades. During this vulnerable period, the stocking may also help to protect the juvenile mussels from fish predators whilst they are unattached to any substrate. This study investigated whether differences in the strength and weave of three types of stocking (i.e., a 54-loop weave commonly used in New Zealand, a smaller and more tightly woven stocking used in shellfish hatcheries, and a 42-loop stocking that combines two weaves of cotton together) might affect the amount of fish predation on juvenile mussels that were newly seeded onto growing rope. In an experiment, the three types of cotton stocking were each subjected to three levels of predation by restricting fish access to the growing ropes seeded with juvenile mussels by attaching full, partial and no plastic mesh cages around the ropes. The number of mussels lost from each of the treatment combinations were assessed after 10, 31, and 42 days. At 42 days on average only 15.1% (± 1.7 SE) of the seeded juvenile mussels remained on those growing ropes subjected to full fish predation, with no differences in mussel losses among three types of socking (Figure 1). In contrast, on average 90.7% (± 2.1 SE) of the seeded juvenile mussels remained on growing ropes protected from fish predation by the full mesh cages, and 87.5% (± 3.7 SE) for partial cages. For both types of protective cages there was no difference in the numbers of remaining juvenile mussels among the three types of stocking. Remote underwater video camera observations confirmed Australasian snapper (*Chrysophrys auratus*) were feeding on the juvenile mussels from the dropper ropes without protective cages. These results show that physical protection by cages protects juvenile mussels from fish predation, while cotton stocking, regardless of the type used, is not effective for preventing fish predation. The results also show that the majority of mussel losses in the uncaged treatment occurred in the first 10 days of the experiment, indicating that vulnerability to predation may be associated with the initial lack of byssus attachment to the growing rope. These results point to a need to develop more effective methods for mitigating the high losses of seed mussels after they are seeded onto growing ropes.

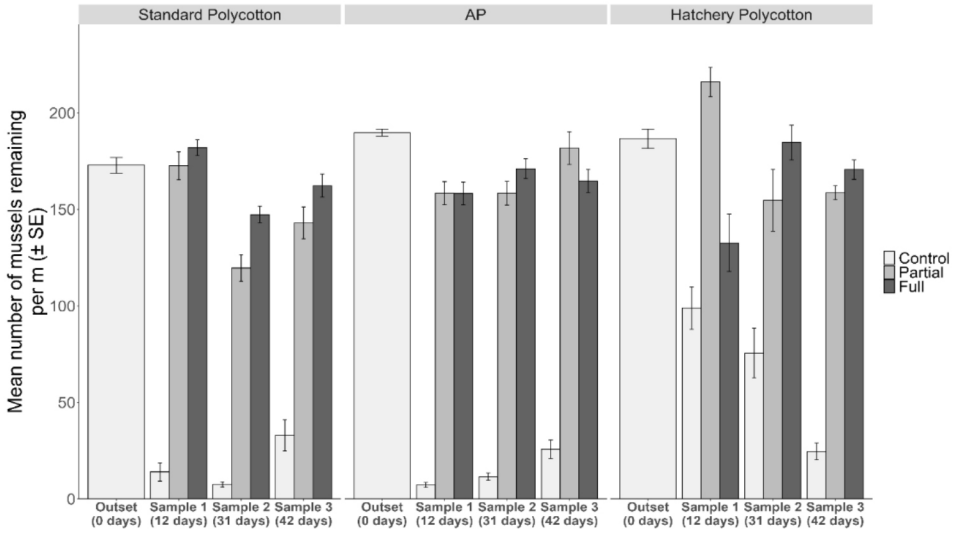

Fig 1. Mean number of mussels ($m^{-1}$ ± SE) remaining attached to dropper ropes in each of three stocking types and three cage treatments over the course of the 42-day experiment.

# FATTY ACID QUALITY IN FARMED FISH: EXPLORING THE USE OF INSECT MEAL

M. Mastoraki[1,2*], E. Antonopoulou[2] and S. Chatzifotis[1]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, Greece.
[2]Department of Zoology, School of Biology, Aristotle University of Thessaloniki, Greece.
Email: mmastoraki@hcmr.gr

## Introduction

In general, insect meal is increasingly recognised as an emerging, promising and sustainable raw material for fish and animal feed. Being the subject of extensive studies, current research lines focus on ensuring optimal growth performance and fish production with the aim to deliver fish with exceptional nutritional value. Fish is an important source of protein and fat for the human nutrition. The higher polyunsaturated fatty acid content (PUFA) of fish compared to other animal products has been associayed with the prevention of many chronic illnesses. In this context, this study evaluated the effect of dietary insect meal on the quality of the fatty acids in farmed sea bass and sea bream.

## Materials and methods

A detailed description of the feed composition and experimental conditions is given by Mastoraki et al. (2020, 2022). Briefly, four diets were designed and formulated for sea bass and sea bream. The control diet contained fish meal as the main source of protein (65% inclusion), while in the three experimental diets 30% of the fish meal was replaced by insect meal derived from *Tenebrio molitor* (TM), *Hermetia illucens* (HI, defatted) or *Musca domestica* (MD) larvae (19.5% inclusion). The diets were formulated to be isoproteic and isoenergetic, and for this purpose, the remaining ingredients were added in different amounts to each diet (fish oil was included in higher amounts mainly in the control diet and in the diet containing defatted HI). Sea bass and sea bream were reared in open flow indoor cylindrical tanks (500 L) for three months. At the end of the feeding trial, the whole body composition was determined and the indices were calculated from the fatty acid profile of the bodies (Mastoraki et al. 2020, 2022) as follows: Atherogenicity index (AI) = (aC12:0 + bC14:0 + cC16:0)/ (dP + eM + fM'); Thrombogenicity index (TI) = (C14:0+ C16:0+ C18:0)/ [(nM + oM' + p(ω-6) + q(ω-3) + (ω-3/ω-6)], where P is the sum of ω-3 and ω-6 fatty acids , M is the percentage of C18:1, M' the sum of the remaining monounsaturated fatty acids (MUFA), and a, b, c, d, e, f, n, o, p, q empirical constants (Ulbricht and Southgate, 1991); hypocholesterolemic / Hypercholesterolemic fatty acid ratio (h/H) = (C18:1 ω-9 + C18:2 + C18:3 + C20:5 + C22:5 + C22:6)/ (C14:0 + C16:0) (Santos-Silva et al., 2002); and the ratios characterizing the fatty acid profile PUFA/saturated fatty acids (SFA) and ω-6/ω-3.

## Results and Discussion

The fatty acid quality indices of the experimental fish are shown in Figure 1. The different diets, especially the different inclusion of fish oil in the diets, affected the ω-3 content of the fish. Thus, sea bass and sea bream consuming the FM and HI diets showed significantly lower ω-6/ω-3 ratios compared to the TM and MD groups. Substitution of FM with MD and TM led to a decrease in AI in sea bass due to higher MUFA and ω-6 fatty acid content. Partial FM substitution did not affect TI in sea bass as the index gives more weight to ω-3 fatty acids, which are present in higher levels in FM and HI fish. However, TI increased in sea bream fed TM compared to FM and HI. The higher the h/H index, the more beneficial the food is for protecting against cardiovascular disease. In this study, the highest h/H were observed in sea bass fed TM and MD, likely due to their higher content of C18:1 and C18:2 fatty acids (Mastoraki et al. 2020). In sea bream, the h/H index was not significantly affected by the different diets, possibly because the higher MUFA and ω-6 fatty acids levels in TM and MD fish were balanced with the higher ω-3 fatty acids in FM and HI fish (Mastoraki et al. 2022). In the present study, the sea bass fed with TM had significantly higher PUFA/SFA ratio compared to the other groups. The sea bream had a similar PUFA/SFA ratio among them. Fatty acid quality ratios in the fish body were within the appropriate limits for a healthy human diet, however, fish consuming non-defatted insect meal had lower ω-3 content.

## Conclusion

Fish fed with insect meals maintain suitable fatty acid profiles for human consumption. Defatting insect meal may enhance the nutritional quality of both the feed and fish by increasing the ω-3 levels. Insect meal in aquafeeds can indirectly affect the cardiovascular health markers depending on the fish species and the fatty acid composition of the fish diet. These findings highlight the importance of carefully selecting raw materials to preserve the nutritional value of the farmed fish.

*(Continued on next page)*

Figure 1. Fatty acid quality indices (mean ± standard deviation) of fish fed diets containing 19.5% of insect meals. Different letters in each graph indicate statistically significant difference among the diets (one way ANOVA, Tukey HSD, $P$<0,05).

Email: mmastoraki@hcmr.gr

**Introduction**

Winter syndrome is a recurring condition affecting gilthead sea bream, causing significant mortalities across several Mediterranean regions during specific cold periods (<13°C) over the years. Is characterized by reduced feed intake and impaired growth while the causes of mortality may include not only thermal stress but also metabolic dysfunction, immunosuppression and opportunistic pathogens (Ibarz, et al. 2010). One potential strategy to reduce the adverse effects of the winter conditions is the inclusion of dietary functional ingredients intended to enhance fish immune status. This study evaluates the effects of Phyto AquaNity, a natural additive blend of Artepillin C (Green propolis) and curcuminoids (turmeric) on growth performance and immune support under water temperature variation condition.

**Materials and methods**

Fish (71.64g ± 0.58) were fed a control diet designed to resemble a commercial formulation or diets containing 0.1% Phyto AquaNity at optimal temperature (23°C) for 55 days. Then the water temperature was decreased by 1°C per day until it reached 13°C, where it stayed for 30 days. The trial was performed in triplicate within a recirculating aquaculture system (RAS). A transcriptomic and qPCR analysis of several immune response genes were performed at distal intestine samples from fish taken at the end of each rearing phase.

**Results and Discussion**

At 23°C, daily weight gain (DWG) and specific growth rate (SGR) were numerically higher in the treatment group compared to the control group, although the differences were not statistically significant ($p>0.05$) and the feed conversion ratio was similar between the groups (Table 1). At 13°C, fish fed Phyto AquaNity showed significantly higher SGR and DWG compared to the control group ($p<0.05$).

Transcriptomic analysis revealed that Phyto AquaNity influenced the expression of more than 290 genes at 13°C. The combination of Artepillin C and curcuminoids did not show any notable gene regulation changes compared to the control group in the higher temperature. However, at cold temperature a significant body of genes were regulated involving the enrichment of immune and metabolic pathways including the enrichment of the beta-alanine metabolism pathway.

The results of the qPCR analysis of the gene expression of immune response genes are presented in Figure 1. At 13°C, key inflammation associated genes (B2M, Cats and NCCRP) were down-regulated when fish ate Phyto AquaNity. Specifically, HSP70 and NCCRP were significantly down-regulated at 13°C.

The results suggest that dietary Phyto AquaNity may enhance the immune and metabolic pathways, while helping to mitigate inflammation and cellular stress responses in fish, potentially enhancing growth performance during rearing at low temperatures.

carlotam@icm.csic.es

## Introduction

In the context of climate change, the warming of the Mediterranean Sea, along with the increased frequency of heat waves, poses a high significant risk to mussel farming. High water temperatures (above 28ºC) lower the physiological performance and may result in mass mortality events. Mussels (*Mytilus galloprovincialis*) cultured in enclosed environments are especially vulnerable to climate change, compromising ecosystem goods and services such as good water quality, food provision and the socioeconomics in the area.

## Material and Methods

To investigate the effects of temperature in the performance of *M. galloprovincialis,* field experiments were carried out monthly from March to July 2025 in the mussel farms from Fangar Bay (Ebro Delta, NW Mediterranean Sea) following the expected increase of temperatures from spring to summer. Feeding behavior of cultivated mussels was determined using the biodeposition method as described in Galimany et al., 2011, estimating parameters such as clearance, ingestion and absorption rates. Temperature was recorded continuously and water quality, according to the particulate matter available for the mussels, was evaluated monthly during the feeding experiments. Other biological parameters such as valvometry, biomarkers and the histopathological condition of the mussels were also evaluated although the results are not reported in this abstract. Linear models and Generalized Additive Models (GAMs) were used to model the feeding behavior response to temperature.

## Results and Discussion

The results showed that the water temperature increased from 14.4ºC in March to 27.6 ºC in July. In response to this increase in temperature, mussels exhibited a tendency to reduce both their clearance and absorption rates. The clearance rate exhibited a pronounced decline as temperature increased, followed by a stabilization around 20ºC, suggesting a non-linear physiological response to thermal stress (Fig. 1A). Nonetheless, the absorption rate which is dependent on the organic content of the water, decreased linearly with rising temperatures, indicating a consistent negative physiological response when water quality is also considered (Fig. 1B).

The results obtained during the experiments are similar to others found for the same specie (Anestis et al., 2010) and specific area (Galimany et al., 2011) where physiological performance decrease significantly when temperatures exceed 20ºC. These findings highlight the sensitivity of mussels' behavior to thermal stress, emphasizing the potential impact of rising temperatures on the species' performance, survival and aquaculture production.

# SUPERIOR GROWTH PERFORMANCE IN CARP FRY ACHIEVED WITH CHITOSAN-ALGINATE ENCAPSULATED A-GHRELIN VERSUS FREE PEPTIDE

M. Matinfar*, B. Heidari, A. Valipour

Department of Biology
Faculty of Science
University of Guilan
Rasht, Iran
E-mail: matinfar@gmail.com

**Introduction**
Ghrelin is a potent stimulator of growth hormone (GH) secretion and plays a key role in appetite regulation, metabolism, and immune modulation in fish. However, its oral delivery is limited due to degradation in the gastrointestinal tract. This study aimed to evaluate the efficacy of encapsulated A-Ghrelin using chitosan-alginate (Cs-Al) nanocarriers to improve its bioavailability and enhance growth, immunity, and stress response in common carp fry.

**Materials and Methods**
A-Ghrelin was synthesized via Fmoc-based solid-phase peptide synthesis and encapsulated into Cs-Al nanoparticles using ionic gelation. The particles were characterized by DLS (size, zeta potential), FTIR, FE-SEM, and AFM. In vitro release studies simulated gastric and intestinal pH. A 4-week feeding trial included six groups: control, free A-Ghrelin, A-Ghrelin-Cs, A-Ghrelin-Cs-Al, Cs-Al + A-Ghrelin, and Cs-Al alone. Growth metrics (weight gain, FCR, SGR), biochemical indices (cortisol, glucose, ALT, AST), immune parameters (IgM, C3, lysozyme), and gene expression (igf1 via qRT-PCR) were assessed. Histological analysis of intestines and gills was performed.

**Results**
Cs-Al nanoparticles (150 nm, +22 mV) showed 73.8% encapsulation efficiency and pH-dependent release (70% in 6 h). A-Ghrelin-Cs-Al significantly increased weight gain (2.3 g), SGR, and intestinal wall thickness (0.518 mm). GH and igf1 expression were elevated across all ghrelin treatments. Immune modulation was noted in Cs-Al groups, with reduced IgM and C3 in encapsulated ghrelin-fed fish. ALT and AST levels varied with treatments, indicating altered hepatic activity. 100% survival was recorded across all treatments.

**Conclusion**
Chitosan-alginate encapsulation effectively delivered A-Ghrelin, enhancing growth performance and physiological responses in carp fry. This nanocarrier approach shows strong potential for sustainable aquaculture through improved feed efficiency and peptide stability.

# DEGRADATION OF AQUATIC ECOSYSTEMS IN UKRAINE: WARTIME CHALLENGES

N. Matviienko*[1,2] D.Montvydiene[2], A. Kucheruk[1], N. Savenko[1], O. Oliinyk[1], S. Skrotskyi [3]

**Introduction**

The ongoing war in Ukraine has precipitated significant environmental challenges, notably impacting aquatic ecosystems and posing substantial obstacles to sustainable aquaculture development. This study presents findings from a comprehensive assessment of water bodies across multiple Ukrainian regions, including Kyiv, Kherson, Mykolaiv, Chernihiv, Kharkiv, and Odessa.

**Materials end methods**

Hydrophysico-chemical analyses were conducted in Ukraine in accordance with the national standard of Ukraine "Water. Fishery water bodies. Ecological indicators of water quality" (SOU 73.1-41-050:2006), which establishes the requirements for ecological characteristics of water bodies suitable for fish farming. ons were conducted in accordance with the accepted classification of water quality in Ukraine The heterotrophic microorganisms (saprophytes) in the water body were found to be less than 0.5 thousand cells/mL, indicating a Class I (xeno-saprobic zone) status (very clean). The number of heterotrophs in the water body was found to be between 0.5 and 5.0 thousand cells/mL, indicating a Class II (oligo-saprobic) status (clean). The number of heterotrophs in the water body was found to be between 5.1 and 10.0 thousand cells/mL, indicating a Class III (beta-mesosaprobic) status (moderately polluted). The number of heterotrophs in the water body was found to be between 10.1 and 50.0 thousand cells/mL, indicating a Class IV (alpha-mesosaprobic) status (polluted); between 50.1 and 100.0 thousand cells/mL, indicating a Class V (beta-polysaprobic) status (very polluted) and more than 100.0 thousand cells/mL, indicating a Class VI (alpha-polysaprobic) status (extremely polluted. Structural indicators of ichthyofauna were studied using catch data from 2024. The material was collected from fixed gillnets and drift gillnets with different mesh sizes. Biological analysis was carried out using standard ichthyological methods.

**Results**

Hydrophysico-chemical analyses revealed elevated levels of organic pollutants in certain areas. For instance, the River Kozka in the Kyiv region exhibited biological oxygen demand (BOD) and chemical oxygen demand (COD) values exceeding permissible limits, indicating significant organic pollution. Additionally, increased mineralization was observed in Lake Sasyk (Odessa region), with chloride, sulphate, and iron concentrations surpassing standard thresholds.

In 2024, the Kosheva river (Kherson region) exhibited the highest degree of pollution, with a heterotrophic count reaching 16,000 cells/ml, indicative of an alpha-mesosaprobic status. In Kyiv region, the Chorne and Kalynivka lakes exhibited an increase in pollution, reaching 9.55 thousand cells/mL, which suggests an imminent ecological instability. The water bodies in the Mykolaiv region exhibited a stable status with a bacterial count of up to 5,500 cells/mL. In contrast, the ecosystems in the Odesa and Chernihiv regions demonstrated fluctuations from "clean" water in spring to "moderately polluted" in summer, with a peak of bacteria in June-August. The results indicate an intensification of water pollution in regions most affected by anthropogenic impact and the consequences of military actions. Furthermore, elevated counts of saprophytic and opportunistic microorganisms, including *Salmonella spp*. and Pseudomonas spp., were detected, reflecting deteriorating water quality and potential risks to aquatic life. The increase in saprophytic bacteria demonstrates a disturbance of ecosystem balance, leading to the transition of waters to higher saprobity classes. This confirms the irreversibility of degradation processes in aquatic ecosystems under the impact of military actions.

*(Continued on next page)*

A survey of the fish populations revealed a significant decline in commercial catch rates observed in the tested water bodies. A decline in species diversity from 18-19 to 13 species was observed in the Desna river (Chernihiv region), accompanied by a notable reduction in the bream population. These findings suggest that the ecosystem is undergoing degradation. A shift in the ichthyofauna structure was observed in the Kyiv Reservoir (Kyiv region), with a notable increase in silver carp dominance. This was accompanied by a decline in catches of pike, perch, bream, and roach, which is likely associated with deteriorating habitat conditions. In the Yuzhny Bug River (Mykolaiv region), the commercial fish stock declined by 95%, while natural fish mortality increased to 0.34, indicating the destruction of ecosystem processes. The analysis indicates serious degradation processes in the ecosystems of water bodies, manifested in the loss of biodiversity, reduction in the number and biomass of dominant species, as well as a reduction in the commercial potential of fish stocks. This decline was accompanied by a complete loss of the ecological services that these waters had previously provided.

The study highlights the multifaceted impact of armed conflict on Ukraine's aquatic environments, emphasizing the urgent need for integrated management strategies to mitigate environmental degradation and support the resilience and sustainability of aquaculture practices in wartime conditions. This requires rapid and effective solutions that take into account political, economic, environmental and social aspects.

The research was conducted as part of the NATO Peace and Security Science (SPS) project "Developing a Strategy for the Assessment and Restoration of War-Affected Aquatic Ecosystems" No. SPS G6085..

# HEMPSEED BY-PRODUCT AS AN ALTERNATIVE PROTEIN SOURCE FOR ATLANTIC SALMON (*Salmo salar*)

S. McMillan*[1], L. Martinez-Rubio[2], S. Wong[3], S. Shivaprasad[3], R. Broughton[1] and M. B. Betancor[1]

## Introduction

The rapid expansion of aquaculture must be pursued sustainably, with an emphasis on using responsibly sourced raw materials that align with the circular economy and zero-waste principles. As a result, there is an ongoing search for more environmentally friendly terrestrial plant-based alternatives to traditional feed ingredients like fishmeal, fish oil, and even current substitutes such as soy. One promising option is hempseed, derived from industrial hemp varieties containing low levels of cannabinoids (THC < 0.3%). Grown domestically in the UK, and in Europe, industrial hemp offers environmental advantages, including higher CO absorption compared to many other commercial crops (Visković et al., 2023). Additionally, hempseed is a secondary by-product, further minimizing its carbon footprint, as the primary purpose of hemp cultivation is to produce construction and energy materials from the plant's stalks.

## Materials and Methods

Building on previous findings that demonstrated the favourable digestibility of hempseed in Atlantic salmon diets, the present 13-week study aimed to assess fish performance, fillet quality for consumers, and the effects of a hempseed-based diet on gut health. The trial compared two experimental diets: a control diet containing 15% soy protein concentrate (SPC) and a test diet in which SPC was fully replaced with 15% hempseed meal (HM). At the end of the trial all fish were humanely euthanized, performance and welfare indicators were recorded, and samples collected for biochemical, gene expression and histological analysis.

## Results

No significant differences were observed in growth performance, feeding parameters, or welfare between Atlantic salmon fed a commercial diet and those fed the experimental hempseed-based diet. Similarly, there were no notable differences in any of the nutritional parameters assessed. These findings suggest that hempseed is a viable substitute for SPC in salmon diets, offering benefits for both fish health and human consumption. Further analyses—including histological examination, short-chain fatty acid profiling, and gene expression studies—are underway and are expected to provide additional insights into the effects of hempseed on gut health.

# ALTERNATIVE SUSTAINABLE AND ORGANIC PROTEIN SOURCES TO FISH MEAL IN WHITE SHRIMP *Litopenaeus vannamei* DIETS

I. Megder[1*], Y. Melendez Reyna[1], R. Olivares-Perona[1], S. Martínez-Llorens[1], D.S. Peñaranda[1], M. Jover Cerda[1], A. Tomás Vidal[1]

## Introduction

The shrimp aquaculture industry, particularly for *Litopenaeus vannamei*, relies heavily on fish meal as a primary protein source in feed. However, the sustainability and rising cost of fish meal have driven the search for alternative protein ingredients. Various animal- and plant-based proteins are being explored to reduce dependence on fish meal while maintaining growth performance and feed efficiency. Identifying effective, sustainable, and economically viable protein sources is crucial to support the continued expansion and environmental responsibility of shrimp farming.

## Material and methods

Six dietary formulations (isoproteic, 31% crude protein and isolipidic, 10% crud lipid) were formulated with organic ingredients and the fish meal was replaced by the following organic protein meals: organic chicken carcass (CAR), organic trout by-product (TRU), pig lung (PULCER), a chicken by-products mix (legs, heads and necks, PACACUE), a combination of all these ingredients (MIX), in addition to a control diet (CON) that included 13% fish meal. Growth trial was conducted over 99 days at the Aquaculture Laboratory of the Department of Animal Science, Universitat Politècnica de València.

The growth trial was performed in a recirculating aquaculture system (RAS) using 90 L tanks, with triplicate groups (n=3) per treatment. 16 juveniles *Litopenaeus vannamei* (initial mean weight 7.1 g) were distributed in 18 tanks. Shrimp were individually weighed and monitored every three weeks to assess growth performance, survival, and feed intake adjustments.

## Results and discussion

During the 99-day trial, all shrimp fed the experimental diets supported continuous growth (figure 1), increasing weight from 7.1 g to 16.4 g at the end of the study. The shrimp fed the trout by-product diet showed the highest final weight (17.7 g) and net gain (10.6 g), even so, all diets showed comparable effectiveness with the control diet.

Across all dietary treatments (table 1), no significant differences ($p > 0.05$) were observed in feed conversion ratio (FCR) and survival, indicating that full replacement of fishmeal with organic animal by-product proteins did not compromise feed efficiency or shrimp viability. Although without significant differences, the trout by-product diet (TRU) resulted in the highest final weight and the most efficient FCR ($1.96 \pm 0.28$).

Survival rates were generally high, with the CAR diet achieving 100% survival. Recent research further supports these outcomes. Fanttato et *al*. (2024) demonstrated that inclusion of insect meal and animal by-products maintains growth performance and enhances disease resistance. Together, these results, consistent with Candela-Maldonado et al. (2025), confirm the potential of alternative protein sources to replace fish meal sustainably without negatively impacting key production parameters in shrimp aquaculture.

*(Continued on next page)*

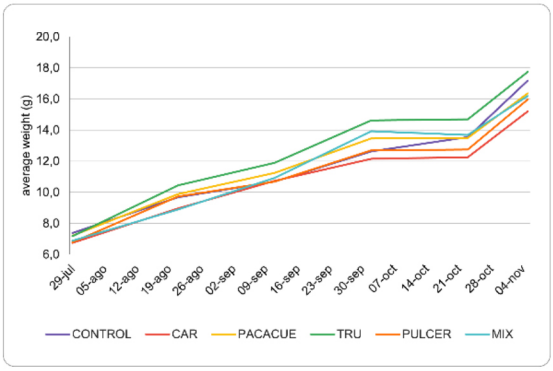

*figure 1. Evolution of the average weight of shrimp*

Table 1. Growth, nutritional parameters, and survival of shrimp at the end of the experiment (99 days)

| Diet | CONTROL | CAR | PACACUE | TRU | PULCER | MIX |
|---|---|---|---|---|---|---|
| **Initial Weight (g)** | 7.4 ± 0.3 | 6.8 ± 0.3 | 7.2 ± 0.3 | 7.2 ± 0.3 | 6.8 ± 0.3 | 6.9 ± 0.3 |
| **Final Weight (g)** | 16.4 ± 1.2 | 14.9 ± 1.1 | 16.5 ± 1.1 | 17.9 ± 1.1 | 15.7 ± 1.1 | 16.0 ± 1.1 |
| **Survival (%)** | 75.0 ± 7.9 | 100.0 ± 7.9 | 95.8 ± 7.9 | 89.6 ± 7.9 | 75.0 ± 7.9 | 83.3 ± 7.9 |
| **FCR** | 2.31 ± 0.28 | 2.35 ± 0.28 | 2.46 ± 0.28 | 1.96 ± 0.28 | 2.13 ± 0.28 | 2.31 ± 0.28 |

Values represent mean ± standard error (n = 3). For each parameter, values not sharing the same letter are significantly different ($p < 0.05$).
FCR: Feed Conversion Ratio = feed intake (g) / biomass gain (g)

## Conclusion

The results demonstrate that sustainable and organic animal protein sources can fully replace fish meal in *Litopenaeus vannamei* diets without compromising growth, feed conversion, or survival. The trout by-product diet exhibited the best performance, confirming its sustainable and economic viability. These findings support reducing fish meal dependency in shrimp aquaculture.

## Introduction

Intensive aquaculture, particularly shrimp farming, necessitates effective and sustainable protein sources to use in the development of feed. Soybean meal is one of the most prevalent plant-based ingredients that is normally used as a fishmeal partial substitute, but it contains nutritional limitations for fish such as shrimp due to its low concentration of certain essential amino acids, the presence of antinutritional factors, and lower digestibility. Controlled fermentation of organic soybeans with *Bacillus subtilis*, was reported to improve their nutritional value by increasing the level of bioavailable proteins, improving the essential amino acid profile.

The current study evaluated the effect of organic soybean fermentation by B. subtilis on protein content, amino acid profile to enhance its application in shrimp feed.

## Material and methods

Two solid-state fermentation trials of soybean meal were conducted at the ICTA laboratory using a *Bacillus subtilis* bacterial inoculum. In the first experiment, an inoculum concentration of $5 \times 10^7$ CFU/mL was applied in volumes of 1, 5, 7.5, and 10 mL, maintaining a volume-to-weight (v/w) ratio of 1:1 (water : soybean meal). Fermentation was carried out at a constant temperature of 43 °C for 62 hours.

In the second experiment, a higher inoculum concentration ($1 \times 10^9$ CFU/mL) was used in volumes of 1 and 2.5 mL, with a water-to-substrate ratio of 1.5:1 (v/w). Fermentation was conducted over periods of 76 and 168 hours under controlled conditions. Then, a proximal nutritional composition analysis was performed to determine their crude protein level and aminoacid profile.

## Results and discussion

In both trials, *Bacillus subtilis* solid-state fermentation significantly increased the crude protein (CP) content of soybean meal (Table 1), from 50.37% in the pre-fermented control to 54.81–56.25% in the fermented treatments ($p < 0.05$). This improvement of 4.5–6.0 percentage points is consistent with the findings of Zhang et al. (2021), who reported an increase in CP from 50.72% to 55.71% following *Bacillus subtilis* fermentation, underscoring the influence of fermentation parameters on protein enrichment. In contrast, Yao et al. (2021) did not observe a direct increase in CP content; however, they demonstrated substantial improvements in protein quality through the marked reduction of anti-nutritional factors such as glycinin and β-conglycinin.

Extended fermentation (168 h) did not result in further increases in crude protein (CP) content, which aligns with findings from Zhu et al. (2023). In their solid-state fermentation study of soybean meal, Zhu and colleagues observed that prolonged microbial activity led to the degradation of macromolecular proteins with consequent heat generation and changes in nitrogen solubility and suggested that excessive fermentation time may provoke protein turnover and diminish CP gains.

Regarding the essential amino acid profile (Figure 1), the treatment involving fermentation of soybean meal with 1 mL of *Bacillus* inoculum over 62 hours (Trial 1) demonstrated notable increases in the concentrations of several key essential amino acids, including methionine, leucine, valine, phenylalanine, and isoleucine.

*(Continued on next page)*

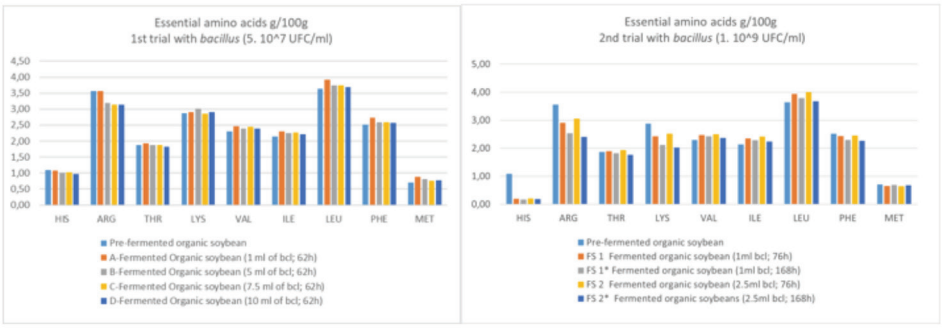

Figure 1: Essential amino acids of soybean meals before and after the fermentation process at different conditions.

## Conclusion

Bacillus subtilis solid-state fermentation effectively improves the crude protein content and essential amino acid profile of soybean meal, enhancing its nutritional value for sustainable shrimp feed formulation.

Email: fmr@unibiogroup.com

**Introduction**
Replacement of fishmeal in fish diets with the ongoing development of sustainable aquaculture is a global and lengthy task. A completely new industrial sector has arisen to produce valuable, novel, and alternative raw materials, among which different single-cell sources of protein could be highlighted. Coming from different fermentation technologies, these raw materials excel in terms of protein content and amino acid profiles, as well as possibilities to be functional ingredients (Hua et al., 2019; Mensah et al., 2025). The case of methanotrophic bacteria is one of the most promising. Because they use methane (natural gas) as a source of energy, companies such as Unibio A/S can produce protein while bypassing the typical cost fluctuations of agronomical practices.

The current study evaluated Uniprotein® (UP) as a fishmeal replacer in diets for gilthead sea bream (*Sparus aurata*). Growth and antioxidant performance were monitored to evaluate the potential of the ingredient for this fish species.

**Materials and methods**
A total of 800 gilthead sea bream (initial body weight = 3.8 ± 0.1 g) were randomly allocated in 16 tanks (500 L) to create quadruplicates of four dietary treatments: control group (UP0, 0 % UP), 25 % fishmeal replacement (UP25, 4.4 % UP inclusion), 50 % fishmeal replacement (UP50, 8.5 % UP inclusion) and 75 % fishmeal replacement (UP75, 12.6 % UP inclusion). The growth trial lasted for 96 days.

Samples of liver, intestine and skin mucus were collected from the fish after the growth trial to analyse the activity of oxidative stress biomarkers.

**Results and discussion**
Growth remained similar up to UP50, whereas fish fed UP75 treatment presented a lower growth performance ($p<0.05$). These results are in agreement with previous results reporting that protein coming from *Methylococcus capsulatus*, in general, does not disrupt fish growth with a maximum inclusion of 5-10 % in the feed, depending on the species (Carvalho et al., 2023; Ruiz et al., 2023).

The antioxidant response remained stable throughout all the analysed tissues and measured parameters in agreement with similar studies using the same raw material (Ruiz et al., 2023). Other studies have reported an increased antioxidant response when fed *Methylococcus capsulatus* meal (Chama et al., 2021). Further research is needed to deepen the study behind the mode of action of this novel raw material depending on the dose supplemented *vs* basal diet as well as on the fish species.

**Conclusions**
The present research proves that Uniprotein® can successfully replace up to 50 % of fishmeal in a gilthead sea bream diet without impairing growth.

## Introduction

One of the main challenges in modern aquaculture is the control of infectious diseases, which are the leading causes of mortality in farmed fish, particularly during the juvenile stages. These losses not only reduce productivity but also lead to a reliance on pharmaceutical treatments, such as antibiotics, whose use raises serious environmental and health concerns, including the emergence of antibiotic-resistant bacterial strains. In recent years, interest on immunostimulation strategies has increased. In this context, microalgae have emerged as promising ingredients in aquaculture diets due to their richness in bioactive compounds such as polysaccharides, carotenoids, polyunsaturated fatty acids (PUFAs), and natural antioxidants with demonstrated immunomodulatory effects (Matin et al., 2024). Previous studies have shown that the inclusion of microalgae in diets for marine species such as gilthead seabream (Sparus aurata) can stimulate parameters of the innate immunity, such as peroxidase and lysozyme activities (Chaves-Pozo et al., 2014). Incorporating microalgae into fish feed represents a sustainable and effective strategy to strengthen the immune response and reduce disease incidence, thereby contributing to improved animal welfare and the efficiency of intensive aquaculture systems. However, several studies have indicated that this is not always reflected in significant improvements in fish physiological condition (Cerezuela et al., 2012). This discrepancy may be due to the presence of a robust cell wall in some microalgae, which acts as a physical barrier that reduces the bioavailability of intracellular compounds for carnivorous fish (Wu and Tian, 2017; Yong et al., 2020). For all these reasons, it is necessary to study whether the introduction of hydrolysed microalgae improves the availability of immunostimulant compounds contained within the cells.

## Materials and Methods

An experimental trial was conducted at the aquaculture facilities of the Oceanographic Center of Murcia (COMU-IEO), CSIC using juvenile gilthead seabream (*Sparus aurata*), with an initial average weight of 25±0.5 g. The fish were randomly distributed in 15 tanks. During 99 days, the fish were fed five different diets: a control diet (C) and four experimental diets including a mix of algal biomass plus the macroalga *Alaria esculenta* at two inclusion levels (5% or 10%), either in raw form (groups R5 and R10) or previously hydrolyzed with cellulase (groups H5 and H10). Experimental groups were established in triplicates tanks. Samples were taken at days 45 and 99 post-treatment (dpt), and bactericidal and peroxidase activities and the levels of different antimicrobial peptides (hepcidin, lysozyme, and Nk-lysin) in the head kidney and serum were evaluated. The bactericidal activity was measured by the inhibition of the growth of a standard culture of the bacterium *Vibrio harveyi*, following the protocol described in (Chaves-Pozo et al., 2019; Sunyer et al., 1995)"ISSN":"00448486","abstract":"The shi drum (Umbrina cirrosa, peroxidase activity was analysed as an indicator of the non-specific oxidative response (Quade and Roth, 1997) and the quantification of hepcidin, NK-lysin and Lysozime (antimicrobial peptides, AMPs) was performed using an indirect enzyme-linked immunosorbent assay (ELISA) (Cervera et al., 2022).

## Results

Serum bactericidal activity showed a significant decrease in all groups at 45 dpt, as well as in the groups supplemented with raw microalgae at 99 dpt. Regarding serum peroxidase activity, a significant increase was observed in the groups fed with raw microalgae at 45 dpt, and in group H10 at 99 dpt.

Several antimicrobial peptides levels in serum were assessed; however, they remained undetectable due to being below the sensitivity threshold of the analytical method used. In contrast, we could detect them using head-kidney homogenates. Thus, at 45 dpt, a significant increase in the levels of antimicrobial peptides was observed. Specifically, elevated levels of Nk-lysin and hepcidin were detected in group H5, and increased lysozyme levels in groups R5 and H10. However, at 99 dpt no significant differences were found between groups in hepcidin levels, although significant increases in Nk-lysin were still observed in group H5, and in lysozyme in groups R10, H5, and H10.

*(Continued on next page)*

**Discussion**

The data obtained indicate that the inclusion of raw microalgae in the diet of fish induces a favourable modulation of the innate immune response. It has been reported that the dietary inclusion of crude microalgae could modulate slightly protease activity, peroxidase and antibacterial activities (Chaves-Pozo et al., 2014). This modulation is reflected in the increased serum peroxidase activity and elevated levels of antimicrobial peptides such as NK-lysin, hepcidin, and lysozyme in the head kidney tissue, especially at 45 days post-treatment. Although a reduction in serum bactericidal activity was observed during the same period, this phenomenon could be interpreted as a homeostatic response aimed at preventing inflammatory overactivation (Soliman and Barreda, 2023).

On the other hand, the elevated levels of NK-lysin and lysozyme observed up to 99 days post-treatment suggest a prolonged immunomodulatory effect of microalgae supplementation. These antimicrobial peptides are key components of the immune response in fish, responsible for the direct destruction of pathogens and the regulation of inflammation (Wang et al., 2017).

Therefore, dietary supplementation with raw microalgae in *Sparus aurata* induces significant modulation of the immune response, evidenced by sustained increases in peroxidase activity and the expression of key antimicrobial peptides (NK-lysin, hepcidin, and lysozyme). These findings suggest a prolonged immunomodulatory effect that could enhance pathogen resistance and improve the organism's immune status.

## Introduction

Nutrition during the larval stage of fish represents one of the main challenges in modern aquaculture due to the high natural mortality rates and the need for highly digestible and balanced diets. In this context, the use of microalgae as functional feed ingredients has gained increasing interest, not only because of their nutritional profile, rich in essential fatty acids, proteins, and pigments, but also due to their potential to enhance growth, survival, and the health of developing fish (Reitan et al., 1997). Various microalgae generous, such as *Nannochloropsis*, *Isochrysis*, and *Tetraselmis*, have been incorporated into experimental feed formulations, showing promising results in various marine and freshwater fish species (Ayala et al., 2020). It has been known that blending microalgae species in animal feed is worthy to provide better balanced nutrition to animals (Sarker et al., 2020), however, it is still necessary to optimize their inclusion in order to maximize the nutritional and functional benefits in fish larval diets.

## Materials and Methods

An experiment was conducted at the aquaculture facilities of the Oceanographic Center of Murcia (COMU-IEO), CSIC, with gilthead seabream (*Sparus aurata*) larvae of 0.034±0.005 mean weight grams. Larvae were randomly distributed in 15 tanks and 5 experimental groups (3 tanks/group) were performed to feed with 5 different diets. A control diet free of algae was used, along with four diets containing mixtures of microalgae (*Arthrospira*, *Chlorella*, *Desmodesmus*, *Tisochrysis*, *Nannochloropsis*, *Scenedesmus*, *Tetraselmis*), either in raw (R) or hydrolyzed (H) form, at inclusion levels of 5% and 10% (R5, R10, H5, H10). Larvae were fed ad libitum for 44 days with the aforementioned diets. Sampling was conducted at day 21 and 44 post-treatment (dpt). The fish were then fed with a commercial diet for a year, followed by an additional sampling (365 dpt). Bactericidal and peroxidase activities as well as the levels of expression of immune-related genes were evaluated in whole larvae at days 21 and 44 post-treatment and in fish serum collected at 365 dpt.

Bactericidal activity was determined by the inhibition of bacterial growth of a *Vibrio harveyi* cultures, following protocols described in (Chaves-Pozo et al., 2019; Sunyer et al., 1995)”ISSN”:”00448486”,”abstract”:”The shi drum (Umbrina cirrosa, the peroxidase activity was analysed as an indicator of the non-specific oxidative response (Quade & Roth, 1997), and immune-related gene expression by real-time PCR (qPCR) (Cervera et al., 2023) was used for characterizing the immunomodulatory role of microalgae. Statistical analyses (ANOVA, followed by Tukey’s post hoc or Student’s T tests ($P \leq 0.05$)) were performed using Statgraphics Centurion 15.2.06 version.

## Results and discussion

The results showed that supplementation with microalgae, both in its raw and hydrolyzed forms, had modulatory effects on various immunological parameters and gene expression patterns over time. Bactericidal activity decreased at 21 dpt in all experimental groups, which may reflect an attenuated initial immune response. Although peroxidase activity showed no significant differences between groups at 21 dpt, a general decrease was observed at 44 dpt, except in the H10 group, where it remained comparable to control levels. In the long term (365 dpt), it showed a significant increase, suggesting a sustained immunostimulatory effect of the hydrolyzed microalgae at this concentration.

Regarding gene expression, an early downregulation (21 dpt) of key genes related to innate immunity (*nkl* and *lyz*) and autophagy (*lamp2*) was detected, which could indicate an adaptation or initial modulation phase of the immune system. However, an up-regulation of the *hsc70* gene was observed in the R5 group, pointing to a compensatory stress. At 44 dpt, the R10 group showed an immune activation, reflected by the overexpression of *nkl, ulk1a, and cd8* genes, suggesting a reactivation of the cytotoxic immune response and autophagy mechanisms.

*(Continued on next page)*

All together, these findings indicate that the immunomodulatory effects of microalgae depend on multiple issues, the form of processing, the concentration or the duration of exposure, showing biphasic effects: an initial suppression followed by immune activation or recovery in later phases.

Age and growth of Nile tilapia, *Oreochromis niloticus* from Lake Hayq were studied from June 8, 2022 to June 7, 2023. A total of 738 otoliths were collected from the shore, open water and river mouth sites of the lake for otolith macrozone analysis. Otoliths were ground and examined under a dissecting microscope at 7–40X magnification for the presence of translucent and opaque macrozones using a reflected light source. The age of the fish was determined from the total number of translucent macrozones counted in the otoliths considering the time of translucent zone formation. The collected samples ranged from 9.3 to 32 cm in total length (TL) and from 14 to 495 g in total weight (TW). However of the fish sampled, 87.7 % were ≤ 13 cm. The maximum life span of *O. niloticus* was 6 years. A strong relationship between otolith length and otolith weight ($r^2 > 0.88$) was found in *O. niloticus*. The relationships between fish length and otolith (length) were ($r^2 > 0.92$). In *O. niloticus*, otolith weight was found to be best correlated with fish weight ($r^2 > 0.81$) and nearly the same correlation was discovered between otolith length and otolith weight. *Oreochromis niloticus* caught in Lake Hayq has asymptotic length ($L\infty = 31$ cm) and have a growth rate (k) 0.90/year, growth performance index (Ø'L =2.93 and scientific information related to growth parameters is one of the fundamental factors for population management in an aquatic area.

**Introduction**

Aquaponics, as an integrated system combining aquaculture and hydroponics, has emerged as a promising solution for sustainable food production, particul Insects provide a promising means to bioconvert organic wastes and side-streams into a protein-rich biomass. In this context, the common carp (*C. carpio*), a resilient and extensively cultivated freshwater species, can be efficiently co-cultivated with leafy vegetables such as lettuce (*L. sativa*), which is distinguished by its abbreviated growth cycle and elevated market value. In aquaponic systems, a considerable amount of solid wastes (fish sludge) is accumulated, the management of which has become a significant issue. The disposal of these water pollutants, containing high levels of nitrogen and phosphorus, poses a serious environmental challenge. Similarly, hydroponic and greenhouse cultivation generate residues in the form of leaves, stems and discarded vegetables, which are mostly wasted. Therefore, effective waste management solutions are necessary for both wastes. One potential approach to address this issue is the upcycling of these non-value organic wastes by using insects as bioconverters.

In addition, the utilization of a treated local municipal wastewater that is able to be used again as a reclaimed water and as a water source for aquaponics is a challenge that will produce fish and vegetables locally with zero environmental foodprint. It combines the circular economy approach and the nutrient recycling and water reuse. Based on the above, in the framework of the AWARE project the performance of larvae of the black solider fly, *Hermatia illucens*, fed with wheat bran-based substrates supplemented with various percentages of fish sludge and hydroponic by-products was evaluated. The aim of the present study was to investigate the growth performance of common carp (*C. carpio*) fed a diet based on conversion of fish sludge into insect meal co-cultivated with lettuce (*L. sativa*), in a laboratory scale one-loop aquaponics system using reclaimed water from the local wastewater treatment plant.

Table 1: Growth performace indicators of common carp co-cultures with lettuce.

Data were expressed as mean ± S.E.M ($n_{fish}$ = 180, $n_{plant}$= 45). Different superscript letters within rows indicate significant differences (ANOVA, $p$ >0.05).

*(Continued on next page)*

**Materials and Methods**

The experiment was conducted at the Aquaculture Laboratory of the University of Thessaly (EL-43BIO/exp-01), approved by the Ethics Committee of the Region of Thessaly (approval no. 112841/23-03-2022). Three one-loop recirculating aquaponic systems (335 L each) were used, each comprising of three fish tanks (50 L), three hydroponic subsystems for plant cultivation (50 L), and one sump filter (35 L). The aquaponics systems were divided into three treatments as follows: the control treatment, which was used 100% freshwater (W0), in contrast to the other two treatments, which were using reclaimed water as follows: 100% reclaimed water (treatment C-W100), and treatment B, which consisted of 60% reclaimed water and 40% freshwater (W60). A total number of 180 common carp (*Cyprinus carpio*), with initial weight of 2.01 ± 0.04 g and 45 lettuce plants (*Lactuca sativa*), with initial weight of 3.91 ± 0.05 g were used. The experiment lasted 75 days. During the experiment, the fish were fed *ad-libitum* by hand twice daily (09:00 and 17:00 with an experimental diet (1.2 mm) (crude protein 52%, crude fat 13.2 %, energy 6.2%). The experimental fish diet was based on insect meal that was produced by insect larvae that were grown on fish sludge and hydroponic by-products. The fish were reweighed every two weeks, while the plant height was remeasured every 10 days throughout the experiment. The fish tanks were cleaned and siphoned daily. At the end of the experiment, the fish were anaesthetize with 0.20 mg/L MS-222, and their final body weight and length were measured. Oxygen levels were maintained at 85%-90% saturation.

**Results and Discussion**

At the beginning of the experiment, there were no significant differences between the initial weight and length of the fish and the initial weight and height of the lettuce in all treatments (Table 1, $p>0.05$). The mean weight of the common carp on day 15, as well as SGR15d, showed statistically significant differences between treatments (Table 1, $p<0.05$). The maximum value was observed in the W60 treatment. The initial mean carp body length and mean carp weight at day 15 used in the present study (4.81 ± 0.03 cm) are in agreement with the results reported in Stamelos et al. al., (2024).

AWARE research project assessed the growth performance and bioconversion efficiency of larvae of the insects fed fish waste- and crop residues-based diets. Specifically, feeding substrates containing wheat bran with different percentages of aquaponic byproducts, i.e., fish faeces and hydroponic plant residues, were evaluated as feed for *H. illucens* larvae. The results showed that most diets containing aquaponic byproducts efficiently supported larval growth, indicating that insect farming could provide a sustainable solution for waste management in aquaponic systems. When fish sludge or hydroponic by-products were included in the diet at <50% rates , no significant differences were recorded compared to the wheat bran control.

## Introduction

The need for Integrated Multi-Trophic Aquaponics (IMTA) systems, especially in brackish water environments, has been highlighted by the growing demand for sustainable food production and the environmental challenges associated with intensive aquaculture. Euryhaline fish species like European seabass (*Dicentrarchus labrax*) can be co-cultivated with halophytes like rock samphire (*Crithmum maritimum*) to enhance nutrient recycling and water quality through natural biofiltration (Vlahos et al., 2023). Ammonia, the primary nitrogenous waste excreted by fish, plays a main role in system sustainability. It is influenced by nutrient inputs, salinity and feeding regimes (Stathopoulou et al., 2021). The efficient removal and conversion of ammonia through plant uptake and microbial nitrification are key components of the functionality of an aquaponic system. Previous studies have demonstrated that high fish and plant productivity can be achieved in brackish aquaponics systems, while reducing the nitrogenous waste load (Pinho et al. 2017). The aim of the present study was to investigate and evaluate the ammonia mass balance in a polyculture brackish aquaponics system produced by gilthead seabream (*Sparus aurata*) and sea bass (*D. labrax*) as an impact of daily food intake and fasting schedule conditions co-cultuvated with glasswort.

## Materials and Methods

The experiment was conducted at the Aquaculture Laboratory of the University of Thessaly (experimental unit EL-43BIO/exp-01), approved by the Ethics Committee of the Region of Thessaly (approval no. 112841/23-03-2022). The rearing system consisted of nine autonomous aquaponic recirculation systems with a total volume of 135 L; each consists of 45 L fish tanks, a 45 L hydroponic subsystem for plant culture and a 45 L sump-type filter. The water turnover rate was calculated to be four times per hour (Stathopoulou et al. 2021). In totaly, were used 90 individuals of *S. aurata* with average body weight and length of 6.33 ±0.73 g and 5.73±0.72 cm, and 90 individuals of *D. labrax* with an average body weight of 5.82±0.77 g and average body length of 6.35± 0.45 cm. The experiment lasted 75 days.

**Table 1**. Filter performance and ammonia balance in the three aquarium systems under treatment A, B, and C throughout the experimental procedure.

| | S0 | S4 | S7 |
|---|---|---|---|
| Filter efficiency (E) | $0.91\pm0.53^{a}$ | $1.08 \pm 0.49^{a}$ | $0.65\pm0.33^{a}$ |
| Ammonia oxidation rate (AAR, g/m2/day) | $0.09 \pm 0.04^{a}$ | $0.08 \pm 0.02^{a}$ | $0.06 \pm 0.02^{a}$ |
| Volumetric Ammonia Oxidation Rate (VTR, $g_{TAN}/m^3/d$) | $4.15 \pm 0.79^{a}$ | $5.43 \pm 0.47^{b}$ | $4.64 \pm 0.93^{a}$ |
| Ammonia inlet, (Q*CTANin) + PTAN | $15.51\pm1.34^{a}$ | $11.32\pm0.59^{b}$ | $12.80\pm0.16^{b}$ |
| Ammonia outlet, (Q*CTANout) + RTAN | $10.03\pm1.55^{a}$ | $19.19\pm1.09^{b}$ | $15.52\pm1.39^{b}$ |

Data were expressed as mean ± S.E.M (n = 75). Different superscript letters within rows indicate significant differences (ANOVA, p >0.05).

*(Continued on next page)*

Food intake was *at libitum* three times per day (Grigorakis & Alexis, 2005) by hand at 09:00 h, 13:00 h, and 17:00 h. with a formulated diet (1,2 mm) (crude protein 43.7 %, crude fat 15.3 %, energy 23.2 Mj/kg). The three aquaponics systems were devided into three treatments according to Ziegelbecker & Sefc (2021) as follows: daily feed intake (S0 control treatment), a 4-day deprivation (S4 treatment, 3 days feeding and 4 days starvation) and a 7-day deprivation (S7 treatment, 7 days feeding and 7 days starvation). The fish were weighed every two weeks, while the plant height was measured every 10 days throughout the experiment.The fish were reweighed every two weeks, while the plant height was remeasured every 10 days throughout the experiment. The fish tanks were cleaned and siphoned daily. Fish growth indicators were measured using the following equations: SGR (%/day)= [(ln Wfin-lnWin) /Δt]x100.Ammonia mass balance was measured from the equation (Q*CTANin) + PTAN= (Q*CTAN**N**out) + RTAN, Volumetric Ammonia Oxidation Rate from the equation: (VTR, $g_{TAN}/m^3/d$)= (TANin – TANout) * Kc * Q/V, and filter efficiency was measured according toy the equation: **E** =[1+(C*R)-C]/C*R.

**Results and Discussions**

There were no statistically significant differences in filter efficiency, ammonia oxidation rate or volumetric ammonia rate in both aquaponics treatments (ANOVA, $p>0.05$). However, total ammonia levels in the influent and effluent of the aquaponic systems showed significant differences between treatments (ANOVA, $p<0.05$), with the highest values in treatment S0 in terms of TAN in and S4 in terms of TAN out (Table 1).

The filter efficiency (E) in the experiment was 0.91 ± 0.53 in treatment S0, 1.08 ± 0.49 in S4 and 0.65 ± 0.33 in S7and is influenced by the ammonia production rate, the ammonia removal rate, fish and planta species, food composition, and rearing conditions (Pinho et al., 2017). Ammonia production rate (AAR) was 0.09 ± 0.04 mg/L for treatment S0, 0.08 ± 0.02 mg/L for treatment S4 and 0.06 ± 0.02 mg/L for treatments S7, which was higher than those reported by Vlahos et al. (2023) which was ranged from 2.79 ± 0.34 to 3.03 ± 0.45 mg/L. Our results showed a range of filter volumetric oxidation rate (VTR, g TAN/m3/d) values from 4.15 ± 0.79 g TAN/m3/d to 5.43 ± 0.47 g TAN/m3/d. The VTR values in the present experiment are in agreement with those (6.44 ± 1.69 g TAN/m3/d) reported by Vlahos et al. (2023) in a study that involved rearing *D.labrax* and cultivating *C. maritimum* in an aquaponic system with water recirculation.

## Introduction

Climate change-driven reductions in dissolved oxygen have led to widespread environmental hypoxia, a primary cause of mortality in salmonid aquaculture (Soto et al., 2019). The gills, which are essential for both gas exchange and immunity (Olaf Koppang et al., 2015. This tissue are highly responsive to low oxygen environment, wich induces oxidative strees and modulate key signaling pathways (Wang *et al.*, 2023). Therefore, understanding the immunological, metabolic, and antioxidant responses to different hypoxia regimes is crucial for optimizing the resilience of *Salmo salar* in aquaculture.

## Methodology

*Salmo salar* individuals were exposed to three conditions: (1) continuous hypoxia at 45% $O_2$ saturation (45% $DO_2$), (2) continuous hypoxia at 75% $DO_2$, and (3) cyclic hypoxia (12 h 50% $DO_2$ / 12 h normoxia). Gill samples were collected on days 1, 3, 5, and 7. We performed microarray sequencing analysis to identify differentially expressed genes in hypoxic conditions (log fold change |±2|) and qPCR analysis was conducted for genes associated with hypoxic response (HIF1α, EGLN, VEGF, EPO), immunity (TNFα, IL1β, IL8, TLR3, TLR5, TLR9, NOD1, NLRX1, NLRC3, NLRC5), and antioxidant activity (GSH-Px, SOD, GSH-Rx).

## Results

Our transcriptomic analysis revealed that the intensity and pattern of hypoxia determined distinct molecular responses in the gills of *S. salar*. At 45% $DO_2$, a sustained activation of immune and cellular stress responses was observed, characterized by early overexpression of mucin and mitochondrial proteins along with ubiquitins on day 1, followed by a progressive increase in cathelicidin from days 3 to 7. Furthermore, Myelin and lymphocyte protein (MAL) gene remained overexpressed throughout the experiment, which has been associate to epithelial remodeling.

At 75% $DO_2$, the response was faster and transient: mucin, aquaporins, and MAL were overexpressed on day 1, while cathelicidin was overexpressed on day 5, with no sustained changes thereafter. In cyclic hypoxia, the overexpression of mucin and complement component C3 genes were mainly on day 1, suggesting a damage response.

Complementary qPCR analysis confirmed these findings: at 45% $DO_2$, there was a sustained increase in *tnfα* (days 1, 5, and 7) and *phd3* (*egln*) (days 1 and 3), decreased *hif1α* (day 5), and reduced expression of antioxidant enzymes such as *gsh-rx* (day 1) and *gsh-px* (day 5), along with decreased expression in *tlr3* (day 3). At 75% $DO_2$, *hif1α* increased on days 1 and 5, accompanied by early increases in *gsh-rx* and *sod* genes, as well as *tnfα* and *il1β*, but with a marked reduction of tlr9 on all days and punctual decreases in *tlr3* and *tlr5*. In cyclic hypoxia, an initial increase in *phd3* (*egln*) (day 1) and *epo* (day 3) was observed, along with decreases in *gsh-rx* and *sod* (day 5) and *nlrc3* genes (day 7).

## Discussion and Conclusion

The combination of transcriptomic and qPCR data demonstrates that hypoxia modulates immunity, metabolism, and redox status in *S. salar* gills in a complex manner. Recent studies showed that chronic hypoxia in *S. salar* can differentially modulate the immune response in the head kidney (Rojas *et al*., 2025). The 45% $DO_2$ condition generated severe and persistent stress, activating innate immune pathways, epithelial repair mechanisms, and metabolic adjustments. At 75% $O_2$, the response was less intense and more transient, although the sustained reduction in *tlr9* gene suggests a potential vulnerability in pathogen recognition. Cyclic hypoxia induced an immediate and short-lived response, aimed at the rapid activation of physical barriers and complement, along with punctual alterations in antioxidant genes.

*(Continued on next page)*

In conclusion, these results showed that salmon adaptation to hypoxia is not uniform but depends on the intensity and pattern of exposure, involving dynamic interactions between physical barriers, innate immunity, metabolic regulation, and antioxidant systems. The identification of these pathways opens opportunities for management strategies and genetic selection to increase hypoxia tolerance and maintain immune functionality in aquaculture environments at risk of low oxygen availability.

# MINING *Lepeophtheirus salmonis* TRANSCRIPTOMES UNEARTHS KEYS TO STAGE-SPECIFIC QUNTIFICATION OF PARASITIC LARVAE

Nathan E. Mertz*, Rachel A. Paterson, Bengt Finstad, Hege Brandsegg, Frode Fossøy, and Amy Ellison

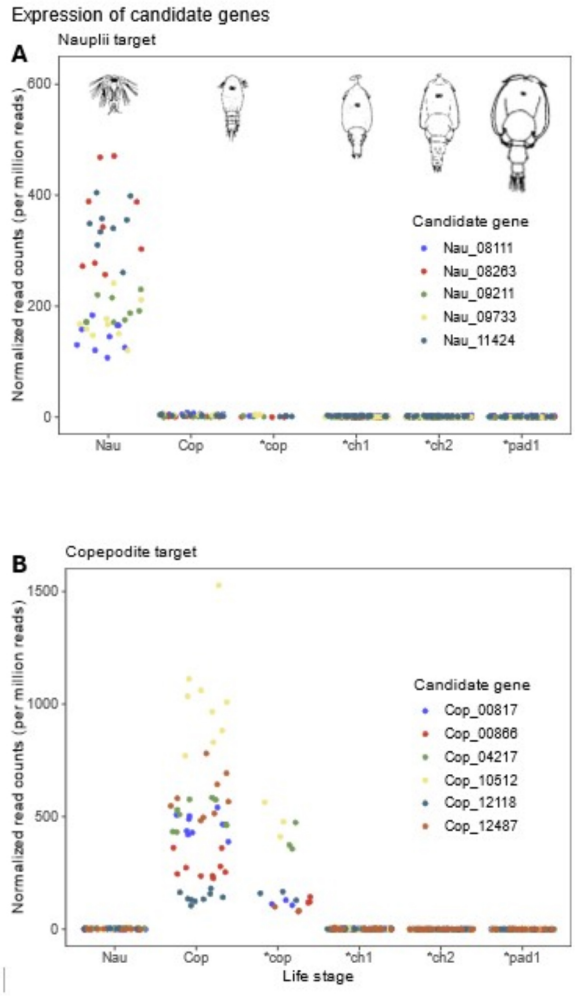
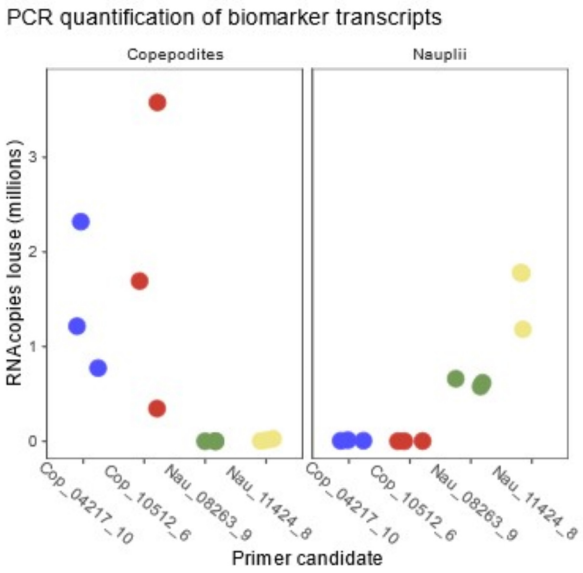
The salmon louse, *Lepeophtheirus salmonis,* is an ectoparasitic copepod which has devastating effects on both wild and farmed salmonids in the North Atlantic region. To better assess risk to wild salmonid populations there is an urgent need to individually quantify the different planktonic life stages of *L. salmonis*. Current molecular methods show great promise reliably identifying and counting *L. salmonis* individuals but are unable to discern between the infective and non-infective larval stage. In the present study, comparative transcriptomics of nauplii and copepodid larval stages was used to identify transcript candidates for stage-specific quantification of *L. salmonis* larvae. We demonstrate that approximately two thirds of *the L. salmonis* transcriptome is differentially expressed between the two planktonic life stages. We present 11 candidate quantitative PCR assays targeting RNA transcripts expressed solely in one of these two life stages, of which four were tested *in vitro*. All four candidates successfully amplified target life stage RNAs with high detection rates, of which three also showed capability as assays for separating the life stages of *L. salmonis* and measuring their densities using quantitative PCR. Applying these assays to well established eDNA collection and processing pipelines could pave the way to significantly upscale lice monitoring practices in regions with high infestation pressure or at-risk salmonid populations.



Two dot plots show normalized gene expression of the 11 candidate genes split into the nauplii(A) and copepodite(B) larval life stages of L. salmonis. Candidate genes are highly expressed in RNAseq samples containing their respective target life stage while non-target life stages have expression at or near zero for all candidate genes. The left two columns in each plot show read counts generated from the nauplii and copepodite samples in this study while the right four columns show expression values extracted from supplemental tables published by Eichner et al. (2018) for copepodite, chalimus 1 and 2, and preadult 1 stages samples. Drawings of the life stage are adapted from Schram (1993).

*(Continued on next page)*



Dot plots showing transcript quantification via ddPCR for triplicate samples of L. salmonis nauplii and copepodites in densities of 10 larval individuals. A high density of transcripts were detected by the assays for each of the target life stages. All non-target life stage samples generated transcript detections near-zero. Copepodite samples showed higher variability of stage-specific RNA abundance across the three sample replicates.

# HARNESSING CURRENTS TO QUANTIFY PARASITES: MOLECULAR ANALYSIS OF PASSIVELY COLLECTED PLANKTON PARTIALLY VALIDATES A SALMON LICE DISPERSAL MODEL

Nathan E. Mertz*, Bengt Finstad, Rolf Sivertsgård, Frode Fossøy

*Presenting author: nathan.mertz@ntnu.no
Department of Biology
Norwegian University of Science and Technology (NTNU)
7491 Trondheim, Norway

Modeling the dispersion of marine species and debris is a critical technological development that has aided fisheries management, aquaculture development, and marine conservation. In Norway, a hydrodynamic particle dispersion model (HPDM) is applied to salmon lice larvae, the planktonic life stages of the ectoparasitic copepod that infests salmonid fishes. These models produce estimated densities of infective larvae along the Norwegian coast which are used to assess risk of infestation of migrating wild salmonids and plan lice prevention strategies at salmon farms. Because the risk assessments generated by these models impact industry regulation and environmental conservation efforts, their predictions in some regions are hotly contested and the capability to provide spot verifications would be beneficial for settling disputes. Based on this need, we designed a method for passively filtering tens of thousands of liters of near-surface seawater to capture planktonic organisms for preservation and downstream analysis by ddPCR eDNA quantification. We deployed 12 of these devices in the Hardangerfjord in western Norway, where surveys of louse infestation risk have been conducted for over 20 consecutive years and the oceanographic data is collected in verification of norkyst800, one of the hydrodynamic models by which salmon louse dispersion is predicted.

Comparing the number of lice larvae we captured with modeled estimates of louse density and the number lice infesting experimental salmon smolts, we found that spatial and temporal patterns of louse distribution were fairly consistent across methods and there was a high correlation between them. Examining the differences between sites, we observed that those with a high density of farms in the vicinity had a significantly greater abundance of lice captured by passive collection than those without, particularly the one site immediately down current of an active farm. At the one site located in a National Salmon Fjord, an area closed to fish farming, both the model and passive sampler failed to predict / detect the occurrence of parasite larvae, but the experimental smolts at that site became infested with low numbers of louse during both two week cage deployments. Overall, our comparisons show that passive collection methods function effectively to generate substantiated larval lice abundances, and deploying this approach on a large scale could provide general verification of the accuracy of model estimates and also present areas where specific inaccuracies in the model need refinement.

*(Continued on next page)*

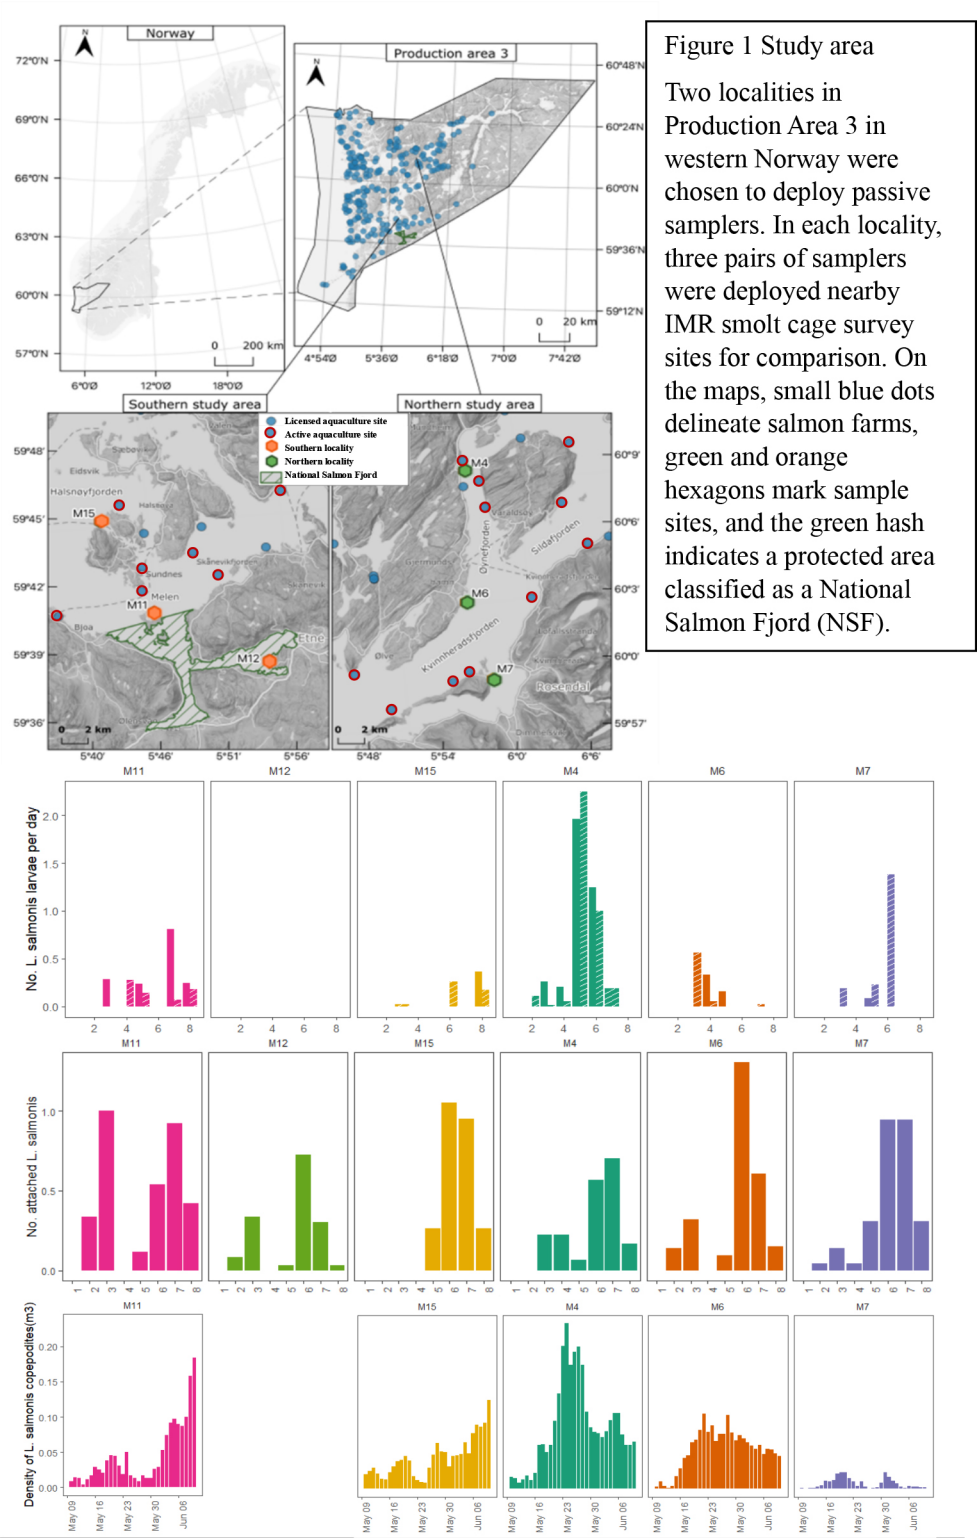


Figure 1 Study area

Two localities in Production Area 3 in western Norway were chosen to deploy passive samplers. In each locality, three pairs of samplers were deployed nearby IMR smolt cage survey sites for comparison. On the maps, small blue dots delineate salmon farms, green and orange hexagons mark sample sites, and the green hash indicates a protected area classified as a National Salmon Fjord (NSF).

Figure 2 Captured / observed / predicted salmon lice larvae from three methods

Bar graphs in the first row show the number of lice captured in each sampler during the eight collection events. Paired samplers at each site are displayed as solid vs patterned bars. Bar graphs in the second row show number of lice attached to experimental fish placed in cages in the fjord. Bar graphs in the third row show daily estimates of lice density as predicted by IMR's salmon louse HPDM. At site M12, inside the NSF, we did not capture any salmon lice and IMR's model was unable to generate louse density estimates.

# DYNAMIC OF THE GUT MICROBIOTA IN RAINBOW TROUT (*Oncorhynchus mykiss*) FED A HIGH CARBOHYDRATE-TO-PROTEIN RATIO DIET

## Introduction

Farmed carnivorous fish have traditionally required high-protein diets, primarily based on fishmeal (FM) and fish oil (FO) derived from wild marine sources. To ensure sustainable development of the aquaculture sector, alternative protein and energy sources are needed to replace FM and FO by renewable, eco-friendly and sustainable feed ingredients such as digestible carbohydrates (CHOs) (Yang, Ai, and Mai 2025). However, carnivorous fish like rainbow trout are considered as poor utilizers of dietary CHOs, often exhibiting metabolic disorders such as persistent hyperglycemia and hepatic dysfunction over 20% incorporation (Kostyniuk et al., 2019). Despite multiple hypotheses, mechanisms underlying this limited CHO utilization remain unclear (Polakof & Panserat, 2016). The intestine, as the first organ exposed to nutrients, plays a key role in mediating interactions between diet, environment, and host physiology (Polakof et al., 2010). Yet, the involvement of gut microbiota in CHO metabolism in fish remains underexplored. This study aimed to investigate the early dynamics of gut microbiota establishment in rainbow trout fed a high carbohydrate-to-protein ratio diet, to better understand carbohydrate utilization in this economically important species.

## Materials and methods

Following a 4-day feed deprivation period, juvenile rainbow trout were reared for 22 days and fed one of two isolipidic and isoenergetic experimental diets: a high-protein, no-carbohydrate diet (NC; ~60% fishmeal proteins), and a high-carbohydrate diet (HC; 30% digestible carbohydrates and ~40% proteins). Samples ($n$ = 12 per diet) were collected on days 1, 2, 3, 4, 10, 15, and 22. The midgut was opened, and digesta and mucus were separated. DNA was extracted using the QIAamp Fast DNA Stool Mini kit (Qiagen, Hilden, Germany), and the V3–V4 region of the bacterial 16S rRNA gene was amplified. PCR products were sequenced at the sequencing center (Bordeaux, France) using 300-bp paired-end reads. Sequencing data were processed using QIIME 2 (v2024.10), and outputs—including ASVs table, taxonomy, phylogenetic tree, and representative sequences—were exported to the *microeco* R and *mixOmics* R package for further analysis. Body and liver weights, along with plasma glucose concentrations (using the GOD-POD enzymatic colorimetric method), were also measured to assess whether the feeding trial successfully induced distinct nutritional responses. Intestine and hepatic genes expression and proteomics analysis were also addressed.

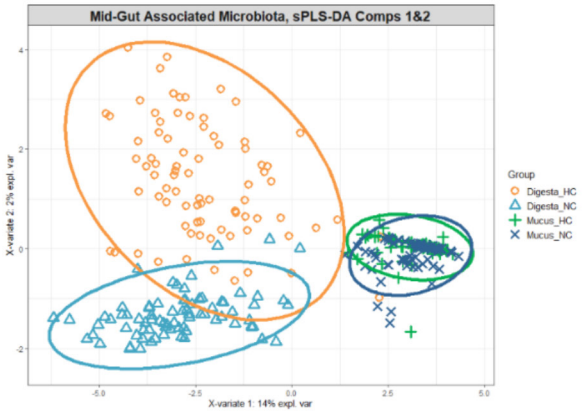

**Figure 1.** Partial Least Squares Discriminant Analysis (PLS-DA) of mid-gut microbiota profiles based on Component 1 and Component 2. Points represent individual samples from mucus- and digesta-associated microbiota under high-carbohydrate (HC) and no-carbohydrate (NC) diets.

*(Continued on next page)*

**Results**

Plasma glucose concentrations and hepatosomatic index (HSI) were significantly higher in fish fed the HC diet from day 1. In contrast, no significant differences in body weight were observed between dietary groups throughout the 22-day trial. Across all compartments, diets, and time points, the mid-gut microbiota of rainbow trout was dominated by *Bacillota* (syn. *Tenericutes*) and *Pseudomonadota* (syn. *Proteobacteria*). At genus level, *Malacoplasma* spp. (syn. *Mycoplasma* spp.) were by far the most abundant taxa, averaging approximately 96% in the mucus and 82% in the digesta. The high carbohydrate-to-protein ratio diet significantly affected beta diversity in both digesta- and mucosa-associated communities from day 3. Differential relative abundance analysis, using Random Forest and non-parametric testing, revealed that this dietary shift significantly altered the relative abundance of several genera within the *Lactobacillaceae* family, as well as *Malacoplasma* spp. In contrast, mucosa-associated communities exhibited no major taxonomic shifts suggesting that the mucosa associated microbiota is more resilient to diet changes (Figure 1).

**Conclusions**

A high dietary inclusion of carbohydrates in rainbow trout impacted the dynamics of the gut microbial community, particularly within digesta-associated microbiota when mucosa- associated microbiota is more resilient to diet changes.

## Introduction

Astaxanthin is a valuable feed ingredient in aquaculture, particularly used in salmonid diets for its pigmentation and health benefits. However, it is highly prone to oxidative degradation during feed processing and storage, leading to color loss and inferior fillet quality, requiring the use of antioxidants. Worldwide regulatory limits on synthetic antioxidants (e.g. BHT, BHA, ethoxyquin) have intensified the need for natural and sustainable alternatives in the dry mix (pre-extrusion) and/or during the fat-coating phase (post-extrusion). Olive oil production residues are rich in potent antioxidants such as polyphenols and triterpenoids. A standardized upcycled olive-pulp was evaluated as potential alternative in feed-preservation programs aimed at protecting astaxanthin and dietary lipids from oxidative degradation.

## Materials and Methods

Pilot-scale extrusion trials were conducted in a three-phase experimental design at the Danish Technological Institute (Denmark). Phase I screened a range of natural antioxidants added to the dry mix against an untreated control and astaxanthin was measured immediately after extrusion. Phase II compared a natural antioxidant program against a conventional synthetic regime. Phase III focused on optimizing the most effective antioxidant programs found in Phase I and II for both the dry mix and the fat coating phases.

All feeds were produced in a pilot-scale twin-screw extruder (Werner & Pfleiderer Continua 37; 35 mm screw diameter, L/D = 24:1, 7.5 kW motor, five-barrel sections). Individual ingredients were milled to <1 mm, weighed, and blended for 15 min in a horizontal ribbon mixer. Each antioxidant test product was hand-premixed with 200 g meal for 30 s to aid dispersion and then incorporated together with synthetic astaxanthin (Carophyll Pink 10 %; 100 mg/kg, DSM).

The mash entered the extruder without live-steam injection; moisture was adjusted by adding 15–17 % water to the feed. Barrel temperatures were set at 103–122 °C; the die-head temperature reached 106–118 °C and the pressure was 15–30 bars. Screw speed was maintained at 60–68 % of rated r.p.m., yielding a torque of 45–54 Nm and a throughput of 40–45 kg/h. Pellets were knife-cut at the die and conveyed to an electric belt dryer (Lytzen; 850 mm belt width, 2.5 m drying zone, 24 kW) operating at 95 °C with a 25 min residence time. Dried pellets were vacuum-coated with 150 g/kg fish oil; diets with a liquid antioxidant were applied via the coating oil.

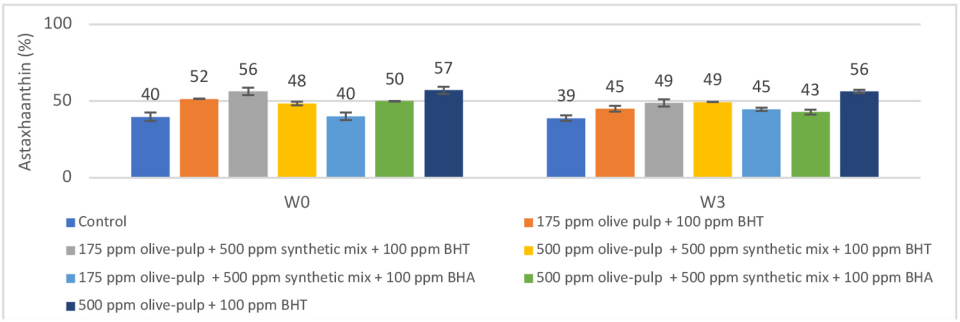

*Figure 1: Astaxanthin recovery (%) in feed after extrusion (W0) and after storage (W3) for the control and six antioxidant programs. Results are reported as mean ± standard deviation of duplicate measurements.*

*(Continued on next page)*

In phases I and II, representative samples were collected immediately after extrusion (Week 0 = W0). To simulate an industrial application program, all treatments in phase III, received 100 ppm liquid BHT or BHA (applied each as 500 ppm of a 20% concentration commercial product) in the fat coating phase. Feed samples were collected at W0 W3 upon ambient storage (20-25°C) to test mid-term stability. Selected treatments were stored up to six months (W26) to check long-term stability.

Astaxanthin concentration was determined by HPLC with photodiode-array detection at 474 nm. Primary lipid oxidation was assessed as peroxide value (ferric thiocyanate method, IDF standard) and secondary oxidation as thiobarbituric-acid-reactive substances (TBARS) expressed as mg malondialdehyde/kg feed. All analyses were performed in duplicate.

**Results**

Phase I: In the control feed with no antioxidant, astaxanthin recovery after extrusion was 51% of the formulated level, indicating a 49% loss under the current pilot extrusion conditions. Incorporation of 500 ppm of olive pulp or 500 ppm of a 30% dry tocopherol in the dry mix (i.e. a typical natural antioxidant industrial application) improved astaxanthin retention at equal levels (approx. 60%). Higher dose (1000 ppm) of olive pulp did not yield additional gains, indicating a plateau effect. No differences were observed in lipid oxidation indicators (PV, TBARS) among all treatments.

Phase II: A conventional synthetic antioxidant blend applied in both the dry mix (at 500 ppm, containing 24% BHA, 8% propyl gallate, and 8% citric acid) and the oil coating (500 ppm of the same blend in liquid form, plus 500 ppm of a mix of 10% ascorbyl palmitate and 5% tocopherols) did not offer any additional astaxanthin protection compared to that of 500 ppm olive pulp applied only in the dry mix, as they both resulted in the same astaxanthin retention improvement (approx. 10 % relative to the control feed). Again, no significant differences were found in PV or TBARS between the two treatments.

Phase III: At all time points, inclusion of 500 ppm olive pulp in the dry mix and 100 ppm liquid BHT consistently resulted in the highest astaxanthin recovery % relative to the control feed, without any further astaxanthin losses at least until W3 indicating an excellent mid-term feed stability (Fig.1; W0: 57% vs. 40%; W3: 56% vs. 39%; and, W26: 37% vs. 29% (data not shown)). Other programs containing lower olive doses (175 ppm) and liquid-BHT, or combination of olive pulp with synthetic mixes (17% BHT, 7% propyl gallate and 25% citric acid) in the dry mix and liquid-BHT or liquid-BHA in the fat coating, did not provide any additional advantage to the ‘olive pulp-based program’, retaining anything between 44–50% of astaxanthin after three weeks (Fig. 1). Peroxide values and TBARS showed no differences among treatments, with the exception of the control that’s showed slightly increased values after 3 weeks (data not shown).

**Conclusion**

A pre-extrusion dose of 500 ppm of olive-pulp as a natural antioxidant paired with a minimal (EU-compliant) level of liquid BHT in the fat coating phase, improved significantly the astaxanthin protection in extruded salmon feed. This holds great promise as our results translated to significant reduction in synthetic antioxidant usage without compromising feed stability. Additionally, by preventing astaxanthin depletion, the olive-pulp based program may also safeguard better pigment deposition in the fish itself as it may contribute to improved fillet color and lipid quality. Further testing is required to account for factors such as the diet composition (fat level, presence of blood meal or endogenous antioxidants), extrusion conditions and drying losses.

# CIRCULAR ECONOMY APPROACH IN AQUACULTURE FOR THE REALIZATION OF NEW MARINE INGREDIENTS TO SUPPORT THE GROWING REQUEST FOR MARINE FOOD PRODUCTS

Concetta Maria Messina [1,2,] Rosaria Arena[1,2], Simona Manuguerra [1], Michelle Marchant Gonzales[1], Alessandra Aiello[1], Eleonora Curcuraci[1], Andrea Santulli[1]

It is known that the blue sector, and in particular aquaculture, has a crucial role in meet the growing request for seafood and to ensure food security goals. Among the strategies, the valorization of side streams and by-products obtained during the process, for the realization of ingredients, new marine biobased food products, or to extract value added bioactive compounds, is more and more suggested to promote diversification, waste reduction and circular economy. These opportunity targets the SDGs 2030 agenda and the blue transformation strategy suggested by the FAO, that focuses on better productions to achieve a better life.

Within this strategy, the reduction of fish wastes for the production of new food, feed or ingredients, are among the proposed solution to increase the sustainability of the aquatic sector, not only from environmental, but also from economic point of view. Our research group has developed protocols, procedure and technologies that are going to be implemented within the project at regional level, thanks to the strong networking with local stakeholders. We have developed novel marine-biobased ingredients and food from side streams obtained after filleting farmed fish or in integrated multitrophic aquaculture IMTA, such as omega-3 enriched fish oils, protein hydrolizates, antioxidants from extractive species, at high Technology Readiness Level (TRL). These compounds have the potential for the development of new food, feed, pharmaceutical and cosmeceutics, up to cellular agriculture, contributing to environmental, social and economic sustainability, according to the blue transformation strategy.

# EFFICIENT HANDLING OF TURBOT UNDER INDUSTRIAL PRODUCTION CONDITIONS: HOW LONG AIR EXPOSURE TRIGGERS THE STRESS RESPONSE?

J.M. Míguez[1*], A. Verde[1], M. Chivite[1], M. Alborja-Valado[1], C. Brea[2], J. Macias-Sancho[2], O. González -Barreiro[2] and C. Ramirez-Rodriguez [1,2]

**Introduction**

Aquaculture is a booming sector due to the growing global demand for seafood. However, intensive fish production requires strictly controlled environments and practices that ensure animal welfare, as a decisive element for the growth and development of farmed fish. Animal welfare has become a key factor in the development of modern aquaculture practices. This concept establishes that animals must be free from any factors that could negatively affect them, whether physically, socially, or psychologically (EFSA, 2009). A crucial aspect of animal welfare is stress reduction. Avoiding stressful situations in aquaculture has been shown to improve fish health and survival, leading to higher farm productivity (Ashley, 2007; Toni et al., 2018). It is therefore important to analyze the stress response due to common practices in aquaculture farms, such as handling of individuals, batch sorting, inadequate stocking density, rearing, slaughter, or transport between farms, in order to improve and optimize them from a welfare perspective.

The aim of this study was to characterize the physiological response to stress caused by exposure to air in turbot, mimicking routine handling practices in land-based aquaculture farms. In addition, an attempt was made to establish a time interval, based on the duration of exposure, in which the welfare of the animals is not significantly compromised.

**Material and methods**

Turbot (*Scophthalmus maximus*, 500–600 g) were acclimated for two weeks under controlled conditions established at the land-based aquaculture farm. After the acclimatization period, groups of fish were caught with a net and exposed to air for 15 seconds, 2 minutes, or 5 minutes, after which they were returned to the water and kept under the conditions indicated above. To evaluate the stress response and its evolution over time, blood samples were obtained at 0.5, 2, 6, and 24 hours after exposure to determine plasma concentrations of stress-related hormones (cortisol and catecholamines), metabolites, and other physiological parameters. The experiments were carried out at the industrial aquaculture facility of Stolt Sea Farm (Ribeira, A Coruña) to replicate real commercial production conditions.

**Results and discussion**

The results obtained in this study suggest that the intensity of the stress response in turbot is directly proportional to the duration of air exposure, with longer exposures resulting in stronger physiological responses. Thus, brief exposure (15 seconds) did not show detectable stress responses compared with the unexposed control group, whereas prolonged exposures (2 and 5 minutes) triggered multiple physiological changes. These variations included reductions in blood gas concentrations, ion levels ($K^+$ and $HCO_3^-$), and pH, along with an increase in plasma glucose levels. These results are consistent with previous studies indicating that air exposure can induce a state of hypoxia, leading to a decrease in oxygen partial pressure and saturation, and a reduction in pH due to lactic acid production as part as a stress defense response (Cook et al., 2015). Prolonged air exposure has been shown to also decrease parameters associated with $CO_2$, likely because of increased opercular activity in response to hypoxia (Gilmour, 2001). As reported in other fish species, plasma glucose levels exhibited a significant increase within the first hours after exposure, reflecting a typical metabolic response mediated by stress hormones such as catecholamines and cortisol (Da Santa Lopes et al., 2023). This hyperglycemic response may, in turn, contribute to the reduction of plasma electrolytes, such as potassium and bicarbonate, to maintain osmotic balance.

Regarding hormonal responses, significant alterations in plasma catecholamine concentrations were only detected in fish exposed to air for 5 minutes. These changes occurred at 0.5 hours post-exposure for noradrenaline and at 6 hours in the case of adrenaline. Cortisol levels in plasma increased significantly within the first hours after prolonged air exposure (2 and 5 minutes), reflecting an activation of the neuroendocrine axis as part of the primary stress response (Pottinger, 2008). All

*(Continued on next page)*

hormonal parameters, however, returned to baseline values within six hours post-exposure, suggesting a rapid recovery to control conditions.

Overall, these findings indicate that turbots can withstand brief air exposure without triggering a significant stress response. Consequently, routine aquaculture farming practices involving short-term air exposure (≤ 1 minute) are unlikely to compromise fish welfare in this species.

# COMPARING THE SUSTAINABILITY OF TECHNOLOGICAL CONCEPTS FOR SALMON-FARMING: OPEN NET-PENS, LAND-BASED, SEMI-CLOSED AT SEA, SUBMERGED PENS

Eirik Mikkelsen*[1], Katrine Eriksen[1], Lars Olav Sparboe[2], Bård Worum[2], Sondre Vedberg[2], Frida Cnossen[2]

**Challenges with open net-pens**

The dominant technology for grow-out of Atlantic salmon has for the last fifty years been open net-pens in the ocean. This is thus by now a well-established technology. Still, there are challenges, as pointed out i.a. in the Norwegian Official Report on aquaculture from 2023 (1). This includes related to the spread of parasites and disease, escapees, and emissions of nutrients, particulate matter and hazardous substances. These in turn have negative impacts, for the welfare and mortality of the farmed fish, on biodiversity, and also on other coastal user groups like fishers and recreationists. In particular, the problems with limiting the impacts on and risks for stocks of wild salmonids have led the authorities to limit growth of the industry, and to reduce aquaculture licenses in some Norwegian regions.

**Emerging technological concepts**

To try to reduce or eliminate these problems, several alternative technological concepts are under development, testing and implementation. They include land-based farms, floating semi-closed plants, and submerged pens. Each of them brings promise of dealing with one or more of the challenges that open net pens face. However, they also come with their own challenges and risks compared to open net pens. There have been events with mass-mortality of farmed fish. The concepts require more energy for operations than open net pens. Investment and operational costs are also different, but in less clear ways, as less lice and diseases reduce costs for treatments, and improve growth and survival which have positive effects on the economic feed factor. The new concepts may reduce the original area conflicts, but can also shift these to new areas, whether to land or elsewhere in the ocean.

**Sustainability comparison**

Available information on how the concepts perform, including their impact on the environment and other dimensions of sustainability, varies from sketchy to more reliable. Aquaculture companies that consider investing in a new concept for their plants would benefit from information on different concepts' performance. This goes both for choosing between concepts that are currently available in the market or deciding whether they should wait for a concept under development to become available. The authorities also need to understand the challenges, risks and opportunities with the new technologies. Firstly, they need it to decide on new policies and regulations. Even though the Norwegian government in their recent White paper to the Parliament (2) have underscored technological neutrality for their planned reform of aquaculture policies, they still need to understand what improvements are possible with new technologies in setting targets and plans. Secondly, to decide on actual site licenses with the new technological concepts they need to consider actual negative environmental impacts and risks.

**This presentation**

This presentation has two main elements. The first is a methodological approach to compare and present the sustainability of different technological concepts for aquaculture, and the second is an actual comparison of different technological concepts for the grow-out of salmon.

*(Continued on next page)*

We have collected data and information on new technological concepts that have undergone trials, pilots or from actual operations. Although this on a basic level gives more reliable information on how the technologies will perform than for technological that are only on the drawing board, the data from trials still has to be interpreted to consider what can be the performance of the commercial version of the technology in commercial operations. The selection, development and presentation of sustainability indicators is based on the authors' previous experience with this (i.a. 3, 4). The method and graphical tools employed are relevant also for other types of aquaculture, while the actual comparison is highly relevant to the ongoing processes for development and management reform of salmon farming in Norway and also elsewhere, like in Canada.

The presentation is based on work in the CoastShift-project, financed through the Norwegian *FRAM – High North Research Centre for Climate and the Environment* (The Fram Centre) (https://framsenteret.no/english/).

# PERCEPTIONS SHAPE SOCIAL ACCEPTANCE FOR AQUACULTURE – BUT ARE PERCEPTIONS SHAPED BY REALITIES?

Eirik Mikkelsen*, Katrine Eriksen, Silje Steinsbø, Thomas Nyrud, Audun Iversen Nofima

Nofima
Muninbakken 9-11
9294 Tromsø
*Eirik.mikkelsen@nofima.no

**Social acceptance and social license to operate**

The concepts of a *social license to operate* and *social acceptance* for an industry or company and their activities have evolved both in a public context and in academic literature. Originally used within the mining industry, the concepts have also been studied within marine contexts (1), including aquaculture (e.g. 2-3). Methods have been developed to try to measure the level of social acceptance for an industry or company within local communities or for a wider population, and to understand what affects it (4-7).

Studies of mining have found empirical support for persons' perceptions on the distributional justice, procedural fairness, and confidence in governance to significantly affect their trust and their level of social acceptance for an industry or company. However, for aquaculture in Norway, these models have been found to explain the level of social acceptance to a lesser degree (8). Instead, the perceptions of the aquaculture industry's environmental sustainability were found to be the most important factor determining the social acceptance level. Yet, the perceptions on the distribution of benefits from aquaculture were found to be relatively important.

**Perceptions and realities**

It seems people's perceptions to a large degree shape their social acceptance for aquaculture. To what degree people's perceptions are shaped by actual impacts from aquaculture is however less clear. We will present data and statistics on the environmental and socio-economic impacts and conditions of aquaculture in Norway from previous studies and Norwegian datasets we have access to (9-11). This will be combined with data on perceptions and social acceptance from a national survey for Norway (12) into preliminary analyses and hypotheses of how local "realities" affect perceptions and social acceptance.

# SMALL BLUE MUSSELS FOR SUSTAINABLE PRODUCTS; ALONE AND AS A SIDE STREAM

Maya Miltell*

SUBMARINER Network for Blue Growth
Email: mmi@submariner-network.eu

**Introduction**
The Baltic MUPPETS project is an investment in a blue bioeconomy that aims to deliver economically and environmentally viable businesses with a positive socio-economic impact. The project sets out to create an entirely new value chain based on small blue mussels, enabling a new circular economy in the Baltic Sea region and supporting mussel farmers throughout Europe to develop, diversify and scale their existing businesses. Ultimately, Baltic MUPPETS aims to bend today's linear nutrient economy, by creating a profitable pet-feed market from recycled nutrients.

**Small blue mussel business cases**
Blue mussel production today is wide-spread through Europe and is mainly produced for food. They provide important ecosystem services such as nutrient recycling, habitat provision, and water quality improvement. Small mussels in the Baltic Sea are small by nature due to the low salinity and have had no commercial market but still provide these valuable ecosystem services (Holbach *et al.*, 2020; Vaher *et al.* 2024), and provide an opportunity for sustainable protein production and circular nutrients. Small mussels are also a side stream from traditional commercial food-mussel production, and valorising them provides an opportunity for stronger business models for mussel farmers also in higher salinity areas.

Projects and studies have also shown blue mussel production could be subject for carbon- and or nutrient credit schemes (BalticBlueGrowth, 2019; Lindahl *et al*., 2005; van den Burg, 2022).

**Case business models**
ECOPELAG in Sweden produces small mussels in the Baltic Sea. Their business is based on donations in exchange for delivered ecosystem services. Pet food can support a more sustainable business case. Wittrup Seafood, a commercial mussel producer in Denmark, and Kieler Meeresfarm, small-scale mussel producer in Germany, both look for market opportunities for unutilised "waste mussels".

**Products**
Poultry feed can be produced from mussels (Jönsson, 2009) including small mussels. The shells provide important calcium carbonate, and the meat contains the needed Omega-3 and amino acids (Jönsson, 2009). The project Five Tons of Green Fish by SLU showed decrease in greenhouse gas emissions by 70% of mussel meal compared to conventional fish feed.

Pet food is a higher value alternative than feed, but requires more refining in the meat and shell separation. In Baltic MUPPETS, Östersjöfabriken built up a processing facility with adapted machinery to process the smaller mussels. This resulted in the product Sjötugg, a sustainable pet snack from 100% mussel meat. The product provides a low-fat, high protein and high Omega-3 alternative, especially suitable for dogs with food sensitivities due to the novel protein source leading to low allergy or over-sensitivity risk.

The shells left over from feed production can also be valorised. Grobruket has developed a soil enhancer and fertilizer; Havsmineral and Havsnäring ("Sea Mineral and "Sea Nutrients") based on mussels and fish side-streams, showing good nutritional properties for plant germination and growth support. The mussel shells provide good liming properties due to the high calcium carbonate content.

**Introduction**

In both Scottish and Norwegian aquaculture, around one fifth of Atlantic salmon (*Salmo salar*) are lost during the seawater phase of production due to a wide range of pathogens, underscoring the need for more robust and resilient fish. One possible contributor to low robustness is suboptimal temperature during embryogenesis. In many species, including Atlantic salmon, exposure to environmental stimuli such as temperature during embryogenesis can induce long-lasting effects on physiology and metabolism, a phenomenon known as metabolic programming (Ziqiang et al., 2019). Notably, embryonic temperature in salmon is positively associated with growth rate during early development (Gorodilov, 1996).

In the COOLFISH project, we hypothesised that relatively higher embryonic temperature regimes sometimes used in salmon aquaculture may lead to biased resource allocation towards growth, with negative effects on immune system development. In support of this hypothesis, a recent study demonstrated embryonic temperature-dependent differences in Atlantic salmon mortality following *Y. ruckeri* exposure at the alevin stage, indicative of higher robustness at 4 °C than 8 °C (Malik et al., 2025). Currently, it remains unclear whether the impact of embryonic temperature on fish robustness is maintained until later life stages due to long-term changes in immune function. In this study, we investigate how changing temperature solely from fertilisation to the eyed stage of Atlantic salmon embryogenesis influences the functional immune response to *Yersinia ruckeri* infection using head kidney (i.e., primary immune tissue) samples at the parr stage using a transcriptomic approach.

**Methods**

Atlantic salmon embryos were reared under three temperature regimes (4 °C, 6 °C, and 8 °C) from fertilisation to the eyed stage, after which all groups were maintained at 8 °C until start-feeding, followed by 10 °C until sampling (Figure 1A). Approximately nine months after the end of the embryonic temperature treatment, head kidney tissue was sampled from 120 parr-stage salmon ($n$ = 4 per treatment group, for both control and *Yersinia ruckeri*-infected fish) across five timepoints (T): T1 (24 h), T2 (48 h), T3 (72 h), T4 (1 week), and T5 (2 weeks) post-infection (Figure 1A). Total RNA was extracted using a Promega Maxwell instrument before its purity and integrity was confirmed. mRNA-seq libraries were produced and sequenced on an Illumina platform by Novogene. Alignment and quantification of reads was carried out through the NF-core RNA-seq pipeline (v3.14) using STAR and RSEM respectively. Using edgeR (v4.4.2) a generalised linear model was constructed to assess differences in infection dynamics across temperature groups, track the immune response over time, and explore interactions between these factors. Additionally, self-organising map (SOM) clustering was applied to identify key gene clusters responsive to infection and temperature. Differential expression tests were conducted for all pairwise temperature comparisons (4 °C vs. 6 °C, 4 °C vs. 8 °C, and 6 °C vs. 8 °C), across all timepoints, with Gene Ontology (GO) enrichment analysis used to interpret the biological functions of significantly differentially expressed genes.

**Results and Discussion**

Pairwise differential gene expression analysis of head kidney control samples (n=20 per temperature group, drawn from T1-T5 control samples) revealed 2,067 genes to be constitutively differentially expressed between temperature groups ($p$-adj < 0.05, logFC>0.5) (Fig. 1.B). The 8 °C group was a clear outlier, showing a much higher number of differentially expressed genes compared to both the 6 °C (466 genes) and 4 °C (2033 genes) groups. In contrast, the 4 °C and 6 °C groups were more similar, with only 60 differentially expressed genes. Cumulative mortality over the course of the *Yersinia ruckeri* challenge differed by embryonic temperature group, with the 4 °C group showing the lowest mortality (~22%), followed by the 6 °C (~31%) and 8 °C (~35%) groups. 3,935 genes were differentially expressed in the head kidney in response to *Yersinia ruckeri* infection across

*(Continued on next page)*

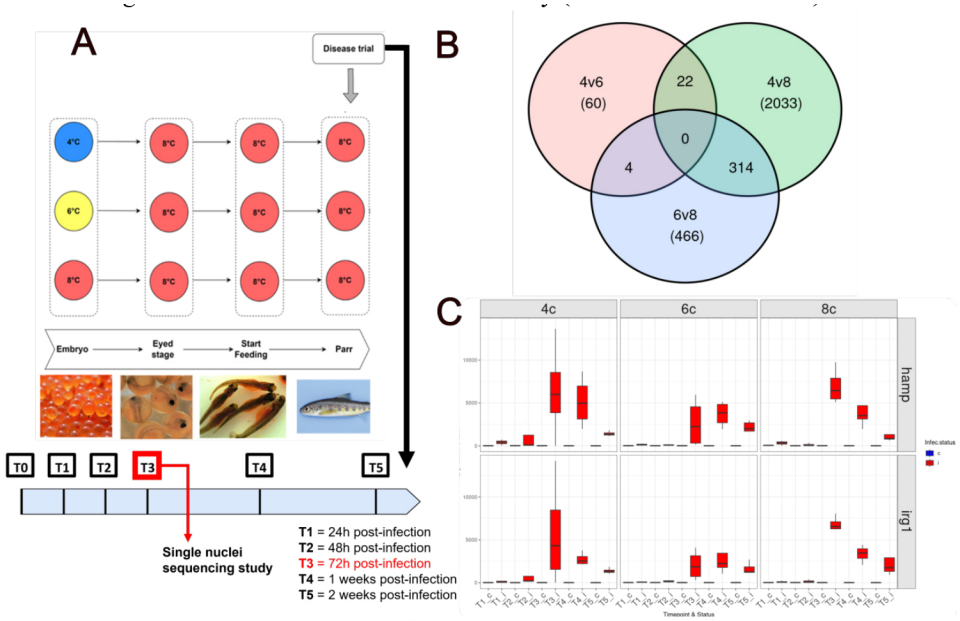

**Figure 1: (A)** Experimental design. (**B**) Venn diagram of differentially expressed genes between temperature groups for n=20 control samples each. (**C**) Boxplots of candidate immune genes showing response kinetics across the infection timecourse.

all timepoints and temperature groups (*p*-adj <0.01, logFC >1). Of these, 2,475 genes displayed temperature group specific expression patterns. Temporal profiling of key immune marker genes revealed T3 to be when the peak inflammatory response occurred in all temperature groups (Figure 1C). However earlier upregulation of numerous immune genes was observed in the 4 °C group, suggesting a more rapid immune activation. This pattern was further supported by enrichment of immune-related GO terms specific to early timepoints (T1 and T2) in the 4 °C group.

Biological interpretation of differential gene expression among temperature groups is ongoing. However, our findings provide clear initial evidence that embryonic temperature exerts long-lasting effects on head kidney gene expression, persisting to the parr stage and shaping the host immune response to bacterial infection. We have also generated head kidney single-nucleus RNA-seq data from timepoint three to gain insights into the cell-type specific nature of these temperature-induced effects during the peak inflammatory response.

## Introduction

Fatty acid composition and lipid contents are a key nutritional and ecological indicator in fish with higher metabolism and widely migratory fish, such as bluefin tuna (*Thunnus thynnus*). The distribution of these lipids is not homogeneous in all the muscles (Nakamura *et al.* 2007). In this study, we assess the quality of Atlantic bluefin tuna muscle by analysing five anatomically distinct muscle tissues, selected to capture potential variability in lipid content and fatty acid composition across the body. Assessing the biochemical composition of these cultured individuals is essential to determine the quality of the product being obtained and to guide future improvements in farming practices.

## Material and methods

Cultured juveniles came from fertilized eggs obtained from commercial tuna floating cages belonging to Ricardo Fuentes Group and placed in San Pedro del Pinatar (Spain) in mid-July 2020. Eggs were hatched and cultured in ICTS-ICAR (Infrastructure for Atlantic Bluefin Tuna Aquaculture, www.icar.ieo.es) facilities, moved to ICRA (Infrastructure for Controlling Bluefin Tuna Reproduction) when became fingerlings, and fed on dry pellets until they reached an average weight of ~100 g. Then diet was change to bait consisting in sardinella (*Sardinella aurita*), European anchovy (*Engraulis encrasicolus*), and Atlantic mackerel (*Scomber colias*). Cultured fish included in the study were individuals that died accidentally due to collisions between November and December, with a mean body weight of 431.1± 170.5 g. Wild specimens were captured in the Bay of Mazarron (SE Spain) by trolling in late September, with a mean body weight of 422.4±70.5 g. Samples were collected from neck muscle (NM), anterior dorsal muscle (ADM), anterior ventral muscle (AVM), posterior dorsal muscle (PDM) and posterior ventral muscle (PVM), and analized to determine lipid content and fatty acids. The data were arc-sin transformed before Kruskal-Wallis tests followed by Bonferroni-corrected post hoc comparisons. Correlation between body weight and lipid components was assessed using Spearman's rank correlation.

## Results

There is a significant positive relationship between weight and lipid percentage in farmed animals ($P = 0.007$), especially in certain muscles such as NM (Table 1). In wild animals, no significant relationship was found between weight and lipid percentage ($P = 0.283$). The percentage of lipids is significantly higher in cultured juveniles in all muscles, especially significant in AVMs (13.5%). The total MUFA is significantly higher in the culture group especially due to the high oleic acid content (20.3%). Both n-3 PUFAs and total PUFAs are significantly higher in wild tunas in the five muscles analyzed, as well as the percentage of DHA. Within the cultured group, the highest PUFA values are found in the two dorsal muscles, although without significant differences. In wild animals, ADM is the one with the highest percentage of PUFAs, with significant differences in most of these fatty acids between the different muscles. The n-3/n-6 and DHA/EPA ratio was significantly lower in farmed fish ($P < 0.001$).

## Conclusions

There is a significant positive relationship between weight and lipid percentage in farmed animals in contrast to wild animals. This pattern could be influenced by factors such as the differentiated metabolic activity between farmed and wild animals. Full-cycle tuna culture produces fish with higher fat content than wild tuna, especially in the ventral muscles, but with a lower percentage of PUFAs in all muscles. Similar results were observed in studies of *Thunnus thynnus* (Miras *et al*. 2024) and *Thunnus orientalis* (Nakamura *et al.* 2007), indicating that the fat composition of the feed was not directly reflected in the muscles of farmed tuna, suggesting proper lipid metabolism. As *Nakamura et al.* (2007) suggested the composition of fatty acids may not depend directly on the food, as factors such as lack of physical exercise or excess energy could be an explanation and further studies should be conducted.

# EFFECT OF PHOTOPERIOD ON BLUEFIN TUNA (*Thunnus thynnus*) LARVAL REARING

A. Miras*, M.J. Arenas, A. Ortega, P. Baixauli & F. de la Gándara

Instituto Español de Oceanografía IEO-CSIC) Planta de Cultivos Marinos
arretera de la Azohía s/n

email: amanda.miras@ieo.csic.es

## Introduction

In the production of juvenile bluefin tuna, larval rearing is one of the critical stages. Several studies have been carried out to improve growth and survival at this stage. Photoperiod is one of the most important conditions affecting survival and growth in larval rearing. In the case of bluefin tuna this factor is still more important. In a previous study, Ortega *et al.,* (2014) observed that it seems that long photoperiod lead to a greater mortality and short photoperiod led to a smaller growth. This study tries to increase the knowledge of the effect of the photoperiod on bluefin tuna larval rearing.

## Materials and methods

Fertilized bluefin tuna eggs, coming from broodstock in floating net cages owned by Ricardo Fuentes e Hijos, off the Cartagena coast (El Gorguel SE Spain) were transported to the Spanish Institute of Oceanography (IEO) Planta Experimental de Cultivos Marinos (Puerto de Mazarrón, Murcia, Spain). After cleaning and counting the just collected eggs (145,000 buoyant eggs) were separated and directly inoculated in larval rearing tanks. Initial density was 10 eggs/l. The trial was carried out in 12 1200 l cylindrical tanks in four replicates. Three different photoperiod conditions (12hL:12hD, 16hL:8hD, 24hL:0hD) were assayed. The light intensity was about 800 luxes and temperature ranged between 22.0 and 23.5ºC. The renewal rate was 100 %/day of filtered sea water (37ppt salinity). Tanks had water and air bottom inlet, and water outlet from surface. Surface cleaners were used from 3dph. Aeration was increased during the night in order to avoid sinking of the larvae. Feeding during all the period was rotifer enriched with Algamac 3050 (Bio-Marine Inc) and Origreen (Skretting) completed to 10 rot/ml. every day during photophase, but trying to eliminate the unenriched rotifers during the night time. Phytoplankton (Tiso) was also added to the tank twice per day. A sample of 20 larvae were measured at 3, 6, 10 14 and 17dph. At the end of the experiment (17dph) all the survival larvae were counted.

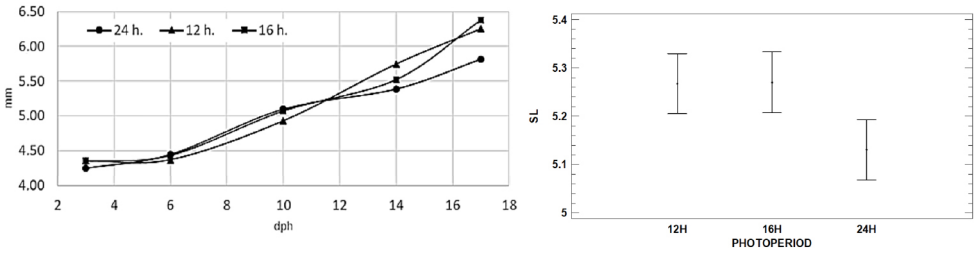

Figure 1. Effect of photoperiod on bluefin tuna larvae growth; left: larval growth (SL mm) in different photoperiods; right: ANOVA between SL and different photoperiods with Least Significant Difference (LSD) intervals, for all the experiment.

| Photoperiod | Survival rate% |
|---|---|
| 12hL:12hD | 7.70±2.30 (a) |
| 16hL: 8hD | 2.68±1.79 |
| 24hL: 0hD | 3.38±2.15 |

*(Continued on next page)*

**Results**

With regard to growth rate, results obtained at 17dph with 12hL and 16hL were similar and significant better ($p<00.1$) that those obtained with 24hL photoperiod (Figure 1).

Results on survival (%±SD) in photoperiod experiment are summarized in the table. In order to normalize the data, survival rate have been transformed according to arch sin function. Letter points significant differences ($p<00.1$)

**Discussion and conclusion**

Results of this study show that 24hL lead to a low survival rate and smaller growth. These results are partially in line with those obtained previously by Ortega *el al.,* (2014) in which 24hL lead to a low survival rate but a greatest growth. In a similar study, Kumon *el al.*, (2018) noted that survival of Pacific bluefin tuna larvae (*Thunnus orientalis*) under 24hL was significantly higher than 14hL, while there was no significant difference in growth between different used photoperiods (14hL and 24hL). In a similar work but on *Thunnus albacares* larvae, Partridge *et al.,* (2011) found that larvae cultured under the 24hL were significantly larger and exhibited more advanced development than those reared under the 12hL photoperiod, suggesting that the improved survival and growth achieved under a continuous photoperiod is due to the extended foraging time combined with the prevention of mortality caused by night-time sinking. The reasons for these different results are unclear. In the previous study with this species, the low survival rate of fast-growing larvae could be related to size-dependent mortality. A short photoperiod leads to slower growth, and the larvae did not experience the second mortality peak, related to notochord flexion and the onset of metamorphosis. However, extending the rotifer feeding period from 13 to 17dph, as occurred in this trial, could induce selective mortality in the larger larvae exposed to long photoperiod, which could partially explain the results obtained in the present experiments. Therefore, further studies are needed to clarify this contradiction and determine the effect of photoperiod on the growth and survival of bluefin tuna larvae.

## Introduction

Anthropogenic chemical pollution has the potential to pose one of the largest environmental threats to humanity, but global understanding of the issue remains fragmented. Water pollution becomes alarming since anthropogenic activity results in the contamination of water bodies with various contaminants, which in turn reduces ecosystem functioning and poses human health risks. Pesticides and pharmaceutical and personal care products (PPCPs) stand out for their widespread occurrence and highly diverse biological effects and are considered as emerging contaminants (ECs). Pesticides can enter adjacent water bodies through different ways and their residues may be overtaken by non-target organisms, leading to chronic lethal and sublethal effects. In the European Union, herbicide terbuthylazine (TBA), a member of the chloro-s-triazine group, has emerged as one of the most frequently detected herbicides in water bodies. Triclosan (TCS), is one of the most widely used antimicrobial agents in both pharmaceuticals and personal care products, and it is a frequently detected emerging organic contaminant in the environment. Despite frequent detection in surface waters, the mixture effects of these emerging contaminants on the aquatic organisms remain unclear. To address the knowledge gap of the effects of emerging contaminants and their mixtures, we aimed to test mixed exposures of frequently detected pesticide Terbuthylazine (TBA) and antimicrobial Triclosan (TCS) to duckweed *Lemna minor*.

## Methods and materials

Experiments with *L. minor* were conducted in the controlled environment growth chambers. Duckweeds were exposed to 6 different Triclosan (TCS) and Terbuthylazine (TBA) concentrations (range from 1 to 200 $\mu$g $L^{-1}$). TCS and TBA were exposed to *L.minor* in glass jars (450 ml), at 5 replicates in a 200 ml Steinberg growth medium (pH 5.5 ± 0.20). Single TCS and TBA as well as their mixture (TCS+TBA) toxicity experiments following 10 days exposure were conducted according to standardized OECD protocol No. 221 (OECD 2006). Mixture of TCS and TBA were formed based on effective concentration ($EC_{50}$) values from single chemical toxicity, where selected TU (toxic units) (0.25 – 2 TU) were used in a mixture. After 10 days of exposure *L.minor* growth parameters (total frond area (FA) and oxidative stress parameters (lipid peroxidation (MDA)) were evaluated.

## Results

Results showed that single exposure to triclosan (TCS) and terbuthylazine (TBA) inhibited *L. minor* growth. Strong negative correlation was detected ($r = -0.73 – -0.84$, $p < 0.05$) between concentration of both tested chemicals and *L. minor* frond area. Triclosan was a little bit more toxic to duckweed growth as effective concentration of TCS was slightly lower in comparison to TBA (observed $EC_{50}$ were 34.99 $\mu$g $L^{-1}$ and 39.11 $\mu$g $L^{-1}$, respectively). Similalrly to a single exposure of TCS and TBA, it was discovered that with increasing contaminant concentration of mixture (toxic unit, TU), the growth of *L. minor* had tendency to decrease ($r = -0.92$, $p < 0.05$). Observed $EC_{50}$ of a mixture (TBA+TCS) was 37.34 $\mu$g $L^{-1}$. In our experiment it was found that mixture of chemicals under was sligltly antagosnistic as predicted $EC_{50}$ of mixture was predicted to be 36.98 $\mu$g $L^{-1}$, and observed was slightly higher (37.34 $\mu$g $L^{-1}$).

## Conclusions

Duckweed Lemna minor growth was inhibited by single and combined exposure to triclosan and terbuthylazine. The toxicity of chemicals in the mixture did not differ significantly, although it was slightly antagonistic.

# OPTIMIZING STOCKING DENSITY AND SEMI-MOVABLE PADDLEWHEEL AERATION FOR ENHANCED PERFORMANCE AND PROFITABILITY 0F NILE TILAPIA (*Oreochromis niloticus*) IN CONCRETE POND CULTURE

Radi Mohammed*, Mohamed El-Rewiny, Ashraf Elhetawy, Attia Abou Zaid, Wasseem Emam, Mohamed Abdel-Rahim

*Department of Aquaculture
Faculty of Aquatic and Fisheries Sciences
Kafrelsheikh University
Egypt
r.mohamed.vet@gmail.com

This study examined the effects of stocking density on water quality, growth performance, and economic viability in Nile tilapia (*Oreochromis niloticus*) cultured in concrete ponds aerated using a semi-movable paddlewheel aeration system. Three stocking densities (80, 120, and 160 fish/$m^3$), representing the experimental groups were evaluated over a 90-day production cycle. Results confirmed that while higher densities significantly increased total biomass, they adversely affected dissolved oxygen levels, ammonia accumulation, survival, and growth performance. In particular, the highest density group (160 fish/$m^3$) exhibited elevated unionized ammonia concentrations, lower survival, and reduced final body weight, despite generating the highest gross profit. Conversely, the 120 fish/$m^3$ treatment achieved an optimal balance between growth performance, size uniformity, survival, and economic return, with a benefit–cost ratio. Increased density was associated with impaired water quality, reduced survival rates, and a shift toward smaller size classes. Although the semi-movable paddlewheel system improved oxygen distribution and waste dispersion, its capacity was limited under high-density conditions. These findings underscore the importance of aligning stocking density with aeration design and support the use of moderate density (120 fish/$m^3$) and adaptive aeration as critical components for achieving sustainable intensification in concrete-based tilapia production systems.

# COMPARISON OF WATER SOURCE EFFECTS IN AQUAPONICS: TAP WATER AND RECLAIMED WATER FROM URBAN WASTEWATER TREATMENT PLANT

**Introduction**

Aquaponics is a non-traditional approach to producing both fish and crops, integrating aquaculture with hydroponic systems. It can be implemented in areas with rocky, saline, or non-arable soils, without the need for fertilizers or chemical pesticides. This method helps to reduce land use and degradation, eases pressure on water supplies, and lowers the environmental footprint of agriculture [1].

Urban wastewater is increasingly being utilized in agriculture due to growing water scarcity and stress, alongside rising populations, greater volumes of wastewater, and pollution incidents. Urban environments should explore new opportunities for repurposing wastewater, channeling more of it inland for productive uses—not just in agriculture, but also in aquaculture and aquaponics [2,3]. For instance, reclaimed water can lessen aquaculture's dependence on freshwater sources, enabling it to be located near urban wastewater treatment facilities. This would reduce production costs and provide communities with fresh, protein-rich food [4]. However, limited public acceptance and the absence of clear regulations remain major challenges [5].

The main objective of this work is to demonstrate (i) the efficiency of the advance tertiary wastewater treatment to produce acceptable water quality for aquaponics reuse; and (i) thatthe yields of plant and fish in tap water-fed aquaponic systems are comparable to those obtained with reclaimed water from urban wastewater treatment plants. Within the framework of the project Aquaponics from WAstewater REclamation (AWARE) project, GA No. 101084245, a small-scale experimental aquaponic system has been integrated with a pilot urban wastewater treatment facility at URJC in Madrid, Spain. Wastewater undergoes advanced tertiary treatment specifically adapted to feed the aquaponic system, which is used to grow lettuce and tilapia. The water quality of the aquaponic farm using reclaimed urban wastewater has been assessed.

**Materials and Methods**

An advanced tertiary water treatment process was applied to further purify the effluent from a wastewater treatment plant (WWTP). This treatment system included sequential modules of Ultrafiltration (UF), electrooxidation (EO), and UVC-LED irradiation, using a total of 60 UVC-LEDs. The UF membrane, made of $Al_2O_3$, had a pore size of 100 nm and dimensions of 0.23 m² by 1.2 m. In the EO module, the anode was composed of titanium with mixed metal oxides (Ti/MMO), while the cathode was titanium. Operating parameters included a surface area of 270 cm², a current of 5.2 A, voltage between 10–15 V, and energy input of 78.85 J. The UVC-LEDs emitted radiation within a 268–280 nm range, peaking at 275 nm, with a total energy output of 102.99 J. The system operated at a flow rate of 200 L/h.

The study involved a 1 m³ aquaponic system using reclaimed urban wastewater, stocked with 50 Nile tilapia (*Oreochromis niloticus L.*) at a biomass density of 5.7 kg per system, and 72 lettuce plants (*Lactuca sativa*, Batavian Red variety), cultivated across 22 five-week crop cycles. The experiment was carried out over 19 weeks in a small-scale, closed-loop, recirculating aquaculture system (RAS). A control setup using dechlorinated tap water served as the baseline for comparison.

The measurements analyzed involved physico-chemical such as nitrogen and phosphorus species, organic carbon, turbidity, total suspended solids (TSS) apart from temperature, oxygen, electrical conductivity, pH. Microbiological parameters were quantified by serial dilution and plate count method and plate count not only in water, but also in lettuce and fish.

**Results**

Compounds which are toxic to fish in aquaponics are nitrite ($NO_2^-$) and ammonia ($NH_4^+$). During the aquaponic cycle with reclaimed water, levels below the toxicity threshold were achieved. The difference between both cycles was significant in terms of some nutrients such as total phosphorus, reaching over 5 ppm in the reclaimed water source, compared to levels below 0.5 ppm in the tap water source. This is probably because reclaimed water contains more nutrients than dechlorinated tap water. Since nutrients are beneficial to the hydroponic system, this increase may increase the produce yields.

Regarding parameters related to organic matter, similar values have been observed in terms of Chemical Oxygen Demand (COD) (10–40 ppm mg $O_2$/L) and turbidity (<0.5 NTU) in both cycles.

Regarding bacterial load in water within the aquaponic system, total aerobic bacterial growth was slightly higher in the reclaimed water cycle, as this type of water initially contained a certain microbial load. However, levels gradually stabilized over time, reaching values comparable to those observed in the tap water production cycle. This is a highly positive indicator of the water quality within the system. Notably, no significant pathogens such as *Escherichia coli* ,*Salmonella* , *Clostridium perfringens*, MS2 coliphage, Enterococcus were detected in any of the water sources. On the other hand, during the first weeks of the cycle, reclaimed water has fewer coliform bacteria compared to the aquaponic cycle with tap water. However, over the weeks, coliform levels in both cycles become similar.

**Conclusions**

The physicochemical and microbiological parameters analyzed do not indicate that feeding reclaimed water into an aquaponic system affects the yields of plants and fish within the system. Key parameters related to organic matter suggest that organic content in the medium is limited, thus not depleting the available dissolved oxygen and preventing the proliferation of anaerobic bacteria that produce undesirable compounds such as hydrogen sulfide, methane, or ammonia. It has been demonstrated that the introduction of reclaimed water into an aquaponic system does not result in an increase in bacterial load, nor is this reflected in the bacterial populations found in the animal and plant species within the system. No significant pathogenic species, as previously mentioned, were detected. Meanwhile, levels of aerobic bacteria and coliform bacteria were found to be comparable across both water sources.

## Introduction

Stress in aquaculture animals increases their susceptibility to infections. One of the most concerning pathogens is *Vibrio vulnificus*, a zoonotic aquatic bacterium whose distribution is expanding due to global warming. It causes warm-water vibriosis in fish, with haemorrhagic septicaemia as its most severe form. Its virulence is linked to the pVir plasmid, which harbours genes like *fpcrp* and *ftbp*, essentials for evading the fish's innate immune system and forming a "blood survival kit"[1]. Recent studies demonstrated that farming conditions have driven the evolution of this pathogen. Therefore, the development of sustainable preventive strategies is urgently need. These strategies could act as bottleneck against the horizontal transfer of adaptation genes, thereby limiting the emergence of more resistant strains and contributing to improve environmental, animal, and human health. This study is part of a project whose main goal is to propose a preventive protocol based on two pillars: functional feeding and vaccination (unpublished results). Specifically, this study focuses on developing a phytobiotic-supplemented diet with stimulatory and protective effects for eels (*Anguilla anguilla*) against vibriosis caused by *V. vulnificus* pv. *piscis*.

## Materials and methods

Phytobiotics and functional feeds. The activity of a series of phytobiotics against *V. vulnificus* strains was determined by calculating the minimum bactericidal concentration (MBC). Functional diets (A and B), including most the most active products (0.9 g phytobiotic/kg feed), were prepared. The best candidate (based on their immunostimulatory effect) was used to prepare a more concentrated feed (1.8 g phytobiotic/kg feed).

Feeding trials. In the stage 1, after 3-weeks acclimation period with the control diet, eels were feed control or A or B functional diets for 4 or 5 weeks. In stage 2, eels were fed the control diet during an acclimation period of 3 (trial 1) or 4 weeks (trial 2). Thereafter, each group was subdivided into 3 subgroups and fed daily the control or functional diets selected in stage 1 for five weeks. The feeding rate was 2% in all assays.

Blood sampling. Blood samples were collected before and after 4 and 5 weeks to obtain plasma.

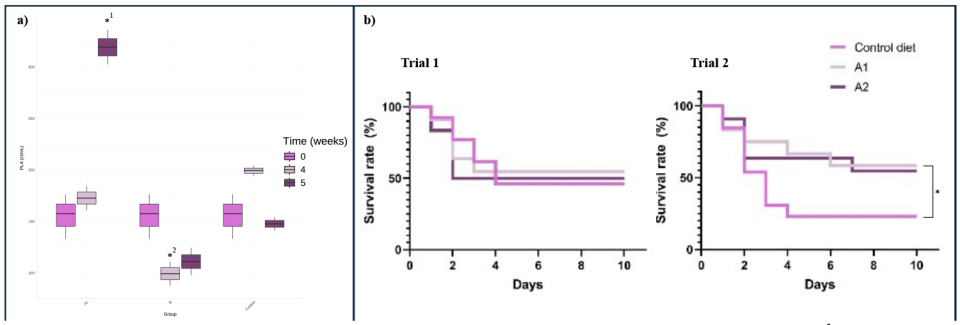

*Figure 1. a) Plasma lysozyme activity of eels fed control or functional diets. *[1]. Significant differences with the other groups and the pre-feeding values. *[2]. Significant differences with the other groups except for the group fed A1 diet for 4 weeks. b) Eels' survival after challenge with Vibrio vulnificus* pv. *piscis. *Significant differences (p-value<0.1).*

*(Continued on next page)*

Plasma lysozyme activity (PLA). This activity was assessed using a microplate turbidimetric assay. A *Micrococcus lysodeikticus* suspension was mixed with plasma samples (1:10), and absorbance at 450 nm was measured at 0 and after 20 min at 28 °C. PLA (U/mL) was calculated from a standard curve using egg white lysozyme.

Challenges. Infection challenges with *V. vulnificus* CECT4999 strain were conducted after the feeding period by prolonged immersion (1 hour), using the previously estimated infection dose. The protective effect conferred was calculated using the Relative Percentage of Survival (RPS).

Statistics. PLA values were statistically analysed using two-way ANOVA tests and Tuckey's post hoc test with Bonferroni correction ($p<0.05$). Eel survivals were statistically analysed using Kaplan-Meier approach and log-rank test as post hoc analyses ($p < 0.1$).

**Results**

All phytobiotics showed high bactericidal activity against *V. vulnificus*, regardless of the strain (113–173 ppm). UV-1 and UV-9 were selected for the formulation of functional diets (A and B) based on their efficacy and cost-related composition. PLA activity significantly increased in the plasma of eels fed A diet for five weeks (319.2 ± 23.6 U/mL). Based on these results, the A diet — and thus the phytobiotic UV-1 — was selected to assess protection against vibriosis at two concentrations (0.9 g/kg feed and 1.8g/kg feed, A1 and A2 diets respectively). In infection trial 1 (3 weeks of acclimation), eels fed functional diets for five weeks showed a slight reduction in mortality compared to controls, with RPS values of 15.58% (A1) and 7% (A2). Conversely, trial 2 (4 weeks of acclimation) showed a much stronger protective effect, with RPS values of 46% (A1) and 41% (A2).

**Discussion and conclusion**

The rise in vibriosis outbreaks in aquaculture has motivated the implementation of effective control protocols as a priority. This work is part of an ambitious project aim at proposing a protocol that not only prevents the transmission of vibriosis caused by *V. vulnificus* but also limits the spread of virulence genes responsible for the resistance to the fish's innate immune system. In this study, we evaluated the best phytobiotic to protect eels. UV-1 emerged as a promising candidate for functional diets, provided the eels are adequately acclimated. Furthermore, its broad-spectrum potential is further supported by previous evidence of its efficacy against *Vibrio. parahaemolyticus* infections in shrimp[2]and at the same time minimizing antibiotics treatments, is the major challenge in shrimp aquaculture. A sustainable strategy could be to include immunostimulants in diet. Phytobiotics, harmless plant extracts with immunostimulatory and biocidal activities, are promising candidates. In this study, we evaluated the effectiveness of two diets (E and F. Based on our results, we propose the following preventive protocol: upon arrival at the farms, eels are acclimated in tanks. Subsequently, vaccination is carried out at the glass eel stage and includes: the vaccination with Vulnivaccine via immersion and boosters with the Fpcrp-Ftbp subunit vaccine (unpublished results) during the fattening period, administered via nanoparticles-enriched feed (a) or immersion (b). Moreover, under stress conditions eels could receive a UV-1-supplemented diet for 5 weeks to enhance their resistance to vibriosis. Routine vaccination resumes once welfare normalises.

**Introduction**

In 2022, an estimated 1.05 billion tonnes of food were wasted globally, with fruits and vegetables being the most misused types (UNEP, 2024). Therefore, the recovery and valorisation of bioactive substances from those low value biomass and by-products is a challenging and important task. Not only land-based by-products have potential, since marine by-products have evolved over time from being considered as a secondary material to an opportunity for value-added products. Those bioactives have potential for boosting fish mucosal health and endogenous antioxidant capacity, and specifically proactively reinforcing the health status implied in the defence against pathogen and environmental challenges during developmental stages, such as post-larvae stages. To assess the potential of these eco-innovative functional by-products and value-added bioactives as fish health boosters, it is essential to previously characterize and evaluate their potential antioxidant/immunomodulatory activity.

Thus, the objective of this study was to evaluate, through sequential *in vitro* and *in vivo* experiments, the antioxidant and immunomodulatory activities of terrestrial and marine by-product extracts in gilthead seabream (*Sparus aurata*) post-larvae.

**Material and Methods**

Nine extracts from by-products and low value biomass were tested, 4 of terrestrial origin and 5 of marine origin. Those of terrestrial origin were 2 extracts of pomegranate, one rich in punicalagin and the other rich in ellagic acid (PG and EA, respectively), an extract rich in citrus flavonoids (CF) and a grape seed extract (GSE). The marine ones were extracts of *Rhodomonas lens* (RH), *Osmundea pinnatifida* (OS), *Gracilaria sp.* (GR), *Desmodesmus sp.* (DE) and *Dyctiota sp.* (DY). Extracts phenolic compounds and flavonoids content, as well as their antioxidant activity by ABTS and FRAPs activities were assayed. An *in vitro* screening of the extracts antioxidant and immunomodulatory activities was performed using seabream head kidney leukocytes. Specifically, viability, respiratory burst, peroxidase content and phagocytic capacity of the leukocytes were analyzed. Based on the results obtained on the in vitro asssays, two extracts were chosen, one of terrestrial origin and the other of marine origin (PG and RH) to be tested *in vivo* at two dietary dosages in seabream post-larvae. This experiment (CEEA_ULPGC 33-2023) was carried out from 49 days post- hatch (dph) to 90 dph, testing each diet in quadruplicate tanks with 600 larvae/tank. After the feeding period, a stress challenge was performed by exposing 30 larvae from each tank to air for 2 minutes and observing their recovery for 24h. The analyses of this experiment are currently in progress.

**Results**

Regarding the *in vitro* results, different trends were observed depending on the origin of the extracts (i.e. terrestrial or marine). In the case of terrestrial extracts, a higher content of phenolic compounds and flavonoids was observed ($p$-value < 0.0001), which resulted in a higher antioxidant capacity ($p$-value < 0.0001) compared to marine extracts. Among the terrestrials, GSE presented the highest levels in phenolics compounds and flavonoids ($p$-value < 0.0001), which was related to a higher antioxidant capacity according to ABTS ($p$-value < 0.0001) but not by FRAPS, where the best results were obtained with pomegranate extracts ($p$-value = 0.0003). This may be due to the dependence of the antioxidative capacity of the extracts on their structure, presence of hydroxyl groups or their glycosylation (Parcheta et al., 2021) rather than their total content. On the other hand, a more direct relationship between phenolic compounds and flavonoids with the results in ABTS and FRAPs was observed in marine extracts, with the best candidate being RH. All compounds, except RH and OS, presented an inverse relationship between dose and cell viability. In terms of immunomodulatory activity, the marine compounds showed generally higher activity, possibly caused by the presence of Marine Sulphated Polysaccharides (MSP) (Petit et al., 2024).

*(Continued on next page)*

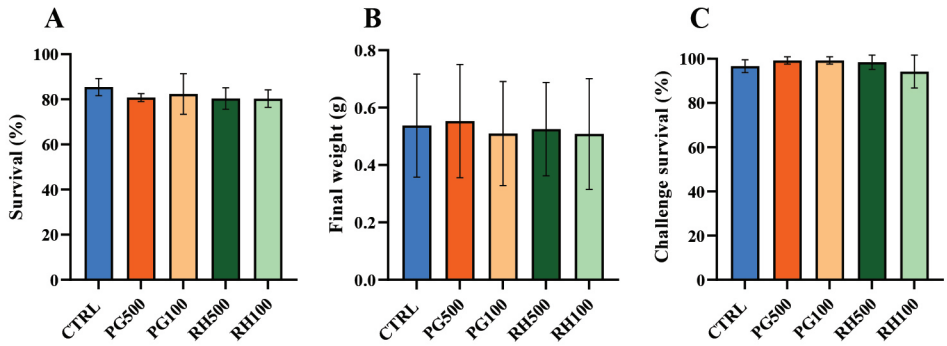

**Figure 1**. Survival rate (**A**), final weight (**B**), and challenge survival rate (**C**) of *S. aurata* post-larvae supplemented with different extracts and inclusion percentages. The results are expressed as the average ± SD. No statistically significant differences were observed from the one-way ANOVA analysis.

Considering the above, PG and RH were chosen as candidates for the *in vivo* assay. The results obtained so far show that supplementation with these extracts did not affect either growth or survival of seabream post-larvae. In addition, survival to a stressor such as air exposure was not affected either, with all groups showing values above 90%.

The rest of the analyses: histology, RNA sequencing and antioxidant enzymes activity, parameters that will provide valuable information, are currently in progress.

# THE EFFECT OF BOAT NOISE ON BEHAVIOUR AND PHYSIOLOGY OF EUROPEAN SEA BASS (*Dicentrarchus labrax*)

P. Mongillo*, C. Guérineau, A. Meloni, M. Bortoletti, F. Solis, V. Bevilacqua, D. Bertotto, L. Marinelli

**Introduction**

The impact of anthropogenic noise on marine ecosystems has emerged as a critical area of research in recent years. Increased shipping traffic, marine construction, underwater mining, and recreational boating contribute significantly to noise pollution, altering the natural acoustic landscape. Fish are particularly sensitive to these changes, as they rely on sound for communication, navigation, and predator avoidance.

Noise acts as a potential stressor, inducing both physiological responses (increased cortisol secretion, changes in plasma metabolites, and expression of heat shock proteins) and behavioral changes in fish (startle, avoidance, altered foraging, and disrupted collective dynamics) (Wysocky et al., 2006; Cox et al., 2018).

This study adopts a dose-response approach to explore the relationship between sound intensity and both physiological and behavioral variables in European seabass exposed to boat noise, determining how these parameters mirror their respective variations and at which intensity noise may potentially cause harm.

**Materials and Methods**

We exposed 160 European seabass to sound stimuli realistically reproducing fishing boat engine noise. Fish were housed in experimental tanks (350 l) in groups of five, with each tank exposed to one of six distinct sound levels (95-154 dB, re 1 µPa) for one hour.

After exposure, we collected fish plasma following anaesthetic overdose and stored samples at -20°C for cortisol and glucose/lactate analysis via radioimmunoassay (RIA) and an automatic analyser (BIONSEN, EKF Diagnostics). Physiological indicators were compared across treatment Levels through ANOVA.

Behavioral data were collected on videos during three non-consecutive 10-min intervals before exposure and other three 10-min intervals during exposure. A focal animal, continuous sampling method was used to collect data on swimming behaviour (forward swimming, hovering). DeepLabCut, a machine learning video analysis software, was trained to track fish and collect data about swimming speed and distance from other fish. Behavioural data were analysed separately for each Level of exposure via Generalized Estimating Equations, with sampling interval as a fixed factor and fish identity as a random factor.

**Results and Discussion**

The percentage of time spent swimming forward increased significantly with exposure to sound for all Levels between 0 and 3 ($p < 0.001$ for all models) in the first 10 min of exposure, but remained increased for longer with increasing sound intensity, to the point that no return to baseline was observed for exposure to Level 3; a delayed increase in forward swimming was observed in Level 4 ($p < 0.001$) and no increment was observed in Level 5 ($p = 0.644$). Hovering showed a mirroring pattern, decreasing significantly upon exposure to noise ($p < 0.001$), and taking longer to revert to baseline (if at all) with increasing sound intensity up to Level 3. As already observed for swimming, such response was delayed in Level 4 and absent in Level 5. Average swimming speed significantly increased in the first 10 min of exposure compared to all other sampling intervals, in Levels 0 to 3 ($p < 0.05$), while no change was observed in Levels 4 and 5.

*(Continued on next page)*

Overall, these results indicate that noise exposure increases swimming activity, in agreement with previous studies (Buscaino et al., 2020). However, the increment in swimming speed was short-lived and independent of sound pressure, representing a transitory response scarcely indicative of the intensity of the effect of noise exposure. Conversely, the increment in forward swimming/decreased hovering and the clear relationship between noise intensity and the duration of such response likely represents the results of stress/arousal due to exposure and of subsequent habituation. The delayed and reduced effect observed in Levels 4 and 5 might reflect a disruptive effect of too intense noise, impeding the expression of an active behavioural response.

Overall, these results indicate that quantification of forward swimming and/or hovering is better suited than swimming speed to measure the impact of noise exposure. These results also suggest that the greatest effects of noise exposure on seabass behaviour occur for noise intensities around or above 130 dB (re 1 μPa).

No differences were found in cortisol, glucose and lactate concentrations across treatments, indicating a lack of conventional physiological stress response despite significant behavioral alterations. This suggests a disconnection between immediate behavioral reactions and typical physiological stress markers in the context of noise exposure requiring further investigation.

**Conclusions**

In conclusion, this study identifies behavioural patterns which seem useful to characterise different aspects of European seabass response to noise exposure. The study indicates 130 dB as the intensity threshold around which seabass can no longer produce adaptive responses. The lack of significant changes in acute stress physiology indicators such as cortisol and glucose levels suggests that current models of stress measurement may require re-evaluation in the context of acute noise exposure. Further research is needed to explore these findings across different environmental contexts and stressors, for instance to assess the long-term impacts of noise pollution on fish survival, foraging, and reproductive success. Understanding the nuanced relationship between stressors and biological responses is vital for formulating effective conservation strategies and ensuring the welfare of marine organisms in increasingly noisy oceans.

## Introduction

Mediterranean aquaculture of European sea bass (*Dicentrarchus labrax*) is of high economic relevance, with feed representing the main production cost. The adoption of low fishmeal diets (Oliva-Teles et al., 2015), combined with functional additives (Balbuena-Pecino *et al*., 2022) or management strategies such as sustained swimming, are key approaches to improving the sector's sustainability (García-Pérez *et al*., 2024). In this study, we first evaluated *in vitro* the effects of antioxidant products with potential as additives, including several agricultural byproducts and taurine, on the proliferation and redox status of muscle satellite cells from juvenile European sea bass. Based on *in vitro* results, the most promising additives (antioxidant byproduct (AO-1) and Taurine (T)) were incorporated into experimental low fishmeal diets and tested in a two-month *in vivo* feeding trial with juvenile sea bass, under either voluntary or sustained swimming conditions. The findings provide insights into nutritional and exercise-based strategies to enhance growth and oxidative stress tolerance, supporting the development of more sustainable feeding practices.

## Material and methods

Fingerlings for *in vitro* and *in vivo* experiments (8 ± 3 g) were supplied by Culmarex (Mallorca, Spain). Primary cultures of E. sea bass myocytes were established from epaxial fast muscle. Cells were seeded at $7.5 \times 10^5$ cells/mL in 6 well plates coated with poly-L-lysine and laminin. Cultures were maintained at 23 °C and 2.5% $CO_2$. AOs stock solutions (100×) were prepared under sterile conditions, diluted according to their active compound content, and tested for cytotoxicity using the MTT assay. Products were added on day 3, and cells were incubated with 0.5 mg/mL MTT for 5 h on day 5, for toxicity assessment. Two AOs (AO-1 and AO-2) and taurine (TAU, 10 mM) were selected for the antioxidant capacity assay, which was performed in 96 well plates using $H_2$DCFDA dye (10 $\mu$M) after product incubation, oxidative challenge with TBHP, and fluorescence reading. Quercetin (QC, 10 $\mu$M) was used as positive control. The best AO (AO-1) was tested at two different concentrations (10 ppm and 2 ppm) for RNA analysis. The other treatments, quercetin and taurine, were prepared at the same concentrations as described above. RNA was extracted on day 5 after 24 h of treatment, gene expression related to the Gh/Igfs axis, myogenesis, and antioxidant related enzymes was assessed via RT-qPCR. The *in vivo* trial involved nearly 2,000 tagged fingerlings (5.49 ± 0.03 g) distributed for each condition into three tanks at density of 2 g/L. Conditions differed according to swimming activity: voluntary swimming (VS) or sustained swimming (SS, 1.5 BL/s). Four diets were tested over two months: high fishmeal (D1), low fishmeal (D2), low fishmeal + AO-1 (D3), and low fishmeal + taurine (D4). Fish were fed three times daily at 4% ration of body weight (BW), with ration adjusted to 2.5 % BW after weight control at midpoint. Fish were weighed and measured at the start, midpoint (week 4), and the end (week 8). Biometric parameters (SGR, VSI, MFI, HSI, MSI) were calculated. Statistical analyses (SPSS v30, GraphPad v8) included normality testing (Shapiro–Wilk), homoscedasticity (Levene's test), one- or two-way ANOVA (for *in vitro* or *in vivo* analyses, respectively) with Tukey's or Dunnett's T3 post hoc tests; $p < 0.05$ was considered significant. Biometric parameters (length, weight, and condition factor) were analyzed with a mixed linear model including tank effect, which was minimal.

*(Continued on next page)*

**Results and discussion**

*In vitro*, toxicity analyses showed no significant effects at the treatment doses tested. AO-1 displayed the highest antioxidant capacity among products, with effects comparable to quercetin (QC) under oxidative challenge with TBHP, whereas taurine (TAU) and AO-2 did not reduce ROS levels. Based on these results, AO-1 and TAU were selected for *in vitro* further analyses and as the dietary additive in D3 and D4, respectively, for the *in vivo* trial. RNA analyses under basal redox condition (without oxidative stressors) revealed downregulation of *gshr* in AO-1 at 2 ppm and in QC, accompanied by a trend towards *gpx* upregulation in QC. QC also induced significant upregulation of *igf-2*, *pcna*, and *myod2*, while *igfbp-5b* was downregulated. TAU did not cause significant changes in late-proliferative phase (day 5) myocytes but showed a tendency to upregulate *gshr* and *myod2*, which could indicate potential changes during the differentiation phase (day 8-13).

*In vivo*, final body weight was highest in D1-SS and D4-SS (21.5 ± 0.3 g and 20.9 ± 0.3 g, respectively), both significantly greater than other treatments, whereas D3-SS had the lowest value (19.1 ± 0.3 g). Final SGR was significantly higher in D1, followed by D4 and D3-VS. Additionally, D4-SS exhibited a higher muscle somatic index and a tendency towards a lower mesenteric fat index, indicating better overall performance in this group.

In summary, further analyses are required for the *in vivo* experiment, whereas *in vitro* data indicate that AO-1 may exhibit a redox profile similar to that of QC and could be a promising additive to mitigate stress in E. sea bass fingerlings. However, when included in a more sustainable diet with reduced fishmeal content, it does not fully compensate for nutrient deficiencies needed to optimise growth performance, whereas TAU could provide this compensation and potentially confer antioxidant effects.

marta.monteiro@ciimar.pt

**Introduction**

Protein hydrolysates have gained significant attention in recent years for their ability to deliver high-quality peptides with nutritional and health-promoting benefits in both human and animal nutrition. Among their bioactive properties, their antioxidant potential is particularly noteworthy, along with their potential to modulate microbial growth and anti-inflammatory effects, making them versatile functional ingredients. Beyond their nutritional value and bioactive properties, protein hydrolysates may offer a sustainable solution for waste valorization, particularly within the framework of a circular economy. A deeper understanding of protein hydrolysates and their functional properties is crucial for optimizing their applications in animal nutrition. This study aimed to evaluate the functional and bioactive properties of five protein hydrolysates derived from shark, fish, insect, and swine by-products, using CPSP90 as reference.

**Materials and Methods**

Four protein hydrolysates (PHs) were produced from different animal by-products: shark cartilage and muscle (SHARK), fish trimmings (FISH), swine meat and bone (SWINE), and whole insect larvae of *Hermetia illucens* (INSECT). Raw materials were hydrolyzed using either enzymatic or chemical-free thermal processing methods, optimized according to raw material type and target peptide profile. Hydrolysates were subsequently spray-dried and stored under dry conditions before analysis. Each hydrolysate was characterized in terms of dry matter, crude protein, lipids, ash, phenolic content, chitin, amino acid profile and molecular weight distribution of peptides. Protein solubility was assessed at pH 3.0, 5.0, and 7.0 using the Bicinchoninic Acid (BCA) method. Antioxidant capacity was assessed based on 2,2'-Azino-bis (3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activities and Oxygen Radical Absorbance capacity (ORAC). Antibacterial activity was assessed for Eight bacterial pathogens relevant to aquaculture. Bacteria were cultured in 96-well microplates with hydrolysate solutions (40 mg/mL) added to the medium. Optical density (OD600) was measured over time to monitor growth dynamics over a period of 24h. All assays included CPSP90, a commercial soluble fish protein concentrate, with wide application in aquafeeds, as a reference.

**Results**

All PHs showed high protein content (55.1–89.5% DM), with SHARK and SWINE richest in collagenic amino acids (e.g., hydroxyproline), and FISH and CPSP90 showing highest essential amino acid (EAA) proportions. INSECT, though lowest in protein (55.1% DM), was high in aromatic and branched-chain amino acids (BCAAs), with total phenolics representing 2.7% DM.

Molecular weight analysis revealed that FISH and INSECT had higher proportions of small peptides (<1 kDa), while SHARK was rich in small to medium-sized peptides (1–3 kDa). In contrast, CPSP90 and SWINE exhibited a more uniform distribution of peptides across different molecular weight ranges.

INSECT displayed the highest solubility (61–65%) across all pH levels, significantly higher than CPSP90. On the other hand, SHARK showed poor solubility (26–36%), likely due to its hydrophobic collagenic composition.

In terms of bioactive potential, INSECT and FISH exhibited the strongest antioxidant activity in both ABTS (11.8 and 8.9 Trolox eq %DM, respectively) and ORAC assays. SHARK showed the lowest antioxidant potential, aligning with its low content in aromatic and sulfur-containing amino acids. No DPPH activity was detected in any PH.

*(Continued on next page)*

Regarding bacterial growth modulation, SWINE hydrolysate consistently inhibited the growth of several pathogenic strains, including *Vibrio parahaemolyticus, V. anguillarum,* and *Aeromonas salmonicida.* In contrast, FISH and SHARK hydrolysates often promoted bacterial growth, particularly of *V. parahaemolyticus, V. anguillarum*, and *Photobacterium damselae* subsp *damselae.* INSECT hydrolysate had mixed effects—enhancing the growth of *V. anguillarum, Pseudomonas aeruginosa,* but inhibiting *Tenacibaculum maritimum*, A. *salmonicida* and *V. harveyi*

**Discussion and Conclusion**

The functional and nutritional profiles of animal-derived PHs varied widely with source and hydrolysis process. FISH and CPSP90 exhibited the highest essential amino acid content, while SHARK and SWINE hydrolysates were rich in collagenic amino acids. The higher proportion of small and small to medium peptides in INSECT, FISH, and SHARK hydrolysates is likely due to enzymatic hydrolysis using alcalase. In contrast, the more uniform peptide distribution in SWINE may be due to the thermal-pressure process of hydrolysis without added chemicals.

INSECT and FISH hydrolysates demonstrated superior antioxidant activity, while SWINE stood out for its selective antibacterial properties. While INSECT also exhibited the highest protein solubility, its effects on bacterial growth were mixed—it enhanced the proliferation of certain bacterial strains. Similarly, FISH and SHARK hydrolysates promoted the growth of specific bacteria, likely due to their high content of small and small to medium peptides, which may support microbial proliferation. While this could raise concerns in some contexts, it also suggests potential for these hydrolysates to be used as components in microbial culture media, as readily available sources of nitrogen and carbon. The selective growth-promoting properties of some hydrolysates could also be harnessed to cultivate beneficial bacterial strains or modulate microbial communities in aquaculture systems.

Overall, these findings support the targeted application of PHs in sustainable feed and food systems and highlight their potential to replace conventional protein sources, contributing to circular bioeconomy goals. Future research should focus on in vivo validation and detailed peptide characterization to fully unlock their functional potential.

## Introduction

One of the major bottlenecks in Atlantic cod (*Gadus morhua*) farming is the consistent production of quality larvae and juveniles. Moreover, nutrition plays a key role in the overall health of larvae. Positive development and optimization of weaning feeding protocols, with alternative live prey and novel micro diets in a co-feeding regime, are essential for enhancing larval survival and growth performance. Early introduction of formulated feeds during the weaning stage, gradually replacing live prey, is an efficient way to reduce overall production costs and minimize external sources of variability, leading to higher and constant production of juveniles. This study aimed to investigate the effects of early dry feed introduction in a co-feeding strategy on growth performance and survival.

## Material and Methods

Atlantic cod larvae (*Gadus morhua*) from Ode AS (Stadsbygd, Norway) were randomly disturbed in triplicate 400 L tanks at 2 days post-hatching (DPH) and kept to 74 DPH. The light regime was 24L:0D, and water temperature ranged from 7.9 to 9.9 ºC. In addition, algae paste (*Nanochloropsis gaditana*, AlgaSpring, The Netherlands) was used throughout the trial (2 to 43 DPH). The live feed was the same for the two treatments, a sequence of enriched rotifers (Ode AS) at 3 DPH, followed by small barnacle nauplii (Cryo-S, 10 DPH), and large barnacle nauplii (Cryo-L, 18 DPH), provided by Planktonic (Trondheim, Norway). Barnacle nauplii were cryopreserved, thawed, and reactivated with saltwater in a separate container, and all live feed was supplied to the tanks through different peristaltic pumps. Regarding dry feed, a microdiet tailored for cod was supplied by SPAROS (Olhão, Portugal), and it was used in both dietary treatments, Control (CTRL) and Early (EARLY). The cod microdiet started to be introduced in the two treatments at 20 DPH and 12 DPH, respectively. Dry feed was delivered through the tanks via automatic feeders. Sampling points occurred at 12, 20, 43, 60, and 74 DPH, and zootechnical parameters were analyzed, including standard length (SL) and wet weight (WW).

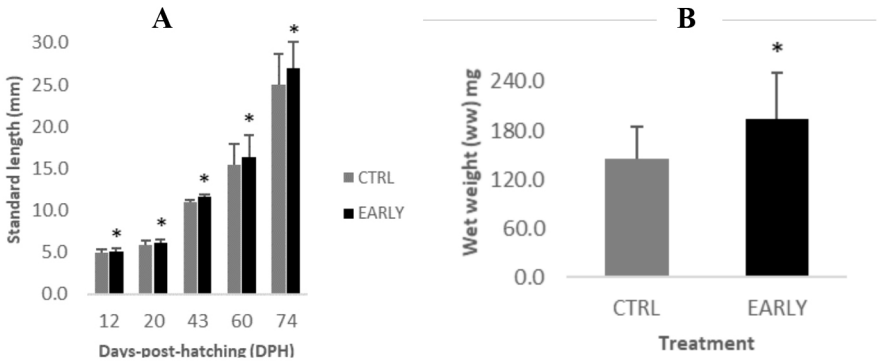

Figure 1. Standard length (A), at different sampling points; and wet weight (B), at 74 DPH, of cod larvae. Results are expressed as mean ± standard deviation. (*) represents significant differences between dietary groups ($p<0.05$).

*(Continued on next page)*

## Results

At every sampling point, the early introduction of a micro diet (EARLY) had a significant impact ($p<0.05$) on SL (mm) (Figure 1 A), and at 74 DPH on WW (mg) (Figure 1 B), compared to the control (CTRL) treatment. Relative growth rate around (3%/day) and survival rate from 20 to 74 DPH (13.4% CTRL; 17.4% EARLY) did not show any significant effect of the early introduction of dry feed.

## Discussion

Results suggest that early dry feed introduction in a co-feeding system, 12 DPH, can be an effective strategy to enhance growth performance on Atlantic cod larvae, both in standard length and wet weight, without compromising survival rates, comparing to CTRL group. This improvement in growth in the EARLY dietary treatment, is a promising result and can be helpful for the commercial aquaculture, since standard length can be a good indicator of future juvenile quality. While these results are encouraging, it is necessary to incorporate more detailed analyzes, including health markers and skeletal deformities, in order to have a more comprehensive view of larvae and juvenile quality.

**Introduction**

Immunonutrition strategies are increasingly recognized as effective tools for enhancing disease resistance and post-stress resilience in farmed fish. One of those strategies involves the use of alternative ingredient, either protein- or lipid-based, that include bioactive compounds to improve fish health and robustness. Among the different alternative ingredients with bioactive compounds, single-cells proteins (SCPs) cover the different characteristic, as they combine readily digestible protein with bioactive compounds that support health, making it a nutrient-dense addition to aquafeeds. Among the different SCPs available, PEKILO® is a single-cell protein produced by cultivating the filamentous fungus *Paecilomyces variotii* on agricultural or forestry by-products. Animals fed PEKILO®-based diets exhibit better feed conversion efficiency, and they demonstrate higher survival rates under typical farming conditions. Moreover, the β-glucans and nucleotides in PEKILO® act as immunostimulants, enhancing the expression of pro-inflammatory cytokines and chemoattractant molecules and thereby strengthening the innate immune response of fish, including Atlantic salmon (*Salmo salar*) (Hooft et al., 2024; Mesah et al., 2025). However, the effect of this ingredient in marine warmwater fish, particularly during the early-development stages, when rapid growth coincides with immune system development—remain poorly understood. Therefore, the present study aimed to evaluate the inclusion of PEKILO® in weaning diets for gilthead sea bream larvae, with the goal of improving both growth performance and health status during this critical life stage.

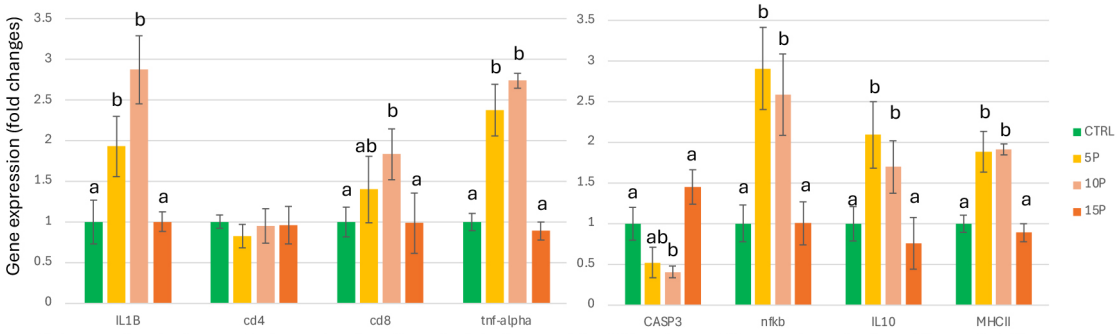
**Material & Methods**

For that purpose, four different weaning diets were formulated diets with increasing levels of PEKILO® (0, 5, 10, and 15% inclusion) and the effect on larval growth performance, survival, stress resistance, and disease resistance against *Vibrio anguillarum* was studied. The experiment was conducted with 28 days post hatching (dph) larvae fed over 18 days in triplicates. Larvae were assigned to 12 fiberglass cylinder tanks with conical bottoms (170l), at 890 larvae/100L. Tanks were supplied with filtered seawater at an increasing debit from 1 L/min at the beginning of the experiment to 2 L/min at the end of the experiment and continuous aeration during the entire experiment. Water temperature was 22.2 ± 0.8 ºC and the dissolved oxygen was 6.57 ± 0.1 g/L. Larvae were hand-fed every 45 min from 8:00 am to 8:00 pm for 18 days until 47 dph. Photoperiod was 12:12 L:D and larvae mortality was daily registered by individually counting the dead larvae. At the end of the feeding period, two different tests were conducted with groups of thirty larvae from each tank (triplicates for each experimental diet): i) a stress test (2 min of air exposure) ii) a challenge test against infection with a sublethal dose of *Vibrio anguillarum* ($10^5$ CFU/ml). Mortality was recorded for 48 h, and the relative percentage of survival (RPS) was calculated at the end of the challenge.

At the beginning and at the end of the experiment, samples of whole larvae were taken to analyze proximal composition (crude protein, crude lipid, ash, moisture) and whole-body fatty acid and amino acid profiles. Whole larvae samples were also taken for histological studies. At the end of the feeding period and after challenge test, samples of whole larvae were also taken for analysis of relative expression of immune-related genes through real-time quantitative PCR (RT-qPCR) analysis. The analyzed genes included interleukin-1β (*il1b*), interleukin-10 (*il10*), tumor necrosis factor-α (*tnf-a*), nuclear factor kappa β subunit 2 (*nfk□2*) caspase 3 (*casp3*), cluster of differentiation 4 (*cd4*), cluster of differentiation 8 (*cd8*) and major histocompatibility complex II (*mhcII*) and using *b-actin* as housekeeping. Relative expression was calculated by the $2^{-\Delta\Delta Ct}$, where ΔCt was determined by subtracting the housekeeping from the Ct value of the target gene described by Livak and Schmittgen (2001).

*(Continued on next page)*

**Fig. 1**. Immune-related gene expression of whole larvae of Sparus aurata after 48 of challenge test against *V. anguillarum* and fed with different levels of *P. variooti* in weaning diets



Values are referred to the normalized expression of gene from animals feeding control diet. Different letters within a gene denote significant differences P<0.05

## Results

Results indicated a dose/dependent effect of *P. variotii* and could effectively use up to 10% of PEKILO® in diet without negatively affecting growth performance and survival, the inclusion of 15% of PEKILO® significantly ($p<0.05$) affecting larvae growth both in terms of weight and length. Larvae fed with higher levels of PEKILO® (15%) showed a significant ($p<0.05$) decrease resistance to pathogen in terms of survival, but had no effect on survival after stress test. Increasing levels of *P. variotii* did not affect whole-larvae proximate composition but did affect their fatty acid content, by increasing the n-6 fatty acids in whole larvae, and specifically the linoleic (18:2n-6) content in whole larvae. The inclusion of PEKILO® in seabream larval weaning diets improved the response of immune-related genes after 48h of infection with *V. anguillarum*, by increasing the relative expression of genes implied in the immune response against pathogens, such as *il1b*, *il10*, *tnf-a*, *nfk□2* or *mhcII*. However, the inclusion of 15% of *P. variotii* meal in larval diets failed to induce a proper response to the infection with *V. anguillarum* (Fig. 1).

This study demonstrates the potential of *Paecilomyces variotii* fungal meal as a sustainable and functional ingredient in weaning diets for gilthead sea bream. Levels of inclusion up to 10%. improve larval growth and the response of larvae to infection with *Vibrio anguillarum*, but higher level of inclusion (15%) induced negative effects on larval survival after challenge test against pathogen, denoting a dose-dependent effect.

[3]D.K. Zabolotny Institute of Microbiology and Virology of the NASU, Akademika Zabolotnoho str. 154, Kyiv, Ukraine

*Corresponding author: E-mail: danguole.montvydiene@gamtc.lt

The investigation is focused on evaluating the ecotoxicological status of aquatic ecosystems within conflict-impacted regions of Ukraine. This assessment is based on physicochemical and biological analyses of water and bottom sediment samples from 12 selected water bodies. Preliminary chemical analyses indicated that concentrations of heavy metals (Ni, Pb, Cr, Cu, Hg, Cd, Zn) and 15 polycyclic aromatic hydrocarbons (PAHs) in surface waters were below the detection limits of the analytical methods employed. Sediment analyses revealed low concentrations of heavy metals within regulatory thresholds and slightly elevated PAH concentrations in certain locations, suggestive of legacy contamination associated with military activity. Nutrient and organic matter content in sediment eluates exhibited substantial spatial variability, with Lake Sasyk (Odessa region) demonstrating the highest levels of total carbon (11.47 mg/L), total organic carbon (4.91 mg/L), and total phosphorus (0.055 mgP/L). These findings suggest significant organic and nutrient loading, likely attributable to anthropogenic sources. Radiological analyses identified only natural radionuclides at background levels; artificial radionuclides (e.g., $^{137}$Cs) were below the detection limits of the analysis. Ecotoxicological assessments employed a battery of bioassays involving multiple trophic levels, including green alga *Desmodesmus communis*, the higher plant *Lepidium sativum*, crustaceans (*Daphnia magna, Thamnocephalus platyurus*), ostracods (*Heterocypris incongruens*), and 8zebrafish (*Danio rerio*). The analysis revealed that several samples elicited biologically significant effects, including increased mortality, sublethal growth inhibition, oxidative stress, and behavioral alterations, despite the absence of detectable concentrations of the tested contaminants. It is noteworthy that *D. rerio* exhibited developmental impairments, and crustaceans demonstrated acute and chronic toxicological responses. These outcomes underscore the potential presence of bioavailable, mixture-based, or unidentified toxicants that elude standard chemical analyses. The findings underscore the limitations of relying exclusively on chemical profiling in environmental risk assessment, particularly in post-conflict contexts. The observed species-specific and endpoint-specific responses emphasize the necessity of incorporating integrative ecotoxicological approaches that account for physiological and ecological traits to accurately characterize environmental health and inform remediation strategies.

# PROTEIN HYDROLYSATES FROM PORCINE BLOOD FOR AQUACULTURE FEED: INFLUENCE OF HYDROLYSIS TIME ON THEIR BIOACTIVE PROPERTIES

C. Moreno-Mariscal[a], F. Moroni[b], J. Pérez-Sánchez[b], L. Mora[a*], and F. Toldrá[a]

E-mail: cmormar@iata.csic.es

**Introduction**

The valorisation of meat industry by-products, such as pig blood, represents an efficient strategy to generate functional ingredients for animal nutrition that would contribute to the sustainability of the meat and aquaculture sectors simultaneously. Blood is a rich source of high biological value proteins, whose enzymatic hydrolysis allows the production of peptides with bioactive properties (Bah et al., 2013). These compounds can contribute to the health and behaviour of aquatic organisms when incorporated into functional feeds, while promoting the circular economy of the agri-food sector (Salin et al., 2018).

In this context, the aim of this study was to optimise the sequential hydrolysis time of porcine blood with commercial proteases (Alcalase 4. 0 L and Protana™ Prime), evaluating parameters such as the degree of hydrolysis and peptide profile, as well as the effects on the inhibition of enzymes of metabolic and physiological interest (DPP-IV, NEP, TACE, MGL), completed with *in silico* peptidomic studies to predict the potential functionality and characteristics of the identified peptides.

**Materials and Methods**

Porcine blood hydrolysis was performed according to Moreno-Mariscal et al. (2025). Briefly, after an ultrasound pretreatment (1 hour, 35 kHz) and diluted 1:1 with bidistilled water, 2% Alcalase 4.0 L (endoprotease) was added to all hydrolysates at 65ºC at different times: 2h (APP2), 6h (APP6) and 24h (APP24). After that, 5% Protana™ Prime (exoprotease) (overnight, 55ºC) was added to each hydrolysate and then finally inactivated by heating. The degree of hydrolysis was determined using OPA reagent and the peptide profile of hydrolysates was studied through membrane ultrafiltration with different cut-offs (30, 10 and 3 kDa). The inhibition of dipeptidyl peptidase IV (DPP-IV) and neprilysin (NEP) enzyme activities were assessed to evaluate the hypoglycemic potential, while the inhibition of tumor necrosis α-converting enzyme (TACE) and monoacylglycerol lipase (MGL) enzymes was measured to investigate the anti-inflammatory potential of the peptides present in the different hydrolysates. Finally, peptides were identified by tandem mass spectrometry (LC-MS/MS) and subjected to an *in silico* analysis to predict its potential to be bioactive (Peptide Ranker tool), allergenicity (AllerTOOP v.2.0 tool), toxicity (ToxinPred tool) and cell penetrating probability (CPPpred tool).

**Results and Discussion**

Enzymatic hydrolysis with Alcalase 4.0L does not necessarily imply a higher degree of hydrolysis (DH). Statistical analysis showed that the APP6 (23.43±0.95%) hydrolysate had the lowest DH value, while APP2 (25.50±0.46%) and APP24 (24.23±1.48%) showed no significant differences between them. However, peptide profile analysis revealed that longer Alcalase 4.0L treatment time was associated with a higher proportion of low molecular weight peptides. The high proportion of peptides smaller than 3 kDa (~80%) can be attributed to the high exoprotease activity of the enzyme Protana™ Prime. In vitro enzyme inhibition assays indicated differences in peptide profiles between the different hydrolysates. While no significant differences were observed in DPP-IV enzyme inhibition, variations were identified in NEP inhibition, where inhibitory activity appeared to be correlated with larger peptide size. In the case of TACE inhibition, APP2 (80.68±4.43%) showed the highest percentage of inhibition, followed by APP24 (66.18±7.29%) and APP6 (57.49±6.03%). In contrast, MGL inhibition was most pronounced in APP24 (64.76±7.54%), followed by APP6 (48.87±2.33%) and finally APP2 (33.13±0.11%), suggesting that the responsible peptides might be of smaller molecular size. Mass spectrometry analysis (LC-MS/MS) identified 16 peptide sequences in APP2, 3 in APP6 and 7 in APP24, all with a PRR value > 0.75, indicating a high bioactive potential. Of these sequences, 12 had no allergenic potential and only one showed signs of toxicity.

*(Continued on next page)*

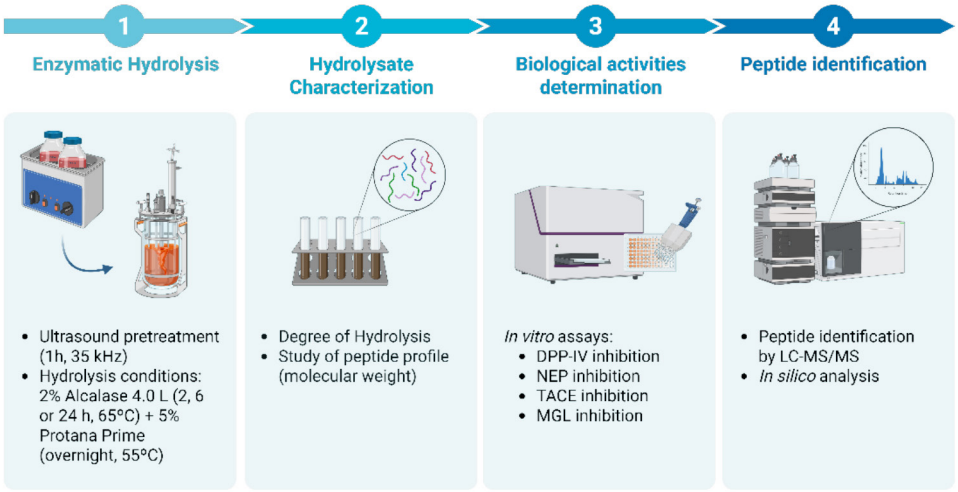

**Figure 1.** Graphical summary of the production and characterization of bioactive peptide-rich hydrolysates from porcine blood (created in https://BioRender.com).

## Conclusions

In conclusion, the hydrolysis of porcine blood using Alcalase 4.0L and Protana™ Prime is an effective strategy for the generation of small molecular size bioactive peptides with low risk of toxic or allergenic effects, constituting an important source of new ingredients for the formulation of aquaculture functional feeds.

## Introduction

Inflammation in aquaculture species can arise from various stressors such as suboptimal diets, environmental fluctuations, and pathogen exposure. Chronic or unresolved intestinal inflammation impairs nutrient absorption, compromises immune function, and ultimately hinders growth performance and overall fish welfare. Exploring functional ingredients with anti-inflammatory properties offers a promising strategy to support intestinal integrity and enhance resilience in farmed fish. Spain, by far the world's largest olive oil producer, generates large volumes of by-products, including olive pomace containing valuable bioactives like triterpenoids. Therefore, olive-derived by-products have great potential to offer a circular, eco-friendly approach to mitigate inflammation, and enhance productivity and animal well-being, improving overall aquaculture sustainability. To test this hypothesis, we used a protocol developed by Sparos Lta. to chemically induce intestinal inflammation in European seabass using dextran sodium sulphate (DSS).

## Materials and methods

The trial comprised 2 phases. In phase I, the whole fish population was fed a diet containing DSS for 15 days to induce a leaky gut and inflammatory response. Then, six fish were sampled to assess the intestinal inflammatory status, and the remaining were sorted and homogeneously distributed into quadruplicate 500L tanks, with 45 fish/tank, supplied with recirculated and aerated water. Phase II consisted in hand feeding the fish (start weight: 35.0±2.1 g) the experimental treatments to visual satiety, 2-3 times per day, for 61 days. A control diet (CTRL) was formulated mimicking a practical low fishmeal diet, with 44% crude protein, 17% crude fat level and 21.3 MJ/kg gross energy. Two additional treatments were prepared by supplementing the same formulation with 0.2% or 0.4% of an additive containing olive pomace extract (OE). Water quality was monitored throughout the trial and kept at good levels; average temperature was 19.5±0.3ºC. At the end of phase II (day 77), all fish were weighed, 6 fish/tank were pooled for whole-body composition analysis, and 3 individual fish/tank were sampled for subsequent analysis, to assess growth, feed utilization and intestinal health status (recovery from inflammation).

## Results and discussion

At the end of phase II, fish reached, on average, 87.6g, 88.2g or 102.5g in the CTR, OE 0.2% or OE 0.4% treatments, respectively. This represented a significant 17% higher growth in fish fed OE 0.4% during the recovery period. Feed intake was not affected by OE dietary inclusion. As a result, FCR was also significantly improved (by 11.7%) in fish fed the OE 0.4% diet. Moreover, this treatment had a higher whole-body retention (% of intake) of protein, fat and energy (Fig. 1).

Intestinal gene expression was analyzed by RT-qPCR in the general fish population on day 15 (end of the DSS administration period), and on day 77 in each treatment to verify the degree of recovery from intestinal inflammation. A panel of genes was selected to evaluate the inflammatory response (Fig. 2) and integrity (Fig. 3) of the intestinal epithelium. Results were normalized by the average expression of *ef1a*, *bact* and *gapdh*.

All results shown below correspond to the mean ± SEM. Bars with different letters denote significant differences, assessed by one-way ANOVA and Fisher's LSD ($P<0.05$).

Intestinal expression of inflammatory mediators (*il6, il8, il10, il1β, tnfa* and *nfkb2*) was significantly reduced between day 15 and day 77, indicating that fish were able to at least partly recover from inflammation by the end of phase II (Fig. 2). Additionally, the expression of *il6, il10* and *tnfa* was significantly lower in OE 0.4% than in the CTRL on day 77, suggesting that the lowest inflammatory status was achieved in this treatment.

*(Continued on next page)*

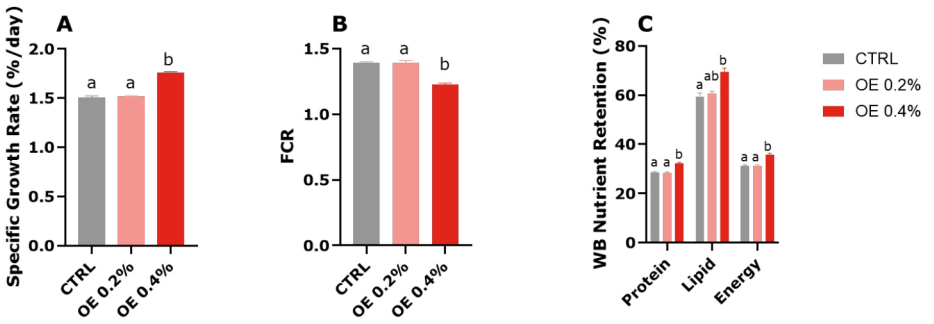

Fig. 1. Zootechnical performance at the end of phase II. A- Specific growth rate (%/day). B- Feed conversion ratio (FCR). C- Whole-body nutrient retention (% of intake).

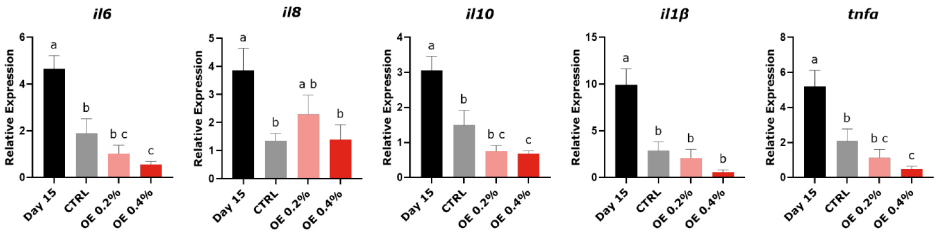

Fig. 2. Relative expression of selected inflammatory mediators at the end of phase I (day 15) and on day 77 in the three experimental treatments fed during phase II.

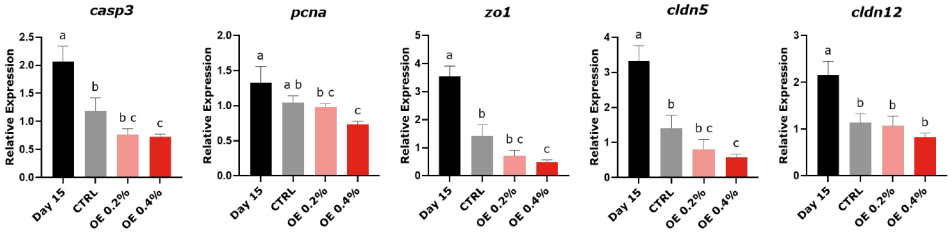

Fig. 3. Relative expression of selected intestinal integrity markers at the end of phase I (day 15) and on day 77 in the three experimental treatments fed during phase II.

Markers of apoptosis (*casp3*) and cellular proliferation (*pcna*), and genes coding for tight junction proteins (*zo1*, *cldn5* and *cldn12*) were significantly elevated on day 15 (Fig. 3). This suggests that a compensatory mechanism was activated to counteract the loss of intestinal barrier integrity. Conversely, the significantly lower expression of these genes (except *cldn12*) in the OE 0.4% treatment, relative to the CTRL, could be a sign of improved membrane integrity and higher recovery from DSS-induced damage.

These results clearly indicate a positive effect of the OE at 0.4% dietary inclusion level in alleviating intestinal inflammation in European seabass. Moreover, the faster and/or higher recovery from the DSS-induced disruption of intestinal integrity and inflammation was associated with significant improvements in fish growth, feeding efficiency and whole-body nutrient retention. Results are still pending on histological examination of the intestine, and plasma and feces inflammation markers, which are expected to further support the potential of triterpene-rich OE as a practical solution for mitigating intestinal inflammation challenges in fish farming.

# SUPEROXIDE DISMUTASE ACTIVITY AND ISOENZYME PATTERN IN THE DIGESTIVE GLAND OF SUBADULT AND JUVENILE WILD *Octopus vulgaris* OVER A 24-HOUR PERIOD

## Introduction

Behavior and physiology in living organisms are regulated by endogenous rhythms that allow them to anticipate to predictable changes in their environment, which is essential for survival (Häfker et al., 2023). These oscillations are directly related to the daily rhythm of activity of antioxidant enzymes (Wilking et al., 2013), making them excellent bioindicators of animal lifestyle and welfare. Among antioxidant enzymes, the superoxide dismutase (SOD) family, which protects against oxidative damage by catalyzing the dismutation of superoxide anion radicals into oxygen and hydrogen peroxide, has been reported to play a key role in physiology and disease. The condition of the digestive gland in *Octopus vulgaris* is considered a good indicator of feeding habits and welfare since it is responsible for digestion, absorption and storage of nutrients. In this study, we investigate both the specific SOD activity and the SOD isoenzymes present in the digestive gland (DG) of wild subadult and recently settled juvenile *O. vulgaris* over a 24-hour cycle using espectrophotometric and electrophoretic analysis.

## Materials and Methods

*Collection of material*: *O. vulgaris* individuals were collected using an artisanal fishing boat from the Vilanova i la Geltrú fishing fleet (NW Mediterranean). A total of 35 subadults were collected between 5:30 and 10:30 hours of October 9th, 2023, using octopus pots (Sauer et al., 2021) placed at 5–27 m depth in the sampling area. Size of subadults was selected aiming to sample non-mature individuals to avoid adding unknown sexual maturity factors that can potentially influence internal rhythms. A total of 35 juveniles were collected between 06:30 and 11:00 h of November 11th, 2023, using experimental juvenile octopus' collectors (Escolar et al. 2021) placed at 5–15 m depth on sandy bottoms of the same area. Each collecting day, both subadults (mean weight: 587 ± 111 g; range: 408–850 g) and juvenile (mean weight: 0.427 ± 0.622 g; range: 0.183-3,428 g) were kept in containers onboard, transported to aquarium facilities of the ICM-CSIC, located at 50 km, and placed in rearing tanks by 13:00 h. All individuals were maintained in the aquarium facilities of the ICM provided by an open seawater system under natural photoperiod and water temperature (23.9 °C for subadults, and 17.2 °C for juveniles). To avoid agonistic interactions, individuals were distributed in the tanks based on their size, and for subadults the sex was also considered. Light intensity at tank bottom was 80-90 lux for subadults and 15 lux for juveniles. Natural sunrise and sunset during the experiment with subadults were 7:57 and 19:19 local time, and 07:45 and 17:45 local time for juveniles, respectively. No food was provided.

*Sampling for endogenous rhythms analysis*: The day after they were captured, five individuals were sampled every 4 hours across seven time points starting at 12:00 h (t0 (midday)), 16:00 h, 20:00 h (t4, t8 (afternoon, evening)), 24:00 h (t12, (midnight)), 04:00 h, 08:00 h (t16, t20, (early morning, sunrise)) and 12:00 h (t24 (midday, after 24h)). Special care was put into avoiding any light source during night sampling hours in the aquaria facilities, and operations inside the aquaria facilities were performed using infrared lights. Digestive glands (DG) were dissected after the death of the individuals and stored at -80 °C until analysis. Animal welfare procedures followed EU guidelines (Directive 2010/63/EU) and cephalopod-specific recommendations (Fiorito et al., 2015).

*(Continued on next page)*

*Superoxide dismutase enzyme assay:* SOD specific activity was measured by the ferricytochrome c method using xanthine/xanthine oxidase as the source of superoxide radicals (McCord and Fridovich, 1969). Enzyme assay were carried out at 25 °C using a PowerWaveX microplate scanning spectrophotometer (Bio-Tek Instruments, USA) and run in duplicate in 96-well microplates (UVStarR, Greiner Bio-One, Germany).

*Analysis of SOD isoenzymes*: For the separation of SOD isoenzymes, nondenaturing PAGE was performed on 10% acrylamide slab minigels (MiniProtean II, Bio-Rad). SOD isoenzymes were detected in gels by the photochemical NBT (nitroblue tetrazolium) staining method (Beauchamp and Fridovich, 1971).

**Discusion**

The daily dynamics of the specific activity of SOD in the digestive gland of *Octopus vulgaris* shows a maximum in the early morning (4:00 h) in subadults and juveniles, and only in juveniles an increased activity was also found near the midday. Regarding SOD isoenzymes, the daily dynamic is similar than that reported for specific activity, but whereas in subadults only the Cu/Zn-SOD was present in juvenile individuals both Cu/Zn-SOD and Mn-SOD were identified. Cu/Zn-SOD and Mn-SOD are the two main SOD isoenzymes present in eukaryotes, the first found in cytoplasm and the second in mitochondria (Perry et al., 2010). *Octopus vulgaris* is a meropelagic cephalopod species, with juveniles suffering a drastic change from an active planktonic life to a more sedentary benthic stage during the settlement period, which involves important physiological and morphological changes that might be responsible for these changes in the SOD activity and isoenzyme pattern. Although subadult and adult *Octopus vulgaris* are known to be mostly nocturnal predators, the predatory habits of juveniles in the wild are unknown (Escolar et al., 2024). Whether or not the present results reflect different predatory habits in juveniles requires further ecological and physiological studies.

## Introduction

Salmonid products represent ~20% of global seafood exports by value. Projections from the Food and Agriculture Organization indicate that fish farming will continue to expand in the coming decades (FAO, 2024). However, high mortality rates – driven by multi-stressor conditions (e.g., infectious diseases and environmental problems), remain a significant challenge in major salmonids producing countries such as Norway and Chile. To address this problem, the combination of vaccines and functional feeds with bioactive additives is a strategy that has gained interest in recent years. In the Resilient salmon project (RCN 294821) we aim to improve the immune response of Atlantic salmon (*Salmo salar*) against *Tenacibaculum maritimum*, a bacterial skin pathogen that threatens Norwegian aquaculture, and for which no commercial vaccines currently exist.

To achieve our goal, we combined a specific nutritional program with novel feeds containing fucoidan from sugar kelp (*Saccharina latissima*) during freshwater (FW) stage, along with a commercial pentavalent vaccine that do not contain *T. maritimum* antigens. Previously, we have described how fucoidan fractions are able to modulate the expression of immune-related genes in salmon head kidney cells (Michalak et al, 2023). We also reported that vaccinated Atlantic salmon fed fucoidan up-regulated and increased the protein level of antimicrobial peptides (e.g., *hepcidin* and *cathelicidin2*) in head kidney after stimulation with inactivated *T. maritimum* (by intraperitoneal injection) in seawater (SW) stage. However, further characterization is needed to understand the bioactive properties of fucoidan in fish. Therefore, in the current study, a proteomic approach was used to analyze the potential health effects of this compound in the distal intestine and head kidney of Atlantic salmon.

## Materials and Methods

At the NMBU's Center for Fish trials, pre-smolt Atlantic salmon were vaccinated with ALPHA JECT micro 6 vaccine (PHARMAQ). Then, fish were distributed into 300 L tanks (45 fish per tank) supplied with recirculated FW. Each tank (in duplicate) was assigned to a commercial-like diet (Ctr) or an experimental diet containing 0.2% fucoidan extract from sugar kelp (FD) for four weeks. After this period, 35 fish per tank were transferred to the SW facilities at the Norwegian Institute for Water Research (Solbergstrand, Norway) and fed the Ctr for the reminding experiment. After four weeks in SW, fish were intraperitoneally (IP) injected with inactivated *T. maritimum*. Samples from distal intestine (DI) and head kidney (HK) were collected from six fish per tank at different time points: end of FW stage (S2), after four weeks in SW (S3), one day post IP injection (S4) and seven days post IP injection (S5). Total proteins were obtained from each sample and then quantified with the BCA method. To perform a proteomic analysis, six protein samples from each organ, dietary group and sampling were digested and analyzed through mass spectrometry by the Proteomics Unit at University of Bergen (PROBE) according to Mensah et al (2025). Raw data files were processed by Perseus v.1.5.6.0 (MaxQuant). Thereafter, Limma v.3.61.9 was used in RStudio to determine the differentially modulated proteins between dietary groups. A contrast matrix between the FD and Ctr was created, and the significantly modulated proteins (p-value < 0.05) were determined. Modulated proteins (LAP: low abundance proteins; HAP: high abundance proteins) were used for a functional analysis by KEGG mapper (Pathways and Brite databases) according to Purushothaman et al (2024). Our study presents the results in which four or more hits were detected per term.

*(Continued on next page)*

**Table 1**. Modulated proteins in FD group compared to fish fed Ctr.

| Organ | Sampling | LAPs | HAPs | Total |
|---|---|---|---|---|
| DI | End of FW stage (S2) | 113 | 28 | 141 |
| | 4 weeks in SW (S3) | 61 | 168 | 129 |
| | 1d post IP injection (S4) | 250 | 271 | 521 |
| | 7d post IP injection (S5) | 181 | 361 | 542 |
| HK | End of FW stage (S2) | 223 | 383 | 606 |
| | 4 weeks in SW (S3) | 386 | 241 | 627 |
| | 1d post IP injection (S4) | 217 | 184 | 401 |
| | 7d post IP injection (S5) | 347 | 318 | 665 |

**Results and Discussion**

Overall, the comparison of proteomic data from fish fed FD and Ctr revealed that HK had a higher number of modulated proteins (LAPs and HAPs) than DI (Table 1). In addition, after the functional analysis of these proteins, DI from S2 had LAPs related to glycosaminoglycan binding proteins, whereas HK at the same sampling point showed HAPs linked to transcription machinery, cell adhesion molecules, cytoskeleton proteins, cytokine receptors, chaperones and folding catalysts (among others). This suggests that the dietary inclusion of fucoidan can modulate a primary lymphoid organ such as HK, which is involved in the coordination of local and systemic immune responses.

After the stimulation with inactivated *T. maritimum*, both DI and HK had HAPs associated with CD molecules and transporters at 1d post IP injection (S4). Also, HAP-related pathways such as endocytosis and antigen processing and presentation were detected in HK, while neutrophil extracellular trap formation, NOD-like receptor signaling, as well as complement and coagulation cascades were detected in DI. By contrast, S5 showed LAPs in DI linked to transcription factors and cytokine receptors, and LAPs in HK such as chaperones and folding catalysts, proposing a regulation of the response seven days post IP injection.

**Conclusions**

The inclusion of fucoidan in functional feeds for vaccinated Atlantic salmon pre-smolts showed the modulatory capacity (at the phenotypic level) of this compound in DI and HK. Interestingly, after seawater transfer and 1d post-IP stimulation with inactivated *T. maritimum*, fish previously fed fucoidan in FW exhibited enhanced health-related responses in SW, which declined 7 days post-IP stimulation.

## Introduction

The rising costs of fishmeal and fish oil have created the need to search for new feed ingredients, allowing these feedstuffs to be replaced by more sustainable and costeffective alternatives while maintaining the nutritional value of aquafeeds. In this regard, algae appear as a promising option for inclusion in fish feed, due to their valuable nutritional value, making them a great source of protein, omega-3 polyunsaturated fatty acids, antioxidants, pigments, vitamins, and minerals, which can improve the health and development of animals (Galafat *et al*., 2024). In addition, species diversification can increase the competitiveness of the aquaculture sector. In this way, the golden grey mullet (*Chelon auratus*) emerges as a promising species due to its low dietary protein requirements and its high fillet quality (García-Márquez *et al*., 2024). However, the nutritional value of algae may be limited by the presence of a thick and complex cell wall, which hinders the bioavailability and accessibility of nutrients and intracellular compounds. Therefore, biotechnological pretreatments, such as enzymatic hydrolysis or microbial fermentation, become essential, as they have been shown to improve nutrient bioavailability (Vizcaíno *et al*., 2024). For this reason, the aim of this study was to evaluate the dietary inclusion of a hydrolysed and fermented algal blend on the growth and digestive functionality in *Chelon auratus* juveniles.

## Material and Methods

The algal blend used contained 30% *Arthrospira* sp., 20% *Chlorella* sp., 10% *Microchloropsis* sp., 10% *Tisochrysis* sp., and 30% *Ulva* sp. It was supplied by the company LifeBioencapsulation S.L. (Almería, Spain) and stored at -20 °C until use. A sequential biotechnological process was carried out, first subjecting the algal biomass to enzymatic hydrolysis with a mixture of hydrolytic enzymes (carbohydrases, cellulase, and proteases) during 5 h, and then followed by microbial fermentation using $10^9$ CFU/mL of *S. cerevisiae* and $10^9$ CFU/mL of *B. subtilis* for 36 h.

A 62-day feeding trial was conducted at the Marine Culture Facility of the University of Cádiz. For this purpose, two experimental diets, L50 and L100, were formulated to replace 50% and 100% of the fishmeal and fish oil, along with a control diet (CT) including 15% fishmeal and 5% fish oil without algal biomass. At the end of the trial, fish growth was analyzed, and biological samples were collected to evaluate the proximal composition of the muscle, digestive enzyme activities, and the ultrastructure of the intestinal mucosa.

## Results and Disc[illegible]

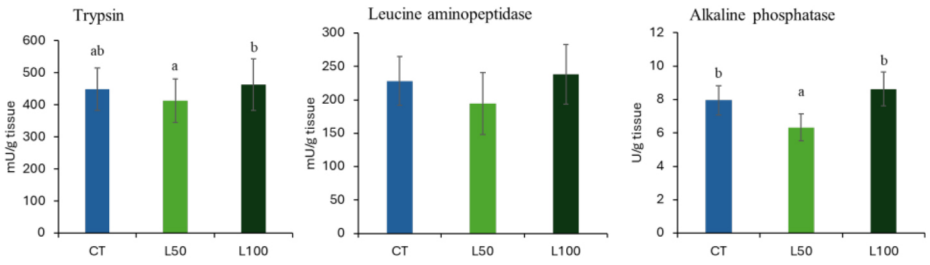

Figure 1. Digestive enzyme activities of *C. auratus* juveniles fed the different experimental diets.

*(Continued on next page)*

On the one hand, no significant differences were observed in growth performance among treatments. Similarly, the proximal composition of the muscle showed no differences, except for the total lipid content, which was higher in the L100 group. On the other hand, enzymatic activity assays showed that trypsin and alkaline phosphatase activities were significantly higher in the fish fed the L100 diet compared to the CT group (Figure 1), which could indicate an improvement in the digestive capacity of these fish. In addition, scanning electron microscopy (SEM) images showed a healthy intestinal mucosa, with no signs of damage in any of the treatments evaluated. Results obtained confirmed the suitability of total replacement of fishmeal and fish oil in practical diets for this fish species.

# MONITORING THE GROWTH OF NILE TILAPIA (*Oreochromis niloticus*) USING ACOUSTIC TECHNIQUES

Sergio Morell-Monzó[2*], Luis Lorenzo Carrillo La Rosa[1], Vicente Puig-Pons[2], Isabel Pérez-Arjona[2], and Víctor Espinosa[2]

## Introduction

The Nile tilapia (*Oreochromis niloticus*) is the second most farmed fish species globally, typically reared under high-turbidity conditions that hinder direct visual monitoring. This study aimed to develop methods for non-invasive growth assessment using lateral target strength (TS) as a proxy for fish length in free-swimming individuals under production-like conditions.

## Data and Methods

Eighty-seven specimens were reared in controlled environments, and biometric measurements (length, weight, swim bladder dimensions) were obtained to define size groups. Lateral TS measurements were collected using a BioSonic echosounder (~200 kHz), yielding 30,477 individual traces. Two regression models relating mean group length to both mean and maximum TS values were fitted. Numerical simulations using the Method of Fundamental Solutions, based on swim bladder geometry derived from X-ray imaging, were performed to produce TS estimates comparable to experimental values.

## Results

Regression models achieved high correlations ($R^2 > 0.9$) between fish length and TS parameters. Simulated TS values showed consistency with measured data. An empirical equation was proposed to link TS and mean length, enabling average population size estimation from acoustic data. Findings demonstrate that lateral TS is a robust indicator for growth monitoring in *O. niloticus*, supporting its potential application for biomass estimation in aquaculture systems. Future research will address the application of this methodology across complete production cycles.

# FIRST APPROACH FOR THE ACOUSTIC FEEDING MONITORING OF SHRIMP (*Penaeus vannamei*)

Sergio Morell-Monzó[1*], Vicent Simó-Morant[1], Álvaro Lloret-Gaona[1], Isabel Pérez-Arjona[1], and Víctor Espinosa[1]

sermomon@upv.es

Universitat Politècnica de València, Campus de Gandia

## Introduction

Feed management in *Penaeus vannamei* culture represents the main operational cost and a key sustainability challenge. This species produces characteristic short-duration "click" sounds while feeding on pellets, generated by the collision of its calcareous maxillae. Passive acoustic monitoring (PAM) offers a non-intrusive method to detect and characterize such feeding activity. This study aimed to record and analyze these clicks as a first step toward developing acoustic-based feeding control systems, and to explore the relationship between shrimp size and click sound pressure levels (SPL).

## Material and Methods

Forty-eight specimens were measured, weighed, and fed pellets of uniform size in a controlled laboratory tank. Feeding activity was recorded with a calibrated omnidirectional hydrophone system. SPL values were calculated from the recorded data, and spectral analysis was performed using Fast Fourier Transform of the signal.

## Results and Discussion

A total of 413 clicks were identified, with durations averaging 0.01 ± 0.003 s, SPLs typically between 140–144 dB re 1 $\mu$Pa, and maximum values around 168 dB. The clicks' frequency content ranged from 3 to 38 kHz. Direct oscilloscope measurements confirmed SPL estimates. The recorded sound levels were higher than those reported in previous studies, possibly due to methodological or environmental factors. This acoustic characterization establishes a foundation for future work aimed at optimizing feeding strategies by integrating PAM systems in shrimp aquaculture.

# LEGAL RESPONSES TO MICROPLASTICS IN EUROPE: AN INTERDISCIPLINARY REVIEW FROM A MARINE ECOLOGY PERSPECTIVE

Esteban Morelle-Hungría*, alud Deudero, César Bordehore

*PhD Student, Marine Ecology Program, University of the Balearic Islands, Spain
esteban.morelle@uib.es
PhD in Law, Senior Lecturer in Criminology and Criminal Law, Center of Research in Criminal Law, Criminology and Intelligence, Jaume I University, Castellón, Spain

Microplastics (MPs) are increasingly recognized as a planetary boundary threat (Persson et al., 2022, p. 1513), severely impacting marine ecosystems, food chains, and human health. Despite extensive evidence on their ecological harm—from cellular damage in plankton to bioaccumulation in top predators (Bucci et al., 2020, p. 5)—Europe's regulatory framework remains fragmented and largely inadequate. This interdisciplinary review critically analyses the state of the art on marine microplastic pollution from a legal-ecological perspective, with a focus on European Union regulations and their implications for marine biodiversity protection and enforcement mechanisms.

We review scientific findings on microplastic dispersion, degradation, and toxicity in coastal and marine habitats (Kurniawan et al., 2024, p. 3; Bamigboye et al., 2024, p. 261), alongside legal instruments such as the Marine Strategy Framework Directive, REACH regulation, and the recent EU ban on intentionally added microplastics (Zuccaro et al., 2024, p. 2592). Drawing from jurisprudence across more than 30 jurisdictions (Varvastian, 2023, p. 636), we evaluate the emerging role of courts in filling governance gaps and driving state accountability.

Our findings highlight a mismatch between the complexity of microplastic pollution—particularly its invisible, diffuse, and transboundary nature—and the enforcement capacities of administrative and criminal law. We argue that while legal regimes recognize the environmental harm of plastics, current implementation lacks the ecological sensitivity and interdisciplinary coordination required for effective mitigation. Notably, cruise ship-related pollution and antifouling paint degradation are emerging as critical, yet understudied, legal blind spots (Compa et al., 2023, p. 12; Morelle-Hungría, 2022, p. 5).

We propose a multi-layered governance approach integrating marine ecological evidence with enforceable legal standards. Specific attention is given to the potential role of environmental criminal law and citizen science mechanisms to enhance compliance and monitoring efforts. This work contributes to the dialogue between marine science and environmental law, advocating for stronger regulatory instruments aligned with planetary boundaries and the precautionary principle.

# BOOSTING SEA BREAM WELFARE AND WELLBEING USING PORCINE BLOOD HYDROLYSATE AS A FUNCTIONAL FEED INGREDIENT

C. Moreno-Mariscal[a*], F. Moroni[b], P.G. Holhorea[b], L. Mora[a], F. Toldrá[a] and J. Pérez-Sánchez[b]

E-mail: cmormar@iata.csic.es

## Introduction

The escalating global demand for animal proteins has led to a substantial increase in the generation of animal by-products (ABPs) by the meat processing industry. Among these, porcine blood -constituting approximately 3% of the live weight of pigs- emerges as a promising substrate for its valorisation into high-value bioproducts through environmentally sustainable methodologies, thereby contributing to the advancement of circular economy practices (Toldrá et al., 2021). In this regard, sequential enzymatic hydrolysis has been identified as a key methodological procedure, as it not only enhances the digestibility of protein substrates but also facilitates the release of bioactive peptides and free amino acids. Accordingly, this approach holds significant potential for the development of functional feed ingredients tailored for aquaculture applications, with the dual aim of promoting aquatic animal health and welfare and reinforcing the environmental sustainability of aquaculture systems (Boyd et al., 2020). To achieve this goal, we evaluated *in vitro* the properties of a novel feed ingredient derived from a porcine blood hydrolysate (PBSH), and *in vivo* its bioactivity in a fish feeding trial with gilthead sea bream as a farmed fish model. Such in vivo testing was based on a multi-layer metabolic, transcriptional, and gut microbiota approach, including measurements of behaviour, swimming performance and dynamics of fasting weight loss and weight regain during a fasting/refeeding challenge.

## Materials and Methods

PBSH enzymatic hydrolysate was obtained according to Moreno-Mariscal et al. (2025) and then filtered (<10 kDa) and spray-dried. Antioxidant activity and inhibitory activity against dipeptidyl peptidase IV (DPP-IV), neprilysin (NEP), tumor necrosis α-converting enzyme (TACE) and monoacylglycerol lipase (MGL) enzymes were studied. PBSH was fractionated by RP-HPLC and peptide sequences from the most bioactive fraction were identified by mass spectrometry techniques and later synthetised to confirm their biological activity. For the *in vivo* analysis, juvenile fish of approximately 19 g were fed with control (CTRL) or PBSH-supplemented diets for 10 weeks. At the end of this period, blood, liver, intestine and gut microbiota samples were collected after 24 and 48h of fasting for biochemical, gene expression, histological, and gut microbiota composition analyses. After the feeding trial, the pre-feeding fish behaviour was monitored by video recording. In parallel, swimming performance was assessed to determine basal and maximum metabolic activity rates (BMR, MMR) and critical swimming speed (Ucrit). Finally, a fasting and refeeding challenge of ten and eight days, respectively, was performed to assess the fasting weight loss and weight regain during refeeding.

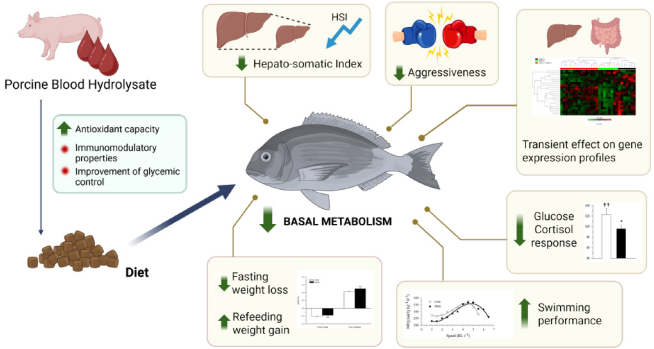

**Figure 1.** Graphical summary representation of the main outcomes (created in https://BioRender.com).

*(Continued on next page)*

**Results and Discussion**

As summarized in Figure 1, the optimised hydrolysis of porcine blood resulted in an extract enriched in free amino acids and bioactive peptides with a molecular size lower than 10 kDa. These peptides conferred antioxidant, hypoglycaemic, anti-inflammatory, and immunomodulatory properties to the extract. In fact, five peptide sequences were identified and confirmed as inhibitory of DPP-IV and NEP enzymes. A synergistic effect of these peptides was observed at a concentration of 1mM with inhibition values of these enzymes of 56.43% and 83.54%, respectively. In agreement with these potential benefits, all fish in the trial showed an optimal growth performance (SGR = 2.3; FCR = 1), which was accompanied in PBSH fish by a lower hepatosomatic index and a down-regulated expression of key hepatic lipogenic enzymes (diminished risk of liver steatosis). While no signs of histopathological damage were found in CTRL and PBSH fish, data on gene expression profiling indicated a transient influence of the experimental diet for both liver and intestine profiles, which was prone to reduce overall metabolic rates highlighting an anti-inflammatory appearance in the intestine. PBSH fish also showed an improved welfare condition with lower plasma glucose and cortisol levels in concurrence with a less aggressive behaviour during pre-feeding (30 min before feeding). Otherwise, the PBSH diet enhanced physical performance (20% increase in Ucrit) and reduced basal metabolic rates with a minimised weight loss during starvation, and accelerated weight regain during re-feeding. Finally, the intestinal microbiota was also reshaped by the dietary intervention with a redistribution of dominant bacterial genera associated to the PBSH group.

**Conclusions**

Enzymatic hydrolysis of pig blood offers a sustainable approach to revalorise this by-product by producing a new functional ingredient enriched in essential amino acids and bioactive peptides. The inclusion of the PBSH hydrolysate into fish diets enhances resilience to environmental stressors and improves overall fish welfare and wellbeing contributing to more sustainable and efficient aquaculture practices.

**Funding**

This study forms part of the ThinkInAzul program and was supported by MCIN with funding from European Union NextGenerationEU (PRTR-C17.I1) and by Generalitat Valenciana (THINKINAZUL/2021/024, IP1: J. Pérez-Sánchez, IATS; GVA/THINKINAZUL/2021/023, IP1: F. Toldrá, IATA). E-mail: turid.morkore@nmbu.no

## Introduction

Standard feeding strategies in Atlantic salmon farming are typically size-based, with high-protein diets (>40%) used for juveniles and high-fat diets (≥35%) during grow-out to promote protein sparing (Weihe et al., 2018). Ensuring good fish welfare and fillet quality is essential for sustainable production. Skin wounds are a major welfare concern, increasing vulnerability to infections and contributing to quality downgrading at harvest. Other relevant indicators include normal morphology and eye health (Moldal et al. 2025). Fillet quality is determined by factors such as nutritional composition, appearance, and texture. Visual attributes include the typical salmonid pink-red coloration and the absence of melanized spots, which influence consumer acceptance. Firmness is particularly important for both processing yield and sensory quality (Mørkøre, 2025).

This study evaluated three feeding strategies for autumn-transferred smolts farmed in Arctic conditions, assessing the potential benefits of high-protein diets with high marine protein share applied during winter alone or extended through both winter and spring, with respect to fish welfare and fillet quality.

## Materials and methods

The trial was conducted at the Cermaq farming site Toknebuktneset, Finnmark (70.57°C, 24.07°E, Norway). Each of nine 120 m circumference open sea cages were stocked with 120 000 Atlantic salmon (*Salmo salar* L.) smolts averaging 75 g in June 2021. The trial started in October 2021, when the body weight averaged 570 g. The dietary regimes were:

Control: Standard feed during the production phase, October 2021-October 2022.

HP-W: High protein feed during the winter period from October 2021-March 2022; thereafter the fish were fed the Control feed until harvest.

HP-WS: High protein feed during winter and spring period from October 2021-June 2022; thereafter the fish were fed the Control feed until October 2022,

Potential effects of the dietary treatments on growth performance, morphology, welfare indicators, nutritional status, and sensory quality were assessed at baseline in October 2021 and subsequently in March, July, and October 2022.

## Results and discussion

Over the one-year feeding trial, average body weight increased from 0.57 kg to 3.17 kg. While no statistically significant differences in final body weight were observed among dietary treatments, the control group showed a tendency toward reduced growth, particularly in July and October. The thermal growth coefficient (TGC) averaged 3.23, which is above commonly reported values for salmon farmed under commercial conditions with optimal feeding and environmental parameters. TGC was significantly higher for the HP-W and HP-WS groups compared to the control between March and July. Biological feed conversion ratio (FCR 1.13) and mortality rates (6.9 %) remained acceptable and comparable across all treatments.

*(Continued on next page)*

Operational welfare indicators (OWIs), including skin condition and eye lens opacity, indicated improved welfare in fish fed high-protein (HP) diets. In July, wound prevalence was significantly higher in the Control group (26.7%) compared to the HP-WS group (6.7%, $P = 0.04$), and scale loss was greater in the Control group than in the HP-W group ($P = 0.05$). In October, eye lens opacity affected 22.7% of fish in the Control group, versus 4% in both HP groups ($P = 0.03$), further supporting long-term welfare benefits of HP feeding.

Quality grading of whole fish showed a high proportion of superior share (91%), with no significant difference among the dietary regimes. Improvements were observed for fillet integrity and the occurrence of dark melanin spots. At harvesting in October, the share of fillets with severe gaping (score $\geq 3$) and soft texture (breaking force $\leq 6$ N) was halved for the high-protein (HP) groups compared with the Control ($P \leq 0.04$). These results show that feeding the fish HP diets can prevent the development of gaping and soft texture, that are two commercially important traits. Fillet colour, measured using SalmoFan scores, showed that the HP-WS group achieved higher colour score in July (25.2 vs. 23.9; $P < 0.0001$), suggesting an interaction between diet composition and pigment retention. However, at harvesting four months later, visual colour was similar for all dietary groups.

Focal melanized spots are a major quality issue in farmed salmon (Mørkøre, 2025). In March, the prevalence of melanized spots in the cranio-ventral fillet averaged 11.1%, with no significant differences between the groups. By July, the prevalence of the Control group increased (30.7%), while the HP-W and HP-WS groups had lower prevalences (8.3% and 0%, respectively). At harvest, the Control group maintained a prevalence of 20%, while it was lower for the HP-W group (3.5%, $P = 0.05$). No significant difference was observed between the Control and HP-WS group (10%) ($P = 0.22$). From July onward, the number of dark-stained muscle segments was lower in the HP groups, with a significant difference observed between the Control and HP-WS groups in July ($P = 0.05$), and between the Control group and both HP groups in October ($P = 0.02$).

This study is the first to demonstrate that feeding high-protein diets with high marine protein share during the first winter (and following spring) can improve fish welfare by decreasing skin issues and effectively mitigate eye defects and quality issues such as gaping, soft flesh, and melanin deposition at slaughter.

# ONE FUNCTION, MANY FACES: A MULTI-SPECIES DIVE INTO THE FUNCTIONAL CORE OF FISH GUT MICROBIOMES

F. Moroni[a]*, F. Naya-Català[a], R. Domingo-Bretón[a], G. Terova[b] and J. Pérez-Sánchez[a]

[a]Institute of Aquaculture Torre de la Sal (IATS, CSIC), 12595 Ribera de Cabanes, Castellón, Spain

## Introduction

Among the microbiomes closely associated with animals, the intestinal populations represent the most abundant and biodiverse. This microbial association is also characterized by a strong inter and intra-species variability, which however came with a high functional redundancy. These two aspects together make the investigation and the prediction of the microbiota modification an ongoing challenge (Vatsos, 2017). Therefore, the definition of feasible microbial biomarkers and the understanding of the inner bacterial relationships are particularly relevant in the context of aquaculture sector, as it is broadly documented how microbiota can impact the performance and the welfare of farmed animals (Luan et al., 2023). Hence, the aim of the present study was to find similarities and differences in the gut microbial populations of three main European farmed fish (gilthead sea bream, European sea bass, rainbow trout) with focus on the functional role of the core microbiota species using a computational and Bayesian network approach.

## Materials and Methods

The present study was conducted using a total of seven intestinal microbiota datasets, four for European sea bass (*Dicentrarchus labrax*), three for rainbow trout (*Oncorhynchus mykiss*), and an additional meta-analysis sea bream (Sparus aurata) data taken from (Moroni et al., 2025). The considered bacterial profiles have been obtained from different feeding trials focused on the effects of partial substitution of fish meal and fish oil with innovative and alternative feed ingredients. The different microbiota results were used to construct a hierarchical and stochastic Bayesian network (BN) to identify the relationships within the populations and the role of the core microbiota fraction previously identified. Functional characterization of the microbiota was performed using a cluster-based approach, identifying densely connected nodes and inferring their functional contribution using PICRUSt2 protocol (KEGG). Multi-species final comparison was performed using a Partial-Least Square Discriminant Analysis (PLS-DA).

## Results and Discussion

For all the fish species analysed, feed composition and genetic represent the main driving factors, which modulate and change the intestinal microbiota composition. Despite this variability, a reduced number of bacteria, which however represent the most abundant fraction, has been identified as core. In particular, sea bass showed a total of 40 bacteria, while trout only 23. The BN construction allowed the identification of the stochastic structure of the bacterial population for each fish species, and the hierarchical role of core microbiota, highly distributed within the community (Fig. 1A). The importance of this microbial fraction was also confirmed by the inferred functional analysis, as the metabolic profiles of the core-associated clusters played as principal actors in all the pathways identified (Fig. 1B). The results also highlighted that European sea bass and rainbow trout shared similar metabolic routes, but carried out by distinct bacterial communities, confirming that within a strong functional redundancy, the two farmed species presented a completely separate intestinal microbial organization. Furthermore, the importance of the core microbiota as feasible specific signature was also confirmed from an ecological and evolutionary perspective. In fact, the introduction of the gilthead sea bream microbiota profile in the analysis clearly indicated a stronger similarity with European sea bass, confirming that genetic background and environmental factors play a pivotal role in the shaping of the intestinal microbiota (Fig. 1C). These results finally allowed the identification of bacterial markers specific to the two phenotypes, functionally determining and belonging to the core fraction.

## Concluding remarks

This study demonstrates the potential of a functionally core microbiota driven approach to identify bacterial biomarkers that not only reflect taxonomic signatures but also reveal deeper ecological phenotypes. Ultimately, these results provide a valuable tool for monitoring intestinal health status, welfare assessment and defining more sustainable production strategies for numerous aquaculture species.

## Introduction

Aquaculture sustainability is increasingly challenged by climate change, with projections indicating more frequent marine heatwaves and prolonged periods of thermal stress (Haberle et al., 2024). While elevated temperatures can enhance growth within species-specific thermal optima (e.g., up to 28°C for gilthead sea bream), exceeding these thresholds disrupts metabolism, impairs immune function, and destabilizes gut homeostasis, resulting in tissue damage and shifts in microbiota composition. Functional dietary additives have shown promise in mitigating these effects; however, the potential of alternative protein sources and novel feed formulations remains unclear (Fernandes et al., 2024). This study evaluated the performance of three successive gilthead sea bream stocks over a four-year temperature profile that mirrors natural climate-driven thermal fluctuations, assessing the long-term effects of alternative protein sources and novel fish feed formulations on growth performance, histopathology, blood metabolites, multi-tissue (liver, white skeletal muscle, anterior intestine, head kidney gene expression) and resilience to environmental stressors.

## Materials and Methods

For the study, gilthead sea bream (*Sparus aurata*) juveniles from Mediterranean origin (Avramar, Burriana, Spain) were raised at the Institute of Aquaculture Torre de la Sal (Spain) under natural photoperiod and temperature conditions. The study spanned three consecutive production cycles (Trial 1: April 2020–December 2021, Trial 2: April 2021–December 2022, Trial 3: May 2022–December 2023). In Trials 1 and 2, attention was focused on growth performance with fish fed standard commercial diets (Biomar, Spain). In trial 3, three experimental diets were tested. The control diet (CTRL) mimicked current commercial formulations with FM, FO and plant ingredients as the main dietary protein and lipid sources. The other two experimental diets were partially or totally devoid of FM with plant ingredients and poultry meal as the main FM replacer in the PAP diet, while the main FM replacer for the named ALT diet were plant proteins together with insect proteins and microbial biomass. Otherwise, salmon-oil by-product and DHA algae oil were used as alternative oils in PAP and ALT diets, respectively. Across the trial, blood and tissue samples were collected in summer, autumn, and winter for biochemical, histological and gene expression analyses, using customized tissue-specific arrays with 106 selected markers of growth, lipid metabolism, antioxidant defence, and immunological status. In parallel, the effect of the nutritional background on stress susceptibility and resilience was assessed in a crowding stress test (changing the density from 16 to 48 kg/m$^3$) by the individual tracking of physical activity and respiratory frequency, using AEFishBIT biosensors externally implanted to the operculum (Calduch-Giner et al., 2022).

## Results and Discussion

The temperature always represents a factor that strongly affects metabolic activity and growth performance of ectotherm animals. Accordingly, the rise of incidence of intense marine heatwaves and heat stress events are worsening risks for aquaculture, especially in the Mediterranean basin. However, the present results exhibited a contrary and promising trend for gilthead sea bream, because the achieved growth align with the historical water temperature records in the Mediterranean Sea along the summers of 2022 and 2023, reaching the commercial size in a 1-2 months shorter period (Fig. 1A). This important finding highlights that a correct feeding schedule is able to promote an enhanced growth with the water temperate rise regardless of the use of different fish feeds. Certainly, the achieved growth with the three tested diets was almost undistinguishable, and no signs of histopathological damage were found in both liver and intestine in any experimental dietary group. However, going deeper with the analyses, the transcriptomic profiles revealed different temporal metabolic strategies that clustered together different fed fish for a given particular tissue. Thus, liver and muscle gene expression patterns clustered together CTRL and ALT groups

*(Continued on next page)*

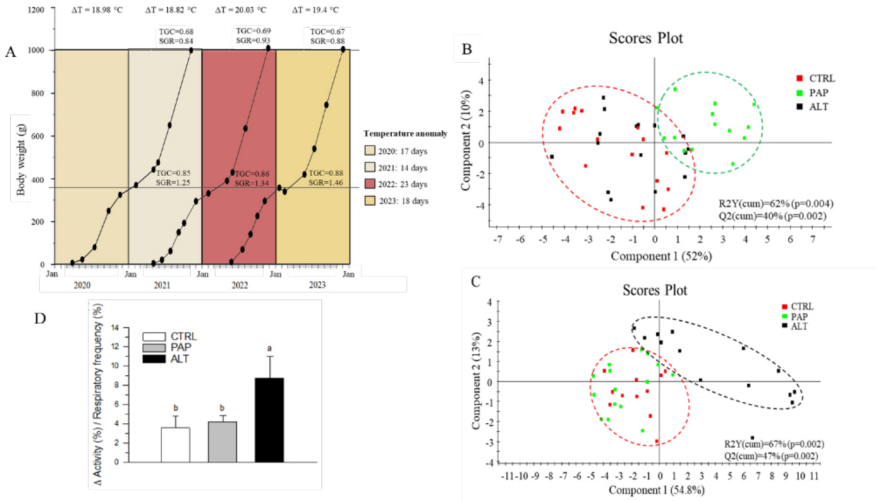

**Figure 1.** A) Growth performance and temperature anomaly during 2020-2023. B-C) Separation of experimental groups in PLS-DA using gene expression profiling in liver and intestine, respectively.

at the end of trial (Fig. 1B), mostly due to the confluent expression pattern of markers of lipid metabolism and mitochondrial respiratory chain. In contrast, the differential expression pattern of immune-related genes of the intestine clustered together CTRL and PAP fed fish (Fig. 1C). These different gene expression features also shaped a different stress response with a more reactive behaviour (increased activity) immediately after stress confinement in ALT fed fish, which rendered an enhanced activity/respiratory quotient with 2-3-fold lower plasma cortisol levels under standard basal conditions (Fig 1D). Accordingly, it was hypothesized that the ALT feed would avoid a chronic stress condition (improved welfare and wellbeing), which supports at the same time a more reactive response when fish are stress challenged.

## Concluding Remarks

This work demonstrates how a correct management of animals during the production cycle, combined with adequate feed formulations, can contribute not only to mitigate the negative impact of climate change, but also to take advantage of a scenario of a global warming. This feature was achieved with different feed formulations, although gene expression analysis and behavioural tests allows different physiological trade-offs that need to be considered in depth to ensure a customized and more efficient aquaculture.

**Background & Aims**

The European Commission's 2021 *Strategic Guidelines for Sustainable and Competitive EU Aquaculture* highlight the urgent need to transition towards more sustainable feed systems in aquaculture. In response, the Commission has commissioned a comprehensive study—currently ongoing—focusing on aquafeed systems across the EU, with additional comparative insights from the UK, Norway, and global producers. This study supports policy development by identifying good practices, evaluating sustainability challenges, and proposing data-driven solutions to reduce the sector's dependency on fish meal and fish oil from wild stocks.

The study encompasses five key objectives: (1) mapping the policy and regulatory frameworks and applicable standards for aquafeed; (2) analysing the aquafeed market, including aquafeed products, ingredients and additives, and the respective producers; (3) evaluating traceability and transparency practices across supply chains; (4) exploring trends and readiness levels of emerging and novel feeds, feed ingredients and feed additives; and (5) assessing economic, environmental, and social sustainability dimensions, including the role of certification schemes and circularity in feed production.

**Methods**

The research follows a mixed-methods approach, combining extensive desk-based analysis with field research. The latter includes survey consultations with stakeholders from across the sector including industry, academia, national authorities, producers and farmers, NGOs, amongst others. Emphasis is placed on the various life stages of the predominant commercial species in EU aquaculture including carp, meagre, sole, seabass, seabream, salmon, trout, shrimp, sturgeon, turbot and bluefin tuna.

**Conclusion & Outlook**

The aquafeed, aquafeed ingredient and aquafeed additive sector involves long and complex supply chains, which are threatened further by shifting climate and environmental dynamics, global economic shocks and socio-political threats. The draft results of this study, expected by September 2025 (and anticipated final results by January 2026), will provide a detailed overview of the current state of the aquafeed market, which will inform future guidance and investment in sustainable aquafeed strategies, aligning with EU food security and climate objectives.

# ENVIRONMENTAL BENEFTIS OF POND & WETLAND FISH FARMING AND CHALLENGES AND OPPORTUNITIES IN PROMOTING THOSE BENEFITS

**Background**

The Strategic guidelines for a more sustainable and competitive EU aquaculture[1] outline the steps required to drive the development of aquaculture in a manner that aligns with goals of the European Green Deal. Low trophic aquaculture, in particular the farming of low-trophic finfish (in ponds, lagoons, estuaries, reservoirs and wetlands) presents a viable option for a resilient, competitive and enviro-compatible aquaculture sector in the EU due to the favourable ecosystem conditions, markets for and historical experience in farming such species. Despite indications that these types of aquaculture can have minimal impact on the environment (and in some cases be beneficial to the environment), there are no defined measures for, and standardized techniques to assess the sustainability and eco-compatibility of these types of aquaculture.

**Methodology & Aims**

The present study aims to assess the environmental benefits of finfish farming in ponds and wetlands through a semi-quantitative analysis of the available scientific evidence and through engagement with key stakeholders. The study seeks to highlight if and how these types of aquaculture can and are being promoted across the Member States, as well as providing recommendations to overcome barriers. The study looks to provide an overview of how these types of aquaculture, and their positive environmental impacts, can be successfully promoted, with the aim that aquaculture in the EU can become a global reference for sustainability.

**Results**

The project highlights the contribution of pond and wetland farming to several ecosystem services across regulating, provisioning and cultural services. Opportunities for developing the sector (including greater recognition and valorisation of ecosystem services, improving climate change resilience and addressing social acceptance challenges) are discussed as potential solutions to challenges facing the sector. Several case studies draw on examples of good practices to illustrate potential pathways for sector development.

This study falls under the EU Commission project *Assessing the environmental benefits of aquaculture and challenges and opportunities in promoting those benefits.*

# UNVEILING THE SPECIFIC MICROBIOMES OF BIVALVES: INSIGHTS INTO HOST MICROBIAL DYNAMICS AND PATHOGEN INTERACTIONS IN A SHARED ENVIRONMENT

Miriam Muñoz-Martínez*, Magalí Rey-Campos, Raquel Ríos-Castro, Beatriz Novoa and Antonio Figueras

Institute of Marine Research (IIM), National Research Council (CSIC), Vigo, Spain
Email: mmmartinez@iim.csic.es

**Introduction**

The microbiome is essential for the health and resilience of marine species (Diwan et al., 2023); however, its complexity and host-specific dynamics remain poorly understood. This study presents the first comprehensive analysis of eukaryotic and prokaryotic microbiomes in three ecologically important bivalves - mussels (*Mytilus galloprovincialis*), clams (*Ruditapes philippinarum*), and cockles (*Cerastoderma edule*) - from a shared environment of Meira in the Ría of Vigo (NW Spain), between 2016 and 2018.

**Materials and methods**

The V9 (18S rRNA) and the V4 (16S rRNA) regions genes sequenced using Illumina and Ion Torrent. Alfa diversity, beta diversity (Bray-Curtis, PCoA) and PERMANOVA were used to evaluate eukaryotic and prokaryotic communities for each bivalve sample in different seasons.

Network analyses based on Spearman correlations and corrected CLR data were conducted to detect potential keystone interactions within prokaryote communities of each bivalve and its surrounding environment (mussel-water column, clam-sediment and cockle-sediment). Finally, functional activities associated with keystone taxa from each bivalve-habitat network were also identified using PICRUSt2.

**Results and discussion**

Each bivalve species harbored a distinct, host-specific microbiome with stable composition across seasons pointing that intrinsic host factors affect the composition of the bivalve microbiome regardless of environmental conditions and time (Neu et al., 2021).

Specific parasites, including *Mytilicola intestinalis* in mussels and trematodes such as *Bucephalus minimus* in cockles, were identified. *Perkinsus olseni* and *Marteilia cochilia,* protozoans linked to bivalve mortality and ecosystem disruption under environmental stress, were also detected.

Endozoicomonas and Vibrio dominated prokaryotic communities. A meta-analysis showed that despite the microbial diversity in the water column and sediment, each bivalve maintained its own stable and specific microbiome, distinct from its environment. These results suggest that bivalves can regulate their core microbiome through host-selective mechanisms (Brennan & Gilmore, 2018; Pierce & Ward, 2018)

We could identify *Vibrio*, *Woeseia* and *Lutimonas* as keystone genera shaping these microbiomes through competitive and cooperative interactions (Lu et al., 2022; Zelezniak et al., 2015). Mutualistic relationships enhanced host health via metabolic and defensive roles involving the biosynthesis of secondary metabolites.

**Conclusions**

Understanding host-microbe-environment interactions, particularly concerning pathogens, underscores the importance of improving ecosystem resilience and sustainability. These findings provide essential insights into microbiome dynamics, offering valuable perspectives for ecosystem and bivalve health monitoring and management.

# MANIPULATION EFFECTS OF JACK MACKEREL MEAL IN THE DIET SUBSTITUTING 50% OF FISH MEAL WITH CORN PROTEIN CONCENTRATE ON THE GROWTH PERFORMANCE AND FEED AVAILABILITY OF OLIVE FLOUNDER (*Paralichthys olivaceus*)

Hong Min Na[1*] and Sung Hwoan Cho[2]

## Introduction

Fish meal (FM) is expensive because of its increasing demand and unstable production worldwide. Therefore, searching for an alternative protein source for FM is necessary for sustainable aquaculture. Nevertheless, low-FM diets often lead to deteriorated palatability and reduced feed consumption by fish, ultimately resulting in lowered growth performance of fish. Therefore, this study aims to investigate manipulation effects of jack mackerel meal (JMM) in a diet substituting 50% of FM with corn protein concentrate (CPC) on the growth performance and feed availability of olive flounder (*P. olivaceus*).

## Materials and Methods

Seven experimental diets were prepared to be isoproteic (52.0%) and isolipidic (12.0%) (Table 1). The control (Con) diet contained 60% FM. In the Con diet, 50% of FM was substituted with CPC and then graded (0%, 10%, 20%, 30%, 40%, and 50%) levels of JMM were included at the expense of FM, referred to the CPJ0, CPJ10, CPJ20, CPJ30, CPJ40, and CPJ50, respectively. A total of 525 juvenile (6.3 ± 0.02 g; mean ± SE) olive flounder was randomly distributed into 21 of 50-L flow-through tank (25 fish/tank) with triplicate. Fish were hand-fed to apparent satiation twice a day for 50 days.

## Results

Weight gain (WG) of olive flounder fed the Con and CPJ50 diets was significantly ($P < 0.003$) higher than that of fish fed the CPJ0 diet (Figure 1). Specific growth rate (SGR) of fish fed the Con diet was significantly ($P < 0.001$) higher than that of fish fed the CPJ0, CPJ10, CPJ20, and CPJ30 diets. In orthogonal polynomial contrast, WG and SGR of fish revealed linear ($P = 0.0009$ and $P = 0.0006$, respectively) relationships with dietary inclusion levels of JMM. Regression analysis showed linear relationships as the best suitable models between increased levels of JMM in diets substituting 50% of FM with CPC and WG ($Y = 0.597540X + 17.9022$, $P < 0.0003$, $R^2 = 0.5851$) and SGR ($Y = 0.000437X + 0.0270$, $P < 0.0003$, $R^2 = 0.5850$), respectively. However, feed consumption and feed utilization were unaffected by dietary treatments.

## Conclusion

Incorporation of 10 and 40% JMM in the low-FM diets substituting 50% of FM with CPC could achieve comparable WG and SGR of olive flounder, respectively, to fish fed the 60% FM based diet.

In addition to growth hormone (GH) synthesized in the pituitary gland, various hormones and peptides are involved in the control of growth performance in fish. However, it remains unknown how the fish growth is regulated comprehensively by the endocrine networks, although understanding the endocrine system is important to maximize and optimize the target species in aquaculture. The present study aimed to explore the effect of thyroid hormone (TH) and thiourea (TU), an antithyroid agent, on the growth of the Malabar grouper, *Epinephelus malabaricus*, which is an important species in aquaculture in southern Japan.

Juveniles of the Malabar grouper (142.1 ± 3.28 mm) used in this study were obtained from Okinawa fish framing center and housed in tanks with seawater at the Nakagusuku Aquaculture Innovation Center. Fish were fed commercial pellets with thyroxine (T4, T4 group), TU (TU group), and T4 and TU (T4+TU group), and without T4 and TU (control group). Fish were reared with feeding of these diets for 4 weeks, and body weight (BW), condition factor (CF), specific growth rate (SGR), feeding efficiency (FE), and hepato-somatic index (HSI) were measured. Total RNA was extracted from the liver and pituitary gland, and cDNA was obtained by reverse transcription. The transcript levels of insulin-like growth factor-1 (*Igf-1*) in the liver and thyroid stimulating hormone (*TSH*) and growth hormone (*GH*) in the pituitary gland were measured by quantitative PCR.

BW, SGR (Fig. 1), FE, and HSI of the control and T4 groups were significantly higher than those of the TU group, suggesting that TH is involved in the growth of juvenile Malabar grouper. The transcript levels of *Igf-1* increased in the TU group. Although the transcript levels of *GH* were not significantly different among groups, those of *TSH* significantly increased in the T4+TU and TU groups. These results indicate that the hormone network in relation to TH synthesis and secretion is involved in the growth of this species through the expression alternation of growth-related genes in the liver. This study was supported in part by COI-NEXT (JPMJPF2012) of JST program.

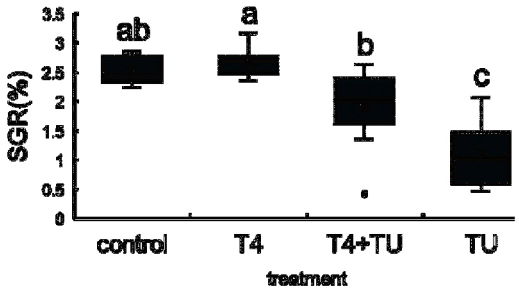

Fig. 1. Effect of hormone treatment on specific growth rate (SGR) of the Malabar grouper. Control; treatment without hormones, T4; single treatment with thyroxine, T4+TU; co-treatment with thyroxine and thiourea, TU; single treatment with thiourea. Different letters show statistic difference ($P < 0.05$).

# INFLUENCE OF MICROALGAE-ENRICHED DIET ON SPERM QUALITY PARAMETERS IN COMMON CARP *Cyprinus carpio*

## Introduction

Aquaculture is a key contributor to global food security. However, it faces numerous challenges that threaten its sustainability and its ability to meet the growing demand for animal protein (Ruben et al., 2025). The common carp is one of the most important freshwater species both in Europe and globally (FAO, 2024). Meeting the nutritional requirements of broodstock is a key factor in ensuring a healthy breeding population, successful reproduction, and ultimately, healthy offspring (Fernández-Palacios et al., 2011). Alternative feed additives, such as microalgae (Ansari et al., 2021), may improve gamete quality and contribute to more consistent reproductive outcomes. However, data on reproductive parameters of broodstock fed algae-supplemented diets remain limited. The aim of our study was to investigate the effects of 3% microalgae feed supplement on sperm quality and quantity in common carp.

## Materials and methods

The experiments were conducted at a Hungarian fish farm (Szegedfish Ltd). To carry out the sperm quality and quantity analyses, two groups were established. The control group was fed a conventional diet, while the experimental broodstock received feed enriched with 3% microalgae (*Chlorella* spp., *Scenedesmus* spp., *Coelastrella* spp., *Acutodesmus* spp.) 1 month prior to the spawning season. Sampling was performed at three consecutive date ($N = 6$ individuals per sampling and group) during the spawning season. Average body weight and length were recorded prior to stripping. During sampling, the following parameters were measured and calculated: total volume of milt (TVM), volume of milt per kg of body weight (VOM), spermatozoa per millilitre (SPZ), total sperm production (TSP), total sperm production per kilogram of body weight (TNS), osmolality and pH of the seminal plasma, as well as sperm motility and kinetic parameters (Cejko et al., 2011). Sugar and ion content: glucose (GLU), fructose (FRU), calcium (Ca), potassium (K), sodium (Na), and magnesium (Mg), and sperm fatty acid profile: total fatty acids (TFA), saturated fatty acids (SFA), unsaturated fatty acids (UFA), polyunsaturated fatty acids (PUFA), omega-3 fatty acids (OM3), and omega-6 fatty acids (OM6) were also assessed.

## Results

Results were evaluated using two-way ANOVA. First, control and algae groups were compared at the same temperature. Second, values at different water temperatures (18,5 °C; 20,5 °C; 21,8 °C) were compared within each group.

### Traditional Sperm Parameters

At 20.5 °C, VOM and TNS were significantly higher in the algae group. OSM differed significantly across all sampling times. At 21.8 °C, pH was lower in the control group.
In the control group, SPZ increased with temperature, OSM peaked at 20.5 °C, and pH was highest at 18.5 °C. BCF was highest at 18.5 °C. In the algae group, SPZ, TSP, and TNS peaked at 20.5 °C, while pH was highest at 18.5 °C.

### Sugar and Ion Content

At 20.5 °C, K and Mg were higher in the control group; at 21.8 °C, K was higher in the algae group. In the control group Ca, K, Na, and Mg concentrations peaked at 20.5 °C. In the algae group, K concentration was significantly lower at 18.5 °C, while Na peaked at 20.5 °C. Mg concentration also differed significantly between 18.5 °C and 20.5 °C.

*(Continued on next page)*

Fatty Acid Content

Fatty acid composition showed the largest differences. At 20.5 °C, TFA was higher in the control group; at 21.8 °C, it was higher in the algae group. Fatty acid composition showed the largest differences. At 20.5 °C, TFA was higher in the control group; at 21.8 °C, it was higher in the algae group. In the control group, all fatty acid parameters (except OM6) peaked at 20.5 °C. In the algae group, most values were significantly higher at 20.5 °C than at 18.5 °C. No significant differences were observed in this group between the lowest and highest temperature.

**Discussion and conclusion**

A 3% algae supplementation significantly improved sperm quality parameters compared to the control. Physiological values (sugar, ion, fatty acids) were influenced by both treatment and temperature, with highest values generally at 20.5 °C. The algae group showed increasing quantitative values with rising temperature.

Our findings suggest that pre-spawning algae supplementation improves sperm quality in common carp under optimal temperature. Future research should include closed-system, multi-group experiments, extending to fertilization trials.

**Acknowledgements**

The experiments were funded by the EKÖP-24-V/MATE-6 University Research Fellowship Programme and co-financed by the project 2022-1.2.6-TÉT-IPARI-TR-2022-00002 within the framework of the National Research, Development and Innovation Fund announced by the Ministry of Culture and Innovation. ## Introduction

Integrated Multi-Trophic Aquaculture (IMTA) is one of the most promising pathways toward sustainable aquaculture systems. Its goal is to reduce negative environmental impacts while increasing productivity. It is a nature-based solution that is conceived to mimic natural ecosystems by combining multiple species from different trophic levels into a single system. The inorganic and organic waste produced by fed aquaculture species (e.g., fish) is consumed and recycled by secondary autotrophic species (e.g., phytoplankton, macroalgae) and/or heterotrophic species (e.g., filter feeders, detritivores). In this way, the by-products of one species become resources for another. However, in marine environments, commercially scaled IMTA systems remain rare due to their management complexity and the lack of knowledge about the role of each productive component. It is therefore essential to develop solid scientific understanding of each species' role and knowledge about their interaction in nutrient and energy use.

Oyster farmers in the salt marshes of Nouvelle-Aquitaine (France) already practice a summer polyculture system that combines farming of kuruma shrimp (*Marsupenaeus japonicus*) with oysters (*Magallana gigas*), using supplemental exogenous feed. A strong demand from the industry aims to further diversify aquaculture practices by introducing winter farming of rainbow trout (*Oncorhynchus mykiss*) into this system. The main objective of this study was to assess the extent to which (1) trout farming could increase the productivity of oysters and clams (*Ruditapes philippinarum*) when reared together in the same ponds during winter and (2) summer production of shrimp, oyster and clam could be supported by the nutrients that accumulated during winter**.** We hypothesized that semi-intensive winter production of rainbow trout, fed exogenous feed, would cause organic nutrients to accumulate in the sediment which would increase the development of benthic invertebrates in the sediment (e.g., benthic macroinvertebrates), as well as phytoplankton and zooplankton in the water column. Benthic invertebrates could serve as a food source for shrimp, while phytoplankton and zooplankton are the primary food sources for oysters and clams.

## Materials and Methods

The experiment was performed in six salt marsh ponds of ca. 600 m² each at the Lycée de la Mer et du Littoral in Bourcefranc-le-Chapus (France). During the winter phase (November 2024 to March 2025), in three of the ponds, oyster and clam were reared with rainbow trout fed commercial feed pellets *ad libitum* (IMTA treatment). In the three other ponds, oyster and clam were reared without rainbow trout (no treatment (i.e., control)). At the end of the winter phase, survival and growth rates of clam, oyster and trout; organic carbon, nitrogen and phosphorus contents of sediment; and phytoplankton, zooplankton and benthic macroinvertebrate productivities were measured in each pond.

The food sources used by rainbow trout, clam and oyster were determined using stable isotope analysis of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$). Five individuals of each species were collected in each pond. Sediment organic matter (SOM) and suspended organic matter (SPOM) were also sampled in each pond. Sampled were dried, weighed and packed into pressed tin capsules for simultaneous $\delta^{13}C$ and $\delta^{15}N$ analysis, using an isotope ratio mass spectrometer interfaced with an elemental analyzer. The contribution of food sources to diets were estimated using Bayesian stable isotope mixing models.

*(Continued on next page)*

**Results and discussion**

During the winter phase, sediment in both treatments had similar organic carbon, nitrogen and phosphorus contents.

The $\delta^{13}C$ and $\delta^{15}N$ values of rainbow trout indicated that the fish consumed only the commercial feed and not the natural food sources in the ponds, such as benthic macro invertebrates. This result was expected, since the fish had been fed a highly palatable exogenous feed *ad libitum*.

Clam and oyster had the same survival and growth rates, as well as similar $\delta^{13}C$ and $\delta^{15}N$ values, in both treatments. Mixing models indicated that the oyster consumed both SPOM and SOM. Clam were $^{13}C$-depleted and $^{15}N$-enriched compared to oyster. The isotopic niches of oyster and clam did not overlap, which suggests that they are complementary filter-feeder species in IMTA ponds. Clam had similar $\delta^{13}C$ values in both treatments but significantly lower $\delta^{15}N$ values in the IMTA treatment than in the control, likely due to having consumed fish-feed waste. The commercial feed, which contained plant ingredients, had lower $\delta^{15}N$ values than the natural food sources in the ponds did.

In the IMTA treatment, the lack of increase in organic carbon, nitrogen and phosphorus contents in the sediment was likely due to fish biomass not exceeding the assimilation capacity of the ponds, or perhaps due to clam consuming fish waste effectively, which decreased biodeposition in the IMTA ponds.

The summer phase of the experiment will end in October 2025. Its results will help understand the extent to which nutrients accumulated with or without fish in winter support the production of oyster, clam and shrimp in summer.

# ENVIRONMENTAL SUSTAINABILITY OF LUXURY AQUACULTURE PRODUCTS UNDER PRESENT AND FUTURE CLIMATE SCENARIOS

R. Napolitano[1,2]*, F. Capoccioni[1], D. Pulcini[1], M. Sprague[2], R.W. Newton[2]

[1]Consiglio per la Ricerca in Agricoltura e l'Analisi dell'Economia Agraria (CREA) Centro di ricerca "Zootecnia e Acquacoltura" Via Salaria 31, 00015 - Monterotondo (Roma) - Italy

*E-mail: riccardo.napolitano@stir.ac.uk

## Introduction

Today's luxury food products are increasingly expected to meet high environmental sustainability standards. New generations of consumers no longer seek only sensory excellence and exclusivity but also demand ethical and ecological values (Li & Kallas, 2021; Menozzi et al., 2020). As a result, sustainability has become a defining feature of modern luxury, where quality can be measured not only by taste and rarity, but also by the product's environmental impact. While aquaculture remains a vital sector for providing affordable protein to the human growing population, it also includes luxury products, such as caviar and bottarga, or traditionally associated with exclusivity but now becoming increasingly accessible thanks to advancements and expansion in aquaculture practices, such as oysters. While many studies have assessed the environmental impact of farmed seafood, such as salmon, mussel, or tilapia (Gephart, J. A., et al., 2021), only a few focused-on luxury products (Dias et al., 2025; Melas et al., 2024; Napolitano et al., 2025; Vélez-Henao, J. A., et al., 2021). The aim of this research is to quantify the environmental impact of caviar and oyster production systems, incorporating a wide range of case studies to reflect the variability associated with farming methods and environmental conditions. Furthermore, the study aims to develop and analyze alternative scenarios, within the framework of climate change, to provide evidence-based recommendations for producers to uphold high sustainability standards.

## Materials and methods

This research is part of the PhD project "Environmental sustainability of luxury aquaculture products under present and future climate scenarios" developed in collaboration with "CREA" an Italian research institute and the University of Stirling (UK). Environmental impacts associated to luxury aquaculture productions, will be analyzed through the Life Cycle Assessment (LCA), a standardized method widely used. In this study, the environmental performance of the various products will be compared using different functional units (FU), including mass units (e.g., 1 kg), economic (e.g., 100 €) or new specific indicators that can better fit these specific products (e.g., sensory score, aromatic/taste profiles, VOC's quantity, etc..). Being luxury food products not merely intended for nourishment having functions with social and cultural implications, since they are not seen as part of a healthy diet, but rather as "unnecessary pleasure" it is complicated to find a dimension in which to measure them. Finally, a simulation modelling of the effects of environmental variables, expected to change in the next years due to climate change, on aquaculture luxury productions will be carried out in different geographical locations. The results of simulations will be matched with the direct experience of the farmers and the effects observed during recent extreme weather events, causing higher mortalities and the need for adaptation strategies. This information will be used to conduct scenario analyses to assess the effects of climate change and short- and long-term adaptation strategies on the environmental performance of the production chains.

## Results

Preliminary results on the Italian caviar supply chain show a relatively high environmental impact with high variability depending on the species (e.g. Global Warming (GW) potential ranged between 53.4 and 82.9 kg CO2 eq/kg of caviar), mainly due to the long production cycle and related high feed use (Napolitano et al., 2025). Impact levels are also influenced by how they are allocated between co-products (caviar and meat). Scenario analysis suggests that early female detection through genetic techniques could improve resource efficiency. For oysters, environmental performance appears generally good across sites ranging between 1.85 – 2.5 (kg CO2 eq/kg of oysters). Differences in cycle length and product traits, such as taste and aroma, may significantly influence results and pose methodological challenges in LCA integration.

## Conclusions

This work will give an overview on environmental performance of different luxury aquaculture products, considering factors such as different farming methods, environmental variables, co-product allocation, intensification scenarios and climate change.

# INTEGRATING PRECISION AQUACULTURE STRATEGIES WITH SUBMERSIBLE PEN TECHNOLOGIES

Langley Gace

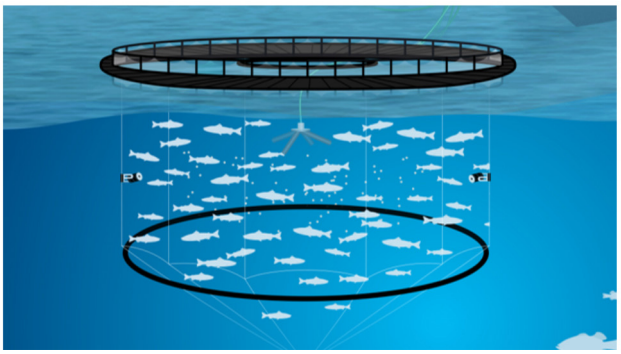
Innovasea Systems
266 Summer Street
2nd Floor
Boston, MA, 02210 United States
LGace@innovasea.com

Warm water aquaculture is expanding into open ocean areas, necessitating the submersion of aquaculture systems to avoid surface energy and warming temperatures. Specialized equipment is required to house fish, facilitate their growth, and monitor growing conditions. An integrated system of equipment and technology has been developed to address these needs. Submersible net pens can stay submerged throughout most of the grow-out cycle, allowing for a majority of the activities, from feeding to mortality removal, to be accomplished while submerged and in environments that the fish are most comfortable with. Waterborne feeding also offers many advantages, including a significant reduction in energy use and improved feed conversion ratios (FCR) due to feed pellets staying more intact. Stocking and harvesting, however, need to be done at the surface but can be scheduled around weather conditions.

Precision aquaculture is essential for the success of this system. Wireless sensors distributed throughout the site constantly measure environmental parameters such as salinity, temperature, dissolved oxygen, and other necessary data that can be viewed in real time. High-definition cameras connected to an efficient data transmission backbone allow feed managers, assisted by cutting-edge machine learning and AI algorithms, to optimize feeding regimes. Environmental data, fish behavioral data during feeding, and pellet detection provide detailed guidance for efficient feed delivery and consumption.

In addition to optimizing feeding, biomass estimations are collected and analyzed to help prescribe upcoming feeding levels and amounts and advise other managers in the company when the fish will be ready for harvest and even how much to expect. Furthermore, purchasing managers can monitor feed consumption and be ready to place orders to achieve just-in-time inventory for feed.

This fully integrated approach ensures efficient and sustainable aquaculture practices, enhanced productivity, and reduced environmental impact.



# ADVANTAGES AND CHALLENGES OF INCORPORATING RAS INTO MARINE HATCHERIES

George Nardi

Innovasea Systems
266 Summer Street
2nd Floor
Boston, MA, 02210 United States
GNardi@Innovasea.com

As opposed to both nursery systems and ongrowing RAS units, marine hatchery systems have multiple inputs that pose unique challenges to RAS units, but once addressed also offer substantial advantages. The main challenges are addressing the cycling of live feeds, flushing and removing them from the system, while the advantages are focused on a stable larval rearing environment and reduced energy costs for enhanced temperature control critical during the larval phases for some marine species.

E-mail: marta.narvaez@csic.es

## Introduction

There is an ongoing effort in the scientific community to minimize the use of animals in research. *In vitro* studies have been a major development toward achieving this goal. However, even in *in vitro* methodologies, animal-derived products are still used. In cell culture, fetal bovine serum (FBS) is widely used as a supplement in media. FBS purpose in cell culture media is to provide essential amino acids, nutrients, growth factors, and hormones, all of them necessary for the cell to growth, proliferate, and differentiate.

However, FBS is not chemically defined which results in a high degree of variability between batches. This can affect experimental results and their reproducibility, as well as introduce unknown molecules and contaminants that could interfere with certain analyses (Chung et al., 2025). Furthermore, from an ethical point of view, the use of FBS in research raises concerns regarding animal welfare. Ensuring animal welfare is essential at all levels, both in aquaculture practices and in aquaculture research. Likewise, for aquaculture to become truly sustainable, the research supporting it must also adopt more sustainable and ethical approaches. Despite all the inconvenience, FBS continues to be used since no suitable alternative has yet been found. The main objective of this work is to contribute to the establishment of cell lines capable of growing in serum free media (SFM).

## Materials and methods

For this study, *Epitheloma papulosum cyprinid* (EPC) cell line from fish and A549 and Huh7 cell lines from human were used. Five commercial media were tested: basal medium normally used with the cell line (m0), OptiMEM (m1), MegaCell DMEM (m2), MegaCell RPMI (m3), ExCell 293 (m4), and DMEM/F12 PLUS (m5).

The approach consisted of a semi-indirect adaptation. The adaptation was direct to 2% FBS and then was gradually reduced through several steps from 2% to 0%. Passages to a lower concentration were performed when cells reached 90% confluence, using a 1:3 split ratio. Total number of cells, growth rate, cell size and viability by Trypan Blue staining were determined. After three consecutive passages at 0% FBS, the adaptation process was considered complete, and the cell lines were then cryopreserved.

## Results

All three cell lines (EPC, A549, and Huh7) were successfully adapted to SFM. Both human cell lines were adapted to m5, meanwhile the fish EPC line was adapted to m4. The adaptation process required 6-7 passages in all cases, but the total duration varied. A549 and Huh7 completed the adaptation in 28 and 22, respectively, whereas EPC required 111 days.

Although passages were always carried out when the cells reached 90% confluence, the total number of cells varied significantly throughout the adaptation process. In EPC, the cell count returned to baseline levels by the end of the adaptation. However, A549 and Huh7 maintained lower cell count at 0% FBS. This reduction was not due to increased cell death, as cell viability remained relatively stable throughout all passages in all three lines, with cell death rates consistently around 3-4%. Instead, the lower cell count was associated with an increase in cell size. Fewer cells were needed to reach the same confluence due to the larger volume occupied by each cell.

In terms of growth rate, cells proliferated rapidly during the initial passages, requiring subculturing every 24 hours. However, as FBS concentration was gradually reduced, the time between passages increased. By the final passage at 0% FBS, the time between passages had extended to 3 days for Huh7, 10 days for A549, and up to 24 days for EPC.

*(Continued on next page)*

## Discussion

This study proves the possibility of adapting cell lines to grow in SFM, which represents a great advance towards more ethical and reproducible methodologies. The results show a significant difference between the total duration of the adaptation process between human and fish cell lines, which could be attributed to physiological differences such as varying sensitivity to growth factor (Jozef et al., 2025; Radošević et al., 2016). Additionally, each cell line adapted to a different medium: EPC was successfully adapted to m4, while both human cell lines thrived in m5. This is likely due to differences in their specific requirements for amino acids and other nutrients (Jozef et al., 2025; Liu et al., 2017).

The variation in the total number of cells is explained by the increase in cell size, resulting in fewer cells occupying the same surface area at confluence. This may be due to the fact that, under starving conditions, cells activate mechanisms such as apoptosis. Another possible explanation is cell cycle arrest in G1 phase, where cell growth occurs. Further studies may be needed to explore the physiological and molecular differences between adapted and non-adapted cell lines.

## Conclusion

The use of chemically defined medium enhances experimental reproducibility and facilitates cross-study comparisons. The successfully adapted cell lines provide a foundation for future research and support the 3Rs principles in science: replacement, reduction, and refinement. Moreover, implementing serum-free systems in aquaculture research contributes to making the field more sustainable and ethically aligned. These advances are essential to ensure that aquaculture development is supported by responsible scientific practices.

## Introduction

Spawning induction in patellid limpets is essential for aquaculture and conservation, as these broadcast spawners rely on synchronized gamete release for reproduction (De Girolamo *et al.*, 2024). Published guidelines favour non-invasive environmental cues, particularly thermal shock and intense aeration, which successfully stimulate spawning in species such as *Patella aspera*, *P. candei*, *P. caerulea*, and *P. ferruginea* (Castejón *et al.*, 2022; Nunes *et al.*, 2024). Pre-conditioning of broodstock and timing induction to natural reproductive cycles improve success (Castejón *et al.*, 2022; De Girolamo *et al.*, 2024). Such methodological developments represent significant progress toward the establishment of closed-cycle limpet aquaculture, thereby enhancing the potential for sustainable resource exploitation and contributing to the restoration of natural populations (Castejón *et al.*, 2022). Nevertheless, critical gaps persist in spawning induction reliability. The present work directly addresses new induction trials advancing standardized practices for reproducible gamete production in Azorean limpet species.

## Material and methods

Two spawning induction series (2 trials + 1 trial) were conducted for each species, *Patella aspera* and *P. gomesii*, during the reproductive season, adapting methodologies described by Castejón *et al.* (2022) and De Girolamo *et al.* (2024). Each trial comprised 40 individuals, distributed equally among four treatments (10 individuals per treatment). Induction treatments included: thermal shock (high and low temperature), intense aeration, gamete addition, osmotic shock, and a combined treatment (low temperature + aeration + gamete addition + osmotic shock). Prior to treatment, a one-hour pre-treatment under dry, room-temperature conditions was applied. Subsequently, each specimen was placed in an experimental vessel containing 700 mL of sterile filtered seawater (FSW) for a 4.5 h treatment exposure period. At the end of the treatment, FSW was totally renewed (400 mL at environmental temperature). Gamete emission was monitored continuously during treatment and every 30 minutes for 3 hours during the post-treatment. Water temperature, dissolved oxygen, and salinity were recorded throughout all phases. Finally, at least 45% of the limpets from each spawning induction series were dissected to calculate the gonadosomatic index (GSI) (spawners excluded), and gametes released were quantified for comparative analysis.

## Results

In addition to the influence of gonadal maturation, as indicated by the gonadosomatic index (GSI), preliminary results demonstrated that the type of induction treatment was a key determinant of spawning success in both species. The combined treatment yielded the highest efficacy for male gamete release, whereas no oocyte emission was observed in females under any treatment. Sperm release occurred predominantly during the post-treatment phase (Table 1).

## Discussion

Overall, spawning induction was successfully reached in both species, with the combined treatment demonstrating the greatest efficacy, even in cases where GSI values were higher for alternative treatments. Spermatozoa concentrations were variable, with maximal values typically observed in the post-treatment phase. These findings contribute to advancing the understanding of spawning dynamics in Azorean limpets. However, further investigation is required, particularly regarding gamete quality, consistency of spawning responses and scalability.

## Introduction

Flathead grey mullet (*Mugil cephalus*) is a catadromous, omnivorous fish species that has recently gained attention from researchers due to its potential as a sustainable, low-trophic-level candidate for aquaculture. Its omnivorous feeding habits and resilience to high temperatures make it particularly suitable in the context of climate change. For these reasons, the mullet represents an interesting model species for studying the interactions between environmental factors, such as temperature, growth performance, and feeding strategies. Understanding the effects of temperature is especially relevant in the current scenario of global warming. Optimizing feeding strategies in relation to environmental conditions is essential to improving aquaculture efficiency and sustainability. Among abiotic factors, temperature stands out as a key driver, significantly influencing metabolism, nutrient utilization, animal welfare, and gut health.

## Materials and Methods

Two isoproteic experimental diets were formulated to contain two lipid levels (Diet 10% and Diet 15%) and were tested at two temperatures: 22 °C and 28 °C. Diets were administered to triplicate groups of 30 fish each (initial weight: 90.5 g) over a period of 100 days at both temperatures. During the trial, feed was provided to apparent satiation during a single 6 hour meal per day, and dissolved oxygen was maintained above 7.5 mg $L^{-1}$. At the end of the trial, final body weight (FBW), specific growth rate (SGR), feed intake (FI), and feed conversion ratio (FCR) were calculated. Samples for gut evacuation analysis were collected at 1, 3, 5, 7, 9, and 12 hours post-feeding, while samples for microbiota analysis were taken at 4 hours post-feeding. Differences among treatments and temperatures were considered significant at $p < 0.05$ (two-way ANOVA followed by Tukey's test).

## Results and Discussion

At the end of the trial, fish fed with 10% and 15% lipid diets at 28°C exhibited significantly higher final body weights compared to those fed the same diets at 22°C. A similar trend was observed for specific growth rate (SGR), with the exception that fish fed with 10% lipid diet at 22°C showed no significant differences when compared to those fed either lipids level at 28°C or the 15% lipid diet at 22°C. These findings indicate that fish reared at 28°C exhibited enhanced growth compared to those at 22°C, likely due to the warmer temperature being closer to the range (26–27°C) where improved growth performance has been reported in previous literature (Crosetti and Blaber, 2015)commonly known as grey mullets, are one of the most ubiquitous teleost families in coastal waters of the world. They occur in most temperate, sub-tropical and tropical waters in both hemispheres. As a family they have an extraordinary adaptability, which has resulted in species that are found mainly in the clear and pristine waters of coral reefs to those that prefer highly turbid estuarine and freshwaters . Some species can even survive in some of the most polluted waters in the world, e.g. in the harbour at Viskhapatnam in India (Blaber 2000. At 28°C, fish were presumably able to more efficiently utilize dietary nutrients to meet their energy demands, thereby supporting improved growth performance. In contrast, the reduced energy expenditure at 22°C may have limited nutrient utilization and growth. Regarding feed conversion ratio, fish fed with 15% lipid diet at 28 °C showed a tendency toward a lower FCR compared to all other treatments. However, fish fed with 10% lipid diet at 28 °C didn't show significant differences in FCR across the different lipid levels or temperature conditions. Moreover, feed intake was significantly lower in fish fed with 15% lipids at both temperatures compared to those receiving the 10% lipid diet. These results suggest that flathead grey mullet exhibited superior feed conversion efficiency with the 15% lipid diet at 28°C, indicating minimized feed waste and enhanced nutrient utilization.

*(Continued on next page)*

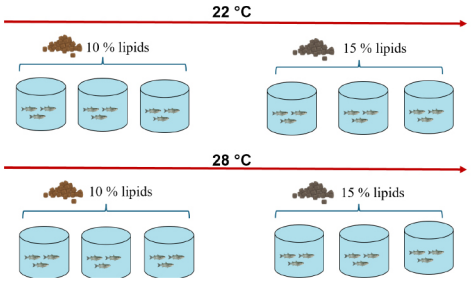

Figure 1. Experimental design of the trial: two diets differing in lipid content (10% and 15%) were tested at two temperatures (22°C and 28°C) in flathead grey mullet.

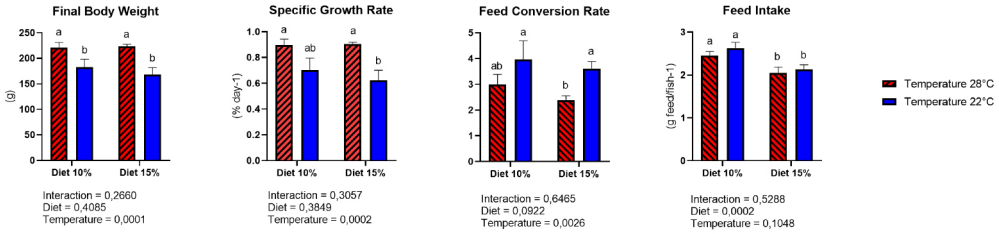

Figure 2. Final body weight, specific growth rate, feed conversion rate and feed intake of flathead grey mullet after a 100-day feeding trial conducted at two different temperatures (22°C and 28°C). Different letters indicate significant difference (two-way ANOVA $p \leq 0.05$ followed by Tukey's test) between treatments and temperature.

## Conclusion

In conclusion, the growth of the mullet at 28°C remained consistent across both dietary treatments. However, considering feed conversion ratio and feed intake, fish exhibited improved growth when provided with a diet containing 15% lipids at this temperature. A comprehensive understanding of the protein and energy requirements of this emerging species at varying temperatures is essential for optimizing growth performance and developing effective aquaculture practices.

**Introduction**
Flathead grey mullet (*Mugil cephalus*) is a catadromous, omnivorous fish species that has recently attracted growing scientific interest due to its potential as a sustainable, low-trophic-level option for aquaculture. In the context of a rapid global changing understanding how temperature and different environment interact is crucial for improving aquaculture sustainability. This abstract summarises preliminary findings from two growth trial conducted on flathead grey mullet, aimed at assessing the influence of temperature (Trial 1, T1) and sand-based environmental enrichment (Trial 2, T2).

**Materials and Methods**
(T1) Two isoproteic experimental diets were formulated to contain two lipid levels (Diet 10% and Diet 15%) and were tested at two temperatures: 22 °C and 28 °C. Diets were administered to triplicate groups of 30 fish each (initial weight: 90.5 g) over a period of 100 days at both temperatures. (T2) An experimental diet was formulated to contain low fishmeal (3%) and soybean meal (10%) levels. Diets were administered to triplicate groups of 18 fish each (initial weight: 124.5 g) over a period of 60 days at both different environmental enrichment (three of these tanks had been filled with 15 kg of sand each).

During both trial, feed was provided to apparent satiation during a single 6-hour meal per day and dissolved oxygen was maintained above 7.5 mg $L^{-1}$. At the end of the trial, final body weight (FBW), specific growth rate (SGR), feed intake (FI), and feed conversion rate (FCR) were calculated. Differences among treatments and temperatures were considered significant at $p < 0.05$ (one or two-way ANOVA followed by Tukey's test).

**Results and Discussion**
Environmental conditions significantly influenced fish growth performance in both trials. In T1, conducted at two water temperatures (28 and 22°C) and with two dietary lipid levels (10% and 15%), higher temperature resulted in increased final body weight, specific growth rate (SGR), along with improved feed conversion rate (lower FCR values). In T2, conducted with two environmental enrichments, the presence of sand appears to significantly modulate final body weight and specific growth rate showing also a tendency for a lower feed conversion rate. In both T1 and T2, feed intake was not influenced by environmental conditions. Results from this study indicate that flathead grey mullet exhibits strong tolerance to elevated water temperatures, including levels comparable to those recorded during heatwaves in Mediterranean regions. Moreover, environmental enrichment with sand, based on the observation that wild individuals often have sand present in their stomach contents, was associated with improved feed conversion rates (Whitfield et al., 2012). This suggests a possible correlation between natural substrate availability and digestive efficiency.

**Conclusion**
Although the flathead grey mullet is not considered a high-value species, its wide environmental adaptability and potential for sustainable production make it a promising candidate for diversified aquaculture systems. The development of rearing protocols that minimise environmental impact while supporting biodiversity will be essential for ensuring that future aquaculture practices remain both productive and ecologically responsible.

## Introduction

The successful restocking of pikeperch (*Sander lucioperca*) into natural habitats is a crucial strategy for both fisheries management and the conservation of this ecologically and economically valuable species (Lyutikov et al., 2024). Pikeperch, as an apex freshwater predator, exhibit pronounced phenotypic plasticity in response to environmental and dietary changes (Pourhosein-Sarameh and Falahatkar, 2024). However, transitioning from controlled aquaculture environments, often characterized by artificial diets and stable conditions, to the complex and variable wild poses significant physiological and behavioral challenges for RAS reared fish (Kozłowski and Piotrowska, 2024). One promising approach to enhance post-release survival is to reintroduce natural prey into the diet before restocking. These dietary interventions may facilitate the re-acclimatization of sensory systems, enabling more effective prey detection and capture in the wild.

## Material and methods

Five experimental groups were established, each maintained in a separate tank (one tank per group; five tanks in total) for a period of 30 days. All dietary treatments, including granular feed, granular feed with vitamins, and prey fish feed (administered for 10, 20, and 30 days), were provided ad libitum. All tanks were monitored under identical environmental conditions. At the end of the 30-day period, blood samples were collected, dissected to obtain liver, spleen, and gonad tissues, and all samples were processed for subsequent analyses. Blood biochemical parameters were measured using the Catalyst one analyzer.

## Results

An increasing trend in weight was observed across the five dietary groups (Gr, GrV, P10, P20, and P30), suggesting that all feeds adequately supported metabolic requirements ($p > 0.05$). In terms of blood biochemistry, cholesterol levels were significantly higher in the prey fish-fed groups (P10, P20, P30) compared to the granular control (Gr) and the vitamin-supplemented granular feed (GrV) ($p < 0.05$). Triglyceride levels showed an overall decreasing trend from the granular to prey fish-based diets, with statistically significant differences observed between Gr and P20 ($p < 0.05$), and between GrV and both P20 and P30 ($p < 0.05$). Although amylase activity did not follow a consistent trend, GrV showed significantly different values compared to the prey fish-fed groups (P10, P20, P30) ($p < 0.05$). Lactate levels decreased progressively across the groups, with Gr showing a statistically significant difference from P20 and P30 ($p < 0.05$). Glucose levels exhibited a declining trend across the treatments ($p > 0.05$). Ammonia levels showed no clear trend, but Gr differed significantly from P20 ($p < 0.05$). Additionally, significant associations were observed between glucose and ammonia, as well as between lactate and ammonia, particularly when comparing prey fish-fed versus non-prey fish-fed groups ($p < 0.05$)(Figure 1). No statistically significant differences were observed in the hepatosomatic index (HSI), viscerosomatic index (VSI), or gonadosomatic index (GSI) across the dietary groups ($p > 0.05$).

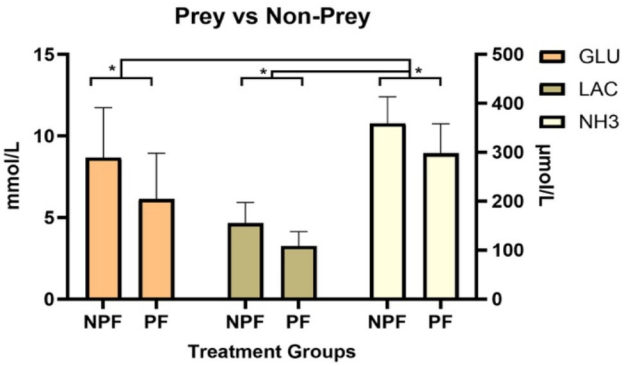

*Figure 1-Plasma glucose (GLU), lactate (LAC), and ammonia ($NH_3$) levels in non-prey (NPF) and prey fish (PF). * symbol stands for significant differences between different groups*

*(Continued on next page)*

**Conclusion**

The study found that all dietary treatments supported comparable pikeperch growth, but prey fish feed and granular diets differed significantly. Prey-fed groups had higher cholesterol and altered triglyceride levels, suggesting enhanced lipid metabolism consistent with natural prey consumption. Reduced lactate concentrations indicated improved anaerobic metabolic efficiency, which could be advantageous for wild reintroduction(Kestemont and Henrotte, 2015). Higher HSI tendency in certain groups reflected better liver health and potential resilience (Zhao et al., 2024). Integrating natural prey improves the likelihood of successful adaptation and survival in the wild.

Microalgae hold significant potential in biotechnology as a source of animal feed, high-value compounds, biofertilizers, and biofuels. Their high lipid and protein content makes them particularly valuable in aquaculture, where they are used either as live feed for fish and crustacean larvae or juveniles, or as ingredients in formulated feed.

However, the productivity of microalgae is often constrained by environmental factors such as light and temperature stress. Global warming and climate change further exacerbate these challenges, significantly compromising the biotechnological potential of microalgae. In this study, we aim to develop genetically modified microalgae strains with enhanced tolerance to elevated temperatures and light intensities, thereby improving their applicability in aquaculture and other green technologies. As a model organism, we employ the green alga *Chlamydomonas reinhardtii*, widely used in studies of microalgal genetics, physiology and ecology.

By combining random insertional mutagenesis with high-temperature selection, we have generated several mutant strains of *C. reinhardtii* exhibiting enhanced tolerance to heat stress. One strain, in particular, displays the highest level of thermotolerance – up to 38°C– compared to the WT strain, this phenotype being maintained under high light intensity. Functional and metabolomic studies revealed changes in photosynthetic efficiency as well as in redox and bioenergetic metabolism in the mutant strain. The mutated gene has been identified as encoding a membrane transporter. Comparative transcriptomic analyses between the mutant and WT strains are being conducted. Additionally, physiological assays and subcellular localization studies are ongoing, to elucidate the mechanisms underlying the enhanced thermotolerance observed in this mutant strain.

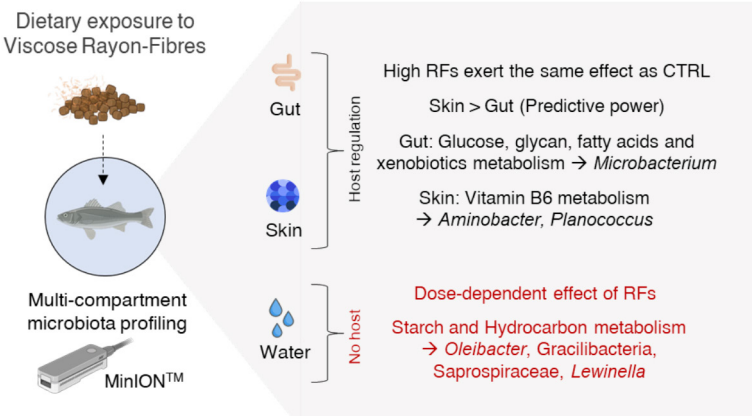
## Introduction

Viscose-rayon microfibres (RFs) are polymers derived from the textile industry that are widely dispersed throughout aquatic environments worldwide. Whether ingested or simply present in the surrounding environment, their presence would affect both wild and farmed animals (Matias et al., 2024a). Thus, a recent study on European sea bass (*Dicentrarchus labrax*) showed that the increased presence of RFs in aquafeeds (CTRL – no RFs; RF1 – 0.001 g/kg; RF2 – 0.01 g/kg; RF3 – 0.1 g/kg) was linked to an exponential increase in RF particles in the water, ranging from none in the tanks with CTRL-fed fish to 0.40 ± 0.21 RFs/L in those with fish fed the highest inclusion level (RF3) (Matias et al., 2024b). This increased RF release and exposure was associated to a fatty liver without signs of growth impairment in the short term. However, a multi-tissue, multivariate gene expression analysis identified up to 19 discriminant genes, which depicted changes in hepatic lipogenic enzymes and intestinal/head kidney inflammatory markers, among others. Besides, these expression patterns denoted opposing regulation of immune responses at the systemic and local levels, which contributed to distinguishing CTRL_RF1 from RF2_RF3 fish. To further explore other disruptive physiological processes, this study aimed to assess the impact of RF exposure on the host and associated microbial communities, employing a multi-layered approach for the integrative profiling of gut, skin, and environmental water microbiota.

## Materials and methods

European sea bass juveniles (5.8 g) were distributed in triplicate groups (180 fish per dietary treatment) in an flow through system. Fish were fed for 68 days to visual satiety with CTRL, RF1, RF2 and RF3 diets near to the visual satiety with automatic feeders (3 times per day). At the end of trial, 9 overnight fasted fish per diet were randomly sampled for gut and skin microbiota. Water samples (1L) were taken from the outlet water flow (OW) of each tank with fish, and from the inlet water flow (IW) from tanks without fish. Sequencing libraries were loaded in a MinION device, amplifying the full-length 16S rRNA gene with universal primers, using recently standardized sequencing procedures (Domingo-Bretón et al., 2024). Bioinformatic analyses included demultiplexing, quality filtering and taxonomy assignment. Richness and alpha-diversity were calculated in R. Partial least squares-discriminant analysis (PLS-DA) was used to depict the separation of experimental groups to be validated through permutation analyses (500 permutations). A minimum VIP value for the correct clustering of the 80% of samples was fixed in any microbiota layer, being 1.6, 1.3 and 1 the thresholds established for AI, skin and water, respectively. Bacteria taxa overcoming this threshold and displaying a high relative abundance (>0.5%) were selected as the main drivers. Inferred metagenome analysis was performed with Picrust2 tool and significant genes were considered at an FDR < 0.05.



*(Continued on next page)*

**Results and discussion**

A total of 95,000 reads per sample were assigned to 978 taxa in at least one of the three microbial compartments. In both the gut and skin, dietary RF exposure decreased bacterial richness at low and intermediate doses (RF1, RF2), while similar values were found in CTRL and RF3 fish. In water samples, RF diets did not significantly alter microbiota richness, although the general trend was a decrease in bacterial diversity in RF2 and RF3 that reached similar values to those found in IW samples. Overall, these findings highlight that the presence of RFs in fish feeds can alter the microbiota of both the host and its surrounding aquatic environment, with different allosteric loads that seem to require a certain threshold level for activation. This assumption is corroborated by PLS-DA analysis, which clustered the AI and skin samples of the CTRL and RF3 groups together, while in water samples, the clustered groups were CTRL_RF1 and RF2_RF3. Discriminant analysis further revealed that the number of bacterial taxa with a discriminant value increased exponentially from AI (27 taxa) to skin (141) and water (792), again reflecting a different allosteric capacity – higher in animal mucosal environments than in the aquatic environment. Additionally, this buffering capacity appeared greater in the gut environment compared to the skin, the latter being more susceptible to environmental fluctuations due to its open nature. Upon applying an abundance filter, the number of discriminant bacteria was reduced to 3, 6, and 13 in AI, skin, and water, respectively. Inferred metagenomic analysis indicated that the abundant gut bacteria (*Microbacterium* and Alcaligenaceae spp.) are primarily involved in the activation of polysaccharide and xenobiotic metabolism, whereas predominant skin bacteria (*Aminobacter* and *Planococcus*) are associated with vitamin B6 biosynthesis. In the water microbiota, up to 28 metabolic pathways appeared altered as a result of changes in taxa abundance, with particular relevance to starch and hydrocarbon metabolism through the action of *Oleibacter*, Gracilibacteria, Saprospiraceae, and *Lewinella* taxa.

**Concluding remarks**

This integrated perspective highlights the multifactorial nature of environmental pollution, microbial ecology, and host-microbe interactions, suggesting novel bacteria taxa and pathways through which microplastics exposure can influence host metabolic regulation.

# HARNESSING THE POTENTIAL OF *Nannochloropsis* GROWN ON BREWERY WASTEWATER AS A SUSTAINABLE FEED FOR SEA BREAM

F. Naya-Català[a]*, Q. Ma[b], P.G. Holhorea[a], Á. Belenguer[a], R. Domingo-Bretón[a], F. Moroni[a], J. Calduch-Giner[a], D. Van Mullen[c], R. Halim[b] and J. Pérez-Sánchez[a]

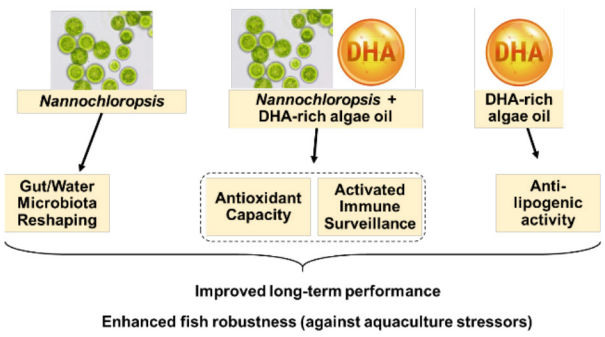
Email: fernando.naya@iats.csic.es

## Introduction

Microalgae are increasingly recognized as a sustainable solution to environmental challenges, particularly in the field of wastewater treatment. Certainly, these remarkable microorganisms are able to extract excess nutrients from wastewater and transform them into high-value biomass - eco-friendly resource - that can be turned into nutritious aquaculture feed. Among various microalgae, *Nannochloropsis* stands out due to its robust growth, high protein and lipid content, and significant levels of polyunsaturated fatty (Han et al., 2019). However, the in-depth potential of *Nannochloropsis* for the valorisation of waste products (e.g., brewery waste) into aquafeeds remains largely unexplored. The aim of this study was to investigate some of the physiological consequences in fish of the use of such microalgae-based production systems with focus at the systemic, tissular and environmental level from a holobiont perspective (i.e., the interconnected system of the host and its associated microorganisms), using gilthead sea bream as a model of Mediterranean farmed fish.

## Materials and methods

The potential of *Nannochloropsis* diets to revalorize brewery waste was analysed in a 96-days gilthead sea bream trial from April to July under natural temperature and daily photoperiod at the IATS latitude (40° 5' N; 0° 10' E). The experimental design with triplicate tanks per dietary treatment (210 fish per diet, 11 g initial BW) included four diets: a commercial-based diet as a negative control (D1), and three fishmeal-free diets with varying inclusion levels of *Nannochloropsis oceanica* (D2, 0%; D3, 2%; D4, 14%). For the most extreme diet formulation (D4), fish oil was replaced by a DHA-enriched microalgae oil, resulting in a diet devoid of fishmeal and fish oil and with an EPA+DHA content (1.80%) above the established nutrient requirements for juveniles of gilthead sea bream. All four diets were formulated by LSAqua (Hooglede; Belgium) to be isoproteic (48% dry matter) and isolipidic (18% dry matter) feeds with different inclusion levels of fishmeal, fish oil, plant proteins and other alternative ingredients (soya oil, poultry meal, processed animal proteins, single cell proteins, and microalgae biomass) to facilitate aquaculture eco-intensification through increased circularity and resource utilization. At the end of trial, 12 fish per dietary treatment were sampled for analyses of total plasma antioxidant activity, host gene expression, and bacteria composition of the adherent mucus layer and water environment. Antioxidant capacity was measured as Trolox activity. Gene expression was made using customized tissue-specific arrays with 89 selected markers of growth, lipid metabolism, antioxidant defence, and immunological status. Microbial characterization was performed amplifying full-length 16S rRNA using Oxford Nanopore sequencing. Bioinformatic analysis comprised demultiplexing, quality filtering and taxonomic assignment. Statistically significant differences ($p < 0.05$) on growth performance, and gene expression were assessed by one-way ANOVA/Kruskal-Wallis test followed by a Holm-Sidak *post-hoc* test.



*(Continued on next page)*

**Results and discussion**

All fish groups grew efficiently and only slight differences on final weight (< 5%) were found between D1-fed fish and the other three experimental groups fed fishmeal-free diets (D2-D4), which remained almost undistinguishable in terms of growth and feed conversion. However, fish fed the D4 diet showed an up-regulated hepatic expression of two key endocrine regulatory factors, *igf1* and *ghr1*, suggesting an improved growth potential at the transcriptional level in fish fed with the highest microalgae inclusion level. No signs of histopathological damage were found in the liver and intestines of any experimental group, but D4 fish displayed a reduced lipid vacuolization of enterocytes accompanied by a depletion of hepatic lipid droplets. Certainly, PLS-DA highlighted a consistent down-regulation of genes involved in fatty acid synthesis, such as desaturases (*scd1a*, *fads2*), elongases (*elovl1*, *elovl5*, *elovl6*), and fatty acid transporters (*hfabp*), alongside the up-regulation of hepatic lipase (*hl*). This shift is indicative of a metabolic adaptation that favours tissue-fatty acid uptake over de novo fatty acid synthesis. Likely this metabolic feature was primarily due to the highest PUFA content (DHA-rich algae oil) of D4, while the increased plasma antioxidant capacity of D3 and D4 fish would be the result of a combination of enzymatic and non-enzymatic antioxidant mechanisms that become activated with the increased dietary supply of PUFA and microalgal biomass. The microalgae-based diets also modulated the expression of several intestinal genes, including interleukins, galectin binding receptors, brush border enzymes, and markers of tight junction integrity (*il1b*, *il34*, *tnf□*, *lgals*, *alpi*, *tjp1, csflr1*, *cxadr*), encompassing both pro- and anti-inflammatory roles. Such finding denotes a delicate balance in the host intestinal transcriptome of D3-D4 fish, which helps to avoid excessive inflammatory responses while keeping the immune system alert to prevent the entry of invading pathogens. Such adaptive gene expression pattern would be favoured by the reshape of gut microbiota with an overrepresentation of 17 bacterial genera with potential detoxifying, antioxidant and anti-inflammatory properties. Among them, up to seven bacteria genera were markedly overrepresented in the intestine of D4 fish (*Vibrio, Hydrogenispora, Marinobacter, Palleronia-Pseudomaribius, Ruegeria, Atopostipes, Thaumasiovibrio*). The microbiota of the water environment was also altered by the dietary treatment, denoting the presence of active feeding fish, changes in diet composition and, more specifically, the degree of *Nannochloropsis* supplementation.

**Concluding Remarks**

*Nannochloropsis* supplementation largely reshaped the microbiota inhabiting the intestine and the water environment, promoting in turns a healthy intestinal core microbiota. Microalgae biomass, together with DHA-rich algae oil, would drive the expression pattern of key enzymes of lipid metabolism, antioxidant defence and immunological surveillance, while changes in lipid metabolism could be primarily attributed to a dietary surplus of PUFA rather than to an increased supply of microalgal biomass.

# SOCIO-ECONOMIC AND ECOLOGICAL IMPACTS OF FORAGE FISH USAGE IN FISHMEAL: A CASE AGAINST INEQUITIES IN FISHERIES AND AQUACULTURE£

Amir Neori (1,*), Moshe Agami (2)

(1) Morris Kahn Marine Research Station, Marine Biology Department, The Leon H. Charney School of Marine Sciences, The University of Haifa, Haifa 3498838, Israel

(2) School of Plant Sciences and Food Security, The George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv 6997801, Israel

**Introduction**

Forage fish are essential for food security in developing countries and fulfill critical roles in marine ecosystems. However, 20 to 30 million metric tons of forage fish are harvested yearly in low-income countries for use in the fishmeal and aquafeed industries (Fig.1, depicting catch allocation trends), mainly catering to developed countries. This exploitation of fish diminishes the supply to fresh fish markets, escalating local fish prices and marginalizing artisanal fishermen and their communities in leading fish-producing nations.

Ecological consequences are equally troubling—overfishing disrupts marine food webs, depleting piscivores like mackerel, seabirds, and marine mammals. The ethical implications of such practices are profound, particularly for low-income populations in forage-fish-producing nations (Fig. 2, illustrating the main stakeholders in the forage fish industry). Rising fish prices diminish access to nutritious diets and create financial strain for millions in fish-producing nations (Fig. 3, typical fish markets in low-income communities; removing fish from this market to the industry raises prices for the local consumers).

**Analysis**

Our research evaluates these trends' financial and nutritional effects, exploring the financial impact of a hypothetical 10% drop in fresh forage fish allocation to local markets for illustrative purposes. The findings suggest that even such a slight fish supply shift could significantly impact consumers' expenses by hundreds of millions of dollars globally and tens of millions of dollars nationally, as well as increase the catch of larger fish and significantly improve household nutrition in underprivileged communities.

We advocate for industry and policy reforms to rectify these inequities, including promoting alternative aquafeed protein sources and cultivating non-carnivorous fish. Only by prioritizing equitable access can the fisheries industries ensure that forage fish resources serve both human and ecological well-being.

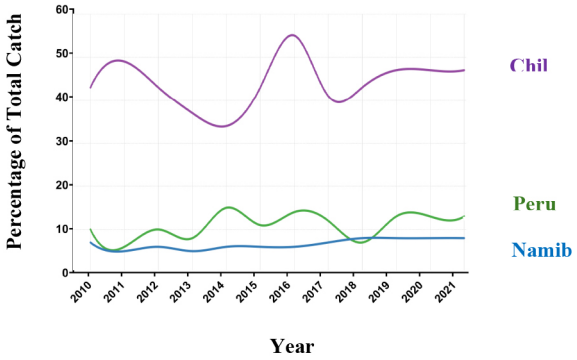

Fig. 1: Trends in forage fish catch fraction sold in the fresh fish markets, most of the catch goes to the fishmeal and aquafeed industries (2010–2021).

Figure 2: Key stakeholders and issues related to forage fish fisheries in this presentation. Overlooking the needs of poor consumers, fishermen, and the ecosystem gives undue advantage to the fishmeal and aquafeed industries.

# EFFECTS OF SIZE GRADING ON GROWTH PERFORMANCE, SURVIVAL AND SIZE DISTRIBUTION OF WHITELEG SHRIMP (*Litopenaeus vannamei*) IN AQUACULTURE

J. Neuse*, F. Tölke, M. Bögner

Alfred Wegener Institute Helmholtz Center for Polar- and Marine Research
Am Handelshafen 12
27570 Bremerhaven, Germany
*Corresponding author: E-mail: Janek.neuse@awi.de

## Introduction

Size grading is an established practice for a variety of aquaculture species. A more homogeneous size distribution often reduces cannibalism and allows optimal feed management. It was indicated that size grading also positively influences the growth performance of *L. vannamei* and could be implemented in a farming environment (LI et al., 2010). Nowadays, the most established grading techniques for shrimp in aquaculture are hand sorting and screening, which are rather invasive and labor-intensive. Possible positive effects on the survival and growth of the smaller shrimp after sorting are mostly unknown.

The aim of the present experiment was to evaluate the effects of size grading on growth performance and survival of small shrimp, large shrimp and unsorted shrimp groups.

## Material and Methods

After a 14-days acclimation period, a batch of shrimp (0.4 ± 0.6 g) sourced from Aquapurna, Germany, was graded into two different size categories (small and large) using a sorting grid with a 4.7 mm opening size. Additionally, a not sorted shrimp group was used as the unsorted control (CU). The sorted animals were divided into three treatments: 1. Small Sorted (SS, 0.1 ± 0.0 g); 2. Large Sorted (LS, 1.0 ± 0.1 g) and 3. Control Sorted (CS, 0.5 ± 0.1 g). For the CS, the initial ratio of small to large animals was calculated after sorting and the animals were recomposed following that exact ratio. Afterwards, shrimp from each treatment were randomly selected, photographed, weighed, and stocked into a 100 L tank. Each treatment had four replicates, adding up to 16 tanks in total with 20 shrimp per tank. The shrimp were fed following the Le Gouessant "VANNA RANGE" feeding table. After 57 days, the experiment was finalized and all shrimp were weighed and measured.

## Results and Conclusion

The total biomass, average body weight (ABW) and coefficient of variation (CV) of the initial sampling (day zero) are shown in Table 1.

After 57 days, all treatments showed a significantly higher final biomass than the SS treatment (Holm-Sidak, $p < 0.001$). While the LS treatment had the highest average biomass, the differences were not significant compared to CU and CS. Similar results were shown for the biomass gain and the average body weight. The SS treatment had the highest SGR (6.3 ± 0.2 %) which was significantly higher than all other treatments. There were no significant differences between the survival rates of the different treatments (One-way ANOVA, $p = 0.481$) (Table. 2).

The results indicate that while small shrimp are able to partially compensate for the initial size difference due to their higher SGR, full compensatory growth could not be achieved through size grading. Nevertheless, size grading can positively impact the production of *L. vannamei* by increasing the uniformity. The CV of the large sorted shrimp group was lower compared to the controls. While slightly increasing the total biomass production, a lower CV additionally results in harvesting a more homogeneous and therefore higher-value product. It lowers the risk of harvesting undersized shrimp that cannot be sold or have to be sold at a much lower price. Animals that are too small can be removed from the system in an early stage, saving resources and increasing profits.

## Introduction

The grooved carpet shell, *Ruditapes decussatus*, is a high-value bivalve, native to European and North African coasts and widely targeted by fisheries and aquaculture. Successful hatchery production remains limited by larval settlement and metamorphosis, stages that represent the transition from planktonic free-swimming to benthic juveniles. Across marine invertebrates, settlement and metamorphosis are triggered by biological, chemical and physical factors. Chemoreceptors detect these environmental cues and activate neural circuits that drive the morphological and behavioural changes associated with larval metamorphosis. In bivalves, neuroactive compounds, such as catecholamines (e.g., epinephrine) and neurotransmitters (e.g., serotonin), have been widely investigated for their capacity to induce larval metamorphosis[1]. These compounds have been used to induce, synchronise or accelerate the metamorphosis of different molluscan species. Catecholamines and some neurotransmitters have some amino acids as precursors. For instance, L-tyrosine and L-phenylalanine are precursors in catecholaminergic pathways, while L-tryptophan is a serotonin precursor. Therefore, this study explores the ability of these specific amino acids – L-tyrosine, L-phenylalanine, and L-tryptophan – to act as metamorphic inducers in *R. decussatus* larvae under controlled conditions.

## Material and Methods

This study evaluated the effects of different concentrations of L-tyrosine (TYR), L-phenylalanine (PHE) and L-tryptophan (TRYP) ($10^{-4}$, $10^{-5}$, and $10^{-6}$ M) and exposure times (24, 48, and 72 hours) on the metamorphosis of *R. decussatus* larvae. The larvae were reared in filtered and sterilised seawater and fed daily with a bispecific diet of *Tisochrysis lutea* and *Chaetoceros calcitrans*. Larvae were considered competent for settlement after being retained twice on a 150 µm sieve (approximately 18 days). The experiments were conducted in glass beakers with 300 mL of clean seawater (FSW) with stimuli. Each treatment beaker contained a sieve (150 µm mesh) with approximately 1000 larvae. Beakers were under continuous aeration and a constant temperature (21ºC) and salinity (33.2). After each exposure period, larvae were removed from the test solution, rinsed with FSW, observed under a microscope, and placed back into the beakers filled with FSW until completing 6 days of the experiment. Metamorphosis percentage, validated by the presence of branchial arches, and survival rate were assessed after each exposure period and at the end of the experiment.

Results were analysed with R 4.4.1 software. Percentages of metamorphosed larvae and mortality were analysed using the Aligned Rank Transform (ART) method, followed by Tukey's *post-hoc* test. This non-parametric approach enables testing the main effects and interactions by aligning and rank-transforming the data[2], followed by standard ANOVA. Statistical significance was set as $p < 0.05$.

## Results

The effects of the different chemical treatments on larval metamorphosis after 6 days of experiment are represented in Fig. 1. Exposure during 24 hours of TYR $10^{-5}$M and $10^{-4}$M, PHE $10^{-5}$M and TRYP $10^{-6}$M and during 48 hours of TYR $10^{-5}$M and PHE $10^{-6}$M induced a significantly higher metamorphosis rate than the respective control, with no significant differences. Exposure of 72h to all compounds, except TYR $10^{-5}$ M, PHE $10^{-5}$ M and $10^{-6}$ M and TRYP $10^{-6}$M, evoked a significantly lower percentage of metamorphosed larvae. TRYP at $10^{-4}$M was revealed to be lethal, with 100% mortality. Similarly, only less than 10% of larvae treated with PHE $10^{-4}$M survived. The 72-hour control showed less than 50% mortality, with the highest percentage of metamorphosed larvae. Other compounds did not influence the percentage of metamorphosis compared to the control.

*(Continued on next page)*

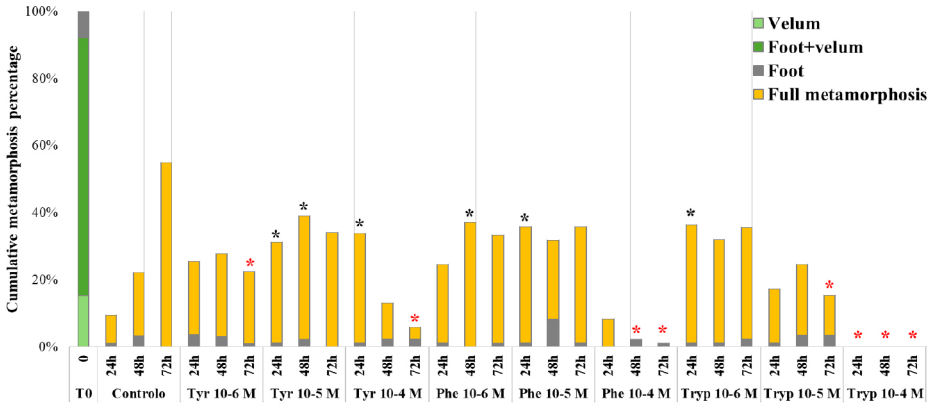

**Fig. 1**. Effects of L-tyrosine (Tyr), L-phenylalanine (Phe) and L-tryptophan (Tryp) exposure (24, 48 and 72 h) on larvae of *R. decussatus* at different concentrations ($10^{-4}$, $10^{-5}$ and $10^{-6}$ M) after 6 days. Column colours represent different development stages of larvae. Black (*) and red asterisks (*) indicate positive and negative significance differences against the control, respectively.

## Discussion and Conclusion

The present study demonstrates that L-tyrosine and L-phenylalanine had the best results in inducing metamorphosis in *R. decussatus* larvae. Both amino acids are biochemical precursors in catecholaminergic pathways, leading to the synthesis of dopamine, norepinephrine, and epinephrine, which have been implicated in metamorphosis induction in other bivalve species[1].

For L-tyrosine, the higher metamorphic and lower mortality rates occurred at $10^{-5}$M for 24–48 h or $10^{-4}$M for 24 h, indicating that a higher concentration may be required for receptor saturation over shorter exposures. In contrast, L-phenylalanine achieved similar effects at $10^{-6}$M for 48 h or $10^{-5}$M for 24 h, which may indicate that lower concentrations and exposure may be sufficient to induce a higher metamorphosis rate. L-tryptophan, a precursor in the serotonergic pathway, was found to be only efficient at low concentrations and short exposures and lethal at higher concentrations, with 100% mortality at $10^{-4}$M.

That precursors of catecholamines exhibited better results in inducing metamorphosis is in accordance with the literature, in which catecholamines are more suitable inducers for metamorphosis than serotonin[1]. The effectiveness of L-tyrosine and L-phenylalanine highlights their potential use as chemical inducers for metamorphosis. These amino acids are affordable and may be easily introduced in hatchery protocols optimisation.

# NOVEL CAPACITY BUILDING APPROACH TO SUPPORT FUTURE COMPETENCE NEEDS IN THE AQUACULTURE SECTOR

A. Neyts*, B. Finstad, I. Salaverria-Zabalegui and B.E. Asbjørnslett

Norwegian University of Science and Technology (NTNU)
7491 Trondheim
Norway
E-mail: Alexandra.Neyts@ntnu.no

## Introduction

Knowledge is fundamental for developing smarter, greener, and more efficient solutions that foster societal trust and enhance the reputation of the aquaculture industry. Like many sectors, the seafood industry faces major challenges driven by climate change, environmental issues, resource constraints, and heightened demands for improved animal welfare, necessitating innovation and sustainable development. At the same time, Norwegian seafood companies anticipate employment growth and a substantial shift in skills needs toward 2030. Recent data from Møreforskning show that 60% of seafood companies report unmet competence needs, with half experiencing recruitment challenges. In addition to operational personnel, there is a growing demand for specialists including engineers, economists, biologists, lawyers, and data scientists.

## Materials and methods

To address these challenges, the regional public-private partnership Bridgehead Aquaculture, has been established. The initiative aims to align workforce competencies with sector demands through cross-level and interdisciplinary education. A key element involves connecting university students with pupils at vocational schools in coastal communities, promoting mutual understanding, sharing experience, and inspiring future careers within the blue sector.

Innovative educational models have been implemented, such as a two-semester practical aquaculture course for bachelor's and master's engineering students. It allows them to manage a complete fish production cycle, from fertilized egg to smolt, gaining deep insight into production processes, health management, welfare considerations, and environmental interactions. Students from diverse engineering disciplines learn to contextualize their expertise within aquaculture systems, enhancing both technical understanding and ecological awareness.

## Results

This cross-disciplinary approach is extended to PhD education, where candidates from technology, natural sciences, and humanities collaborate under NTNU's strategic research area Ocean and Coast - Strategic research area. By integrating interdisciplinary collaboration and real-world exposure into aquaculture education at all levels, the initiative enhances educational relevance, fosters targeted recruitment, and drives science-based innovation. This model contributes to preparing the next generation of specialists to address evolving sector challenges, supporting the sustainable growth of aquaculture aligned with societal values and environmental imperatives.

# HEAD KIDNEY LEUKOCYTES REMEMBER: MOLECULAR INSIGHTS INTO TRAINED IMMUNITY IN ATLANTIC SALMON (*Salmo salar*)

Thinh Hoang Nhan[1,2,3*], Lluis Tort[2], Carlo C. Lazado[1]

[1] Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 1433 Ås, Norway
[2] Faculty of Biosciences, Universitat Autònoma de Barcelona, 8193 Bellaterra, Spain
[3] Faculty of Bioscience Engineering, Ghent University, 9000 Gent, Belgium
[*]Email: thinh.nhan@ugent.be

Introduction

The immune system in teleost fish, similar to other vertebrates, consists of both innate and adaptive immunity. Immunological memory has long been believed to be a unique characteristic of the adaptive immune system that generates specific and long-lasting responses to antigens. However, a novel understanding has emerged recently demonstrating that the innate immune system also possesses memory-like capabilities, a phenomenon referred to as "trained immunity". This is a significant finding because the innate immune system was previously considered a rapid but non-specific defence lacking immunological memory. Studies in fish have suggested that innate immune cells, such as macrophages and neutrophils, can exhibit an enhanced response upon re-exposure to stimuli, highlighting a new layer of complexity in host defence. Studying "trained immunity" in fish is particularly novel and relevant due to their evolutionary position as early vertebrates with a well-developed innate immune system. This capacity for innate immune cells to "remember" prior encounters, potentially through metabolic modulation and epigenetic reprogramming, offers a promising direction for understanding broad-spectrum protection and developing sustainable disease management strategies in aquaculture.

**Materials and Methods**

In this research, leukocytes were isolated from the head kidney of 100 g Atlantic salmon (*Salmo salar*) in freshwater stage and cultured under standardized conditions for 2 days. Cells were first stimulated for 24 hours with β-glucan (10 μg/mL) to induce a training response, followed by a five-day resting period in the same cultured condition. Subsequently, cells received secondary stimulation with phosphate-buffered saline (PBS, control), β-glucan (100 $\mu$g/mL, homologous stimulus), and lipopolysaccharide (LPS, 100 $\mu$g/mL, heterologous stimulus). Cell's immune activity was assessed by phagocytosis, nitric oxide (NO), and reactive oxygen species (ROS) production. To evaluate metabolic regulation, intracellular levels of lactate and fumarate were quantified. In addition, quantitative PCR was performed to assess gene expression related to immunity, glycolysis metabolism, and epigenetic regulation.

**Results**

Preliminary results showed that trained cells exhibited a noticeable enhancement in phagocytic activity upon secondary stimulation with both β-glucan and LPS compared to untrained cells. ROS production increased in β-glucan-stimulated cells, while NO levels remained relatively consistent among groups. Besides, fumarate concentrations were higher in β-glucan treatments and appeared to decline in trained groups, meanwhile, intracellular lactate levels remained relatively stable across both trained and untrained groups. Gene expression analysis of cells after the resting period showed elevated immune and metabolic gene expression in the trained group, with significant differences mainly in metabolic genes. While gene expression profiles were largely similar between trained and untrained leukocytes, several genes demonstrated distinct expression levels in the trained group, indicating potential targets of trained immune regulation. In addition, LPS stimulation elicited higher immune and metabolic gene expressions compared to PBS and β-glucan within the same group. In contrast, most epigenetic-related genes tend to exhibit minimal variation in expression levels across treatments and groups.

**Conclusion**

These findings provide preliminary evidence that β-glucan can induce trained immunity in Atlantic salmon leukocytes. The observed functional and metabolic shifts suggest that trained innate responses in fish may contribute to broad-spectrum immune protection. This study highlights the potential of trained immunity as a novel approach for improving disease resilience and supporting sustainable health strategies in aquaculture.

# DISTANCE DECAY EFFECTS AND PUBLIC ATTITUDES TOWARDS AQUACULTURE AND MARINE ACTIVITIES IN IRISH COASTAL COMMUNITIES

Ní Éinniú M.*, Hynes S.

Socio-Economic Marine Research Unit
J.E. Cairnes School of Business and Economics
Nua Mara, Irelands Marine Innovation Centre
*E-mail: maire@midc.ie

## INTRODUCTION

As global seafood demand continues to increase, aquaculture is playing an increasingly vital role in food security. Despite its potential, the sector's expansion often encounters resistance, particularly in coastal regions where marine space is contested (Hynes et al., 2018). This study examines public attitudes toward aquaculture in Connemara, Ireland, with a focus on the relationship between proximity to aquaculture operations and public perception of their environmental and socioeconomic impacts. Specifically, it explores the "distance decay" effect, offering insights to support evidence-based Marine Spatial Planning (MSP). Understanding the drivers of social acceptance is essential as Ireland aims to grow its blue economy in line with EU directives, while maintaining environmental integrity and community support.

## MATERIALS AND METHODS

Face-to-face surveys were conducted across Connemara, County Galway, between June and July 2019. A total of 245 fully completed questionnaires were collected, yielding a response rate of 67%. Participants aged 18 and older were interviewed in their homes, with a focus on the Galway Gaeltacht and adjacent areas.

The survey captured demographic data alongside respondents' awareness of aquaculture, environmental concerns, and preferences for future marine developments. Perceptions of threats to the marine environment and support for various marine activities were assessed using Likert-scale questions. Preferences for activity intensity were measured on a scale from 0 (no activity) to 5 (very high intensity).

Data were compared with findings from previous national surveys and a case study in Mulroy Bay, County Donegal. A logistic regression model was used to identify predictors of perceiving aquaculture as an environmental threat, including age, gender, education, proximity to aquaculture sites, and sub-regional location within Connemara.

## RESULTS AND DISCUSSION

The findings reveal strong local support for aquaculture in Connemara, with 73.7% of respondents supporting medium to high levels of activity in their local bay. Only 11% identified aquaculture as a significant environmental threat—considerably lower than in Mulroy Bay (17%) and the national average (40%). These results suggest that familiarity with aquaculture may mitigate negative perceptions.

Age emerged as a key demographic predictor: respondents under 35 were significantly more likely to express environmental concerns ($p < 0.05$), whereas those over 55 showed the highest levels of support for aquaculture expansion. Education level also influenced attitudes—university-educated individuals were more environmentally cautious than those with only secondary education (odds ratio = 1.72, $p < 0.05$).

Economic priorities were prominent among respondents, with 54% identifying employment as their top concern, compared to 41% prioritising environmental protection. This diverges from national patterns, where environmental concerns typically dominate. Notably, 84% agreed that "fish farming creates opportunities for local employment."

Significant regional differences emerged within Connemara. Support for aquaculture was highest in Carna (89%), followed by Cashel (76%) and Carraroe (64%). Regression results indicated that Carna was the only region where aquaculture was not perceived as an environmental threat (coefficient = -2.78, $p < 0.05$), likely reflecting the area's long-standing engagement with the sector. In contrast, respondents in Spidéal, Carraroe, and Clifden expressed stronger support for marine protected areas (coefficients = 35.55, 20.02, and 45.85, respectively; $p < 0.05$).

*(Continued on next page)*

Among specific environmental concerns, waste accumulation and sea lice were cited most frequently (42% each), while escaped farmed fish (18%) and feed sourcing (14%) were considered less significant. These concerns differed from national priorities, where the use of wild fish in feed was more prominent (30%).

Local ownership was strongly favoured: 85% of Connemara respondents preferred locally owned fish farms, compared to 75% in Mulroy Bay and 56% nationally. Similarly, 78% believed coastal planning should be led by local authorities, with only 15% favouring national control.

Support for complementary marine activities was also high: 92% supported marine renewable energy, 88% supported seaweed harvesting, and 77% supported sea fisheries. Seabed mining, however, faced strong opposition (71%), particularly in areas with recent mining license proposals. These findings suggest opportunities for integrated multi-trophic aquaculture (IMTA) and broader marine planning strategies.

**CONCLUSION**

This study highlights how public attitudes toward aquaculture are shaped by proximity and experience. Communities with long-term exposure to fish farming—such as Carna—exhibit more positive perceptions, supporting the existence of a "distance decay" effect. Conversely, communities more removed from aquaculture operations express greater environmental concern.

Tailoring aquaculture development strategies to specific regional and demographic contexts is essential. The influence of age, education, and economic priorities underscores the need for targeted stakeholder engagement and communication strategies.

The strong emphasis on employment benefits reflects the socioeconomic realities of rural coastal communities. Policies that promote local ownership and emphasise local job creation are likely to enhance public acceptance. Broad support for multiple marine activities also points to the potential for integrated marine spatial planning approaches.

To improve MSP implementation, policymakers should:

1. Engage directly with affected communities.
2. Address environmental concerns transparently through monitoring and mitigation.
3. Emphasise local employment benefits.
4. Promote local ownership of marine enterprises.
5. Explore integrated aquaculture systems such as IMTA.

# DRIVING SUSTAINABLE AQUACULTURE THROUGH KNOWLEDGE AND INNOVATION

Lídia Nicolau[1,*], Cátia Lourenço-Marques[1,2], Pedro Pousão-Ferreira[1,2]

[1] S2AQUA - Collaborative Laboratory, Association for a Sustainable and Smart Aquaculture, Olhão, Portugal
[2] Aquaculture Research Station (EPPO)/Portuguese Institute for the Ocean and Atmosphere (IPMA), Olhão, Portugal
[*] lidia.nicolau@s2aquacolab.pt

Over the last few decades, there has been an urgent need to increase knowledge in the blue economy to promote sustainability and enhance the literacy of employees working in marine areas. Education and training are key drivers for developing and maintaining the skilled workforce required to meet the global challenge of achieving a more sustainable aquaculture industry. Investing in capacity building in aquaculture, marine sciences, and the blue economy is essential for promoting social inclusion and enhancing the competitiveness of the aquaculture sector across Europe.

S2AQUAcoLAB is a private, non-profit institution dedicated to research and experimental development in aquaculture. Its mission is to address the needs of the industry by promoting a smarter and more sustainable aquaculture, grounded in scientific knowledge, innovation, and technological development. One of S2AQUAcoLAB's key priorities is the provision of training programs tailored to the specific needs of the aquaculture sector.

In close collaboration with partners and stakeholders, S2AQUAcoLAB develops technical training programs tailored to the real needs of the aquaculture sector, ensuring industry alignment and immediate applicability. The training offer covers both specialized technical skills — such as marine organism cultivation, aquaculture biotechnology, broodstock management, nutrition, and recirculating aquaculture systems (RAS) — and essential transversal skills. Organized into Essential, Tailored, and Innovation programs, these courses are delivered by experts with hands-on experience and combine face-to-face sessions with online modules via the S2AQUAcoLAB Moodle platform. The goal is to empower professionals, enhance the sector's competitiveness and sustainability, and promote knowledge transfer and technological innovation.

All courses are hosted on S2AQUAcoLAB's Moodle-based online platform, enabling replicability across different organizations, regions, and countries. This digital format offers a strategic opportunity to increase access to training throughout Europe, particularly in coastal and peripheral regions where training in aquaculture and marine sciences may still be limited.

By leveraging its multidisciplinary team's extensive expertise, S2AQUAcoLAB aims to support the competitiveness and innovation of the European aquaculture sector, foster social and territorial inclusion, and contribute to the transition toward a resilient, smart, and sustainable blue economy across Europe.

This project is financed by Missão Interface, project co-funded by PRR - Plano de Recuperação e Resiliência pela União Europeia (01/C05-i02/2022.P148).

# VALORISATION POTENTIAL OF MARINE BY-PRODUCTS IN PORTUGAL: FINDINGS FROM THE AQUAFISH 0.0 PROJECT

Lídia Nicolau[1,*], Alexandra Marques[1], Pedro Pousão-Ferreira[1,2], Cátia Lourenço-Marques[1,2]

[1] S2AQUA - Collaborative Laboratory, Association for a Sustainable and Smart Aquaculture, Olhão, Portugal
[2] Aquaculture Research Station (EPPO)/Portuguese Institute for the Ocean and Atmosphere (IPMA), Olhão, Portugal
[*] lidia.nicolau@s2aquacolab.pt

Valorising marine by-products is essential to reducing environmental impacts, enhancing resource efficiency, and strengthening the economic resilience of fisheries and aquaculture sectors. By transforming materials traditionally considered waste into valuable inputs for industries such as aquafeed, pet food, nutraceuticals, and cosmetics, it is possible to advance circular economy practices, open new market opportunities, and reinforce the blue economy value chain, while contributing to biodiversity conservation and aligning with international sustainability targets, including the UN Sustainable Development Goals. In recent years, research in this field has gained momentum due to limited marine resources and growing demand for sustainable sources of functional, nutritional ingredients, and biomaterials. Two main valorisation pathways have emerged: the large-scale production of fishmeal and fish oil for feed, and the development of high-value bioactive compounds using advanced technologies.

Within this context, the AQUAFISH 0.0 project (Interreg Atlantic Area Program) aims to improve the sustainable management and circular use of biomass from fisheries and aquaculture across the Atlantic Area. By fostering collaboration among partners from different regions, the project seeks to identify, quantify, and promote the reuse of by-products and bycatch, driving innovation and reducing waste.

As part of this initiative, an inventory of biomass volumes from by-products and bycatch (category 3, Regulation (EC) No 1069/2009) was undertaken for Portugal. The study applied a combination of direct methods (industry questionnaires) and indirect methods (official statistics, bibliographic sources, and conversion coefficients). Significant data gaps were identified, particularly for aquaculture and fish processing industry by-products, compounded by low response rates from stakeholders. Based on available 2022 production data, marine by-products were estimated at ~41,778 tonnes/year, with the main contributors being the canning industry and frozen fish industry.

A national focus group with sector stakeholders identified key challenges, including the need for refrigeration, storage constraints, and a reduction in the number of processing companies. Participants agreed that the volumes produced are sufficient to support the development of new value-added products, highlighting opportunities for innovation and reinforcing circular economy practices in the Atlantic Area.

This project is financed by “AQUAFISH 0.0: Aquaculture & Fisheries 0.0 – improving the acceptance and social awareness in the consumption of sustainable marine food products developed under the zero-wate philosophy” project co-funded by the Interreg Atlantic Area Programme through the European Regional Development Fund (ERDF) (EAPA_0062/2022).

# EFFECT OF DIFFERENT STOCKING DENSITIES ON CLOSED CAGE HYDRODYNAMICS, WATER QUALITY, FISH HEALTH AND WELFARE

S.W. Dahle*, A. Nilsen, K.V. Nielsen, M. Stormoen, P. Klebert

SINTEF Ocean
7465 Trondheim, Norway
Email: stinewiborg.dahle@sintef.no

## Introduction

Closed cage farming has the possible to solve the most important environmental challenges in farming of Atlantic salmon. The most immediate benefit is effective prevention of sea lice infestation, thus also preventing the use of harmful delousing methods and negative effects of salmon lice on wild salmonid populations. Lower risk of fish escapees and the possibility to collect and reuse particular organic effluents may also contribute to improved sustainability in salmon farming. The closed systems also show good growth rates, low feed conversation rates and low mortality (Nilsen et al., 2020). Closed-cage farming enables tighter control of many factors such as water oxygenation level, temperature and hydrodynamic flow. It also allows for closer monitoring of fish health. However, little knowledge exists about how different production intensities in such closed cage systems affect water quality, fish behaviour, fish health and welfare and the final production economy.

## Material and methods

In the project BIOCLOSED we have performed a study at a commercial producer of Atlantic salmon in closed cages, where cages have been monitored over a production cycle. The study includes measurements of fish behaviour, water flow and water quality, studies of the development in water microbiome, registration of fish welfare indicators and analysis of key biological and financial data. The main aim is to investigate the effect of two different initial stocking densities on cage hydrodynamic, water quality, fish health and welfare, and to evaluate the economic output during commercial production with such different stocking densities. The project is organized as a cooperation between one Norwegian industrial partner and the research institutions SINTEF OCEAN, the Norwegian Veterinary Institute and the Norwegian University of Life Sciences.

## Results

The monitoring at the commercial producer will end in May 2025 and the final results will be ready before the conference.

*frank.nilsen@uib.no

Atlantic salmon (*Salmo salar*) farming faces significant challenges due to infestations by *Lepeophtheirus salmonis*, leading to considerable financial losses. Recently, extensive research has focused on the interaction between host and parasite to create effective treatments or preventative strategies against salmon lice. Adding methionine to fish feed has been shown to improve resistance to bacterial infections. Nonetheless, there has been no investigation into the immunomodulatory effects of this amino acid on parasite levels in aquaculture settings. This study sought to assess the impact of dietary methionine supplementation on the immune response of Atlantic salmon when exposed to sea lice. Juvenile fish (approximately 120g) were fed for a period of four weeks with either a standard control diet (CTRL) or a diet supplemented with methionine (MET, at twice the recommended level of L-methionine), and after sampled (n=12 per diet group). The remaining fish were then exposed to sea lice infection through cohabitation (100 copepods per fish) and sampled two weeks following the challenge. Samples of blood, plasma, liver, and head kidney were collected for haematological assessments, analysis of systemic humoral responses, oxidative stress markers, and gene expression studies, respectively. Moreover, skin samples were taken for proteomic analysis and RNA sequencing at both pre-infection and post-infection stages from parasite attachment sites and skin after this local. Parasite counts per fish showed that 70% were at the chalimus-II stage, with the remainder being at the pre-adult stage, and no significant differences were observed between the dietary groups. At the chalimus-II stage, the parasite feeds exclusively on mucus and skin, which could explain the limited haematological response detected, although infection appeared to elevate white blood cell counts. These findings, alongside the absence of oxidative stress biomarkers and immune gene regulation in the head kidney, indicate that while the ectoparasite was present, it did not provoke a notable systemic reaction in the host. This conclusion is further supported by the lack of lipid peroxidation in the tissues. Taken together, this supports the idea that during early development, the parasite primarily triggers immune responses locally at the skin. These responses, largely driven by tissue damage, may not generate a systemic immune reaction. However, plasma protease activity in the MET-fed group rose significantly following infestation compared to both the basal diet group and the uninfected controls. The proteomics and RNA sequencing data from the skin infected and skin where the lice attachment sites are currently under analysis to provide deeper insights into methionine's immunomodulatory potential and the local immune response associated with resistance to salmon louse.

Work funded by the European Union's Horizon Europe research and innovation programme (GA No.101079467 project GRINNAQUA).

# AQUACULTURE, A FAVORABLE RECOMMENDATION FOR FOOD INSECURITY, POVERTY AND UNDERNUTRITION IN KENYA

Joyce Njenga [1] ,Jonathan Munguti [2] ,Menaga Meenakshisundaram [3]

jnjenga@jkuat.ac.ke

Food insecurity remains one of the most evident aspects of poverty. The growing population and the competition for resources such as land and water imply that global food demand is burgeoning. In Kenya, food insecurity trends are worrying as the population is predicted to hit 55 million by 2030 as the per capita annual growth rate of arable land and the increase in food prices. Aquaculture is vital for enhancing food security, alleviating poverty and promoting sustainable economic growth in Kenya. The main challenges in the aquaculture subsector in Kenya include; Inadequate availability and affordability of quality fish seed (fingerlings), lack of high quality and affordable fish feeds, inadequate supportive infrastructure e.g. hatcheries, fish marketing systems, fish processing plants, shortfall in budgetary allocations to support aquaculture initiatives, weak research- extension-farmer linkages, slow adoption rate of fish farming technologies, innovations and management practices (TIMPs), lack of good credit facilities and schemes for fish farmers, poor security and safety of fish in ponds and cages, poor book keeping and record management leading to inaccurate data, policy and legal framework for fish feed and seed certification to monitor compliance. The opportunities to enhance aquaculture contribution to food security, poverty alleviation and malnutrition in Kenya include; integration of aquaculture into conventional farming, upscaling modern technologies, innovations, and management practices (TIMPs), competency- based training on special skills in aquaculture, organizing fish traders into groups to maximize financial and market opportunities, exploring opportunities in value- added product development, investment in modern fish processing technologies and marketing techniques, promoting public –private partnerships to support aquaculture initiatives.

# SUITABILITY OF CONVENTIONAL INGREDIENTS USED FOR AQUAFEED PRODUCTION IN KENYA

Joyce liti Njenga, Winfred T. Nakawungu

Tel: +254 721312776

The ambitious aquaculture production targets aim at producing 1,000,000 mt, 700,000 mt, 50,000 mt and 160,000 mt in Uganda, Kenya, Tanzania and Rwanda, respectively by 2030;this therefore calls for increased fish feed production however fisheries value chain is challenged by limited access to quality fish feeds that are commercially competitive and environmentally friendly. Small scale fish farmers are limited by high feed cost and logistics associated with feed importation, that limit their access to quality feeds. Accordingly, there is growing interest to promote backyard aquafeed formulation. Traditionally feed formulation focuses on nutrient composition (more so proximate composition) and cost of feed ingredients, and pay less attention to several factors that affect sustainability, including pollution potential, environmental/ecological impacts, competing uses, socio-cultural considerations, yield and fertilizer requirements among others.

We examined a broad range of factors that may affect the suitability of a feed ingredient (including those related to environment, nutrition content and utilization, unit nutrient cost, and socio-economics among others) for five commonly used protein ingredients (i.e., fishmeal, bone meal, soya bean meal, sunflower meal and cotton seed meal), and four conventional energy ingredients (i.e., maize bran, sorghum grain, wheat bran and rice bran) in Kenya. The results indicated that soya bean and cotton seed meals are the most viable plant-based protein ingredients compared to sunflower meal average. Among the animal-based protein ingredients, omena fish meal out performed bone meal. However, continued use of fishmeal in feed formulation seems unsustainable because of the allied ecological and environmental impacts. Maize bran remains the most viable energy ingredient, outperforming wheat bran, rice bran and sorghum, respectively. Overall, animal ingredients are the most suitable protein sources for farmed fish species. However, their use is associated with ecological and environmental impacts that culminate into outstanding negative impacts to the aquatic ecosystem than plant proteins ingredients.

# AQUACULTURE, A PROMISING SOLUTION FOR FOOD INSECURITY POVERTY AND MALNUTRITION IN KENYA

Joyce Njenga [1] ,Jonathan Munguti [2] ,Meenakshisundaram [3]

[1] Jomo Kenyatta University of Agriculture and Techn, P. O. BOX 62000-00200, Nairobi. Kenya
[2] Kenya Marine and Fisheries Research Institute, P.O. Box 451-10230, Sagana, Kenya
[3]International Centre of Insect Physiology and Ecology(ICIPE) P.O Box 30772-00100 Nairobi, Kenya

Food insecurity remains one of the most visible dimensions of poverty. The increasing population amid competition for land and water resources means that the global demand for food will continue to increase. In Kenya, the food insecurity trend is worrying as the population is expected to hit 55 million by 2020 against an annually declining arable land per capita and consequent increase in food prices. The Kenyan agricultural sector has failed to either eliminate or reduce malnourishment for poor populations as the annual national production for both staple food and livestock products fall short of national consumption levels. With increasing food production challenges like dwindling capture fisheries and impacts of climate change becoming more eminent, solutions to food insecurity and malnutrition in Kenya must bring quick results in food availability by stimulating more own-food production. Aquaculture has so far been recognized as an important opportunity to enhance household food security in developing countries. Aquaculture, the controlled land-based or open-ocean farming of aquatic organisms such as tilapia, catfish, finfish, shellfish and plants, is the fastest growing food sector globally alongside terrestrial crop and livestock production. Fish provides protective effects on a wide range on health including obesity, stroke, high blood pressure, and coronary heart disease. Fish has a nutrient profile superior to all terrestrial meats, an excellent source of high quality animal protein, omega-3 polyunsaturated fatty acids (PUFAs) and vitamins. Unfortunately, in Kenya, fish has been only marginally included in the national debate on reduction of micronutrient deficiency, precisely where it could potentially have the largest impact.

# POLYCULTURE IN AN AQUAPONIC SYSTEM : IMPROVING SYSTEM EFFICIENCY BY RAISING REDCLAW CRAYFISH ON PIKEPERCH LEFTOVER FEED

A. Noël[1] *, J. Bossuyt[1,2], C. Rougeot[2] ,V. Gennotte[1,2]

## Introduction

Interest is growing for aquaponics as a way to reduce environmental negative impact of running aquaculture and hydroponics systems separately. The PolyRAS project (Interreg GR) aims to improve the production of fishes with local interest using polyculture in different intensive systems (RAS, aquaponics, biofloc), in order to increase production while optimizing resources use. Intensive pikeperch (*Sander lucioperca*) aquaculture is considered as a good prospect for the European market due to its fast growth rate and economical expectation. However, pikeperch is very sensitive to environmental stressors (light, noise, …) that can impair feeding behavior, leading to frequent overfeeding. Uneaten feed can be turned from waste into valuable feed resource by introducing an auxiliary species in a polyculture scheme. Redclaw crayfish (*Cherax quadricarinatus*) appeared as a good auxiliary candidate as it is an omnivorous bottom feeder, its rearing requirements are compatible with pikeperch and aquaponics, and crayfish are a valuable product on the European market.

The aim of the work was to assess if the efficiency of an intensive aquaponic pilot system can be improved by rearing redclaw crayfish on uneaten pikeperch feed, thus improving productivity while reducing environmental impacts by sharing the same space, water and feed resources.

## Material and Methods

This polyculture combination (pikeperch and redclaw crayfish) was reared in a coupled aquaponic pilot facility to assess the efficiency of the system. The aquaponic facility has a surface of 100 $m^2$, and a total volume of 18 $m^3$. It is composed of 6 rearing tanks (total volume: 9 $m^3$) and a crop production area of 50 $m^2$. Temperature was set at 24°C, mean pH and oxygen levels were 6,8 ± 0,1 and 7,7 ± 0,3 mg/L respectively and mean nitrates concentration ($NO_3^-$) was 492 ± 90 mg/l.

At the start of the experiment, pikeperch stoking densities, ranged from 22 to 30 kg/$m^3$ depending on the size of fish. Crayfishes were placed at the bottom of pikeperch rearing tanks, protected by cages to avoid any predation risk. Crayfish were stocked at 6 individuals/$m^2$ to avoid territorial aggressive behavior. Cages were stocked with animals similar in size, and of the same sex to reduce aggressiveness and avoid reproduction. Moreover, PVC pipes were provided as shelters.

Pikeperch were fed using automatic feeders (LINN Profi) distributing Le Gouessant percid feed for a daily 12h period. Crayfish were only fed on leftover food from the pikeperch for the duration of the experiment.

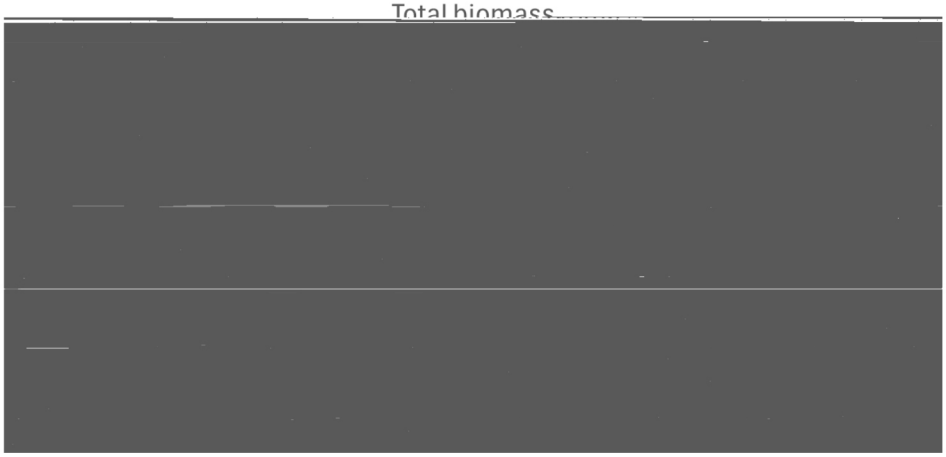

*Figure 1. Number of crayfish and total biomass during the four-month production period.*

*(Continued on next page)*

The vegetal production consisted in lettuce and different aromatic herbs (parsley, basil, cilantro and arugula). System productivity as well as fish welfare and waste production will be assessed on a 6-month period. Pikeperch welfare will be evaluated by measuring cortisol in scales. Crayfish welfare will be assessed using claw integrity as an indicator. Drumfilter functioning and sludge release will be analyzed to assess solid waste production and environmental impacts.

**Preliminary results and discussion**

Pikeperch production reached 438 kg/yr and survival rate was 94%. Global FCR was 1,1 and specific growth rates ranged from 0,5 to 1,2 depending on fish size. Those results are similar to pikeperch monoculture production in the same system. Crayfish growth was positive in all tanks and global crayfish production reached 1,9 kg/yr with a survival rate of 70%.

Reduced crayfish survival rate is still under investigation. Water parameters stayed in the acceptable range for crayfish production and cannibalism could not be the cause as suggested by the good claw integrity level.

Polyculture between pikeperch and redclaw crayfish seems promising to improve system efficiency by producing biomass on leftover feed. The next step will be to assess the impact of this combination on waste management and animal welfare.

# COUPLED BIOMETRIC AND PHYSIOLOGICAL INDICATORS REVEAL THE IMPACTS OF CLIMATE CHANGE–DRIVEN ACIDIFICATION ON THE MEDITERRANEAN MUSSEL (*Mytilus galloprovincialis*)

## Introduction

Human activities have already caused a decrease in the pH of the oceans by approximately 0.1 units, with an average decline of about 0.02 units per decade (Doney et al., 2009). The North Adriatic basin experiences acidification rates that exceed global averages due to river input which intensifies pH fluctuations (Cantoni et al., 2024). Mytilus galloprovincialis, a dominant species in coastal areas responsible for over 60 percent of Italian mussel production, plays a crucial role in the ecosystem through water filtration, nutrient removal, and habitat creation. However, the biomineralization of its shel depends on carbonate saturation and is highly sensitive to decreases in pH (Waldbusser et al., 2015). Reductions in pH can impair linear growth, weight gain, and filtration rate (Bressan et al., 2014). These combined sub-lethal effects undermine the o fitness and commercial value of mussels, making the northern Adriatic a critical area for evaluating the vulnerability of calcifying organisms. Integrated analyses of biometric, and physiological parameters help to address existing gaps in understanding the species' adaptability. The understanding the resilience thresholds of M. galloprovincialis is vital for supporting adaptive management strategies in the climate scenarios projected for the 21st century.

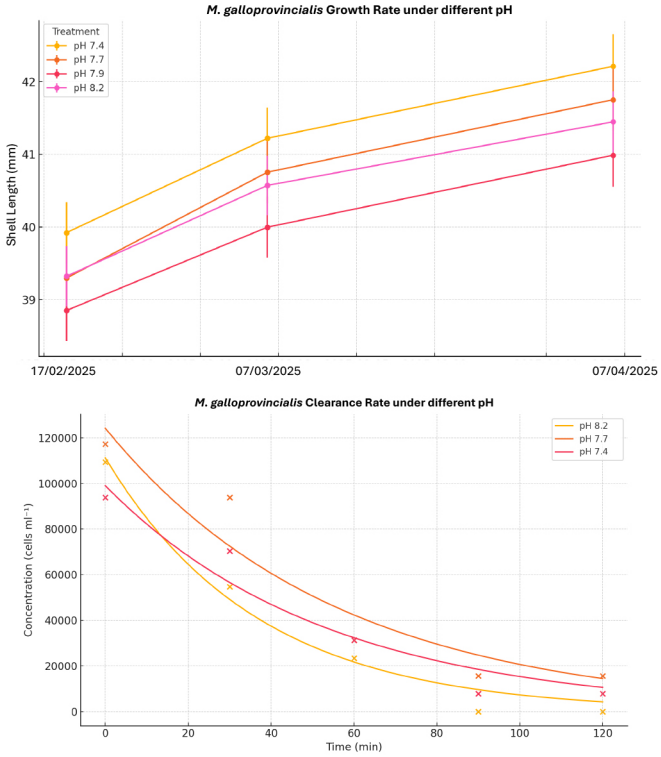
## Material and Methods

Juvenile Medietrranean mussel (*Mytilus galloprovincialis*) were collected from the North Adriatic Sea, cleaned, and acclimated for one week at 24 °C, salinity 27 ‰ and pH 8.2. After tagging and removal of byssal threads, mussels were distributed by weight into 12×70 L aquaria (≈ 25 individuals each). Four pH were imposed—ambient (8.2) plus three acidified levels (7.9, 7.7, and 7.4)—with $CO_2$ bubbling used to reach and maintain target values; each treatment had three replicate tanks. All systems were mechanically and UV-filtered continuously aerated and fed daily with a mixed-algal ration equal to 5–6 % of mussel wet mass. The experiment ran for 90 days, a period expected to allow roughly 1 cm of shell growth to the commercial size of ~4 cm. Temperature, salinity, dissolved oxygen, and pH were monitored daily; total alkalinity was measured weekly thereafter to calculate $pCO_2$, and full carbonate chemistry. Mortality was recorded daily. At day 0, day 45, and day 90, subsamples of ten mussels per treatment were analyzed for shell length, thickness, total wet and dry mass, meat yield, condition index, hepatopancreas mass, and specific growth rate. The clearance rate was quantified at the beginning and end of the trial on three mussels per treatment by tracking the exponential decline of algal cells in 1 L beaker over 2 h, with samples taken every 30 min for microscopic counts.

## Results

At the onset of the experiment shell length did not differ among pH treatments (8.2, 7.9, 7.7, and 7.4). A one-way ANOVA on 250 tagged mussels (n = 62–63 per pH) yielded $F_{3}, 246 = 1.08$, $p = 0.36$, confirming homogeneity of baseline size. Mean length increased steadily at all pH levels. Linear mixed-effects modeling with a random intercept for each individual detected a strong main effect of Time ($p < 0.001$) but neither a main effect of pH ($p \geq 0.07$) nor a pH × Time interaction (all interaction terms $p > 0.10$). Growth therefore followed parallel trajectories irrespective of carbonate chemistry. Mussels elongated by 2.1–2.5 mm, equivalent to 0.043–0.051 mm $day^{-1}$. Shorter windows showed slightly faster daily rates during the first 18 days (0.07 mm $day^{-1}$) than during the subsequent days (0.05 mm $day^{-1}$), but the pattern was consistent across treatments. The data suggest a trend toward faster clearance at the optimal. pH Single-vessel time-courses of algal concentration fitted well to first-order exponential decay. The derived rate constants (k) translated to volumetric clearance rates of 0.28 ml $min^{-1}$ (16.8 ml $h^{-1}$) at pH 7.7, 0.27 ml $min^{-1}$ (16.1 ml $h^{-1}$) at pH 7.4, and 0.41 ml $min^{-1}$ (24.5 ml $h^{-1}$) at pH 8.2.

*(Continued on next page)*



## Discussion

Over seven weeks, the animals grew at identical rates (~0.05 mm day$^{-1}$, ≈ 2.3 mm total) across seawater pH 8.2–7.4, indicating short-term shell-length growth is insensitive acidification. Yet feeding assays revealed a ~35 % drop in clearance rate below ambient pH, suggesting energy acquisition is already compromised. This divergence implies mussels can initially maintain shell extension by reallocating resources, but longer or multi-stress exposures may reveal hidden costs. Thus, while early growth appears resilient to near-future ocean acidification, reduced feeding efficiency emerges as an early warning signal.

# AQUALOOP CROSS-BORDER STUDENT EXCHANGE PROGRAM: PROMOTING CIRCULAR AQUACULTURE THROUGH INTERNATIONAL COLLABORATION

Monika Normant-Saremba*, Laura Ballesteros Redondo, Adrian Bischoff-Lang, Barbara Dmochowska, Joanna Hegele-Drywa, Hanna Łądkowska, Gintautas Narvilas, Nerius Nika, Filip Pniewski

AquaLoop INTERREG SB project
University of Gdańsk
Bażyńskiego 8
Gdańsk, 80-309, Poland
email: monika.normant@ug.edu.pl

## Introduction

The AquaLoop Cross-Border Student Exchange Program, held between January and June 2025, aimed to foster international collaboration and practical knowledge transfer in the field of sustainable aquaculture and circular economy. Organized within the AquaLoop - Aquaculture expert floor for circular economy practice project framework, the program involved bachelor's and master's students from the University of Rostock (Germany), University of Gdańsk (Poland), and Klaipeda University (Lithuania).

Through week-long visits at partner institutions, students were immersed in hands-on activities centered on the AquaLoop project's three pilot actions:

- TARAS: Testing Algae Applications in Recirculating aquaculture systems (RAS) to improve aquaculture circularity potential in the SB region
- NEMATIC: Increasing the nutrient efficiency of commercial aquaculture through increased application of circular economy concepts
- FISHVISA: Development of the Fish-Shrimp-Vegetables integrated system of aquaponics to showcase the potential of circular economy principles in RAS

## Methods

Each university hosted short-term (one week long) exchange visits that included:

- Laboratory and field-based learning: Participants conducted experiments and aquaculture routines based on AquaLoop pilot studies.
- Varied thematic focus:
    - University of Gdańsk: Microalgae cultivation and shrimp farming in RAS (TARAS)
    - University of Rostock: Fish nutrition, aquaponics, and fish leather production (NEMATIC)
    - Klaipeda University: Integrated aquaponics and multitrophic systems (FISHVISA)
- Field visits: Participants visited commercial aquaculture facilities such as:
    - K2 Trout Farm (Poland)
    - Institute for Fisheries at the State Research Centre Mecklenburg-Vorpommern in Hohen Wangelin (Germany)
    - Martynas Klevinis Arctic Char Farm (Lithuania)
- Post-visit surveys to evaluate participants' satisfaction and learning outcomes
- Certificates of attendance

*(Continued on next page)*

**Results**

The program successfully engaged 19 students in structured exchange weeks across the three countries. Key outcomes include:

- Practical skills development in microalgae cultivation, shrimp and fish RAS operations, fish, shrimps, and crayfish feeding trials, aquaponic plant care, and advanced laboratory methods such as parasitology and molecular fish tissue analysis.
- Enhanced students' understanding of circular practices in aquaculture, strengthened cross-border networks, and inspiration for future innovation in sustainable aquatic food production.
- Enhanced cooperation between industry and academia fostered through study visits during exchange stays, providing students with valuable career development opportunities and exposure to real-world challenges in aquaculture.
- High satisfaction across all exchanges. Evaluation scores ranged from 90% to 100% in categories such as communication, organization, collaboration, and overall satisfaction.
- Networking and cultural exchange. Students valued cross-border peer collaboration, sightseeing, and informal discussions with faculty and fellow participants.
- Further collaboration between project partners and their students in the scientific field, fully aligned with AquaLoop's objectives of promoting knowledge exchange and the development of sustainable aquaculture technologies through international collaboration.

**Conclusion**

The AquaLoop Cross-Border Student Exchange Program demonstrated a highly effective model for international, practice-based learning in aquaculture and circular economy. By combining experimental training, interdisciplinary collaboration, and regional aquaculture insights, the program enriched academic curricula and helped shape the next generation of sustainable aquaculture professionals. The strong positive feedback confirms the program's value and provides a foundation for future exchanges in the South Baltic region and beyond.

# IMPROVING THE CIRCULARITY OF AQUACULTURE IN THE SOUTH BALTIC REGION – A PILOT STUDY ON THE USE OF MICROALGAE IN RAS SYSTEMS WITH WHITELEG SHRIMP *Penaeus vannamei*

Monika Normant-Saremba[1]*, Joanna Hegele-Drywa[1], Filip Pniewski[2], Konrad Bräutigam[2,3], Barbara Dmochowska[1], Hanna Łądkowska[1]

[3] Faculty of Agriculture and Environmental Sciences, University of Rostock, Justus-von-Liebig-Weg 2, 18059 Rostock (Germany)
email: monika.normant@ug.edu.pl

## Introduction

Due to climatic conditions and the lack of permanent access to warm seawater, the production of whiteleg shrimp *Penaeus vannamei* in most of Europe is practically only feasible in land-based recirculating aquaculture systems (RAS). Although such systems allow for significant waste reduction by recycling and reusing water, they are not 100% efficient, especially at high stocking densities. Some of the water in the RAS must therefore be regularly replaced. Thus, there is ongoing interest in research focused on developing more effective circular economy solutions for RAS systems which aim not only to minimize waste but also to generate additional value. One promising approach is the cultivation of microalgae, which purify nutrient-rich effluent from a recirculating water system (RAS) during growth and, in addition, produce a biomass rich in omega-3 fatty acids that can serve as a dietary supplement for shrimp. The aim of our pilot study was to identify Baltic microalgae strains able to grow in wastewater from whiteleg shrimp RAS aquaculture, while producing a high yield of biomass.

## Methods

The first step of the research was the preparation of a small-scale laboratory RAS system, consisting of a main unit (equipped with, among other components, a water purification and parameter control system) and four tanks containing water for shrimp cultivation with a total capacity of 1200 L. The next step was importing *P. vannamei* post-larvae (n=1000) from a hatchery in Austria (White Panther Produktion GmbH) and continuing their cultivation at a temperature of 27°C, salinity of 30 ppt, pH ~7.8 and a photoperiod of 15 h of light and 9 h of darkness. The shrimps were fed five times a day with commercial feed, with the daily portion adjusted according to their biomass.

In the 13th week of shrimp farming, 10 L of wastewater was collected, and the concentrations of ammonium nitrogen ($N\text{-}NH_3^+$), nitrates ($N\text{-}NO_3^-$), phosphates ($PO_4^{3-}$) and silica ($SiO_2$) were determined chemically using colorimetric cuvette tests (Hach Lange GmbH, Germany). The water was high in nitrates (122 mg $L^{-1}$), whereas the concentration of other nutrients was low. For this reason the wastewater required certain modifications to achieve a favorable N:P (24:1) as well as to increase the concentration of silica and iron. Microalgae culture was carried out in two media: undiluted wastewater (30 ppt, control) and diluted with Baltic seawater (18 ppt), because many Baltic microalgae are brackish rather than marine ones.

For the tests, three strains of diatoms were chosen, i.e., *Amphora* sp. CP3, *Gedaniella* sp. PL1.21 and *Nitzschia* cf. *aurariae* BA158. The diatoms were grown in the modified wastewater for 12 days. Their growth was monitored every 2 days by measuring their optical density (OD) at 750 nm, which was later converted to cell density. At the end of the culturing period, the concentrations of photosynthetic pigment and biochemical composition of the biomass were determined. Finally, nutrient concentrations were measured to estimate the efficiency of nitrate and phosphate removal.

*(Continued on next page)*

## Results

All of the tested strains actively grew in the RAS wastewater. The best growth was observed for *N.* cf. *aurariae* BA158 in the diluted RAS water supplemented with increased silica and iron amounts (ca. 400 mg $L^{-1}$), which was comparable to the control culture (i.e., f/2 medium, salinity 30 ppt). The same culture also showed the highest production of lipids (70 mg $L^{-1}$) and fucoxanthin (0.75 mg $L^{-1}$). All strains removed a significant proportion of nutrients, however, the most efficient strain was *Amphora* sp. which removed 77-85% of nitrates and 80% of phosphates.

## Conclusion

The results of this pilot study showed that the RAS wastewater can be used as a medium for the efficient growth of Baltic Sea microalgae to remove excess nutrient concentrations. However, the success of this approach depends on appropriate modification of the wastewater to achieve the correct N:P ratio and, if necessary, to adjust silica and iron concentrations. Since all of the strains efficiently removed nutrients, the choice of the strain for cultivation should be based on its ecophysiological and biochemical traits to produce high-quality and commercially viable biomass, thereby adding value to RAS systems.

## Acknowledgements

The research was carried out as part of the AquaLoop INTERREG SB project.

# EFFECT OF ANAEROBIC DENITRIFICATION IN *Penaeus vannamei* PRODUCTION UNDER BIOFLOC SYSTEM

M. Nurgali*[1], A.R. Ferreira[1], J. Brol[1], R. Olivares-Perona[1], A. Tomas-Vidal[1], W. Wasielesky[2], S.M. Llorens1, D.S. Peñaranda[1]

## Introduction

Anaerobic denitrification consists of the microbial conversion of nitrate and nitrite into molecular nitrogen or nitrous oxide, promoting the removal of these compounds from aquatic environments. In aquaculture, this process improves water quality, prevents eutrophication, and reduces dependence on chemical inputs, thus promoting sustainability. This work aimed to test different strategies to optimize anaerobic denitrification in biofloc systems during the cultivation of *Penaeus vannamei*, evaluating different denitrification volumes and different concentrations of suspended solids.

## Materials and methods

A preliminary three-week trial was conducted to assess the potential denitrification capacity of biofloc. Initially, biofloc was concentrated by decantation to levels of 3000 and 4000 mg/L and then exposed to water with a high nitrate concentration (approximately 305 mg N-$NO_3$/L). Since denitrification requires anaerobic conditions, molasses was added to achieve a carbon-to-nitrogen (C:N) ratio of 3:1. The pH was consistently maintained above 8.0 by adding a 1 M sodium hydroxide (NaOH) solution. Dissolved oxygen, temperature, and pH were monitored hourly for 12 hours during the denitrification process until stabilization. The process was considered complete when nitrate concentrations approached 0.0 mg/L. Chemical analysis of ammonia nitrogen (TAN), nitrite ($NO_2^-$, mg/L), nitrate ($NO_3$-, mg/L), phosphate levels ($PO_4^{3-}$, mg/L), alkalinity (mg/L) were analyzed. To evaluate the impact of exchanging 25% of denitrified water in *Penaeus vannamei* production under biofloc technology (BFT), six 350-L tanks stocked at a density of 150–200 shrimp/m² (will be divided into two experimental groups: a control group and a denitrification group, with the latter receiving two weekly water exchanges of 20% of the tank volume using denitrified water.

## Results

Along the progressive scaling of denitrification tanks, the total nitrate was reduced to atmospheric $N_2$ after 48 hours of denitrification process (Figure 1).

Key findings indicate that the higher concentration of suspended solids (4000 mg/L) exhibited nitrate removal efficiency comparable to the lower concentration (3000 mg/L), with minimal differences in stabilization parameters such as pH, DO, and alkalinity.

## Discussion

In the present study, nitrate levels dropped from 341.845 mg/L to 0 mg/L within 48 hours, indicating complete removal. This aligns with Silva (2025), where denitrification occurred within 24 hours in treatments with 2000–2500 mg/L of suspended solids. However, our study required more time, reflecting system variations. The biofloc system effectively maintained low ammonia and nitrite levels while achieving nitrate removal.

# DENSITY-DEPENDENT MODULATION OF SPERM MOTILITY: A REGULATORY MECHANISM WITH CONSEQUENCES FOR MEASUREMENTS STANDARDISATION AND SPERM COMPETITION

D. Nusbaumer*, Y. Karlova and A. Karlov

AKYmed Sàrl, c/o Startlab
Route de la Corniche 5a
1066 Epalinges, Switzerland
E-mail: david@akymed.com

## Introduction

Sperm motility is a key determinant of fertilization success in externally fertilizing fishes. While dilution is inevitable through activation, its effects on motility are not fully understood. In various fish species, we observed a paradoxical pattern: increasing sperm concentration was associated with reduced sperm velocity. This raised critical questions about the biological underpinnings of sperm behaviour and the reliability of motility measurements under varying conditions. We therefore experimentally tested the effect of cell density on sperm motility.

## Materials and Methods

Semen samples were collected from 12 Eurasian perch *Perca fluviatilis* and measured after activation under 5 different dilution ratios (1:25 to 1:200), under constant or variable osmolarity (i.e. 60 treatments), to disentangle effects from cell density and osmolarity variation (typical with dilution). To disentangle potential physical (cell collisions) and biological effects, we conducted an experiment comparing velocity patterns of the same samples in controlled proportion (0, 12.5, 25, 50 and 100%) of live and dead sperm. Motility parameters were quantified using Qualisperm CASA on a total of 180 scenario. Linear mixed-effects models were used to assess the effects of dilution, osmolarity, and live/dead ratio on sperm velocity and progressive motility.

## Results

Sperm motility and dilution were inversely correlated regardless of osmolarity. When looking closer, we found that it was due to the activation of slow sperm (5-25 $\mu$m/s) at lower sperm dilution / higher cell densities. Indeed, neither fast sperm (> 25 $\mu$m/s) nor non progressive sperms (1-5 $\mu$m/s) proportions were affected by dilution. The live-dead sperm experiment revealed that at constant cell density, the velocity was significantly negatively affected by the proportion of live sperm. Together, these results suggest an active, biologically mediated mechanism rather than passive physical interference, which modulates activation of slower sperm in the context of higher live cell densities.

## Discussion

These findings challenge the assumption that sperm motility measurements are concentration-independent and call into question the comparability of published data without standardized protocols. Our results highlight the importance of live-cell-dependent density effects, possibly involving chemical signalling, ionic feedback, or metabolic interactions among spermatozoa. Such mechanisms may reflect evolved strategies of sperm competition, where motility is modulated in response to perceived gametic density. These insights have direct relevance for artificial fertilization practices in aquaculture and offer a new lens for understanding reproductive strategies in externally fertilizing species.

# DL-METHIONINE FORTIFIED AVOCADO SEED MEAL REPLACED 50% OF SOYBEAN MEAL IN THE DIETS OF AFRICAN CATFISH, *Clarias gariepinus*

L. Nwanna* and U. Uzohuo

Department of Fisheries and Aquaculture Technology
Federal University of Technology
Akure-Nigeria
E-mail: drlel@yahoo.com

## Introduction

Avocado pear (*Persea americana,* Mill) is a widely consumed fruit because of its delicious taste, rich nutrient composition and several-health promoting bioactive ingredients. It is rich in minerals, vitamins and protein. However, the seed which is discarded as a waste makes up between 15 and 17% of the whole fruit. Preliminary analysis of the seed used in the study showed high protein level of 42.5% which is closely related to the protein level of 45% in soybean meal. Hence the study investigated the effect of total replacement of soybean meal with the Avocado sees meal (AM) in the diets of African catfish. DL-methionine was added due to its limitations in plant protein feed ingredients.

## Materials and methods

Five isonitrogenous diets were prepared to contain 0, 25, 50, 75, 100% of Avocado seed meal (AM) in replacement for soybean meal in making diets 1 -5. Then diets 1-5 were fortified with 0, 0.20, 0.40, 0.80, 1.0 % DL-Met respectively. The diets were fed to African catfish (10.2 g) for 56 days in indoor glass tanks. Standard procedures were used in data collection and analyses.

## Results

Analysis of the Avocado seed meal used in the study revealed a high protein content of 42.5% and high fibre and lipid contents (Table 1). Assessment of the mean weight gain, specific growth rate, feed conversion ratio and protein efficiency ratio indicated that AM can replace up to 50% of soybean meal in the diet of the fish (Table 2). Similarly, dietary AM significantly improved Mg, Ca, P, Mn and Zn deposition in the fish in comparison with the control diet containing 100% soybean meal (Table 3). Moreover, dietary AM significantly reduced the glucose levels in the experimental fish (Fig. 1).

## Conclusion

Replacement of soybean meal with Avocado seed meal at (50% +0.4% Met) is recommended for the production of African catfish. Replacement of soybean meal with AM also significantly improved the minerals and reduced the carcass glucose levels.

Proximate composition of the Avocado seed meal (AM)

## Introduction

*Aeromonas veronii* is a Gram-negative bacterium that poses a significant threat to sea bass aquaculture in the Mediterranean. This pathogen causes severe systemic infections, leading to high morbidity and mortality rates among farmed sea bass. The economic impact of these infections is substantial, affecting the profitability and sustainability of sea bass farming in the region.

## Methods and Results

Field isolates of *A. veronii*, including both motile and non-motile strains, were collected from commercial sea bass farms in the Mediterranean. These isolates were characterized using a combination of biochemical methods, genotypic techniques (such as metG and gltA sequencing), and serological assays, providing valuable insights into their differences.

Based on these characterizations, experimental vaccines were developed and tested in pre-clinical laboratory trials. The trials involved vaccinating and challenging sea bass with different strains and recording clinical signs and mortality rates. The experimental vaccine candidates demonstrated rapid and effective protection against *A. veronii*, showing promising results for long-term immunity.

## Conclusion

Developing an effective and long-lasting vaccine against *A. veronii* is essential for the sustainability of sea bass farming in the Mediterranean. Our pre-clinical laboratory trials have yielded promising results, identifying vaccine candidates that provide both rapid and extended protection against *A. veronii*. These findings highlight the potential of a future vaccine to significantly reduce the impact of *A. veronii* infections on sea bass aquaculture.

The pre-clinical studies were conducted in line with the “License to Carry out Research on Animals” granted to AquaBioTech Group by the Ministry for Agriculture, Fisheries, Food and animal rights, Animal welfare Department in Malta and in accordance with procedures approved by the Zoetis Animal Ethics Committee.

# ENABLING PRODUCTION OF THE RARE CAROTENOID DIATOXANTHIN AT INDUSTRIAL LEVEL USING CRISPR/CAS9 GENE-EDITED MICROALGAE

Marianne Nymark*[1], Charlotte Volpe[1], Zdenka Bartosova[2], Ralph Kissen[2], Per Winge[2]

1. Department of Fisheries and New Biomarine Industry, SINTEF Ocean, 7010 Trondheim, Norway
2. Department of Biology, Norwegian University of Science and Technology, 7491 Trondheim, Norway
Email: marianne.nymark@sintef.no .

## Introduction

Recent research has indicated that the rare carotenoid diatoxanthin (Dtx) exhibits higher bioactivity than commercially available pigments, and that it has anti-inflammatory and anti-cancer properties (Konishi et al., 2008; Pistelli et al., 2021; Sansone et al., 2025, 2023, 2022). These findings highlight Dtx as a new marine compound of commercial interest. Dtx is only found in a few groups of microalgae where it is produced as protection against exposure to sudden high light intensity, and it can be viewed as a "sunscreen" pigment (Goss and Lepetit, 2015). Large-scale commercial production of this pigment from microalgae is currently not feasible. In fact, Dtx is rapidly converted to the inactive pigment diadinoxanthin (Ddx) when the cells are removed from the high light source (Goss and Lepetit, 2015; Græsholt et al., 2024), which will be the case during large-scale harvesting of algal biomass. In addition, producing commercially interesting levels of Dtx in "natural" microalgae will depend on exposing the algae culture to high intensity light for a prolonged period of time. This can be technically challenging at high cell densities and costly in countries where algae production is dependent on artificial light. Using the gene editing technique CRISPR/Cas9 we have created non-transgenic *zep3Cpsrp54* double knockout (KO) mutants of the marine diatom *Phaeodactylum tricornutum*. The *ZEP3* gene encodes zeaxanthin epoxidase responsible for back-converting high light-accumulated Dtx to Ddx in low light, whereas the *CpSRP54* gene encodes the chloroplast signal recognition particle 54 kDa (CpSRP54) protein involved in insertion of subunits of photosynthetic complexes into thylakoid membranes (Græsholt et al., 2024; Nymark et al., 2021). We have previously shown that loss of ZEP3 can stabilize high light-accumulated Dtx, whereas absence of CpSRP54 causes light sensitivity (Græsholt et al., 2024; Nymark et al., 2021). The loss of both ZEP3 and CpSRP54 in *P. tricornutum* was hypothesised to result in a Dtx production line where both the above-described challenges would be solved. Producing a high-value product like Dtx can cause microalgae cultivation to become economically viable, opening the possibility of using the rest of the algal biomass for feed purposes.

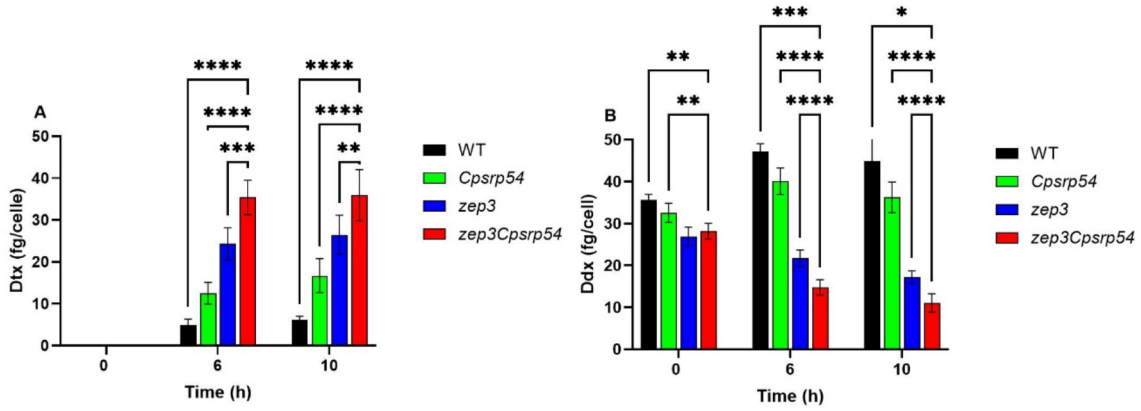

**Figure 1. Dtx and Ddx levels in WT, *Cpsrp54*, *zep3* and *zep3Cpsrp54* cells.** Dtx (A) and Ddx (B) concentrations (fg/cell) in WT, *Cpsrp54*, *zep3* and *zep3Cpsrp54* after exposure of LL acclimated cells (0 h) to 6 and 10 h of ML. Two independent mutant lines were included in the experiment for *Cpsrp54* and *zep3*, and four independent lines were included for *zep3Cpsrp54*. Three biological replicates were included for each of the independent mutant lines meaning that the total number of samples were n=6 for *zep3* and *Cpsrp54*; n=12 for *zep3Cpsrp54* and n=3 for WT.

*(Continued on next page)*

**Material and Methods**

*Zep3Cpsrp54* double KO mutants were generated by introducing mutations in the *CpSRP54* gene in the previously published *zep3* mutant lines using the CRISPR/Cas9 technology (Græsholt et al., 2024; Sharma et al., 2018). Bacterial conjugation was chosen as the method for delivery of the components necessary for CRISPR/Cas9-gene editing to take place to avoid incorporation of "foreign" DNA into the genome of the *P. tricornutum* cells (Sharma et al., 2018). The phenotype of the *zep3Cpsrp54* double KO mutant was characterized and compared to the phenotype of *zep3* and *Cpsrp54* single mutants and wild type (WT) cells. The phenotypic comparisons were performed by assessing their photophysiological performances using Pulse-amplitude modulated (PAM) fluorometry, pigment concentrations by HPLC and growth rates as a daily increase in *in vivo* chlorophyll *a* fluorescence as a response to different light treatments.

**Results and Discussion**

Non-transgenic *zep3Cpsrp54* double KO mutants with bi-allelic mutations were successfully generated using the CRISPR/Cas9 technology. The double KO mutants were found to display the photophysiological features of both *zep3* and *Cpsrp54* single mutants. The double KO mutants were unable to relax their Dtx-dependent photoprotective response in low light, a feature previously observed in the *zep3* single mutants (indicating that high light-accumulated Dtx was stabilized), and they were found to be light sensitive similar to the *Cpsrp54* single mutants (indicating that Dtx can be produced without the use of high intensity light) (Græsholt et al., 2024; Nymark et al., 2021). To test if the *zep3Cpsrp54* double mutants could function as a Dtx production line and outperform the single mutants and WT cells, we exposed low light (LL; 35 µmol photons $m^{-2}$ $s^{-1}$) acclimated mutants and WT to medium light (ML; 200 µmol photons $m^{-2}$ $s^{-1}$) for 6 and 10 h. Pigment analysis performed on material harvested from LL acclimated cultures and 6 h and 10 h ML treated cultures showed that ML was enough to trigger the double KO mutants to produce high levels of Dtx (Figure 1A). The highest concentrations of Dtx were found in the double KOs, followed, in decreasing order, by *zep3*, *Cpsrp54* and WT (Figure 1A). The opposite trend was observed for the Ddx concentration (Figure 1B). The Dtx production in the double KOs clearly outperformed the production in the *zep3* lines showing Dtx concentrations that were 46% and 36% higher than in *zep3* lines after 6 h and 10 h of ML treatment, respectively. The Dtx concentration in the double KO mutants after 6 h in ML reached similar levels as previously reported for *zep3* single mutants exposed to high intensity light (500 µmol photons $m^{-2}$ $s^{-1}$) (Græsholt, 2024). Even though the concentration of Dtx differed significantly between mutant lines, they were highly similar for the same mutant line at both 6 h and 10 h (Figure 1A). An additional experiment using shorter ML exposure times (0.5 h and 2 h) showed that prolonged exposure is necessary to reach maximum Dtx levels. Growth rates of the double KO mutants were at WT levels up to 150 µmol photons $m^{-2}$ $s^{-1}$ supporting the idea that these mutants could function as a production line of Dtx. Future project work will include large-scale cultivation of *zep3Cpsrp54* double KO mutants together with our industry partners to prove that commercial production of Dtx is a possibility.

# EFFECTS OF FOUR TRADITIONAL CHINESE MEDICINES AND HARMFUL MICROALGAE *Karenia mikimotoi* ON THE GROWTH OF RAINBOW TROUT (*Oncorhynchus mykiss*) GILL EPITHELIAL CELL LINE, RTGILL-W1

Ching Yi O*, Wing Yin Mo, Fred Wang Fat Lee, Emily Sze Wan Wong

Department of Applied Science
School of Science and Technology
Hong Kong Metropolitan University
Kowloon, Hong Kong
cyo@hkmu.edu.hk

The fishery industry plays a crucial role in global food supply. According to the projections suggested by the Organisation for Economic Co-operation and Development (OECD), the marine aquaculture production will contribute 87% of global fish production by 2025. However, harmful algal blooms (HABs) formed by *Karenia mikimotoi* have caused substantial loss in aquaculture in various countries, including Japan, Norway, Ireland, New Zealand, and China. The economic impact has been severe, with losses exceeding USD 290 million in Chinese coastal waters in 2012 and USD 82.8 million in Hong Kong and surrounding areas in 1998. In 2015, the Agriculture, Fisheries and Conservation Department (AFCD) reported extensive cultured fish deaths caused by K. mikimotoi in nine fish culture zones across Tolo Harbour, Long Harbour, and northeastern Hong Kong waters.

*K. mikimotoi* is a bloom-forming dinoflagellate occurring worldwide that causes large economic losses through its lethal effects on marine fish, primarily through gill damage. In order to reduce losses and increase marine fish culture yields, algicides and antibiotics are often used in the aquaculture industry. However, these treatments may lead to great environmental impacts and development of antibiotic-resistant bacteria, affecting human health. Therefore, it is crucial to find an alternative to solve this problem. Traditional Chinese medicines (TCMs) may be the potential candidates. In this project, the protective effects of four TCMs, *Astragali Radix* (AR)*, Coptidis Rhizom*a (CR)*, Lonicera Japonica Flos* (LJF)*,* and *Poria* (P), were studied. The four TCMs were meshed into powders and soaked with *K. mikimotoi* (at 10,000 cells/mL) in the concentrations of 1 and 10 mg/mL for 6 and 24 hours. The screening results showed that AR, CR, and LJF have significant inhibitory effects on *Karenia mikimotoi* at 10 mg/mL.

The effects of the four TCMs on rainbow trout gill epithelial cell line, RTgill-W1 (CRL-2523) in the presence or absence of *K. Mikimotoi* was also explored. In the absence of HAB, the fish gill cells were treated with either 0, 0.1, 0.5, 1, 5, or 10 mg/mL of each selected TCM stocking solution for 24 hours. For algal challenge tests, 40,000 cells/mL of *K. mikimotoi* were added to the TCM-treated epithelial cells for a 2-hour incubation.

Three TCMs, including AR, P, and LJF, showed no cytotoxicity on RTgill-W1 at concentration of 1 mg/mL or below. Under algal challenging conditions, these three TCMs at 0.5 mg/mL demonstrated significant protective effects against *K. mikimotoi* compared to the untreated controls. Further research is needed to elucidate the underlying mechanisms.

# HARNESSING THE POTENTIAL OF SEAWEED IN OPEN WATER IMTA

Pauline O'Donohoe*, Catherine Waters, Joanne Casserly, Aoife O'Sullivan and Neil Ruane

Marine Institute
Rinville, Oranmore
Co. Galway, H91 R673, Ireland

Pauline.odonohoe@marine.ie

## Introduction

Integrated Multi-Trophic Aquaculture (IMTA) involves farming multiple aquaculture species from different trophic levels within the same production site or bay. In this system, uneaten feed, waste, and nutrients from one species (e.g., finfish) are utilised as resources—such as fertilizer or feed—for other species (e.g., seaweeds, suspension feeders, or deposit feeders). Feed and waste from the salmon create a nutrient flow across the Low Trophic Grid (LTG) in Lehanagh Pool. As an extractive species, seaweed absorbs dissolved inorganic nutrients, making it an ideal candidate for IMTA. Its ability to reduce nutrient loads from fed species contributes to environmental remediation and supports circular economy principles (Chopin & Tacon, 2020). The expansion of seaweed cultivation could act as a valuable and sustainable resource for the future of global aquaculture particularly in IMTA systems. This concept promotes balanced systems, enhances environmental sustainability, improving ecosystem services and contributes to a greater societal acceptance of aquaculture (Van Osch et al., 2019). This study investigated the growth of *Alaria esculenta* and *Saccharina latissima* in open water IMTA and assessed the nutritional and food safety quality of these species.

This study was conducted to assess the quantity of trace metals in the tissues of fish, water and sediments from Sagbo Koji Riverine Community, Lagos Island, Lagos State, Nigeria. Samples were collected from (8 weeks) in 2023. Eight samples each of *Chrysichthys nigrodigitatus* (Silver Catfish) and *Oreochromis niloticus* (Nile Tilapia) samples were purchased from local fishermen. Water and sediments samples were collected at two sampling points each. Heavy metal analysis was done on the fish tissues, sediments and water samples. Mean heavy metal concentration of water and sediment samples showed that zinc had the highest concentration of 1.636 mg/l and 18.135 mg/l while cobalt had the least of 0.009 mg/l and 0.552 mg/l respectively. Mean iron concentration of 114.152 mg/kg and 99.580 mg/kg was highest in Silver Catfish and Nile Tilapia respectively and the least was cadmium with 0.088 mg/kg and 0.015 mg/kg. Bio-concentration factor (BCF) of lead in fish against the water sample was 815.31 mg/kg for *C. nigrodigitatus* and iron with 685.82 mg/kg for *O. niloticus* was the highest. It was observed that the BCF of heavy metals found in fish sample compared to sediment had high values for lead (22.35 mg/kg and 16.39 mg/kg) for *C. nigrodigitatus* and *O. niloticus* respectively. The results from the study showed that only cadmium in fish samples, chromium in sediment samples, iron, copper, chromium, manganese and cobalt in water samples are within the WHO/FEPA maximum acceptable limit.

# DIETARY EFFECTS OF ORGANIC WASTE CULTURED BLACK SOLDIER FLY (*Hemertia illucensS*) (LINNAEUS, 1758) LARVAE MEAL ON SOME PHYSIOLOGICAL PARAMETERS OF HYBRID AFRICAN CATFISH *Heterobranchus bidorsalisS* ♂ (GEOFFROY SAINT-HILAIRE, 1809) × *Clarias gariepinus* ♀ (BURCHELL 1822)

*Ojo P. Oke[1,2] and Oluyemi K. Gbadamosi[1]

1 Department of Fisheries and Aquaculture Technology, Federal University of Technology Akure, PMB 704, Akure, Ondo State, Nigeria
2 Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, UK
Email: okeojo41@gmail.com
ojo00064@students.stir.ac.uk

This study examined the effect of Black soldier fly larvae meal (BSFLM) on some physiological parameters in African catfish hybrid (*Heterobranchus bidorsalis* × *Clarias gariepinus*). Diets with BSFLM inclusion levels of 0, 20, 40, 60 and 80% denoted as BSFLM0 (Control), BSFLM20, BSFLM40, BSFLM60 and BSFLM80 were tested for 56 - days feeding. Fish fed BSFLM0 exhibited the highest growth and nutrient utilization among the diets, having a weight gain (WG) of 32.55 ± 0.29 g, feed intake (FI) of 54.73 ± 0.51 g, and specific growth rate (SGR) of 1.16 ± 0.35. No significant differences ($p>0.05$) was recorded between the fish fed BSFML0 and BSFML20 in their body weight, feed intake and histology. Higher BSFLM levels reduced performance, with BSFLM80 showing the lowest. Apparent digestibility coefficient (ADC) and histological examination revealed the same trend. These findings suggest that fishmeal can be replaced up to 20% with BSFLM, without compromising the growth, nutrient utilization and general health of hybrid African catfish.

# EDNA ON TRIAL: TOWARD A STANDARD PROTOCOL FOR BIOMONITORING IN SALMON FARMING

M. Oladi*, T.A. Wilding, A. Wyness and T. Stoeck

Rheinland-Pfälzische Technische Universität Kaiserslautern-Landau
Kaiserslautern, Germany
Email: oladi@rptu.de

## Introduction

Environmental DNA (eDNA) metabarcoding is emerging as a scalable, cost-effective tool for monitoring environmental impacts in salmon farming. While it offers advantages over traditional macrofaunal assessments, such as faster processing and broader biodiversity detection, uncertainty around protocol standardization, limits its operational use. Equally important is understanding how much variation naturally occurs between replicate sediment samples. To confidently implement eDNA in routine monitoring, we need to distinguish between biological variability and methodological noise, and ensure that protocol choices do not overshadow meaningful ecological signals.

## Materials and Methods

Sediment samples were collected from coastal salmon farms in western Scotland. Replicates were taken to assess within-site biological variability. Two different PCR protocols (primarily differing in DNA polymerase) were applied to the same DNA extracts to evaluate the effects of methodological variation on diversity metrics and community composition. Microbial communities were characterized via 16S rRNA gene sequencing. The results were compared against traditional macrofaunal assessments to evaluate eDNA's stability and suitability for environmental monitoring.

## Results

The two PCR protocols used in this study yielded statistically significant differences in bacterial community composition, indicating that protocol choice can influence eDNA-based assessments. Furthermore, the comparison of replicate samples showed that within-site variability in bacterial eDNA communities was comparable to that of macrofaunal assemblages collected according to compliance monitoring protocol (~25% variability in both cases), supporting the reliability of eDNA for detecting spatial patterns in benthic environments.

## Conclusion

Despite some sensitivity to laboratory protocols, eDNA-based biomonitoring offers reliable results with variability levels comparable to traditional methods. With protocol harmonization, eDNA has strong potential to serve as a scalable, cost-effective tool for routine environmental monitoring in the salmon aquaculture industry.

# ADVANCING AQUAFEED SAFETY: GENETIC DETECTION OF RUMINANT DNA FOR REGULATORY COMPLIANCE AND BIOSECURITY

Olivares-González, Lorena[1]*, Moldes-Tolosa, María Ángeles, Bermejo-Villodre, Merche[1]; Ruíz-Lafora, Carlos[1]; Blasco-Pascual, Nuria[1], Carmona-Antoñanzas, Greta[1]

[1]Health in Code
Calle de la Travesía s/n
Edificio Biohub 15E Base 5
46024 Valencia (España)
e-mail: lorena.olivares@healthincode.com

**Introduction**
The accurate detection of ruminant-derived ingredients in aquafeeds is critical for ensuring regulatory compliance, safeguarding biosecurity, and protecting brand integrity. The European Commission restricts the feeding of ruminant proteins to non-ruminant animals, making sensitive and reliable detection methods essential for producers operating in both domestic and export markets. While official methods, such as those developed by the Institute for Reference Materials and Measurements (IRMM), remain the regulatory benchmark, their primary focus is qualitative detection and morphological identification, which may limit their applicability for precise quantification in complex feed formulations.

**Materials and Methods**
We present a novel genetic diagnostic system based on real-time PCR that not only detects the presence of ruminant DNA with high specificity but also provides an optional quantitative estimate expressed as % weight/weight (w/w) of the product. This enables sensitive detection down to 0.1% w/w, allowing feed manufacturers to assess contamination levels and make informed decisions regarding product release, reformulation, or supplier management. Validation against a wide range of commercial aquafeeds confirms the robustness of the method across diverse matrices and ingredient profiles.

**Results**
By integrating a molecular approach alongside traditional IRMM methodologies, aquafeed producers can achieve faster turnaround times, increased sensitivity for trace-level contamination, and an enhanced capacity to demonstrate compliance. This innovation strengthens feed quality assurance programs, mitigates regulatory risk, and supports a more transparent and biosecure aquaculture supply chain.

**Conclusions**
Since discrepancies can exist between the results obtained from both approaches, it is essential to comprehensively evaluate the entire methodology, from sample extraction to final result interpretation, as well as the specific purpose of the analysis, to determine the most appropriate method for each application.

# PROTEIN QUALITY EVALUATION OF SUSTAINABLES MEALS FOR DIFFERENTS SPECIES OF MUGILIDAE

**Introduction**

Currently, aquaculture faces two major challenges: the reduction of fish meal inclusion in feeds and the diversification of farmed species. Mugilids (family Mugilidae) emerge as a promising group to address these challenges, their omnivorous feeding habits allow a lower protein content in diets formulation. However, as has been observed in other species, the protein quality is critical to ensure proper growth, for this is essential to cover amino acid requirements. The objective of this study is to analyze the amino acid profiles of various sustainable feed ingredients and assess their suitability for three different mugilid species.

**Materials and methods**

The whole-body composition and amino acid profiles were analyzed for three fishes from three different wild mugilid species (*Mugil cephalus*, *Chelon labrosus*, and *Liza aurata*) at the laboratorie of the Universitat Politècnica de València (UPV). In parallel, the crude protein content and amino acid composition of different raw materials—vegetal, aquatic animal, terrestrial animal, and unicellular origin—were analyzed. Based on the amino acid data, the following nutritional indices were calculated: Amino Acid Ratio (AAR % = (AAsample)/(AAreference)*100), Chemical score (CS, %: Minimum value from AARs), Limiting amino acid (The amino acid that correspond to CS) and Oser´s Index (OI, % = $10^{(1/n*(\log(AAR1)+\log(AAR2)\ldots\log(AARn)))}$).

**Results**

The results obtained show that the most limiting amino acid in different raw materials was methionine (MET) followed by lysine (LYS) (Table 1), depending on the species. For *Mugil cephalus*, methionine was the most limiting amino acid while for *Chelon labrosus* were methionine and lysine and, finally, lysine was the limiting amino acid for *Liza aurata*.

In general, *Chelon labrosus* showed better IO and CS than the other two species for all raw materials. The IO index was higher in raw materials of aquatic animal origin (Figure 1) followed by Brewer's yeast 100%, Fermented soybeans, Potato protein and Beet pulp. For CS was similar than IO index and fish meal had the best CS. However, Brewer's yeast 100% showed better CS than krill and other raw materials had close to these values. and terrestrial raw materials and some vegetables raw materials had the worst values to OI index and CS.

**Discussion**

Results obtained indicate that, depending on the species, different dietary formulations are required to meet specific amino acid requirements. Normally, raw materials, which are not of marine origin, are deficient in methionine and lysine and those of vegetable origin have less protein. The protein and amino acid requirements vary according to the developmental stage of the fish and the specie. Therefore, it is necessary to utilize different combinations of raw materials even within the same species due to the substitution of fish meal with a single alternative protein source should not exceed 40% (Sánchez-Lozano et al., 2009; Valverde et al., 2013). One of the advantages of feed formulation in aquaculture is the ability to combine multiple raw ingredients to compensate for limiting amino acids and to ensure optimal growth performance.

## Introduction

The Senegalese sole (*Solea senegalensis*) is a key species for aquaculture in Southern Europe. As production intensifies, there is an urgent need to develop tailored diets that support not only optimal growth but also resilience during common hatchery procedures such as transport, grading, or tank transfer. Previous studies have shown that certain additives such as curcumin, green tea extract, and grape seed extract can enhance growth and/or stress resilience in postlarval sole (Xavier et al., 2020; 2022). Micro- and macroalgae are rich in bioactive compounds and represent a promising dietary strategy to improve both growth performance and oxidative status in fish. Since the antioxidant system is essential for maintaining physiological homeostasis, especially under stressful conditions, designing diets adapted to specific production phases can improve hatchery protocols and overall biological efficiency. The aim of this study was to evaluate the effects of diets supplemented with a blend of micro- and macroalgae and to identify: (1) a growth-promoting diet suitable for the regular rearing phase, and (2) a functional diet that can enhance the resilience of postlarvae to routine aquaculture stressors.

## Material and methods

A feeding trial was conducted during the benthic phase of *Solea senegalensis* postlarval development (18-45 days after hatching, DAH) in a recirculating aquaculture system. Three experimental diets were tested in triplicate: a control diet (CTRL), a commercial-like formulation, and two diets supplemented with algae biomass, CTRL + *Ulva* sp.and *Tisochrysis lutea* (ULTISO), and CTRL + *Ulva* sp. and *Pavlova girans* (ULPAVL). Growth performance and antioxidant status were assessed at 38 DAH (Sampling 1-S1) to evaluate the effects of each diet during the rearing phase. From 38 to 43 DAH, all groups received a new diet enriched with a *Skeletonema costatum* extract (BOOST diet), aimed at preparing the fish for upcoming challenges. At 43 DAH, fish were subjected to a transport challenge (~24 h), followed by immersion in a virulent bacterial suspension (*Tenacibaculum maritimum*, strain ACC13.1) to induce tenacibaculosis at 44 DAH. A second sampling was performed at 45 DAH (Sampling 2-S2), 24 h post-infection, to evaluate the physiological responses to the BOOST diet under stressful and disease conditions. Growth performance at S1 was assessed through measurements of performance indicators and survival. Oxidative status was evaluated at both sampling points (S1 and S2) by quantifying the activity of superoxide dismutase (SOD) and catalase (CAT), along with levels of lipid peroxidation (LPO) as a marker of oxidative damage. Gene expression analyses were conducted at both timepoints for markers of antioxidant defense (*sod1*, *cat*, *gpx1*), epithelial integrity (*cldn15*, *ocl*, *tjp2*), and inflammation (*il1β*, *tnfα*).

## Results

At 38 DAH, postlarvae fed the ULPAVL diet showed significantly lower dry weight compared to the CTRL and ULTISO groups, which displayed similar values. However, dietary treatment had no significant effect on condition factor, relative growth rate, or survival. Redox status was influenced by diet: ULTISO-fed fish exhibited significantly higher activities of SOD and CAT compared to the ULPAVL group, although not significantly different from CTRL. Interestingly, LPO levels were significantly lower in the ULPAVL group compared to both CTRL and ULTISO fish. After feeding the BOOST diet and exposure to the transport and bacterial challenge, no significant differences were observed among treatments in SOD, CAT, or LPO levels at 45 DAH. At the molecular level, gene expression analysis at 38 DAH revealed no major differences among treatments, except for *cat*, which was significantly downregulated in both ULTISO- and ULPAVL-fed fish compared to CTRL. By 45 DAH, *cat* expression remained significantly lower in ULTISO-fed fish. In contrast, expression of *cldn15* was significantly higher in CTRL and ULPAVL groups compared to ULTISO.

*(Continued on next page)*

## Conclusion

While algae inclusion in diets did not enhance growth, survival, or overall antioxidant capacity in Senegalese sole postlarvae, both algae-supplemented diets modulated specific oxidative stress markers and gene expression. The ULTISO diet stimulated SOD and CAT activities at 38 DAH, indicating activation of the antioxidant system, but without reducing oxidative damage. Conversely, the ULPAVL diet lowered lipid peroxidation, suggesting a protective effect against oxidative stress. However, no diet emerged as a functional strategy to enhance resilience to common hatchery stressors. During the stress challenge phase, when all groups were fed the BOOST diet, no significant differences in antioxidant enzyme activities were detected among treatments. This indicates that the BOOST diet neither conferred measurable advantages over the control diet nor modulated carry-over effects of prior algae supplementation. These results highlight the challenge to obtain stage-specific diets, tailored to either promote growth or prepare fish for stressful production events, that will enhance robustness in marine hatcheries.

## Introduction

The intensification of aquaculture has significantly contributed to meeting global fish demand. However, it has also increased disease outbreaks, particularly in economically important species such as European seabass (*Dicentrarchus labrax*) [1]. Conventional disease management practices, such as the use of antibiotics and chemotherapeutic agents, have raised serious concerns due to the emergence of antibiotic-resistant pathogens and environmental contamination [2]. In response, there is growing interest in sustainable alternatives that promote fish health and reduce reliance on synthetic treatments [3]. Among these, dietary supplementation with natural bioactive compounds has shown potential to enhance antioxidant status, modulate immune function, and improve growth performance [4]. Marine macroalgae are a promising source of bioactive compounds such as polysaccharides, pigments, vitamins, and minerals, which exhibit immunostimulant, antimicrobial, and antioxidant activities [5].

Beyond their general nutritional value, certain macroalgae possess immunomodulatory properties, primarily due to their content of phenolic compounds and complex undigestible polysaccharides such as laminarin, fucoidan, and alginates, which have an immune-modulatory effect in fish [6]. Even at low dietary inclusion levels, macroalgal supplementation has been linked to improved immune function and increased resistance to pathogens [7]. However, the high content of indigestible structural polysaccharides in macroalgal cell walls may limit the accessibility of these bioactive compounds. Therefore, pre-treatment methods such as enzymatic hydrolysis, fermentation, or alkaline treatment are employed to improve the release and bioavailability of immune-stimulating components. [8]. Therefore, the present study aimed to evaluate the effects of dietary inclusion of *Palmaria palmata*, pre-treated using an alkaline hydrothermal pre-treatment followed by autoclaving, on the juvenile European seabass's intestinal immune status and microbiota composition.

## Materials and Methods

*P. palmata* underwent alkaline hydrothermal pre-treatment (1N NaOH; autoclaving at 121 °C for 30 minutes) and was dried before its incorporation in the diets. Five experimental diets were formulated to be isoproteic (48% on a dry matter basis) and isolipidic (18% on a dry matter basis), including a control diet with no *P. palmata*, and four test diets containing 7.5% or 15% of either untreated or pre-treated *P. palmata*, replacing a plant ingredient mixture of the control diet. European seabass (*Dicentrarchus labrax*) with an initial average weight of 38 g were randomly assigned to triplicate groups of 16 fish per tank. The feeding trial lasted for 11 weeks, during which fish were hand-fed to apparent visual satiation, twice daily, six days per week. At the end of the trial, blood/plasma and intestines from three fish per tank were collected and stored at −80 °C for subsequent immune and microbiota analyses. A small portion of distal intestinal tissue from the same fish was stored in RNAlater for the assessment of *TNF-α*, *IL-8*, *IL-1β*, *IL-10*, *COX-2*, *casp9*, and *casp3* gene expression by reverse transcription quantitative PCR (RT-qPCR). Primer efficiency and reference gene stability were verified to ensure accurate data normalization. Innate humoral immune responses, including antiprotease, protease, peroxidase, and lysozyme activities, were quantified using established spectrophotometric methods. Microbial community profiling was performed via Denaturing Gradient Gel Electrophoresis (DGGE) of 16S rRNA gene fragments amplified from bacterial DNA extracted from intestinal digesta and mucosa.

*(Continued on next page)*

Data were tested for normality and homogeneity of variances and normalized when required. Treatment effects were assessed using two-way ANOVA, considering *P. palmata* inclusion level and pre-treatment as fixed factors, followed by Tukey's test when $p < 0.05$. Non-orthogonal contrasts were performed to compare the control with the test diets. Statistical analyses were performed using IBM SPSS Statistics v26. Microbiota analysis used DGGE banding patterns [9]. Band intensities were analyzed with Quantity One software and converted into presence/absence matrices. Primer v7 was used to calculate group similarities and non-metric multidimensional scaling (MDS) based on Bray-Curtis similarities. Diversity indices included Shannon-Weaver and Margalef, while similarity percentages were assessed using SIMPER. DGGE clustering was done via Bray-Curtis dendrograms using UPGMA.

**Results**

The dietary *P. palmata* levels or pre-treatment did not affect plasma immune parameters, including peroxidase, antiprotease activity, protease activity, and lysozyme. However, fish fed non-treated *P. palmata* exhibited higher intestinal expression of *IL-10* and *casp3* than those fed the corresponding pre-treated diets. The intestinal expression of *TNF-*□, *IL-8*, *IL-1*□, *COX2*, and *casp9* was not significantly affected by diets.

In the intestinal digesta microbial community analysis, fish fed the non-treated 15% *P. palmata* diet had higher similarity among replicates than those fed the control diet. No significant differences in similarity were observed between the control and the non-treated 7.5% *P. palmata* or pre-treated 7.5% and 15% *P. palmata* groups. Dietary treatments did not affect the number of OTUs, richness, and diversity in the intestinal digesta. In the intestinal mucosa, richness and similarity were lower in fish fed the pre-treated 15% *P. palmata* than in those fed the control diet. However, no significant differences were found when comparing the control diet to non-treated 7.5% *P. palmata* and treated 7.5% and 15% *P. palmata* diets. Dietary treatments did not affect the number of OTUs and microbial diversity in the intestinal mucosa.

**Conclusion**

Overall, non-treated *P. palmata* induced a more consistent immune stimulation than the pre-treated *P. palmata.* Further studies are required to clarify the potential benefits of using treated or untreated *P. palmata* in European seabass juvenies diets.

# MODULATION OF SEABASS IMMUNITY WITH PRE-TREATED *Codium tomentosum*

Catarina Ramos-Oliveira*[1,2], Rui Magalhães [1,2], Isabel Belo[3,4], Aires Oliva Teles[1,2], Helena Peres[1,2]

## Introduction

Including macroalgae in aquaculture diets has shown potential to enhance the immune system of farmed fish. Rich in bioactive compounds such as pigments and other antioxidant compounds, macroalgae can improve fish immune responses by enhancing antioxidant defenses and increasing resistance to pathogens [1]. Studies have shown that dietary supplementation with macroalgae extracts enhances disease resistance, survival, and stress resistance [2]. These natural immunomodulatory effects are particularly relevant given the frequent stressors and disease outbreaks in farming conditions that can compromise fish immune function, as well as the increased awareness regarding the issues of synthetic additives for aquafeeds [3].

However, the bioavailability of macroalgae functional compounds is limited due to the complex polysaccharide matrix of macroalgae cell walls, which is not digested by fish [4]. To improve the availability of nutrients and biocompounds, treatments that break down algal cell walls are necessary [5]. These include mechanical, thermal, chemical, and biological methods [6,7]. Among them, alkaline chemical treatments are particularly effective, as they partially degrade structural carbohydrates such as hemicellulose and cellulose. This structural modification can improve cell wall permeability, thereby facilitating the release of antioxidants and enhancing nutrient availability [4,8]. The present study aimed to investigate the effects of dietary inclusion of *Codium tomentosum* pre-treated with alkaline solution and autoclaved on immune status and microbiota composition in European seabass (*Dicentrarchus labrax*) juveniles.

## Materials and Methods

*Codium tomentosum* was subjected to an alkaline (1N NaOH) hydrothermal pre-treatment and autoclaved at 121ºC for 30 or 60 minutes. Four isoproteic (48% dry matter basis) and isolipidic (18% dry matter basis) diets, namely, a control diet, with no inclusion of *C. tomentosum,* and three other diets including 7.5% untreated or pre-treated *C. tomentosum* replacing a plant feedstuff mixture of the control diet were used and fed to triplicate groups of 16 European seabass (initial body weight of 38g). The trial lasted 11 weeks, and during the trial, fish were hand-fed twice daily, 6 days a week, until apparent visual satiation. At the end of the growth trial, blood from 3 fish per tank was collected from the caudal vein using heparinized syringes, centrifuged at 6800 x g for 10 min, and the resulting plasma stored at -80ºC until analysis. The intestines of the same fish were also collected and stored in RNAlater for gene expression analysis. The expression levels of the following genes were evaluated by rt-PCR: *TNF-α, IL-8, IL-1β, IL-10, COX-2, casp3, and casp9*. Primer efficiency and reference gene stability were validated to ensure reliable normalization. Plasma innate immune parameters (antiprotease, protease, peroxidase, and lysozyme) were measured using standard spectrophotometric assays.

A log transformation was applied when necessary after testing for normality and homogeneity of variances. Data were submitted to a one-way ANOVA, followed by Tukey's test when $p < 0.05$. Analyses were conducted using IBM SPSS Statistics v26.

## Results

Fish fed the two pre-treated *C. tomentosum* diets showed significantly higher pasma peroxidase activities, both of which were greater than those of the non-treated group. Antiprotease activity was lowest in fish fed the diet including pre-treated *C. tomentosum* autoclaved for 30 minutes, while the highest value was observed in the non-treated *C. tomentosum* diet. Protease and lysozyme activity were not significantly affected by diet composition.

*(Continued on next page)*

The intestinal expression of *IL-8* was upregulated in seabass fed the *C. tomentosum* pre-treated and autoclaved for 30 minutes diet compared to the other three diets. On the other hand, intestinal expression of *IL-1β* and *casp3* was higher in seabass fed the non-treated *C. tomentosum* diet than in those fed the control and *C. tomentosum* pre-treated and autoclaved for 30 minutes diets, respectively. No significant differences between dietary treatments were observed in the intestinal expression of TNF-α, IL-10, COX-2, or casp9.

**Conclusion**

The results suggest that pre-treating *C. tomentosum* with an alkaline solution, followed by 30 minutes of autoclaving, produces a complex yet potentially advantageous immunomodulatory effect. Overall, *C. tomentosum* appears to enhance plasma peroxidase activity and help regulate inflammatory responses, supporting its promise as a functional dietary ingredient for aquafeeds.

# OPERATIONALIZING CLIMATE CHANGE ADAPTATION AND MITIGATION FOR AQUACULTURE – PRACTICAL SOLUTIONS

P. Olsen

Nofima
PO Box 6122
Langnes, NO-9291 Tromsø, Norway
E-mail: petter.olsen@nofima.no

The Operationalizing Climate Change Adaptation and Mitigation for aquaculture (OCCAM) Innovation Action is funded by the Horizon Europe funding programme and consists of 22 industry and research partners from across Europe. The OCCAM objective is to implement, test, and evaluate practical and innovative solutions for climate change adaptation and mitigation in the aquaculture sector, and to deliver scalable, replicable, and exploitable solutions with accompanying recommendations ready for deployment in a wide variety of aquaculture supply chains. Some solutions are generic in nature with application across countries and sectors; this includes a Good Practice recommendation for self-assessment of CO2 emissions, guidelines for how to meet sustainability reporting requirements, templates for requesting and providing scientific advice, and a policy recommendation focusing on gaps and opportunities for climate-resilient aquaculture production. Other solutions are specific for sectors, species, and production methods, including solutions for carp, rainbow trout, salmon, bivalves, and seaweed (Ulva). To reduce emissions and contribute to aquaculture sector mitigation of climate change, sediments from freshwater aquaculture are upcycled, sludge is used to produce biochar, a digital tool for self-assessment of emissions from bivalve production is developed, and nets and pens with significantly reduced emissions are produced. Adaptation solutions include assessment of water availability and quality for freshwater aquaculture, selective breeding of more resilient rainbow trout, digital tools for forecasting and managing sea lice and Harmful Algal Blooms,and change of deployment parameters for oysters and seaweed given the expected changes in temperature and other environmental conditions. A prototype or proof of concept is developed for each solution, and where possible the proposed solution is also evaluated at a different site, and general recommendations are provided to other industry actors wishing to implement similar solutions.

OCCAM started in 2025 and will end in 2029, and in addition to the 22 project partners an Industry Reference Group (IRG) is being established, consisting of aquaculture industry partners interested in testing and evaluating mature prototypes of the various solutions. The IRG will be invited to stakeholder workshops and will be invited to give feedback on the functionality and the potential application of the respective solutions and will thus have an opportunity to influence the final version of these. Membership in the OCCAM IRG is free and might be of particular interest for producers of carp, rainbow trout, salmon, bivalves, and macroalgae.

# PRELIMINARY STUDY ON THE EFFECT OF RAW CHITIN FROM *Hermetia illucens* EXUVIAE AND LAURIC ACID ON GUT MORPHOLOGY AND FUNCTIONALITY IN RAINBOW TROUT (*Oncorhynchus mykiss*) FED SEMI-PURIFIED DIETS

## Introduction

Natural functional feed additives can enhance both fish growth and health (Onomu et al., 2024) through the interplay between bioactive compounds and intestinal mucosa. Insects and their derivatives are considered a promising feed ingredient and additive to promote animal growth and health enhancement (Veldkamp et al., 2021).This study aimed to describe the effects of two compounds derived from black soldier fly (*Hermetia illucens,* BSF): a polysaccharide (chitin from exuviae, CHI) and a fatty acid (lauric acid, LAU). A feeding trial was performed with juvenile rainbow trout (*Oncorhynchus mykiss*) to assess if and to what extent raw chitin from BSF used alone or in combination with increasing levels of lauric acid can affect liver and intestinal morphology by focusing on goblet cells mucus composition, intestinal cell proliferation and differentiation as biomarkers.

## Materials and methods

Four semi-purified diets were formulated for juvenile rainbow trout to be grossly isoproteic (44%) and isolipidic (14%). Starting from a control basal diet (CTRL), three other test diets were produced to include a fixed amount of raw chitin from exuviae of BSF (1.5% dietary inclusion) (C-CHI) without lauric acid or with increasing level of it at 0.1% and 0.2% (C-CHI-LAU1 and C-CHI-LAU2; respectively). A total of 144 rainbow trout juveniles (91.3 ± 2.9 g) were randomly distributed into 12 fiberglass tanks (0.2 $m^3$; 3 tanks per dietary treatment) and fed over 10 weeks at a daily feeding rate of 2% body weight. At the end of the trial, growth parameters were measured and intestinal samples from pyloric caeca (PC) and proximal intestine (PI) were collected and immediately fixed in formalin for histological and immuno-histochemical analyses to assess the gut mucosae status. In particular, hematoxylin-eosin-stained sections were used to evaluate the general morphological aspects, PAS combined with Alcian Blue pH 2.5 staining to analyze the overall complex carbohydrates, and immunostaining for proliferating cell nuclear antigen (PCNA) and peptide transporter 1 (PepT1) to assess cell proliferation and peptides absorption respectively. Finally, the histochemical detection of alkaline phosphatase (ALP) was used to detect fully differentiated enterocytes.

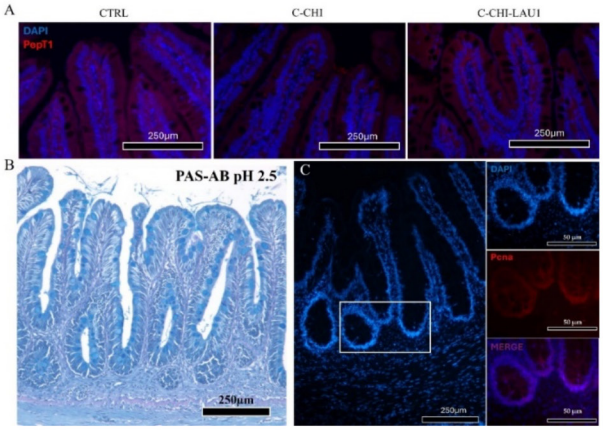

Figure 1: A) immunolocalization of PepT1 in the different dietary treatments, B) PAS combined AB pH 2.5 staining showing a heterogeneous mucus composition, and C) immunolocalization of PCNA restricted at the base of the folds.

*(Continued on next page)*

**Results**

There were no significant differences in the growth performance and body indices between the fish fed the control and the experimental diets. There were no histomorphological changes in the liver of the fish fed the different diets. However, there was a significant reduction in villi length ($p<0.05$) and changes in the mucus composition of goblet cells in the PC and PI ($p<0.05$). Lauric acid (0.2%) in the diet increased the number of mixed mucins in the PC, while chitin (1.5%) significantly increased the acid mucins alongside a significant decrease in mixed mucins in the PI ($p<0.05$). The signal intensity of peptide transporter 1 (PepT1) was lower in fish fed with the C-CHI diet (Fig 1). The PCNA and ALP expressions in PI did not differ significantly among dietary treatments ($p>0.05$).

**Discussion and Conclusion**

This study showed that including BSF exuviae and LAU into trout diets resulted in no differences in growth performances and biometric indices, similarly to what was observed in the same species by Rimoldi et al. (2023) with an inclusion of 1.6%, but unlike what was reported in sea bream fed diet including 0.02% LAU (Ullah et al., 2025).

Raw chitin alone caused a reduction in the folds length, and it affected goblet cell mucin production in rainbow trout fed diet with BSF meal (Elia et al., 2018). Furthermore, raw chitin decreased PepT1 signal intensity, indicating reduced intestinal peptide absorption, similar to what was observed when trout were fed a plant-protein based diet (Verdile et al. (2023). None of the diets affected PCNA and ALP expression, indicating that both raw chitin or LAU, did not induce proliferative state of intestinal tissue and cellular damage in the rainbow trout intestine (Kilemade et al. 2002).

Overall, these findings indicate that 1.5% BSF exuviae supplementation can negatively impact intestinal morphology, mucin production, and PepT1 expression, whereas a combination with 0.1% LAU in the diet seems to ameliorate the adverse effects of chitin.

**Noise in salmon farming**
In modern aquaculture, both at sea and on land, farmed salmon live in environments characterized by significant human-made noise. This noise may potentially have a negative impact on the most farmed animal in Norway. However, the extent and effects is not fully understood. Our aim was to describe the typical sounds within salmon aquaculture, develop methods to investigate long-term effects of noise, test habituation to noise and summarize present knowledge within the field.

**Methods and setup**
Firstly, sound was measured over representative periods at 10 different farms divided among open or closed sea cages and land-based systems. Secondly, we exposed salmon experimentally to known stressful low-frequency sound (10 Hz) for 5 minutes daily, to better understand the responses. Behaviour and physiology, together with molecular markers in the brain were to be identified for stress assessment. Thirdly, salmon smolts were experimentally exposed to "fish-farming sounds" in a predictable or unpredictable setup in freshwater tanks, followed by unpredictable sounds in sea cages to study both short- and long-term effects on stress and habituation. Finally, a review was written.

**Results and discussion**
The sound farmed salmon experience ranges from background levels around 95 dB re 1 µPa to typical levels approaching 134 dB, with very noisy periods up to 157 dB. These levels range within levels measured in other studies but provide further details. Closed sea cages were noisiest, likely caused by pumps continuously supplying water. Land-based systems were somewhat less noisy and open cages quietest, especially at night, though noisy operations and boats were present during the day. On three occasions, extremely high sounds exceeding 175 dB were measured, either when an underwater door was slammed shut or when blastings occurred nearby. The frequency range of the noise fell within the audible range for salmon. Overall, farmed salmon live in a noisy world, with occasionally very high sounds.

Low frequencies (<15 Hz) are particularly stressful for salmonids, and salmon exposed to 142-169 dB re 1 µPa immediately responded with flight reactions, elevated plasma cortisol levels, and reduced neuronal activity in the hypothalamus. Over time, fewer fish reacted to the daily repetitive, familiar sound, and the cortisol physiological stress response diminished. Salmon thus showed behavioural and physiological habituation. However, after a month and 30 exposures, the salmon still had increased serotonergic activity (indicating chronic stress in the brain) and suppressed expression of genes in the hypothalamus that are normally positively associated with growth and reproduction.

Freshwater parr-smolts were experimentally exposed to predictable, unpredictable or control tank sounds, followed by exposure to unpredictable sounds in sea cages. No group differences in the freshwater phase were present, but similar behavioural reactions and no physiological responses in cortisol or neurochemical signalling of serotonin or dopamine were seen. When individuals were further acutely stressed, normal physiological responses suggested that none of the sound environments were more stressful during the freshwater phase. In sea cages the most interesting (and unexpected) finding was that control fish reacted behaviourally the least, while fish that experienced sound in freshwater responded relatively strongly with a disorganized swimming pattern, more so in predictable compared to the unpredictable group. Cortisol responses in seawater were absent when exposed to boat noise or similar, but normal when additional acute stress was given. The neurochemical signalling responses showed that after the acute stress test, both the control and unpredictable groups responded with increased serotonergic activity in specific areas of the brain, while fish exposed to predictable sound did not. Elevated cortisol levels without a corresponding increase in serotonin levels may be harmful by impairing brain health (reduced neuronal plasticity and imbalance in the body's energy budget). Behavioural and neurochemical responses suggest that fish exposed to high levels of predictable sound during the freshwater phase become more stressed when exposed to unpredictable sound in the seawater phase.

*(Continued on next page)*

The review reveals that most research has been measured in sound pressure (dB re 1 μPa), while particle movement ($ms^{-2}$), the most important sound component to which salmon respond, is scarcely studied. Most studies are on physoclistous fish, having hearing thresholds far below the physostomous salmon. Salmonids can detect frequencies from 1 to 1000 Hz, but with lowest thresholds between 100 to 500 Hz, frequencies that overlap noise in aquaculture. Cumulative exposures to sound levels exceeding 177 re 1 $\mu Pa^2s$ caused moderate physiological damage, while levels exceeding 183 re 1 $\mu Pa^2s$ caused lethal damage in chinook salmon. Acute sounds typically trigger a behavioural flight or stress response, where salmon try to avoid the noisy area or swim in disrupted directions and speed. Long-term studies exposing salmon to ≤149 re 1 μPa triggered behaviour that disappeared over time, while physiology and welfare were unchanged (except for the study mentioned above with 142-169 dB re 1 μPa). A few studies report that infrasound (e.g., 5 Hz) is particularly frightening for salmon, supporting the long-term study where daily exposure to 10 Hz resulted in poorer welfare. Habituation to sound is common, both in terms of behaviour and physiology.

The combined works compile a list of recommendations for noise in salmon aquaculture. Noise measurements within the audible range for salmon should be considered against "established" threshold values for known negative consequences on behaviour, physiology, and physical damage. Unnecessary high noise should be avoided, and unpredictable noise minimized. Fish farmers should actively manage the use of noise sources near the fish and consider whether habituation is possible. Blasting work nearby or other acute high sounds can lead to undesirable behavioural changes or injuries and should be avoided. Low noise levels in freshwater may result in more resilient salmon in seawater. Mitigations could include identifying noise sources with frequencies < 500 Hz and dampening the sound by separation or physical attenuation. A good example of noise reduction is to soften the closing of hatches and avoid them slamming shut with a bang.

We must better understand the long-term consequences of different sound environments in the freshwater phase (high vs. low noise). We have already observed that very loud sounds affect the brain in a way that may hinder growth or impair brain health, though the long-term consequences have not been studied.

Normal sounds in aquaculture (<135 dB re 1 μPa) are not expected to have significant negative consequences for the salmon, but short noisy periods (<157 dB re 1 μPa) could have negative effects depending on their duration, while the acute sounds observed (>175 dB re 1 μPa) could lead to hearing loss and physical damage. The knowledge compilation highlights research needs for more precise threshold values of how frequencies and durations affect salmon behaviour, physiology and welfare. Advisory knowledge for blasting is insufficient. Standardized measurement methods should be developed to enable fish farmers to measure relevant noise that could affect salmon, choose mitigation measures, and assess their effects. Data on particle acceleration and its consequences, the most important sound component for salmon, is lacking.

# PHOTOBACTERIOSIS DYNAMICS IN EUROPEAN SEABASS (*Dicentrarchus labrax*) IN CROATIA IN LAST FIVE YEARS

D. Oraić*, M. Alfier, D. Grbin, I.G. Zupičić, S. Zrnčić

Croatian Veterinary Institute
Laboratory for Diseases of Aquatic Animals
Zagreb, Savska 143, Croatia
E-mail: oraic@veinst.hr

**Introduction**

Photobacteriosis is a globally distributed infectious disease caused by the Gram-negative halophilic bacterium *Photobacterium damselae* subsp. *piscicida*. In Mediterranean marine aquaculture, it poses a serious threat, especially when sea temperatures rise above 22°C (Romalde, 2002). In the Adriatic Sea, the disease primarily affects seabream fry in hatcheries and seabass during the ongrowing phase.

Outbreaks are often triggered by prolonged high temperatures, low salinity, and poor farming conditions such as low oxygen levels and handling stress. Infected fish show signs of hyperpigmentation, lethargy, and swimming imbalance. As the disease advances, symptoms include anorexia, darkened skin, skin erosions, pale gills with excess mucus, and necrotic patches. Dead fish are typically found at the bottom of cages. Necropsy findings in acute cases include mild hemorrhages and splenomegaly with small white necrotic foci. Chronic cases show enlarged spleens with coalescing nodular white lesions (Galeotti et al., 2022). Acute mortalities often go undetected, and without prompt treatment, fry losses can reach 70–80%.

The Interreg project MARINET aims to develop an AI-based risk assessment model using environmental data from multiparametric sensors and daily monitoring of operational welfare indicators (OWIs) as defined by Manfrin (2022). This study seeks to establish a baseline for the model using five years of data from Croatian Adriatic farms.

*Material and methods*

All samples submitted to the Croatian Veterinary Institute for diagnostic testing that tested positive for photobacteriosis between 2020 and 2025 were included in this study. The samples originated from marine fish farms located along the Croatian coastline of the Adriatic Sea.

Each sample underwent a standardized diagnostic protocol (Varvarigos 2020). Anamnestic data were collected, followed by weighing of the specimens and documentation of any external abnormalities. Subsequently, necropsies were performed. Observations made during necropsy were recorded, and a presumptive diagnosis was confirmed through bacteriological examination. This involved isolating bacteria on Marine Agar and Tryptic Soy Agar (TSA) supplemented with 1.5% NaCl. Preliminary identification was conducted using the API 20E system, along with an assessment of the bacteria's ability to grow on selective media such as Thiosulfate-Citrate-Bile-Sucrose (TCBS) agar. Final confirmation of *Photobacterium damselae* subsp. *piscicida* was achieved through PCR analysis, following protocols described by Andreoni and Magnani (2014). Co-infections were also confirmed.

All collected data were analyzed using descriptive statistical methods.

*Results*

Between 2020 and 2025, a total of 51 photobacteriosis outbreaks in seabass were diagnosed in our laboratory. Of these, 25 occurred in 2024, six in 2023, none in 2022, four in 2021, and six in 2020. Most of the affected fish weighed less than 100 grams, with only two cases involving larger specimens. Outbreaks most frequently occurred in late summer and autumn, when sea temperatures ranged from 18°C to 26°C. Chronic cases were typically observed in cooler periods (autumn to spring), while acute cases were more common at higher temperatures (up to 26°C) (Fig. 1). Co-infections with *Vibrio harveyi* and/or *Tenacibaculum maritimum* were significantly more common in 2024 compared to previous years, likely due to the prolonged period of elevated sea temperatures during summer and autumn (Fig. 2).

*(Continued on next page)*

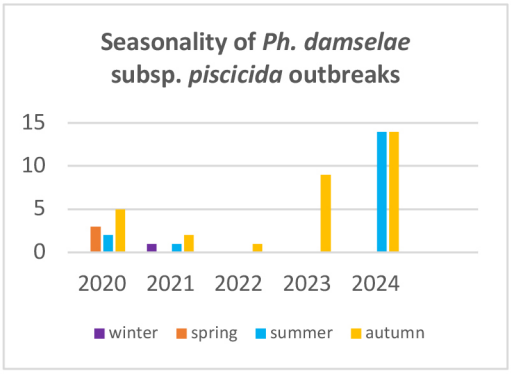

**Fig 1. Seasonality of photobacteriosis during last five years**

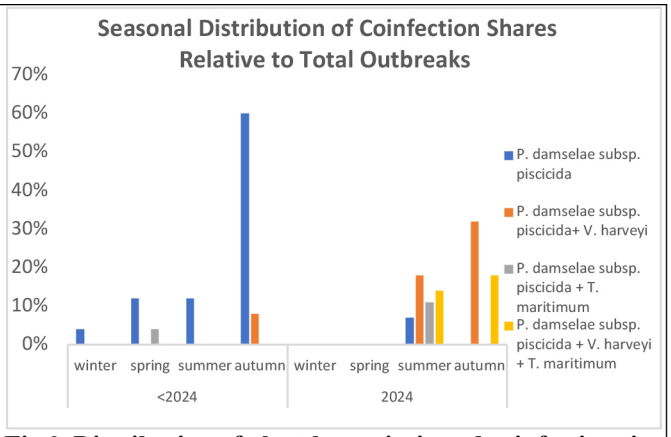

**Fig 2. Distribution of photobacteriosis and coinfections in 2024 and period from 2020-2023**

The disease was characterised by external lesions ranged from petechial hemorrhages on the head, operculum, and pectoral fin bases to more extensive hemorrhaging along the flanks, ventral fins, and around the anus. Gills appeared pale, occasionally with hemorrhagic patches. Necropsy findings varied from splenomegaly with barely visible whitish nodules to hemorrhages in the liver and intestines. Overall, the data suggest that the early onset of elevated sea temperatures acts as a trigger for disease outbreaks, exacerbated by co-infections with opportunistic pathogens such as *V. harveyi* and *T. maritimum*. In some cases, triple bacterial infections were observed, leading to severe losses.

# A NOVEL IN-SITU OXYGENATION SYSTEM FOR RAS AND TANK AQUACULTURE

J. Orellana[1*], F. Rüppel[2], and B. Wecker[3]

[1]Erwin Sander Elektroapparatebau GmbH, 31311 Uetze-Eltze, Germany
[2]Danish Salmon, 9850 Hirtshals, Denmark
[3]Oceanloop Kiel GmbH, 24229 Strande, Germany

Oxygenation in tank culture systems (e.g. RAS and race-ways) is one of the key factors affecting fish growth and welfare, and one of the major important production costs. Recent developments in RAS tank design faced the problem about how to make dissolved oxygen available for the animals in the tank (in-situ), especially in shallow (1.5m) and large surface area, or deep (4-6m) and circular tanks.

The analysis of available oxygenation solutions and potential new oxygen transfer technologies considered relevant aspects such as oxygen input efficiency and dissolved gas distribution over time and space in the tank, as well as energy demand, individuality, and independency.

After a thoroughly analysis, a novel in-situ oxygenation system was developed. It consists of an independent low power consumption unit with a ceramic membrane that operates at both low gas and water pressure. Table I shows the amount of oxygen input level and energy demand of the oxygenation system (named Canox).

As a self-sufficient and plug-and-play device, the unit can be quickly installed and retrofitted into existing tanks. The Canox oxygenation device is installed directly in/at the tank and uses the internal tank circulation and water flow for a very even oxygen distribution, ensuring a good oxygen supply. Due to the low gas and water pressure, there are no generation of harmful pressure release bubbles. Moreover, the normal behaviour of the fish and shrimp were not affected. The unit works completely independent of the main water circulation system and transfers oxygen into the tank even if the main water flow is stopped.

Existing technologies (low head oxygenators, U-tubes, oxygen cones, among others) were found to be inappropriate for an in-situ oxygenation. Other technologies were characterised by an extremely high cost at similar gas input efficiency levels.

Table I. Oxygen input level (L/h, kg/h of oxygen), energy demand (kg of oxygen/kW), and efficiency (%) for two different Canox models.

| Model name | Oxygen input | | Energy demand | Efficiency |
|---|---|---|---|---|
| | L/h | kg/h | kg/kW | % |

[3]Department of Aquaculture and Fisheries Management, University of Ibadan, Ibadan

*osasonagbenga@gmail.com

**Introduction**

The growing demand for sustainable aquaculture has led to increased interest in natural feed additives. *Terminalia catappa* is a promising plant with bioactive compounds like flavonoids and tannins that can enhance fish health and growth Abdel-Tawwab *et al*, 2018; Omitoyin *et al*., 2019; Ajani *et al*., 2020). However, extraction methods significantly influence the quality of the extract (Bae *et al.,* 2012). This study aims to evaluate the impact of different *T. catappa* extracts on the growth, health, and disease resistance of *Heterobranchus longifilis*. By investigating the effects of these extracts on growth performance, gut morphology, hematology, and resistance to *Pseudomonas aeruginosa*, this research contributes to the development of more sustainable and efficient aquaculture practices.

**Materials and methods**

Five experimental diets were formulated with varying concentrations of ethanol and aqueous extracts of *Terminalia catappa*. Diets were fed to triplicate groups of *Heterobranchus longifilis* for 70 days. Growth parameters, feed utilization, and hematological indices were measured. Liver samples were analyzed for antioxidant enzyme activity (SOD, GST, GPx) and lipid peroxidation (MDA). Fish were challenged with *Pseudomonas aeruginosa* to assess their disease resistance. Data were analyzed using one-way ANOVA and Duncan's Multiple Range Test to determine significant differences among treatments.

**Results and Discussion**

The study compared the efficacy of ethanol and aqueous extracts of *Terminalia catappa* on *Heterobranchus longifilis*. Ethanol extracts were found to have higher concentrations of bioactive compounds, but negatively impacted feed intake and growth performance. In contrast, aqueous extracts improved growth, feed utilization, and survival rates. This can be attributed to the varying polarity in the solvents. According to Archundia *et al,* (2019), the polarity in ethanol be described as medium while it is high in water. This suggests that aqueous extracts of *T. catappa* may be a more suitable dietary supplement for enhancing fish growth and health.

Poor nutrient utilization in ethanol extract-based diets led to reduced growth due to high levels of bioactive compounds like phenols. According to Thakur et al. (2019), these compounds act as anti-nutrients at high concentrations. Antioxidant indicators like GST and SOD were higher in aqueous extract diets, showing oxidative stress protection, which is required in fish during the normal feeding cycle. Fish fed T. catappa extracts showed increased resistance to *P. aeruginosa*, improving survival rates.

# DIVERSITY AND ANTIBIOTIC RESISTANCE OF POTENTIAL *Vibrio* PATHOGENS – CASE STUDY OF MEDITERRANEI AND ORIENTALIS CLADES IN THE EASTERN ADRIATIC BIVALVE AQUACULTURE

Karla Orlić*, Snježana Kazazić, Damir Kapetanović, Irena Vardić-Smrzlić, Jakša Bolotin, Valter Kožul, Vedrana Nerlović, Svjetlana Bobanović-Ćolić, Lorena Perić

Division for Marine and Environmental Research
Laboratory for Aquaculture and Pathology of Aquatic Organisms
Zagreb, Croatia
E-mail: korlic@irb.hr

**Introduction**

Bivalves, which filter seawater as part of their feeding process, are particularly prone to bacterial colonization of their tissues. Among the bacteria commonly found in marine environments, *Vibrio* species are predominant and include commensals, opportunistic pathogens, and significant pathogens of both marine organisms and humans. Human infections are most frequently associated with the consumption of contaminated seafood, especially bivalves, which are often eaten raw or undercooked. In addition to the threat they pose to human health, *Vibrio* species can cause serious diseases in bivalves, impacting aquaculture production. Moreover, studies indicate that rising of seawater temperatures associated with global warming will significantly affect the dynamics of *Vibrio* genus species. Therefore, understanding the structure of natural *Vibrio* communities, including the presence of potential pathogens, is crucial for the management of bivalve aquaculture. Species belonging to the Mediterranei and Orientalis clades, such as *V. mediterranei*, *V. bivalvicida* and *V. tubiashii*, have frequently been associated with mortality events in marine organisms, but are under investigated in the context of eastern Adriatic bivalve aquaculture. In addition, the increasing problem of antibiotic resistance, driven by the overuse of antibiotics and anthropogenic pollution in marine environments, represents a growing challenge. Despite its importance, antibiotic resistance among *Vibrio* species in the eastern Adriatic bivalve aquaculture remains poorly investigated when it comes to Mediterranei and Orientalis clade species.

**Materials and methods**

Our study is focused in two protected marine reserves – Lim Bay and Mali Ston Bay, locations which are known for aquaculture of Mediterranean mussel, *Mytilus galloprovincialis* Lamarck, 1819 and *Ostrea edulis* Linnaeus, 1758. On both location we sampled seawater, sediment and bivalve tissue bimonthly over the course of one year. All bacteria isolated on *Vibrio* selective media were screened with MALDI-TOF mass spectrometry to confirm the genus and clade. More precise species identification was carried out by sequencing pyrH gene for improved taxonomic resolution. All isolates identified as members of Mediterranei and Orientalis clade were tested for antibiotic resistance *via* disk diffusion on Mueller Hinton agar for 12 selected antibiotics which are frequently used in aquaculture and medicine.

**Results**

MALDI-TOF MS results showed that 58 isolates belonged to Mediterranei clade while only 21 Orientalis clade isolates were found. Isolates of both clades were found during warmer periods especially in Lim Bay at seawater temperatures above 17°C. Furthermore, Orientalis clade isolates didn't show a high incidence of antibiotic resistance except for erythromycin (42.9%). For Mediterranei clade, higher occurrence of resistance to erythromycin (62.1%) was found. Also, while only 15.5% of isolates were resistant to oxytetracycline, 58.6% were intermediately resistant. Almost 71% of isolates were multi-resistant, meaning that they were resistant to two or more antibiotics.

This study provides the first report on the diversity and antibiotic resistance of *Vibrio* species from the Mediterranei and Orientalis clades associated with bivalve aquaculture in the eastern Adriatic. The findings highlight the need to focus on a broader range of species that make up the *Vibrio* community, in order to improve the current knowledge of the risk for infections and diseases outbreaks in bivalve aquaculture.

This will be crucial in the near future, considering the predictions that increasing anthropogenic pressure and climate change will enhance the susceptibility of farmed bivalves to potentially pathogenic *Vibrio* species and promote the spread of antibiotic-resistant strains, posing a growing threat to the sustainability of bivalve aquaculture.

* Ana.HernandoAriza@bionomous.ch

**Introduction**
Early mortality is a persistent issue for marine aquaculture hatcheries; thus, quality control during this phase is -stage vital to enhance survival rates and overall production. Fertilized egg quality is the first point to be checked so that it is very important to culture only the best batches and to discard them if quality is not good.

This study explores a novel approach to classify fish eggs based on visual characteristics using automation and AI, which has the potential to improve hatchery quality assurance.

The efficacy of this new method was evaluated using bluefin tuna (*Thunnus thynnus*) and sea bream (*Sparus aurata*) eggs under experimental conditions at the IEO-ICAR infrastructure in Murcia, Spain. The impact on egg viability, hatching rates, and operational processing speed were all assessed.

**Materials and methods**
The EggSorter is a new mechanical and fluidic system which can automatically grab individual eggs from an inlet reservoir, analyse each one of them thanks to an optimised optical system and classify the eggs into various categories using image processing and artificial intelligence algorithms. Following analysis, the eggs are directed into one of two fluidic paths according to the analysis criteria.

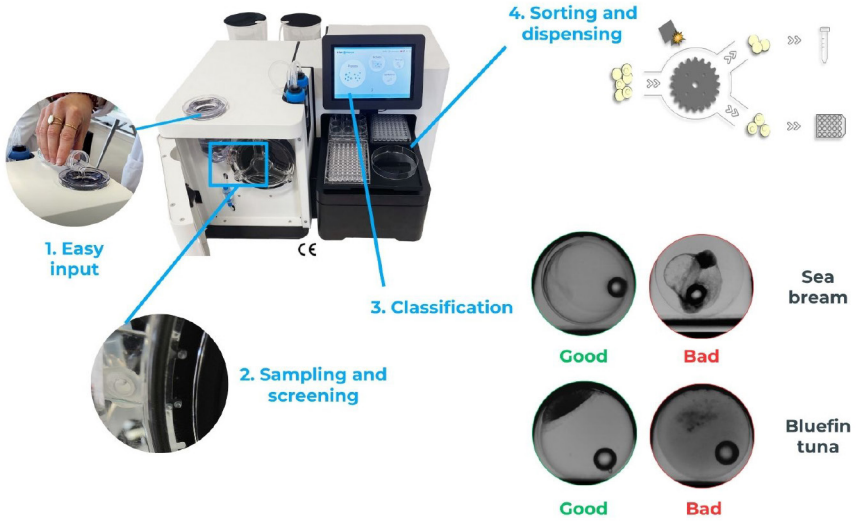
An artificial intelligence–based image analysis pipeline was developed to classify bluefin tuna and sea bream eggs based on the quality and stage of development. High-resolution brightfield images were captured by the EggSorter and annotated by the team at IEO-ICAR. For sea bream, an algorithm was developed to distinguish gastrula-stage eggs of good quality from poor quality, dead, or at another developmental stage eggs. The training dataset consisted of 3657 images, with 738 images labelled as ‘good’ (good quality eggs at gastrula stage) and 2919 images labelled as ‘bad’ (poor quality eggs, dead eggs or eggs at a different developmental stage than gastrula). For bluefin tuna, the training dataset consisted of 686 images, with 126 images labelled as ‘good’ (good quality eggs) and 560 images labelled as ‘bad’ (poor quality eggs or dead eggs).

9 different batches of fertilized sea bream coming from broodstock kept in tanks in IEO-ICAR and 7 different batches of bluefin tuna eggs coming from both, a broodstock kept in tanks in IEO-ICAR and commercial floating net cages off the Cartagena coast, El Gorguel SE Spain, owned by Ricardo Fuentes e Hijos, were used. Eggs coming from cages were transported early morning to the Spanish Institute of Oceanography (IEO), Planta Experimental de Cultivos Marinos (Puerto de Mazarrón, Murcia, Spain), and they arrived in morula stage. All the fertilized eggs were cleaning and placed to incubate until the gastrula stage. Then some eggs were separated as control and incubated in standard conditions until 12 hours after hatching in three small glasses (250 ml sea water, 25 eggs per glass and temperature control at 21±1ºC for sea bream and 24±1ºC for bluefin tuna) and remaining eggs were processed by the EggSorter.

After processing, egg classified as good quality eggs were incubated in the same standard conditions than above. 12 hours after final hatching, all the glasses were counted, and dead eggs, alive larvae and dead or folded larvae were determined). Hatching rate (100 x hatched larvae/fertilized eggs incubated) and Deformity rate (100 x folded or dead larvae/total hatched larvae)

Results
The efficacy of this new method was evaluated using bluefin tuna (*Thunnus thynnus*) and sea bream (*Sparus aurata*) eggs under experimental conditions at the IEO-ICAR infrastructure in Murcia, Spain. The EggSorter is able to process up to 1,300 eggs/hour, separating good and poor quality eggs. The impact on egg viability, hatching rates, and operational processing speed were all assessed. Results demonstrated no significant adverse effects on hatching rates or larval normality when comparing sorted and control groups. In bluefin tuna, automatically sorted eggs showed a slightly higher average hatching rate (88.5%) compared to controls (83.8%), with comparable levels of larval normality.

*(Continued on next page)*



| **ABFT** | Hatching rate % | | Normal larvae % | |
|---|---|---|---|---|
| | Control | Egg Sorter | Control | Egg Sorter |
| Average÷std | 83,82 ± 14,19 | 88,54 ± 10,37 | 87,10 ± 10,60 | 83,71 ± 8,6 |
| **Sea Bream** | Hatching rate % | | Normal larvae % | |
| | Control | Egg Sorter | Control | Egg Sorter |
| Average÷std | 74,30 ± 11.68 | 67.43 ± 6.56 | 84.57 ± 9.79 | 76.86 ± 5.72 |

**Conclusions**

This method shows great potential as a research and broodstock management tool. With further optimization—particularly in processing speed, but also in the number of data of the algorithm —it could become a valuable asset for early embryonic screening, helping hatcheries improve stock quality and reduce early-stage mortality.

# TRANSCRIPTOME ANALYSIS OF RED BLOOD CELLS IN RESPONSE TO THE RED SPOTTED GROUPER NERVOUS NECROSIS VIRUS (RGNNV)

Maria del Mar Ortega-Villaizan*, Veronica Chico, Miguel Angel Garcia-Alvarez, Alberto Cuesta, Celia Garcia-Quintanilla

*Instituto de Investigación
Desarrollo e Innovación en Biotecnología Sanitaria de Elche (IDiBE)
Universidad Miguel Hernández de Elche (UMH)

Email: mortega-villaizan@umh.es

Red spotted grouper nervous necrosis virus (RGNNV) is the most widespread betanodavirus strain affecting numerous fish species, with European seabass (*Dicentrarchus labrax*) being highly susceptible. RGNNV causes up to 100% mortality in larvae and juveniles and significant losses in adult fish by targeting central nervous tissue, particularly the retina and brain.

In order to develop effective vaccines, the host immune response to the pathogen should be fully understood. However, in the infection produced by RGNNV in European sea bass, the role of RBCs is unknown. Nucleated RBCs are known to act as phagocytes, antigen-presenting cells, and modulate leukocyte activity, producing cytokines and other signaling molecules in response to viral infections (1). The aim of this work was to study the participation of European sea bass RBCs in the immune response to RGNNV infection.

European sea bass purified RBCs were exposed *ex vivo* to RGNNV, and the expression of genes involved in the antiviral immune response was evaluated. On the other hand, *in vivo* assays were performed in which juvenile individuals were infected with RGNNV and at 1- and 3-days post infection brain and purified RBCs from peripheral blood samples were used to study gene expression by RT-qPCR. In addition, RBCs transcriptome was also evaluated by means of RNA-sequencing.

The *ex vivo* results showed that RGNNV was able to stimulate the expression of some genes related to the antiviral immune response in RBCs exposed to RGNNV, such as *isg15* (an interferon-induced protein that has been implicated as a central player in the host antiviral response). The *in vivo* results showed that RGNNV was able to stimulate the expression of *mx* (a GTPase that is part of the antiviral response and is known to inhibit viral replication) in RBCs, both at 1- and 3-days post-infection. It is noteworthy that *mx* was also highly expressed in the brain, the target organ of RGNNV infection. The RNA-sequencing results showed over-representation of antiviral immune response pathways in RBCs from RGNNV infected European sea bass, depicting a clear response to the virus, mediated by cytokines and antiviral proteins.

Infectious pancreatic necrosis virus (IPNV) remains a critical challenge in salmonid aquaculture, with conventional vaccines often presenting limited immunogenicity and labor-intensive production (Rimstad 2014). Recognizing that fish nucleated red blood cells (RBCs) are not only the most abundant cells in circulation but also have emerged as pivotal immune actors—capable of antigen processing, presentation, and cytokine production—we developed a recombinant, modular nanostructured vaccine (nanopellets, NPs) to target this cell type as ideal carriers for systemic vaccine delivery (Nombela and Ortega-Villaizan 2018, Puente-Marin, Nombela et al. 2018). These NPs consist of the IPNV-VP2 capsid protein, either alone (IPNV$^{NP}$) or fused to rainbow trout interferon gamma (IFNγ) to generate an adjuvanted construct (IPNV-IFNγ$^{NP}$), while a fluorescent iRFP$^{NP}$ served as a control. NP constructs were expressed in E. coli and characterized by electron microscopy, which confirmed their stable nanostructured assembly under extreme conditions relevant for aquaculture.

In vitro assays with purified rainbow trout RBCs demonstrated that IPNV-IFNγ$^{NP}$ were efficiently internalized by RBCs in a dose- and time-dependent manner, outperforming non-adjuvanted counterparts. Intraperitoneal administration of IPNV-IFNγ$^{NP}$ led to enhanced presence in blood as well as in primary immune organs such as the head kidney and spleen. RNA sequencing (RNA-seq) analysis identified over 1,800 differentially expressed genes in IPNV-IFNγ$^{NP}$-treated RBCs that were enriched in interferon signaling, vesicle trafficking, and mitochondrial pathways. Also, the transcriptomic profiling of RBCs from immunized fish revealed the robust upregulation of antiviral genes (e.g., *mx*, *vig1*, *isg15*, and *ifit5*).

These results underscore the potential of harnessing RBCs as systemic antigen carriers to enhance innate and adaptive immune responses. Further, NP-based subunit vaccine is a promising strategy to promote more sustainable and welfare-friendly aquaculture practices. Ongoing work will focus on functionalizing the NP-based platform with ligands targeting RBCs to improve immunization strategies.

# CLOT FORMATION ASSAY (CFA): A NOVEL METHOD FOR ASSESSING PLASMA CLOTTING CAPACITY IN GILTHEAD SEABREAM (*Sparus aurata)*

María Ortiz*, Mar Collado-González, María Ángeles Esteban

Immunobiology for Aquaculture Group
Department of Cell Biology and Histology
Faculty of Biology, University of Murcia
30100 Murcia, Spain
E-mail: maria.ortizg@um.es

## Introduction

Aquaculture has grown in production and economic importance worldwide. Climate change is expected to increase disease outbreaks in farmed fish, highlighting the need for improved diagnostics. Standardised, non-lethal health monitoring methods are essential. While human haematology is well established for disease diagnosis, fish haematology is gaining recognition as a biomarker system to detect physiological changes caused by nutritional deficiencies, environmental stress, toxins and diseases. This study focuses on the development of a new standardised assay to correlate coagulation parameters with the health status of sea bream (*Sparus aurata*), providing a tool for improved health assessment in aquaculture systems [1].

## Materials and methods

To standardize the assay, it was necessary to determine the concentration of both, sodium citrate, required to prevent coagulation in sea bream blood, and calcium chloride, required to initiate the reaction. Seabream blood samples (250 $\mu$L) were collected in 1.5 mL Eppendorf tubes containing sodium citrate and kept on ice. Sodium citrate concentrations ranging from 3.8 to 20 % were tested. The samples were then centrifuged at 2500 g for 15 min to obtain cell-free plasma (CFP), which could subsequently be stored at -40 °C. In 96-well, clear, flat-bottomed, untreated plates, 150 $\mu$L of 0.9% Braun saline, 40 $\mu$L of CFP and 10 $\mu$L of calcium chloride were added to each well. Calcium chloride concentrations were evaluated from 0 to 350 mM. Finally, absorbance was recorded at 405 nm every minute for 1 hour. Once optimized the assay, the evaluation of the coagulation of fish exposed to chitosan with Mw 20 kDa and degree of acetylation of 60 % for 1 h was performed. An untreated fish group was used as control. Blood samples were taken 8 h after the exposition to chitosan.

## Results

To prevent and induce coagulation, respectively, 15 % sodium citrate and 200 mM calcium chloride were selected as the best salt concentrations for the developed procedure. The analysis of the fish blood coagulation after the exposure to chitosan revealed significant differences in all parameters analysed (Fig. 1), with the experimental group unable to coagulate under the same conditions as the control group (Fig. 2).

## Discussion/conclusions

The methodology developed is a complement for the evaluation of seabream immunity, as plasma procoagulant activity is related to acute stress and potential death from spontaneous thrombi caused by elevated adrenaline in the blood. In teleosts, hypocoagulant capacity correlates with liver damage due to a fall in the concentration of proteins that belong to the coagulation cascade. Nevertheless, when hypocoagulability exists in the absence of liver damage, the compounds or conditions tested may act as protective agents against thrombosis. To our knowledge, the effect of chitosan on fish blood coagulation has never been evaluated before. Further analysis will allow us to determine whether chitosan could serve as a protective compound against thrombus generation [1,2].

*(Continued on next page)*

[3]Institute for Computer Research (IUII), University of Alicante, Alicante (Spain)

Email: marina.ortiz@ua.es

**Introduction**

Due to the increase of $CO_2$ emissions and other greenhouse gases, the oceans are experiencing warming caused by the global phenomenon known as climate change. This effect is especially evident in enclosed seas such as the Mediterranean. In this context, marine heat waves have become an increasingly frequent and intense phenomenon, seriously affecting the stability of marine ecosystems. In this context of climate change, activities such as marine aquaculture are subject to multiple stress factors such as those exerted by global climate change, an effect that affects the physiology, development and growth of fish species.

**Material and Methods**

Using data from Copernicus Marine Services, this study examines the effects of climate change on the thermal structure of the water column along a latitudinal and longitudinal gradient in the Mediterranean. The research focuses on 12 marine aquaculture sites in different countries (Spain, Tunisia, Greece, Croatia, Turkey, Cyprus and Egypt). Specifically, it analyzes seasonality over two periods (a period before and a period after relevant effects of climate change), as well as the evaluation of thermal anomalies during the summer season. To determine the sustainability of marine aquaculture systems throughout the Mediterranean, a climate risk indicator using R Studio will be applied to these locations, together with the interpretation of water column graphs.

**Results and Conclusions**

Thanks to the study of the thermal stratification in the water column, the deepening of the 25º C isotherm influenced by latitude and longitude is detected. The study of two different periods helps to find differences in the deepening of the isotherm, where warm water masses reach greater depths in the period more influenced by climate change, as well as their increasingly earlier appearance in the summer period (Figure 1) (Table 1). The locations of Guardamar (Spain), Ionian Islands (Greece) and Limassol (Cyprus) take the highest values of isotherm deepening in the study period following global warming, with values of 14, 16 and 19 depth-month units, respectively. Specifically, locations located in the eastern Mediterranean area have a higher number of depth anomalies in the summer period. In addition, temperature-based climate risk indices indicate that locations in this area indicate high risk (values greater than 0.7-0.8) in terms of the sustainability of the aquaculture season and potential impacts, such as the Nile River (Egypt) and Limassol (Cyprus).

The continuous increase in mean ocean temperature and the intensification of marine heat waves could significantly affect European aquaculture, as heat stress compromises production. Thermal stratification limits the circulation of nutrients and oxygen, affecting the health and productivity of aquatic crops. Therefore, the sector must adapt to changes in marine ecosystem services to maintain sustainable production. It is crucial to develop climate change management and mitigation strategies in the Mediterranean region in order to have the tools to face these challenges and maintain optimal conditions in aquaculture systems.

*(Continued on next page)*

## Introduction

Finding alternatives to fishmeal is essential for sustainable aquaculture. Biofloc technology is a system that promotes the growth of beneficial microbial communities, which convert waste nutrients into protein biomass, improving water quality and providing a source of food. Biofloc meal, obtained by harvesting and processing aggregates from biofloc systems could be used as a sustainable ingredient for aquafeeds. Moreover, diversification in aquaculture is essential to enhance resilience, reduce economic risks and promote environmental sustainability. In the last years, mullet (*Liza aurata*) has gained a solid foothold in the market, driven by its outstanding nutritional quality. The present study aims to determine the optimal replacement level of fishmeal with biofloc meal as alternative protein source to improve the culture of mullet.

## Material and methods

Three experimental diets were formulated (35% P, 8% L and 40% CH): control diet based on fishmeal and two experimental diets with fish meal replacement by biofloc meal at 20 and 30% levels (C, B20 and B30, respectively). Mullets (*Liza aurata*) were randomly distributed in 9 tanks, each containing 12 fish (initial weigh 112 ± 1g) in 350L tanks with brackish water of 25.0 ± 0.2‰ of salinity and 25.8 ± 0.3ºC of temperature and maintained under a Recirculating Aquaculture System. Fish were manually fed *ad libitum* twice a day, six days a week. After 80 days, 9 fish of each experimental group were sampled and digestive tract excised and divided into pyloric caeca, anterior and posterior intestine. After processing, trypsin and chymotrypsin were determined by Lazo *et al.* (2000) and Faulk *et al*. (2007). α-amylase and lipase were determined by commercial kits (Spinreact, Ref. 41202 and Ref.1001275). Protein concentration was determined by Bradford method. Results are presented as mean ± SEM. Two-way ANOVA was used, with diets and digestive section as fixed factors. When interaction was significant, diet and section effects were analyzed by a one-way ANOVA. F values were significant for $P<0.05$ and differences were determined following a post-hoc analysis using Tukey test. Statistical analyses were performed with SPSS v.25.

## Results

Results for activity of the digestive enzymes assayed are presented in Figure 1. Regarding sections of digestive tract, anterior intestine was the section with significantly highest activity for all enzymes independently of treatment, except for lipase, in which non-significant differences were detected. As for the effect of the dietary treatment, chymotrypsin, lipase, and amylase, except in the pyloric caeca where no significant differences, presented the highest values ($p < 0.05$) in the B30 experimental group, both in the anterior and posterior intestine. In contrast, the B30 group showed significantly lower values in the case of trypsin.

*(Continued on next page)*

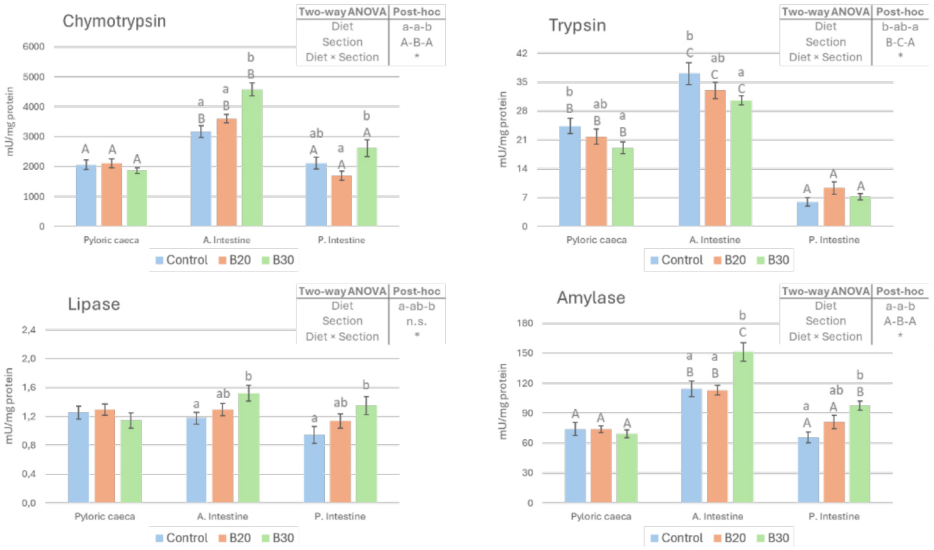

**Fig.1.** Chymotrypsin, trypsin, lipase and amylase specific activities in pyloric caeca, anterior and posterior intestine of *Liza aurata*. Values are means ± SEM (n=9). For two-way ANOVA, letters indicate influence (P<0.05) of experimental diets and asterisks interaction among factors. When interaction was detected, one-way ANOVA was performed. Over the bars, small letters indicate differences (P<0.05) induced by experimental diet in each digestive section. Capital letters indicate differences (P<0.05) among digestive section in each experimental diet.

## Discussion

In fish, pyloric caeca and anterior intestine are the main site of secretion for pancreatic enzymes such as lipase, amylase, and alkaline proteases. Moreover, these parts of the digestive tract are also the sections in which nutrient absorption predominantly occurs, with the posterior intestine contributing to a lesser extent. In the present study, results show that in mullet, activities of chymotrypsin, trypsin and amylase were generally higher in the anterior intestine and, to a lesser degree, in the pyloric caeca and posterior intestine. Dietary changes can affect digestive enzyme activity, and in this study, fish fed a diet containing 30% biofloc meal showed higher activity for all enzymes determined except trypsin. Since macronutrient levels were the same across experimental diets, this improvement could be related to biofloc properties. In this sense, biofloc is composed of microorganisms (bacteria, microalgae, protozoa) and organic matter that might stimulate endogenous enzyme secretion, provide exogenous enzymes, and modulate intestinal microbiota, thereby supporting gut health. Similarly, Ekasari et al. (2019) reported that 10 and 20% biofloc meal dietary inclusion enhanced growth, feed utilization, and health in African catfish (*Clarias gariepinus*). In conclusion, replacing 30% of dietary fishmeal with biofloc meal in mullet may support or even improve an optimal digestive activity.

# EVALUATING REGIONAL GOVERNANCE IN NORWEGIAN AQUACULTURE: A 15-YEAR REVIEW OF COUNTY-LEVEL ADMINISTRATION POST-REFORM

Tonje C. Osmundsen[1], Marit Schei Olsen[1]

[1]NTNU Samfunnsforskning AS
Trondheim, Norway

In 2010, Norway implemented a governance reform transferring aquaculture licensing and site coordination responsibilities from the Directorate of Fisheries to county municipalities (fylkeskommuner). The reform aimed to strengthen regional governance by decentralizing aquaculture management, improving coordination, enhancing regional development, and enabling more holistic coastal zone planning. It also introduced statutory deadlines for processing aquaculture site applications to improve efficiency and predictability for the industry.

This study evaluates the outcomes of that reform 15 years later, focusing on administrative performance, coordination, and regional development impacts.

Using a mixed-methods approach—including 38 stakeholder interviews, document analysis, and statistical review of 1,200+ site applications (2020–2023)—we assessed the counties' delivery capacity, inter-agency collaboration, and effects on the aquaculture sector.

**Key findings**
Counties were well-prepared for their new responsibilities, aided by staff transfers from the Directorate of Fisheries and early investments in capacity-building. Over time, counties developed strong professional environments, particularly through the establishment of the FAKS network (translated: Counties' Aquaculture Cooperation), which has been instrumental in promoting coordination, knowledge sharing, and standardization.

While counties generally meet statutory deadlines for standard applications, overall processing times have increased from 2020 to 2023, due to growing complexity of applications. Also, delays were often due to bottlenecks at other authorities, especially the County Governor (Statsforvalteren) and the Norwegian Food Safety Authority (Mattilsynet).

Findings show that counties have largely succeeded in managing their new responsibilities. The counties have effectively coordinated the multi-agency site approval process and are seen as accessible, competent, and service-oriented. However, challenges remain in ensuring consistent interpretations of what constitutes a complete application and in managing overlapping applications for the same sites. Also, challenges remain in balancing environmental and industry interests.

Counties have leveraged their broader responsibilities in planning, education, and business development to support the aquaculture sector. This includes initiating inter-municipal planning processes, funding knowledge-building projects, support for marine education, and facilitating dialogue between stakeholders.

However, increasing complexity of applications, increasing competition for coastal space and the emergence of new species (e.g., cod) demand improved tools for cumulative impact assessment and stronger cross-sectoral governance.

We conclude that while the reform has strengthened regional governance and service delivery, future success depends on continued investment in coordination mechanisms, digital infrastructure, and adaptive regulatory frameworks.

# EFFECT OF TRANSFER PROCESSES ON CONDITIONS OF JUVENILE PIKEPERCH (*Sander lucioperca*) CULTURED IN RAS: ACCLIMATIZATION AND STRESS ELIMINATION

L. Ostolaza*, T. Pěnka, V. Kučera, J. Kolářová, J. Velíšek, O. Malinovsky, T. Policar.

## Introduction

Pikeperch is a well-appreciated freshwater fish, due to its nutritional value and palatability (Péter et al, 2023). The rearing of these species in Recirculating Aquaculture System (RAS) is not optimized due to the maintenance of high-water quality and high fish stress levels, which causes an overall decrease in production (Thomas et al., 2020). It has been reported that pikeperch is susceptible to changing conditions, given its high basal cortisol levels, and the duration of its recovery period (Baekelandt et al., 2019; Pourhosein-Sarameh et al., 2013; Pourhosein-Sarameh & Falahatkar, 2024).

The transfer from one tank to another is a source of stress and a necessary step duringthe rearing of this species. To minimize the stress caused by this process, assessing the shortest acclimatation time is key. Therefore, the aim of this study was to test the effect of transferring two sizes of juvenile pikeperch into different tanks on length of acclimatation period, survival, growth, oxidative stress, blood biochemistry to identify the optimal juvenile size to perform the transfer.

## Materials and methods

In total, 2700 juveniles for each group as: on-growing with total length (TL) = 161.4 ± 10.4 mm and body weight (BW) 27.2 ± 7.2 g, and early grown-out with TL = 242.1 ± 18.87 mm, BW = 104.1 ± 14.7 g were cultured 3 months before the transfer in three 1.5 $m^3$ tanks connected to an experimental 30 $m^3$ RAS. Three fish per tank were sacrificed and sampled one day before transfer. Fish were transferred manually using nets from three tanks to seven tanks connected with the same RAS.

Three samples per tank were collected immediately after the transfer (T), one day post transfer (1DPT), 7 days post transfer (7DPT), 21 days post transfer (21DPT), 35 days post transfer (35DPT) and 49 days post transfer (49DPT). Samples of blood, brain, gill, liver and kidney were taken for evaluation of blood profile and biochemisry oxidative stress and antioxidant enzymes. The required time for acclimation of each category was assessed by the comparison of founded values with optimal values of each parameter for pikeperch which were mainly published by Kolářová and Velíšek (2012). This procedure was repeated twice for each experimental group.

## Results

Cortisol, glucose, lactate and ammonia presented significantly higher concentrations until 35DPT for on-growing and until 7DPT for grown-out. On-growing individuals required 35 days to eliminate oxidative stress in brain, gill, liver and kidney, in contrast to grown-out group, which took 7 days.

Larger individuals exhibit equivalent levels of stress sensitivity yet demonstrate a more abbreviated acclimatization phase. This suggests that the optimal timing of the transfer process can be determined through strategic selection.

## Discussion

Previous results (Baekelandt et al., 2019; Ende et al., 2021; Malinovskyi et al., 2020), aligns with the fact that pikeperch is a highly sensitive species. (Kozłowski & Piotrowska, 2024; Pourhosein-Sarameh & Falahatkar, 2024). Size seems to be a factor that infuences in the acclimatization period. Recent research has further established differences in stress response between wild and pond-reared pikeprch juvenile (W = 16g) during transfer (Péter et al., 2023). Other parameters such as domestication process of the broodstock, life cycle and individual physiology influences acclimatization period (Falahatkar et al., 2025).

# EXPLORING TRANSFORMATIVE SOCIAL INNOVATIONS: INSIGHTS FROM CROSS-FIELD DIALOGUE AND APPLICATION IN SICILY'S AQUATIC FOOD SYSTEMS

Maria Bustamante Liria[1] · Concetta Maria Messina[2] · Simona Manuguerra [2] · Andrea Santulli [2] · Giovanna Ottaviani Aalmo [1]

[1]Norwegian Institute of Bioeconomy Research (NIBIO)
[2] Consorzio Universitario della Provincia di Trapani, University of Palermo, University of Messina

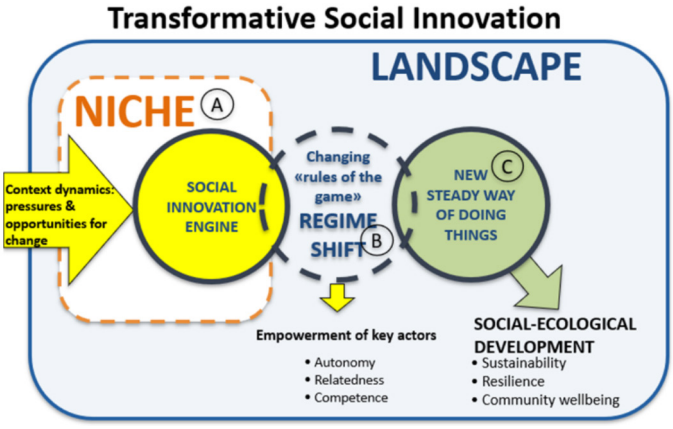
Corresponding author: giovanna.ottavianiaalmo@nibio.no

***Background and aim***
Food systems require systemic change, yet how transformative processes unfold is not always clear. Social innovations, if properly embedded, can generate bottom-up solutions that stabilise new socio-environmental trajectories. This study investigates how a diffuse Living Lab in Sicily (Innovittica, Trapani) mobilises niche experiments, governance structures, and circular bioeconomy practices to transform "waste" into resources and provide new opportunities for coastal fisheries and SMEs.

***Methods***
Semi-structured interviews were conducted with fishers, SMEs, authorities, CSOs and academics, alongside Living Lab observation and document review. Analysis was structured along three transition levels: (i) niche-level innovations, (ii) regime changes, and (iii) stabilisation pathways for improved socio-environmental contexts.

***Results***
Key transformations were observed across three domains. ***Doing***: new products and processes were co-designed and validated through product valorisation and sensory analysis. ***Knowing***: hands-on co-creation workshops and continuous feedback loops facilitated stakeholder learning. ***Governing***: bottom-linked governance via a Temporary Association (ATS), multi-actor roundtables and transparent facilitation mechanisms ensured shared decision-making.

***Discussion and conclusion***
Our study illustrates how transformative social innovation can stabilise a new, equitable way of doing by reframing side-streams as assets, embedding by-product valorisation in policy, and formalising collaborative governance as a regional platform. These processes demonstrate the complementarity of niche experimentation and bottom-linked governance in fostering sustainable and socially just aquatic food systems.



# ENHANCING ATLANTIC SALMON RESILLIENCE THROUGH FUNCTIONAL FEEDS: THE ROLE OF FUCOIDAN IN IMMUNOMODULATION AND DISEASE MITIGATION

M. Øverland[1*], B. Morales-Lange[1], S. D. C. Rocha[1], R. Montero[1], A. Benavides[2], M. Imarai[2], L. Mercado[3], L. T. Mydland[1]

**Introduction**

Norwegian salmon farming is a vital economic sector but faces significant challenges due to high fish mortality rates, particularly during the seawater (SW) phase. For instance, winter ulcers caused by bacteria such as *Moritella viscosa* or *Tenacibaculum* sp. pose a major threat. Functional feeds containing bioactive compounds, such as fucoidan from sugar kelp (*Saccharina latissima*) offer a potential solution to improve fish resilience. The RESILIENT SALMON project (Research Council of Norway – 294821) investigates how fucoidan can enhance immune responses and reduce susceptibility to diseases.

**Materials and methods**

Fucoidan was extracted from sugar kelp using a factorial design to optimize key parameters, such as temperature, acid concentration and time, in a pilot biorefinery process. Bioactivity test in salmon kidney cells (SHK-1) determined the most effective fucoidan fraction for immune stimulation, based on sulfation levels, yield and immunostimulatory effects (Michalak et al 2024). Then, the most promising fraction was upscaled for evaluation in functional diets for Atlantic salmon (*Salmo salar*).

Experiment 1 (Exp.1): After an *in vitro* evaluation in SHK-1 cells, the immunomodulatory effects of fucoidan in pre-smolt Atlantic salmon were tested in freshwater (FW) phase. Fish were fed experimental diets containing 0% (negative control), 0.1%, 0.2%, or 0.4% fucoidan, or a positive control diet containing 0.2% MacroGard®. Distal intestine (DI) samples were collected for microbiota characterization (by 16S rRNA-seq) and detection of immune-related biomarkers (using RNAseq, RT-qPCR, immunohistochemistry and proteomics). Also, primary cultures of head kidney leukocytes (HKLs) were obtained from fish fed experimental diets and stimulated with proteins from *Aeromonas salmonicida*. Then, the protein level of cytokines such as TNF-α and IL-10, as well as effector molecules (i.e., iNOS and HSP70) were detected by indirect ELISA.

Experiment 2 (Exp. 2): We evaluated whether feeding a diet with 0.2% fucoidan for four weeks post-vaccination in FW could enhance the immune response of Atlantic salmon exposed to inactivated *Tenacibaculum maritimum* (via intraperitoneal injection) after SW transfer. For this, immune biomarkers in the DI and head kidney (HK) were analyzed by RT-qPCR and indirect ELISA at the end of the FW stage, and before and after stimulation in SW.

Experiment 3 (Exp. 3): investigate the impact of feeding a 0.2% fucoidan diet on the resistance of Atlantic salmon to *Tenacibaculum dicentrarchi*. Fish were fed the fucoidan-supplemented diet for four weeks in FW, followed by four weeks on a control diet in FW. Then, fish were transferred to saltwater and challenged with *T. dicentrarchi*. The control group, which only received the control diet throughout the experimental period, was also infected with *T. dicentrarchi*. We assessed mortality rates and immune responses to evaluate the mode of action underlying the observed health effect of the functional diet containing fucoidan.

*(Continued on next page)*

**Results and Discussion**

In Exp.1, fucoidan enhanced immune and antioxidant responses in Atlantic salmon. For instance by upregulating expression of *sod-1*and *prx* in SHK-1 (at 72h). Also, HKLs from fish fed 0.2% fucoidan or MacroGard® and stimulated with proteins from *A. salmonicida* had increased production of TNF-α (pro-inflammatory cytokine) and HSP70 (chaperone). In contrast, HKLs from fish fed 0.4% fucoidan had an increased level of IL-10 (anti-inflammatory cytokine). Feeding the 0.2% fucoidan diet also increased the presence of *Bacillus sp* in DI and up-regulated pathways related to immune cell development, tissue repair, and cell adhesion. At protein level, fish fed 0.2% fucoidan showed a higher production of MHC II, CD3, along with the up-regulation of *gata3*, suggesting an enhanced adaptive immunity. By proteomics in DI, we detected higher levels of immune-related proteins (gap junction and NOD-like receptor) and a lower level of proteins associated with amino acid metabolism and fatty acids degradation, indicating a metabolic shift towards immune resilience. These findings suggest that fucoidan, depending on dietary inclusion level, can enhance immune function, gut health, and overall resilience in salmon.

Results from Exp 2, showed that fucoidan supported growth and boosted immune responses when combined with a commercial vaccine. Fucoidan activated key immune-related genes in Atlantic salmon such as pro- and anti-inflammatory cytokines (*tnfa*, *il10*) in DI, while in the HK, an upregulation of antimicrobial peptides (i.e., *hepcidin*, *cathelicidin*) was detected after stimulation with inactivated *T. maritimum.* These effects were also confirmed at the protein level, reinforcing fucoidan's potential as a potent immune-modulating feed component.

Exp. 3 revealed that fucoidan significantly improved fish survival when exposed to the live *T. dicentrarchi*. Atlantic salmon fed fucoidan-supplemented diet showed a 51% higher probability of survival compared to the control group. Further, the levels of CD4-1+ T cells and IgM+ B cells in peripheral blood leukocytes (PBL) and the spleen increased as a result of fucoidan supplementation during the infection. Following the *T. dicentrarchi* infection, cytokine expression levels were also upregulated in the spleen and PBL of fucoidan-fed fish, suggesting that fucoidan may enhance T cell differentiation and immune activation.

**Conclusion**

Functional feeds enriched with fucoidan from sugar kelp, combined with nutritional programming, can significantly enhance salmon resilience and health beyond the specific vaccine effects, supporting the sustainable development of the aquaculture industry.

# INVESTIGATION OF THE EFFECT OF HEAT STRESS ON EPIGENETIC MODIFICATIONS OF TESTES AND SPERM IN NILE TILAPIA *(Oreochromis niloticus)* AND ON ITS SPERM PARAMETERS

Mehmet Özbek*, Şükrü Güngör, Hüseyin Sevgili, Seval Bahadır Koca, Mustafa Öztop, Zafer Usta, Hasan Batuhan Emre Özdoğan, Harun Karaca, Mustafa Akın, Hasan Ali Çay, Meryem Şimşek, Rüveyda Hilal Akı, Ufuk Kaya, Fırat Korkmaz, Mehmet Bilen

E-mail: mehmetozbek2@gmail.com

**Introduction**
Heat stress represents a critical environmental factor that can significantly impair reproductive physiology in aquatic organisms such as Oreochromis niloticus. Chronic exposure to elevated temperatures disrupts spermatogenesis and leads to functional sperm damage. Epigenetic mechanisms, including DNA methylation, histone modifications, and non-coding RNA activity, are known to play essential roles in regulating germ cell development and are sensitive to environmental fluctuations. Despite increasing interest in the relationship between epigenetic mechanisms and male fertility, integrated studies on how chronic heat exposure alters these regulatory layers in Nile tilapia remain limited. The objective of this study was to investigate how long-term thermal stress affects sperm epigenetic signatures and testicular histoarchitecture and to evaluate their association with sperm quality and reproductive success.

**Materials and Methods**
Experimental setup and animal husbandry: Sexually mature male Nile tilapia was randomly distributed into three groups, each exposed to a specific water temperature: the control group at 28 °C, the moderate stress group at 32 °C, and the high stress group at 36 °C. The fish were reared in aerated tanks under natural photoperiod conditions for a duration of 90 days. At the end of the experimental period, testicular and sperm samples were collected for subsequent analyses.

DNA methylation profiling by whole genome bisulfite sequencing: To evaluate global DNA methylation patterns, genomic DNA was extracted from sperm samples. The DNA was sheared to appropriate fragment sizes and ligated to methylated sequencing adapters. Following bisulfite treatment to convert unmethylated cytosines to uracil, libraries were amplified and sequenced using paired-end next-generation sequencing platforms. Raw sequencing reads were analyzed using the Bismark software pipeline, allowing alignment and methylation calling across CG, CHG, and CHH sequence contexts. Differentially methylated regions were identified between control and heat stress groups.

Expression analysis of small and long non-coding RNAs: Total RNA was isolated from spermatozoa using column-based purification kits. For small RNA analysis, libraries were constructed by ligating 3-prime and 5-prime adapters followed by reverse transcription and PCR amplification. For long non-coding RNA profiling, ribosomal RNA was selectively depleted before sequencing library preparation. High-throughput sequencing was performed on Illumina platforms. Sequencing data were aligned using HISAT2 for long reads and Bowtie2 for small RNAs. Transcripts were assembled using StringTie and differential expression was calculated using DESeq2.

Immunohistochemical detection of epigenetic and stress markers: Testis tissues were fixed in modified Davidson's solution to ensure optimal nuclear and cytoplasmic preservation. After fixation, tissues were embedded in paraffin, sectioned at five microns, and mounted on positively charged slides. Immunohistochemical staining was performed using primary antibodies specific to 5-methylcytosine as a marker of DNA methylation and histone modifications. Heat shock proteins Hsp70 and Hsp60, as well as the proliferation marker PCNA, were also evaluated. Sections were incubated with corresponding secondary antibodies and visualized using AEC chromogen. Counterstaining was performed with Gill's hematoxylin and slides were examined microscopically.

*(Continued on next page)*

Histopathological evaluation of testes: Paraffin-embedded testes fixed in modified Davidson's fixative were stained with hematoxylin and eosin. Tissue architecture was evaluated under light microscopy, focusing on the organization of seminiferous tubules, thickness of the germinal epithelium, presence of interstitial edema, and vacuolization. Particular emphasis was placed on identifying features associated with feminization such as disrupted spermatogenic layers and disorganized tubular structure.

**Results**

The 36°C group exhibited significant alterations across all evaluated parameters compared to control. Whole genome bisulfite sequencing analysis revealed widespread hypermethylation, particularly in genes associated with energy metabolism, transcription regulation, and DNA repair pathways. Notably, differentially methylated regions were enriched in fertility-related gene clusters. Small RNA and long non-coding RNA analyses identified numerous differentially expressed small RNAs and novel long non-coding RNAs in heat-stressed sperm. Several downregulated small RNAs were associated with spermatogenic regulation and chromatin remodeling. Long non-coding RNAs were found to co-express with genes involved in oxidative stress response and cellular apoptosis. Immunohistochemical evaluation showed marked increases in nuclear 5-methyl cytosine staining and repressive histone modifications in spermatogenic cells of the 36°C group. PCNA staining was reduced, indicating decreased proliferative capacity, while histone modifications associated with gene activation were also diminished. Increased expression of both Hsp70 and Hsp60 was observed, supporting the presence of a strong cellular stress response. Histopathological analysis revealed degeneration and disorganization of seminiferous tubules, marked reduction in the germinal epithelium, and significant loss of germ cells. In addition, the presence of germ cells resembling oocytes was observed, which was interpreted as a clear indication of partial feminization. Flow cytometric analysis confirmed a substantial decline in sperm viability and mitochondrial function, along with elevated oxidative stress, enhanced lipid peroxidation, and increased rates of apoptosis in the 36°C group. Computer-assisted sperm analysis revealed the lowest motility scores in this group, with sharp reductions in velocity parameters such as straight-line and average path velocities, as well as an increased frequency of morphological abnormalities. Fertilization trials using sperm from heat-stressed males and oocytes from control females demonstrated a marked decrease in fertilization and hatching success in the 36°C group, providing strong evidence that thermal stress leads to epigenetic and cellular disruptions that impair reproductive performance.

**Conclusion**

This study demonstrates that chronic heat stress induces profound epigenetic and physiological changes in the testes and sperm of Nile tilapia. The observed changes include hypermethylation of key fertility-related genes, altered non-coding RNA expression, increased histone repressive marks, and clear histological damage. These molecular and cellular disruptions were strongly associated with decreased sperm function and reduced fertilization success. Collectively, these findings suggest that specific epigenetic markers could serve as predictive biomarkers for thermal stress-induced subfertility and may aid in the development of thermotolerant Nile tilapia lines for sustainable aquaculture.

**Introduction**

Reclaimed water aquaculture for food production exists outside Europe, especially in resource-poor regions. However, currently there is no capacity for reclaimed water aquaculture or aquaponics in Europe mainly due to low public acceptance and lack of regulations [1, 2]. The EU Water Reuse Regulation of 2020/741 [2] regulates the use of reclaimed water for agriculture, laying the groundwork for an extension to aquaculture. The novelty in this work pioneers the use of reclaimed water to farm fish and vegetables fit for human consumption in an aquaponic system, leading not only to a notably water scarcity alleviation but also a reduction of produce prices and carbon footprint avoiding transport costs.

For the first time in Europe, an experimental aquaponic farm has been coupled to a nearby urban wastewater treatment plant in Castellana Grotte, Puglia, Italy within the frame of the project *Aquaponics from wastewater reclamation (AWARE)* GA N. 101084245. Advanced (post-tertiary) treatment of wastewater has been tailored to feed the aquaponic farm to produce lettuce and Tilapia. The performance of advanced post-tertiary treatment and the aquaponic farm has been evaluated not only in terms of chemical and microbiological water quality, but also fish welfare, plant health and food safety. Here, we report on water quality.

**Materials and Methods**

The advanced tertiary treatment has been developed by Aquasoil. MITO3X technology is composed of an ozonation step with the ability to perform ozonation at a dose of 4.5 mg/L $O_3$ with nearly zero contact time (< 10 seconds) excluding the formation of brominated byproducts (bromates), follow by a vacuum ultraviolet (VUV) with an emission at a wavelength of 185 nm. This radiation can directly photolyze water and produce hydroxyl radicals and hydrated electrons, both species able to effectively degrade micropollutants. Then, a reactive storage (biofilter) is used downstream the ozone/VUV system. The biofilter is comprised of two tanks with a total dimension of 15 $m^3$ (5 m x 3 m x 1 m). Water is first subjected to granular activated carbon (GAC) and then, expanded clay and lava rock. This adsorption step can assure total retention of micropollutants. Assuming an average flow rate of 1 $m^3$/h, this ensures an average empty bed contact time (EBCT) of 15 hours. The biofilter is aerated using oxygen wasted by the ozone generator.

*(Continued on next page)*

These systems comprise various compartments (in this case: fish tank, biofilter, sump, DWC floating raft crop cultivation system, settler, and aerobic digester, provided by Green in Blue). In this study two aquaponic lines were studied to ensure reproducibility. Each aquaponic system was set up with three tanks of 350 L each, filled up with reclaimed wastewater, and stocked with a total of 140±6 Nile tilapia (*Oreochromis niloticus* L., initially stocked at 37.5±0.95 g per system) and a 5 $m^2$ of crop planting surface with 36 lettuces. The experiment was conducted in a small scale, closed-loop, simple recirculating aquaculture system (RAS) running for three months. An aquaponic line with dechlorinated tap water was used as control.

Several physico-chemical and biological parameters were monitored not only after the water advanced (post-tertiary) treatment, but also throughout the cycle in the sump of the aquaponic system. In particular, microplastics; metals; organic emerging micropollutants; human enteroviruses such as Sapovirus (SaV), Norovirus (NoV GI, NoV GII), Hepatitis (HAV, HEV), crAssPhage, and Pepper Mild Mottle Virus (PMMoV) which is considered as potential indicator of fecal contamination in aquatic environments; parasites (18S rRNA gene metabarcoding); fecal contamination bacteria indicators such as enterococci, total coliforms, *Escherichia coli*; and antibiotic resistance biomarkers and the bacterial community (16S rRNA gene metabarcoding) were analysed.

**Results**

Regarding the efficacy of the advanced (post-tertiary) treatment for the removal of contaminants, 77±5 organic micropollutants were detected in the inlet of the advanced (post-tertiary) treatment using non targeted screening conducted by high-resolution mass spectroscopy. After the treatment, an overall removal of 51.1% was measured in terms of sum of micropollutants. Furthermore, the stage of the reactive storage was able to achieve an additional removal of micropollutants reaching (relative to the influent) nearly two logs reduction (i.e., 98.7%). Suspect PFAS were not detected in the effluent. Metals were detected in trace concentrations in the inlet and effluent. Microplastics were reduced in 66%. The crAssPhage and PMMoV concentration were quantified in the inlet corresponding to $8.57 \cdot 10^2$ and $2.55 \cdot 10^5$ gc/L respectively. Moreover, 30% of PMMoV particles showed infectivity. SaV, NoV GI, GII, HEV, HAV were not detected (<LoD) or detected below LoQ. After treatment crAssPhage was totally inactivated and PMMoV was reduced to 1-log but no infectivity was confirmed. Bacterial counts were also below LoD. Regarding microbial water quality evolution in the aquaponic system, no viruses were detected through time, not even PMMoV. Accumulation of bacterial contamination was observed through time in the sump, but no *E. coli* was observed. The water microbial community was observed to change during the experimental cycle, and mirrored that of the biofilter, but not of the of fish and plants being cultivated. Various parasitic species were identified, but none have pathogenic significance. Interestingly, no differences in water quality were detected within the aquaponic system using dechlorinated tap water and reclaimed urban wastewater.

**Conclusions**

Advanced post-tertiary treatment was demonstrated to provide high quality reclaimed water. The combination of oxidation processes coupled to a final adsorption led to high reduction of microbial pathogens, micropollutants and microplastic particles. Its reuse in aquaponics showed promising results in comparison with potable water systems.

## Introduction

Aquaponics is an unconventional method of fish and crop production, which combines aquaculture with hydroponics. Aquaponics can be installed in rocky, saline and no-arable lands, with no requirements for fertilisers and insecticides/herbicides. This contributes to reducing soil occupation and deterioration, alleviating the pressure on water resources, and reducing agriculture impact on the environment [1].

Urban wastewater is increasingly used for agriculture due to increasing water scarcity and stress, together with expanding populations, rising wastewater disposal levels and contamination episodes. Urban ecosystems should consider developing new markets for wastewater, diverting a higher percentage of wastewater inland, making productive use of wastewaters not only for agriculture but also for aquaculture and aquaponics [2,3]. For example, reclaimed water can reduce the geographical dependency of aquaculture to freshwater, so that it can be located anywhere near a city with wastewater treatment plants. This would result in a decrease in production costs and the procurement of fresh produce of high protein content to the benefit of local communities [4]. However, low public acceptance and lack of regulations are the main barriers [5].

The main goal of this work is to prove the reduction of environmental footprint of using reclaimed water in aquaponic farms assuring productivity and food safety within the frame of the project *Aquaponics from wastewater reclamation (AWARE)* GA N. 101084245. To do this an experimental small-scale aquaponic farm has been coupled to a pilot-scale urban wastewater treatment plant at URJC, Madrid, Spain. Advanced tertiary treatment of wastewater has been tailored to feed the aquaponic farm to produce lettuce and Tilapia. Environmental performance of reclaimed urban wastewater-fed aquaponic farm has been evaluated.

## Materials and Methods

Water advanced tertiary treatment was used to polish wastewater effluent from a wastewater treatment plant (WWTP). This process was composed of serial modules of Ultrafiltration (UF), electrooxidation (EO) and radiation with a total of 60 UVC-LED. The UF membrane is $Al_2O_3$, size pore of 100 nm, 0.23 $m^2$ x 1.2 m. The anode of the EO module corresponds to Ti/MMO (mixed metal oxides) and Ti is used as cathode, 270 $cm^2$, 5.2 A, 10-15 V, 78.85 J. The wavelength of UVC-LED radiation is in the range of 268-280 nm, with maximum emission of 275 nm, and energy of 102.99 J. The flow rate corresponded to 200 L/h.

In this study 1 $m^3$ reclaimed urban wastewater-fed aquaponic system stocked with 50 Nile tilapia (*Oreochromis niloticus L.*, stocked at 5.7 kg per system) and 72 lettuce plants (*Lactuca sativa* Batavian Red) for 22 lettuce cycles of 5 weeks. The experiment was conducted in a small scale, closed-loop, simple recirculating aquaculture system (RAS) running for 19 weeks. Control with dechlorinated tap water was also performed as base line.

A gate-to-gate life cycle assessment (LCA) was used following a standardised methodology by ISO 14040 and 14044. The selected functional unit (FU) was 1 kg of Tilapia. Mass allocation was applied to distribution environmental impacts and burdens across co-products. To prepare the inventory data the ecoinvent v3.8 was used, and the cut-off options for the unit process were selected. The reference method proposed by the European Commission, Environmental Footprint (EF) 3.0, was employed. To quantify the potential environmental impacts SimaPro 9.4 was used.

## Results

The main system features (including raw materials for building and running the facility); consumptions (energy and water); and production (fish feed, fish, lettuce, dead biomass, sludge) are shown in Table 1. The advanced tertiary treatment was also accounted for raw materials and energy.

*(Continued on next page)*

Table 1. Life Cycle Inventory (LCI) data of dechlorinated tap water-fed aquaponic system.

| Inventory Data-Dechlorinated Tap water (19 Weeks) | Quantity | Units |
|---|---|---|
| **Outputs from technosfere. Products and co-products** | | |

| Electricity, medium voltage {ES}\| market for \| Cut-off, U | 670.3 | kWh |
| **Outputs to the environment** | | |
| **To water** | | |
| Nitrate | 61.7 | g |
| Nitrite | 0.22 | g |
| Phosphate | 3.26 | g |
| Ammonium, ion | 0.27 | g |
| TOC, Total Organic Carbon | 43.6 | g |

## Conclusions

Electricity use (pumps, lights, heaters) is the main contributor to Global Warming Potential together with energy demand depending on climate, and lighting. Nutrients in effluent discharge affect eutrophication potential. Comparing aquaponics using dechlorinated tap water with one using reclaimed urban wastewater introduces key environmental trade-offs. The reclaimed water reduces freshwater demand and embodied energy, but may introduce higher treatment energy.

[3]Universitat Autonoma de Barcelona, Spain

## Introduction

On January 2024 the European Commission designated European Union Reference Centre for the welfare of aquatic animals (EURCAW-Aqua) (Commission Implementing Decision 2024/266). The centre was launched in September 2024. This EURCAW has similar objectives and mandates of the three previous existing EURCAWs focused on the welfare of pigs; ruminants and equines; and poultry and small farmed animals. Reference Centres aim at improving the enforcement of the legislation on animal welfare. The lead of EURCAW-Aqua was awarded to a consortium composed by the University of Crete (Greece), the Biology Centre of the Czech Academy of Sciences (Czech Republic), and the Universitat Autonoma de Barcelona (Spain).

## Objectives and mandate

The objective of EURCAW-Aqua is to provide services to National Competent Authorities (NCAs) in Member States, addressing the main scope to improve the welfare of aquatic animals and the enforcement of the current legislation on animal welfare.

The EURCAW-Aqua will establish a portfolio of competitive services for the European Commission and National Competent Authorities (NCA) of EU member states, based on sound scientific knowledge and operational excellence.

The designation of the EURCAW-Aqua is a very important step to fulfil the gaps in scientific and technical knowledge regarding aquatic animals. EURCAW-Aqua is currently developing validated animal welfare indicators, welfare assessment methods and tools for the improvement of the welfare status of farmed aquatic animals (fish, cephalopods and decapods) in the EU. The EURCAW-Aqua is also providing technical support and advisory services, coordinating assistance to NCAs in carrying out official controls, and disseminating good practices, operating as an information and resources hub. EURCAW-Aqua provides the NCAs with access to case studies, research and scientific findings, technical data, novel welfare tools, techniques and technologies to improve on farm aquatic animals' welfare assessment and the enforcement of the current animal welfare legislation and provides scientific evidence. The EURCAW-Aqua furthermore supports horizontal activities of the Commission and of the MS in the area of welfare requirements for aquatic animals. All relevant material will be publicly available through the Centre's web page (https://www.eurcaw-aqua.eu/). EURCAW-Aqua provides workshops, training courses and training material both to civil servants, inspectors and officers working in EU institutions and NCAs of member states on a free of fee basis.

To cover the need for firsthand official information about the activities of the EURCAW-Aqua and to support the Centre with technical information, a Reflection Board (REB) was set up. The REB represents the farmed aquatic animals supply chain, relevant professional organisations, civil society organisations, and relative advisory councils and reference bodies of EU interest. The European Commission is invited as an observer. The REB meets annually and the exact composition of the REB is defined during in the first year of operation of EURCAW-Aqua.

To address ethical considerations in organizational conflict, an Ethics Committee was established. The role of the Ethics Committee is the establishment of ethical guidelines and a code of conduct for the staff and partners of the EURCAW-Aqua.

## Structure

The EURCAW-Aqua is led by the University of Crete and has the following structure: a coordination team, an Executive Committee and an Operational Team. The coordination Team has three representatives of each Consortium Institutions. The Executive Committee includes the Coordination team members plus the Scientific coordinator and the Project Manager. The Operational Team includes experts in communication and organization devoted to the development of scientific and technical studies, the organization of training courses and the compilation of welfare indicators information.

*(Continued on next page)*

**Activities planned and performed so far**

The activities of the centre involve the following areas: (1) Support and coordinated assistance to national and regional authorities, (2) Animal welfare indicators, methods for the assessment and methods of improvement, (3) Conducting thescientific and technical studies, 4) Organizing training activities, and (5) Disseminating research findings and innovation activities.

During the 2024 Work Programme the Centre produced the following studies: (1) a regulatory framework review regarding live farmed farmed aquatic animals transport and harvest, (2) a list of relevant welfare indicators for common carp (*Cyprinus carpio)*, and European sea bass (*Dicentrarhus labrax*) during transport and at harvest, (3) an overall on-farm score for the evaluation of common carp welfare at transport and harvest, (4) a report on currently available welfare assessment systems for farmed fish, and (5) a blueprint for research to detect loss of consciousness and/or sensibility of fish at slaughter. These outputs are available on EURCAW Aqua portal. Three workshops have been organized during 2024 on specific subjects of interest for the NCAs. The first EURCAW-Aqua online workshop on rainbow trout welfare, was devoted to exploring welfare indicators and assessment methods for farmed rainbow trout. Attendants of NCA, particularly State Veterinary Inspectors, gained insights from leading experts in fish welfare, genetics, health, and behaviour. The second workshop was specifically designed for NCAs to provide targeted knowledge and practical tools for assessing and enhancing welfare in carp aquaculture, with a special focus on harvest, transport and slaughtering practices. The objective of the third workshop was to inform about the state of the art of the current advances and knowledge gaps on European seabass welfare, particularly in stunning and slaughter methods. Advances were reviewed in connection with the results of research projects (PerformFISH, MedAID, Cure4Aqua) as well from guidelines of institutional organisations (EFSA) and producer organisations that were contextualised in the current legislation framework. The Work Programme for the next programming period (2025-27) has been submitted, evaluated and approved by EU authorities.

# DISEASE BURDEN IN FISH FARMING: ASSESSING THE COSTS AND WIDER IMPACTS OF DISEASES

F. Padrós[1]*, I. Mladineo[2,3] and S. Østergaard[4]

[1]Biologia Animal. Dep. Biologia Animal, Biologia Vegetal I Ecologia. Facultat de Veterinària. Universitat Autònoma de Barcelona. Spain

[4]Department of Animal and Veterinary Sciences - ANIVET Management and Modelling. Aarhus University. Denmark
Francesc.padros@uab.cat

**Introduction**

In many instances, the likelihood of disease occurrence and its associated impact has been traditionally perceived as an inevitable phenomenon—subject to randomness—that must be accepted as an intrinsic aspect of human life. A comparable mindset is often observed in sectors involving the cultivation and production of living organisms, such as agriculture, livestock, and aquaculture. It is well established that disease can exert a profound influence on these production systems; nevertheless, comprehensive analysis—particularly from economic and wider perspectives—has been relatively limited. In response to this gap, the concept of Disease Burden has gained significant traction in human medicine over recent years, emerging as a critical tool for evidence-based decision-making in both public and private healthcare systems. More recently, this paradigm has been increasingly adopted in the context of animal production, including aquaculture, where it provides a structured framework for quantifying the various impacts of disease and informing management strategies.

**Materials and methods**

The concept of Disease Burden, when applied specifically to fish farming, is currently being examined from two distinct yet complementary perspectives under the framework of EUPAH&W and the Horizon Europe Cure4Aqua project.

More specifically, within EUPAH&W, this concept is being addressed under Priority Area 5 – Integrated Approach Including Socio-Economic Aspects of Animal Health and Welfare, and more concretely through Specific Objective Action 22 (SOA 22). This action assesses the economic and societal burden and impacts of selected priority diseases and production diseases, including diseases of terrestrial and aquatic farmed animals, on animal welfare, public health, and the environment. This action aims to support better decision-making by evaluating the costs and benefits of disease prevention, enhancing the sustainability of the EU livestock industry through improved health and welfare practices. It also develops bio-economic simulation models.

Concurrently, within the Cure4Aqua project, one of the tasks under Work Package 2 (WP2) focuses specifically on estimating the Disease Burden. This effort aims to quantify the impact of disease in aquaculture systems, providing a data-driven basis for prioritizing interventions and guiding policy and management strategies across the sector.

A preliminary analysis of how the concept of disease burden has been developed within the field of aquaculture—and more specifically in fish farming—revealed that, although certain studies and publications have addressed specific components of the concept in a targeted and applied manner, these efforts have been fragmented and lacked comprehensive coverage of all relevant dimensions. As a result, a more in-depth analysis was deemed necessary to establish an integrative and holistic understanding of the disease burden in this sector.

**Results and discussion**

The outcome of this analysis, conducted by the research team within the Cure4Aqua project during 2023 and 2024, has led to the development of a comprehensive review on the subject (Padrós et al., 2025). This work primarily identifies and elaborates on the following key aspects related to the impacts of disease in fish farming:

-The impacts of mortality and morbidity on the economy and performance of the farm.

-Economic evaluation of the costs associated with the management of diseases: surveillance, diagnostics, treatment, prevention, and biosecurity investments.

*(Continued on next page)*

-Evaluation of costs and benefits related to disease diagnosis and control.
-Evaluation of cost (also environmental) and benefits of therapeutics, non-medicinal, and other disease control strategies.
-Cost of the investments related to risk assessment and prevention at the farm level, including immunoprophylaxis and vaccination
-Impact of disease on farmed fish welfare
-Disease risk assessment, insurance, and quality assessment
-Societal impacts and governance implications
-Impacts of fish diseases and public health: a one health approach

These elements are currently utilized in the development of a novel economic analysis model (Glucksman et al., 2023) that is both flexible and adaptable, capable of supporting disease-specific assessments—such as sea lice infections in Atlantic salmon or sparicotylosis in gilthead seabream—as well as integrative analyses at the farm or enterprise level.

Furthermore, this review will serve as a foundational reference for analyses within Specific Objective Area 22 (SOA 22), as well as within the broader context of the entire Partnership for the years to come.

# IMPACT OF DRYING METHOD ON THE SENSORY EVALUATION OF SHRIMP CHIPS USING THE JAR SCALE

M.J. Pagán*; P. García-Segovía

i-Food, FOOD-UPV
Universitat Politècnica de Valencia
Camino de Vera sn
46022 Valencia, Spain

## Introduction

The growing demand for healthy and functional snacks, driven by consumers seeking convenient and health-promoting options, has led to integrating seafood and aquaculture products into snack development. These products respond to current consumer preferences for options high in quality protein, low in fat, and rich in micronutrients such as vitamins and minerals (Javier Pisco et al., 2024; Carlucci et al., 2015). However, for these products to gain market acceptance, it is crucial to address challenges related to stability, flavour, texture, and nutritional value, with particular emphasis on achieving positive sensory acceptance. This study aimed to evaluate the sensory characteristics of shrimp-based "chip" snacks subjected to two dehydration processes (conventional hot-air drying and freeze-drying), using the Just-About-Right (JAR) scale.

## Materials and methods

The raw materials used in this study included farmed shrimp (*Penaeus vannamei = Litopenaeus vannamei*) (12–16 g) provided by the Aquaculture and Biodiversity Research Group (GAB) of the Institute of Animal Science and Technology at the Universitat Politècnica de València. Additional ingredients—rice flour, potato starch, mashed potato, and salt—were purchased from a local supermarket, along with 28 mm Ø Nojax® cellulose casings (Viskase®, Lombard, Illinois, USA). The processing of the chips followed these steps: cleaning, heading and peeling of the shrimp; mincing; marinade under refrigeration (4±1°C for 20 minutes); stuffing into cellulose casings; cooking (80±2°C for 20 min); cooling; freezing at –18±2°C for 24–48 hours; slicing into 3.5 mm thick slices; and dehydration using either conventional hot-air drying (HAD) (90 minutes at 100±5°C) or freeze-drying (FD)( -50 ºC y 0.05 mbar for 72 h). Sensory perception was assessed using the Just-About-Right (JAR) test. The variables analysed included colour, characteristic seafood aroma, seafood flavour, texture (crispiness) and perceived saltiness. A five-point structured scale was used to determine the degree of appropriateness of each attribute regarding consumer preferences. An incomplete block design was applied, and the tasting panel consisted of 28 untrained participants, following a balanced experimental design.

Table 1. Percentage of consumers who have scored the descriptors using the jar method.

| drying treatment | Attributes | score (% consumers) | | |
|---|---|---|---|---|
| | | Excessive | Just About Right | Too Little |
| HAD | colour | 48 | 38 | 14 |
| | Seafood Aroma | 38 | 43 | 19 |
| | Seafood Flavour | 52 | 33 | 14 |
| | Saltiness | 67 | 29 | 5 |
| | Crispiness | 33 | 43 | 24 |
| FD | colour | 0 | 9 | 91 |
| | Seafood Aroma | 45 | 27 | 27 |
| | Seafood Flavour | 50 | 36 | 14 |
| | Saltiness | 32 | 59 | 9 |
| | Crispiness | 9 | 23 | 68 |

HAD: hot air drying; FD: freeze drying

*(Continued on next page)*

**Results**

The table 1 show the value of JAR results of the attributes evaluated. In the case of the hot-air dried (HAD) samples, significant deviations from the ideal point were observed across several attributes. Saltiness was the most affected, with approximately 67% of consumers perceiving it as too intense, negatively impacting the overall acceptance score. This excessive saltiness may lead to consumer rejection, as it is a critical attribute in snack-type products. Similarly, attributes such as colour, seafood aroma, and seafood flavour were perceived as too strong by many panellists (over 40% in some cases), contributing to a lower overall product perception. Crispiness, on the other hand, showed a more neutral behaviour, with minor deviations.

In contrast, the freeze-dried (FD) samples exhibited a more balanced sensory profile. Most attributes were rated as "just about right," except colour, which was perceived as "too little" by 91% of participants. However, some consumers rated the saltiness and seafood flavour as "too much," their impact on the mean acceptance score was less pronounced than in the HAD samples. Only crispiness was perceived as excessive by a small portion of the panel, without significantly affecting overall acceptance.

**Conclusions**

Overall, the data suggest that freeze-drying promotes a more stable sensory profile by reducing extremes in consumer perception. In contrast, hot-air drying intensifies specific attributes excessively, particularly saltiness.
