Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, Gournes 71500, Crete, Greece

**Introduction**

Fish diseases represent a major challenge for aquaculture, affecting fish health, welfare and growth, ultimately reducing productivity and increasing costs. The monogenean gill parasite *Sparicotyle chrysophrii* is a significant threat to gilthead seabream farming in the Mediterranean (Mladineo et al., 2023; Antonelli et al., 2010). This study examined the seasonal occurrence and mortality associated with *S. chrysophrii* infections in seabream reared in sea cages in the Gulf of Corinth under real farming conditions over the course of one year. The findings underscore the critical need for the implementation of seasonal parasite monitoring and targeted management interventions to effectively mitigate the detrimental impacts of *Sparicotyle chrysophrii* on gilthead sea bream (*Sparus aurata*) aquaculture.

**Materials and methods**

Mortalities and their causes were recorded for each sea cage used in the farming of gilthead seabream and entered into the electronic production management system of Galaxidi Marine Farm in Greece throughout the year. A statistical analysis was conducted to assess the seasonal occurrence of *S. chrysophrii* and the associated mortality due to parasitic infection. In addition, key production parameters were recorded, including average fish weight, stocking density, the month of introduction to sea cages, water temperature and farm unit. Group comparisons were performed using non-parametric Kruskal-Wallis tests followed by appropriate post hoc analyses. Furthermore, two machine learning techniques were applied in R to investigate the relationship between observed mortality and farming characteristics: Random Forest (via the ranger package) and Support Vector Machine (SVM) (via the e1071 package). The dataset included a wide range of numerical and categorical variables, with mortality rate as the primary response variable of interest.

**Results and conclusions**

The highest mortality rates attributed to *S. chrysophrii* infections in gilthead seabream were recorded during the summer and autumn months, with peak values observed in July and October **(Figure 1)**. This trend suggests that the temperature profile during these seasons favors the parasite's biological cycle, resulting in continuous reinfection of the farmed fish. Moreover, a correlation was observed between parasite-induced mortality and fish that were stocked in sea cages during the autumn and winter months. Another notable finding was the increased mortality in cages containing fish of higher average body weight, potentially linked to the absence of effective therapeutic interventions against the parasite. Stocking density also emerged as a significant factor influencing mortality rates, where cages with the highest stocking densities exhibited the highest parasite-related mortality **(Figure 2)**. Ultimately, the value of the collected data lies in its potential to support the development of more robust epidemiological models, improve predictions related to climate change impacts on parasitic infections, and guide the design of more structured and targeted sampling strategies. These insights offer promising opportunities for future research directions in Mediterranean aquaculture.

# *Aeromonas veronii* IN EUROPEAN SEABASS (*Dicentrarchus labrax*): CLINICAL, MOLECULAR AND EPIDEMIOLOGICAL INSIGHTS FROM THE GREEK AQUACULTURE

C. Pagonis[*,1], E. Gourzioti[1] and P. Katharios[2,3]

Irida S.A, Riga Fereou St. 60, Nea Artaki, Evia, Greece

## Introduction

*Aeromonas veronii* has emerged as a significant bacterial pathogen in European seabass (*Dicentrarchus labrax*) aquaculture across the Aegean Sea (Smyrli et al., 2019, 2017). While traditionally overshadowed by other agents such as *Vibrio anguillarum* and *Photobacterium damselae* subsp. *pisicida*, *A. veronii* has increasingly been linked to systemic infections, severe mortalities, and economic losses in intensive marine fish farming. The disease affects primarily commercial-sized fish but has also been reported in juveniles under 50 g. Initially restricted to specific regions within the Aegean Sea (East Greece), recent reports indicate a concerning geographic spread to previously unaffected areas, including the Ionian Sea (West Greece). This trend is particularly alarming given the recent relocation of a significant portion of seabass production to these regions in an effort to escape earlier outbreaks.

In this study, we present new epidemiological data on *A. veronii* infections in Greece, detailing clinical signs, disease progression, and associated pathology. Furthermore, we evaluate current management strategies and treatment options, with particular emphasis on the role of autogenous vaccines as a key preventive measure.

## Materials and methods

Extensive sampling of European seabass exhibiting clinical signs of disease was carried out from April 2024 to April 2025 in the Igoumenitsa Bay region of western Greece. Fish of various size classes were clinically evaluated at both the Irida Fish Disease Diagnosis Laboratory and the Hellenic Centre for Marine Research (HCMR) in Crete.

Bacterial isolation was performed using standard microbiological techniques. Kidney tissues were streaked onto a range of nutrient media, including Tryptic Soy Agar (TSA), Thiosulfate Citrate Bile Salts Sucrose (TCBS) agar, and Blood Agar. Isolates were characterized phenotypically (e.g., pigment production, motility) and biochemically using API 20E and Biolog GEN III systems.

Initial molecular identification involved sequencing of the 16S rRNA and *gyrB* genes. Selected *A. veronii* strains underwent whole genome sequencing (WGS) using DNBSeq and Illumina platforms to assess genomic similarity with previously identified strains, as well as to investigate virulence-associated genes and outer membrane protein (OMP) profiles.

## Results

The first signs of disease appeared in late April, when water temperatures were relatively low (16–17 °C). Initial mortalities were low but persistent. Clinically, affected fish exhibited lethargy, anorexia, ulcerative skin lesions, exophthalmia, and a distinctly icteric appearance. Internally, splenomegaly was observed, with white to cream-colored nodules of varying sizes present in the spleen, as well as nodules and abscesses in the kidney (Figure 1).

Mortalities increased progressively with rising water temperatures, peaking in late August at 28–29 °C. All bacterial isolates were identified as *Aeromonas veronii* biovar *sobria*. The newly isolated strains from Igoumenitsa were motile and showed variability in pigment production. Whole genome phylogenetic analysis revealed that these strains are more closely related to isolates from the eastern Aegean Sea (near the Turkish coast) and are genetically distinct from those previously isolated from the western Aegean (near the Peloponnese). Genomic analysis has shown that the bacterium possesses a very broad toolbox of virulence factors. Several antigenic surface proteins are conserved across different strains, however distinct differences exist between strains according to the geographic area of isolation.

Antibiotic treatment was administered based on antimicrobial susceptibility testing. Most isolates were sensitive to the antibiotics currently approved for use in aquaculture. However, disease management often required multiple treatment cycles. Stress was found to be a critical exacerbating factor, and careful feeding management—especially the avoidance of overfeeding—was essential during periods of elevated water temperature.

*(Continued on next page)*

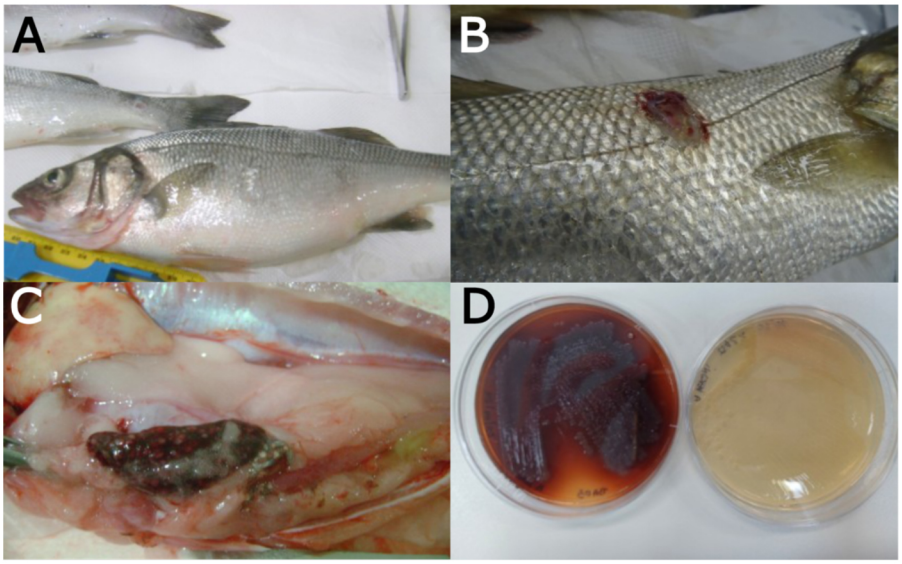

**Figure 1. A.** European seabass exhibiting exophthalmos, icteric skin, and abdominal distension suggestive of ascites. **B.** Focal ulcerative skin lesion. **C.** Splenomegaly with the presence of multiple splenic nodular lesions. **D.** Colony morphology of *Aeromonas veronii* on Blood Agar and Mueller-Hinton medium (evident hemolysis and pigment production, respectively).

## Discussion

*Aeromonas veronii* is now recognized as one of the most significant bacterial pathogens impacting European seabass aquaculture in the eastern Mediterranean, particularly in Greece and Turkey, where the majority of production is concentrated (Smyrli et al., 2019). Although this pathogen has been associated with disease outbreaks in a wide range of cultured fish species worldwide (Triga et al., 2022), including freshwater and marine species, it has not been detected in gilthead seabream (*Sparus aurata*), despite co-cultivation in the same facilities. This host specificity is notable and warrants further investigation.

At present, disease control relies primarily on antibiotic therapy—a short-term and unsustainable solution, especially since outbreaks often occur in fish nearing market size. While no commercial vaccines are currently available, the application of autogenous vaccines has shown encouraging results in reducing mortality and disease severity (Smyrli et al., 2022). Advances in molecular and genomic characterization of regional *A. veronii* strains are laying the groundwork for the development of targeted vaccines and more refined disease management approaches.

Ongoing monitoring and functional studies are essential to deepen our understanding of the pathogen's transmission routes, resistance potential, and seasonal patterns of occurrence, ultimately contributing to more sustainable and species-specific aquaculture health strategies.

# IMPACT OF SALINITY ON THE MODULATION OF ENERGY METABOLISM IN CLAMS *Ruditapes decussatus, Venerupis corrugata* AND *Ruditapes philippinarum*

Paladea-Rojo, R.[1]*; Soengas, JL.[1]; Blanco, AM[1]; Vázquez-Otero[2], E. and Conde-Sieira,M.[1]

**Introduction**
Salinity is a critical factor for the survival and development of clams in the Galician estuaries, where heavy rainfall and reservoir discharges cause fluctuations that dilute seawater. In the context of climate change and water resource management, innovative approaches are urgently needed to protect these ecosystems and sustain their economic activity (Kersting *et al*., 2016). Salinity affects clam metabolism, altering energy reserves such as glucose, glycogen, triglycerides, and fatty acids. While oxygen consumption and energy expenditure changes have been documented (Peteiro *et al*., 2018), alterations in key metabolites remain poorly understood. This study addresses this gap by analyzing metabolites from glucose, fatty acid, and amino acid pathways in commercially valuable clam species exposed to varying salinities (35‰, 12‰, and 6‰) over different exposure times (0, 2, and 4 days).

**Materials and methods**
Specimens of *Ruditapes decussatus*, *Venerupis corrugata*, and *Ruditapes philippinarum* were acclimated at 35‰ salinity under controlled temperature and oxygen conditions, then exposed to salinities of 35‰ (control), 12‰, and 6‰ for 2 and 4 days to mimic environmental variability. At each time point, soft tissues were harvested and homogenized in PCA buffer (0.8 N). Key energy metabolites (glucose, glycogen, lactate, triglycerides, and fatty acids) were quantified via spectrophotometry using commercial kits. Statistical analysis employed two-factor ANOVA with post-hoc tests to determine significant differences between treatments.

**Results**
Glucose levels decreased significantly in *R. decussatus* and *V. corrugata* across all treatments. Glycogen showed a downward trend without statistical significance. Lactate remained stable at 48 hours but decreased significantly at 96 hours, notably at 12‰ salinity. Triglycerides rose significantly at 24 hours in all species. Fatty acids decreased at 24 hours under 6‰ and 12‰ treatments and showed a pronounced, significant decline at 96 hours in *R. decussatus* and *V. corrugata*, whereas *R. philippinarum* displayed no significant changes.

**Discussion**
Our findings demonstrate that environmental salinity distinctly modulates metabolic parameters in *R. decussatus*, *V. corrugata*, and *R. philippinarum*. The marked glucose reduction in *R. decussatus* and *V. corrugata* reflects rapid energy mobilization under osmotic stress, consistent with accelerated substrate utilization under adverse conditions (Zhou *et al*., 2022). This metabolic response is linked to reproductive and other vital functions, as evidenced by Domínguez *et al*., 2021. The continuous yet nonsignificant glycogen decline indicates sustained consumption with limited replenishment capacity. Lactate stability in the short term followed by reduction at 4 days suggests adaptive metabolic adjustments that reduce lactate accumulation during prolonged stress (Peteiro *et al*., 2018). Significant increases in triglycerides suggest species- and context-dependent lipid storage or energy mobilization. Differential fatty acid declines between species indicate varied lipid mobilization strategies tied to salinity tolerance (Zhou *et al*., 2022). These results emphasize salinity as a crucial regulator of bivalve energy metabolism, revealing greater metabolic sensitivity in *R. decussatus* and *V. corrugata* compared to *R. philippinarum*, highlighting the need for tailored management approaches.

*(Continued on next page)*

**Conclusion**

Salinity reduction elicits species-specific energy metabolism responses in *R. decussatus*, *V. corrugata*, and *R. philippinarum*, reflecting distinct adaptation and stress mechanisms dependent on species and exposure duration. These results establish salinity as a key environmental factor modulating metabolic homeostasis and influencing survival and biological performance in Galician estuaries. The generated insights are vital for developing sustainable management and conservation strategies for natural and cultured clam populations under increasing environmental variability driven by climate change and anthropogenic impacts.

# ENHANCING BREEDING DECISIONS WITH COST-EFFECTIVE METHYLOME SCREENING: THE CASE STUDY OF MALE FERTILITY IN ARCTIC CHARR (*Salvelinus alpinus*)

S. Lee, F. Pappas, C. Palaiokostas

Department of Animal Biosciences
Swedish University of Agricultural Sciences
Uppsala, Sweden
Email: christos.palaiokostas@slu.se

## Information

The epigenome is an unexplored resource in aquaculture breeding. Among the known epigenetic mechanisms, DNA methylation is the most well-studied, and it is suggested that it underpins several key traits in fish (Piferrer, 2023). Despite the substantial drop in sequencing costs over the last decade, screening the methylome in sufficient numbers as required by selective breeding practices remains challenging. By utilizing reduced representation sequencing methods, we can obtain genomic and methylome information in a cost-effective manner. As a proof of concept, we used reduced representation sequencing to screen the sperm methylome of Arctic charr (*Salvelinus alpinus*) males and investigated potential links to fertility as previously suggested (Pappas et al., 2025)male fertility in fish remains understudied despite its critical importance to overall reproductive success in nature and captivity. This study investigated the DNA methylation landscape in spermatozoa of domesticated Arctic charr (Salvelinus alpinus.

## Materials and Methods

Fertility traits were recorded from 176 Arctic charr males from the Swedish breeding program. Sperm motility and kinematic parameters were measured using a Computer Assisted Sperm Analysis (CASA) system equipped with the SCA® Motility imaging software. Moreover, sperm concentration was counted using a NucleoCounter® SP-100™. Reduced representation sequencing libraries were prepared using methylation sensitive restriction enzymes. The library preparation followed a modified version of the original ddRAD protocol (Peterson et al., 2012) with previously documented adjustments (Franchini et al., 2017; Palaiokostas et al., 2015) , allowing at the same time scanning the methylome (Marconi et al., 2019). Sequencing was performed in one 10B lane of NovaSeq X Plus. Following sequencing and detection of single nucleotide polymorphisms (SNPs) using the Stacks software (Rochette et al., 2019), association studies for the recorded fertility traits were performed. Simultaneously, methylation levels were calculated and screened for putative associations with the male fertility traits using a weighted region comethylation network analysis with the R package comethyl (Mordaunt et al., 2022).

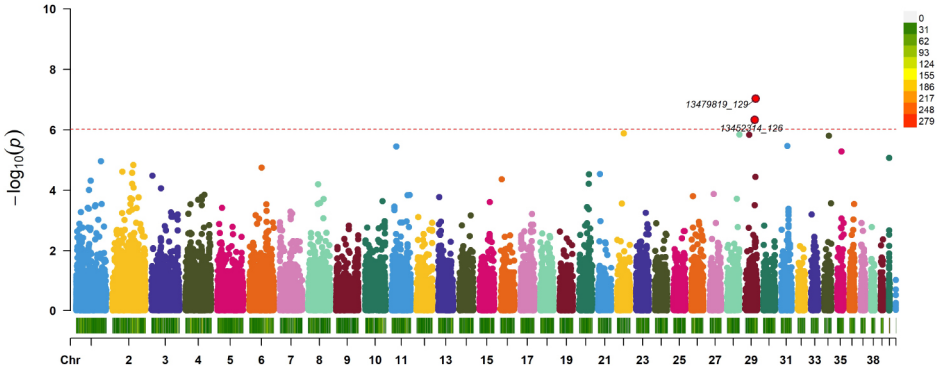

**Figure 1**. Association analysis for total motility in Arctic charr broodfish from the Swedish breeding program.

*(Continued on next page)*

**Results**

Approximately 15,500 SNPs satisfying quality control (found in at least 80% of the animals; minor allele frequency above 0.05; maximum heterozygosity of 0.6 and with a minimum minor allele count of 3) were retained for the association studies. Two SNPs located at chromosome 29 were found statistically significant at a genome-wide level (Figure 1; $p < 0.05$). In addition, 13 comethylated regions were constructed out of which one was found to have statistically significant association with sperm concentration ($p < 0.05$).

**Discussion - conclusions**

Using a cost-effective reduced representation protocol, we obtained genome- and methylome-wide information from over 170 Arctic charr males using one sequencing lane on an Illumina NovaSeq X Plus. As sequencing output continues to increase, our approach is expected to become even more cost-effective. Finally, we obtained novel information about the genome and methylome architecture controlling male fertility in Arctic charr.

E-mail: oswaldo.palenzuela@csic.es

**Introduction**

The hematophagous ectoparasite *Sparicotyle chrysophrii* represents a critical health challenge for net-pen aquaculture of gilthead seabream, one of the main fish species cultured across the Mediterranean and the third most produced in Europe. Current treatment options are limited, with formalin baths being the only approved therapy in Western Europe. However, their application in sea cages is logistically complex, costly, and raises environmental, fish welfare, and operating safety concerns. This context highlights the urgent need for effective, safe, and practical in-feed antiparasitic alternatives tailored to the needs of marine aquaculture.

Our work focuses on investigating the mechanisms of action (MOA) of pharmacological active ingredients with potential against polyopisthocotylean infections. Stemming from previous computational virtual screening of chemical libraries for antiparasitic compounds and *in vitro* studies, several candidate drugs were shortlisted. In this work, we evaluate four drugs belonging to the salicylanilide chemical family: niclosamide, closantel, and their molecular fingerprint compounds ME1.62 and CG047.

**Materials and methods**

Adult specimens of *S. chrysophrii* were obtained from the gills of experimentally infected gilthead seabream. An *in vitro* dose-response assay was performed to evaluate the survival of parasites exposed to selected pharmacological compounds. The trials were conducted in duplicate, in 24-well plates, with 10 worms per well. Worms were observed at various times post-exposure (p.e.) using a binocular microscope, and survival was registered for each of the compounds. Survival data were analyzed using nonlinear regression models fitted to normalized dose-response curves in order to determine the lethal dose 50 (LD50), which is the concentration that results in a 50% mortality rate among the worms. We determined the LD50 at different times p.e., with special focus on the short-term effect (less than 2 hours p.e.).

Moribund or dead worms were fixed for histological examination to assess sublethal effects. We used scanning electron microscopy (SEM) to evaluate the effects of the treatments on the ultrastructure of the parasites' tegument upon exposure to the LD50_2h (n = 10 specimens/treatment). We also used immunolabelling approaches to investigate the MOA of the drugs at the level of the musculature and cytoskeleton.

**Results**

Three of the 4 salicylanilides tested resulted highly effective killing the parasites *in vitro*. According to their LD50 at 2h p.e, they ranked as follows (Figure 1): niclosamide (0.06792 $\mu$M), ME1.62 (0.08778 $\mu$M), closantel (2.294 $\mu$M) and CG047 (188.6 $\mu$M).

The primary MOA of this chemical family is related to uncoupling of the mitochondrial oxidative phosphorylation and eventually disturbing ATP production. Based on this, morphological analysis of exposed worms revealed an antero-posterior body contraction for the three most effective salicylanilides tested. Examination by SEM evidenced that the severe body contraction affected the surface of the parasites' tegument, compared to control untreated worms. The tegument formed deep transverse folds and ridges in all parasites exposed to the treatments. The parasite's haptor, the organ for attachment to the gill filaments provided with two rows of clamps, was also severely affected by the drug treatments. Muscle contraction provoked clamp opening after treatment with closantel and ME1.62, whereas niclosamide induced clamp opening accompanied by the retraction of the clamps within their tegumental sheaths. Additionally, it caused erosive damage in some tegument areas (Figure 2).

*(Continued on next page)*

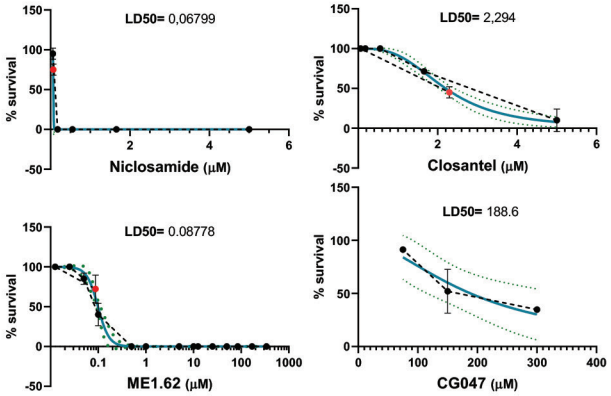

Figure 1. Lethal dose 50% (LD50) for *Sparicotyle chrysophrii* adults after 2h of salicylanilide treatments *in vitro*.

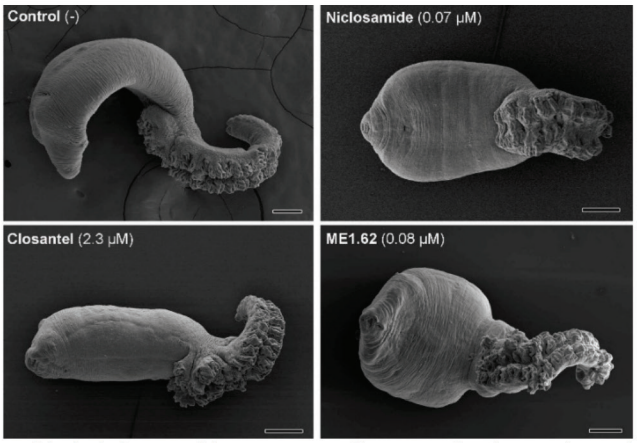

Figure 2. Effect of lethal dose 50% (LD50) on *Sparicotyle chrysophrii* adults after 2h of salicylanilide treatments (scale bars = 100 µm).

## Conclusions

Niclosamide and closantel are routinely used as antihelminthic agents in both human and veterinary medicine, targeting parasite motility and essential physiological processes. This study offers new insights into the mode of action (MOA) of three salicylanilide-based compounds, contributing to a deeper understanding of their efficacy and specific effects on *S. chrysophrii*. The primary MOA of this pharmacological class is linked to disruption of the parasite's energy metabolism, which in this study led to severe muscle fiber contraction, resulting in body shortening and clamp opening, ultimately followed by death. The high effectiveness of some tested compounds was particularly noteworthy, with niclosamide and ME1.62 demonstrating efficacy at doses more than 1,000 times lower than praziquantel, an anthelmintic with known effectivity against polyopisthocotyleans.

## Introduction

Swim bladder inflation effectiveness (SBIE) is a crucial milestone in the early development of all fish species. While Eurasian perch (*Perca fluviatilis*) can survive without an inflated swim bladder, unsuccessful inflation is linked to reduced body size, skeletal deformities, increased energy expenditure from constant swimming, elevated cannibalism, and higher mortality (Czesny et al. 2005). From an aquaculture perspective, maximizing SBIE is therefore essential. Previous studies on percid larvae have shown improved SBIE in Eurasian perch reared in black tanks versus white (Palińska-Żarska et al. 2019), disruption of inflation by even low nocturnal light in yellow perch (*P. flavescens*) (Suchocki et al. 2019), and optimal inflation in pikeperch (*Sander lucioperca*) under a 16L:8D photoperiod (Panana et al. 2023). Despite these insights, no standardized photoperiod protocol exists for Eurasian perch. Although continuous light (24L:0D) promotes growth, it often results in suboptimal SBIE. This study tested three photoperiod regimes (8L:16D, 14L:10D, 24L:0D) to identify optimal light conditions for maximizing swim bladder inflation in Eurasian perch larvae.

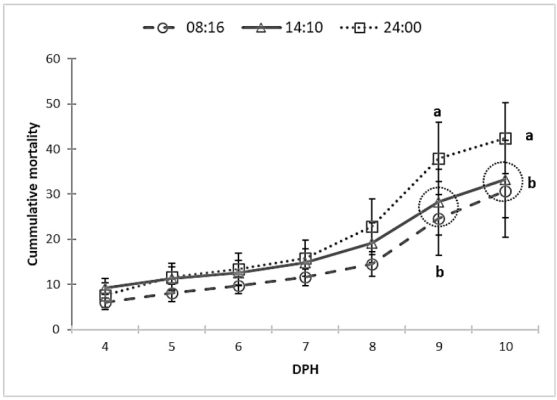

Fig. 2. Cummulative mortality during swim bladder inflation period in Eurasian perch larvae.

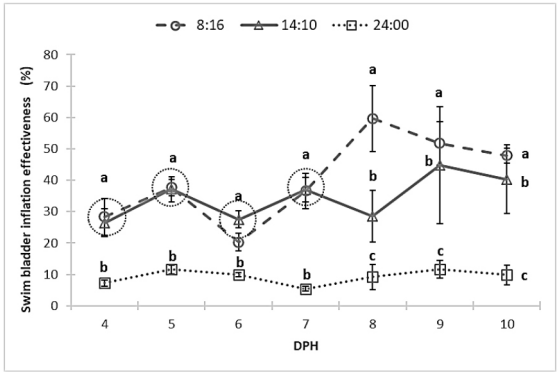

Fig. 1. Swim bladder inflation effectiveness of Eurasian perch larvae reared in three different photoperiods.

## Materials and methods

Eurasian perch embryos and larvae were reared under three photoperiods: 8 Light:16 Dark (8L:16D - minimum required for feeding and hygiene), 14L:10D (natural conditions during this time in nature), and 24L:0D (commonly used to enhance growth). After hatching, larvae were volumetrically counted and stocked at 3000 individuals per tank, with three replicates per treatment. From 4 days post hatch (DPH), larvae were fed *Artemia* nauplii *ad libitum* 3 times daily, following the protocol of Palińska-Żarska et al. (2020). SBIE (%) was assessed from 4 to 10 DPH by sampling ~100 larvae per tank and counting those with inflated swim bladders under a stereomicroscope. Mortality was recorded daily, and at 10 DPH, wet body weight (WBW, mg) and total length (L, mm) were measured.

*(Continued on next page)*

## Results

From 4 to 7 DPH, no significant differences in SBIE were observed between larvae reared under the 8:16 and 14:10 photoperiods ($p>0.05$). However, from 8 to 10 DPH, significantly higher swim bladder inflation rates were recorded in larvae kept under the 8:16 photoperiod compared to those reared under 14:10 ($p< 0.05$). Throughout the entire observation period (4–10 DPH), larvae exposed to continuous light (24:0) consistently showed the lowest SBIE values among all treatments ($p<0.05$) (Fig. 1). At 9 and 10 DPH, cumulative mortality was also significantly higher ($p<0.05$) in the 24L:0 group compared to the other two photoperiod regimes (Fig. 2). No significant differences ($p>0.05$) were found in WBW or total L of larvae at 10 DPH.

## Discussion

As a physoclistous species, Eurasian perch (*Perca fluviatilis*) larvae can inflate their swim bladders only within a limited developmental window . This brief and critical period poses a challenge in aquaculture, as suboptimal environmental conditions during this phase may lead to poor SBIE, compromising the performance and viability of the entire cohort. To date, no standardized larval rearing protocol exists for maximizing SBIE in percid species. In practice, hatcheries and scientists vary in their use of photoperiods, light intensities, and tank colors. For example, some studies have reported better SBIE in larvae reared in black tanks compared to white ones (Palińska-Żarska et al. 2019), although conflicting results have also been documented (Tamazouzt et al. 2000). In our experiment, the highest SBIE was observed under the longest dark-phase photoperiod (8:16), followed by 14:10. While inflation rates of 40–50% may not seem impressive at first glance, they are considered satisfactory for percid larval culture (Palińska-Żarska et al. 2019). Interestingly, the poorest SBIE and the highest cumulative mortality by 10 DPH occurred in larvae reared under continuous light (24:0). Although preliminary, our findings suggest that the presence of a dark phase („night") plays an important role in successful swim bladder inflation in Eurasian perch larvae. In light of the present findings, identifying the optimal photoperiod - and understanding, at both the molecular and physiological levels, how photoperiod influences the early developmental stages of Eurasian perch - emerges as a crucial direction for future research.

## Acknowledgment

This research was a part of the project "Exploration of the development, role and functioning of circadian rhythm in early life stages of *Perca fluviatilis"* funded by the National Science Centre, Poland (OPUS project, number UMO-2021/43/B/NZ9/03056).

# WATER FLOW ENRICHMENT EFFECTS ON ACCELEROMETRIC ACTIVITY PATTERNS, GROWTH, BLOOD PARAMETERS, FILLET QUALITY AND WHITE MUSCLE RNASEQ OF YELLOWTAIL KINGFISH *Seriola lalandi* IN A COMMERCIAL MARINE RAS ENVIRONMENT

Arjan P. Palstra [a]*, Wout Abbink [a], Hans van de Vis [b], Ron P. Dirks [c], Thomas Staessen [d], John Bastiaansen [a]

[d] The Kingfish Company, Kats, The Netherlands

**Introduction**

One of the few enrichment opportunities in commercial aquaculture facilities to boost fish growth, health and welfare is water flow enhancement. Particularly fast-growing athletic species with high metabolic demands for oxygen such as yellowtail kingfish grasp the benefits of flow enrichment and the associated swimming exercise (Palstra et al., 2015, 2024). This study aimed at establishing the physiological effects of water flow enrichment on yellowtail kingfish in commercial marine RAS production tanks.

**Materials and methods**

In the enriched flow tank (regular dodecagon with a volume of 62 $m^3$), flow was generated by a propellor and speeds ranged between 70-75 $cm.s^{-1}$ in the outer curve down to averages of 18-29 $cm.s^{-1}$ near an inner placed ring (Fig. 1). As a result, fish (N= 400 per tank as part of a total of 4,000 fish per tank; initial body-weight ~160 g) could swim at their preferred swimming speed where the maximum was optimal for fish at the start of the trial. The flow in the identical regular flow tank ranged from 13-17 $cm.s^{-1}$ down to averages of 6-10 $cm.s^{-1}$.

Overall Dynamic Body Acceleration (ODBA) was monitored with implanted acoustic transmitters with accelerometer sensors over the first three months (up to a BW of ~1,200 g) and used to demonstrate the increased activity of fish in the enriched flow tank vs. the regular flow tank (N=10 sentinel fish in each tank). Flow enrichment effects on growth, blood parameters, fillet quality and white muscle transcriptomics were determined after seven months (BW ~2,600 g).

**Results and discussion**

ODBA levels were 34% higher in the flow enriched production tanks (Fig. 1) where fish were most active at 7-8 h in the morning. The higher activity levels were supported by higher plasma glucose levels. Under enriched flow, less fish died (36% less than in the tank with regular flow), fish grew faster (10% during the first two months) and more homogenous, and fish had a leaner body shape (lower body height index). Fillet quality data are currently being analyzed while RNAseq data showed up-regulated keratin expression supposedly reflecting increased firmness.

Overall, we can conclude that flow enrichment is beneficial for growth and welfare of yellowtail kingfish in commercial marine RAS production tanks, thereby validating the earlier experimental-scale results (Palstra et al., 2015). If flow speeds could be further increased with increasing fish size, benefits may be more significant along the whole on-growing period. Acoustic sensortags with ODBA settings provide valuable information about the activity of the fish which could be extended to a digital twin model for energy expenditure and useful for precision farming.

*(Continued on next page)*

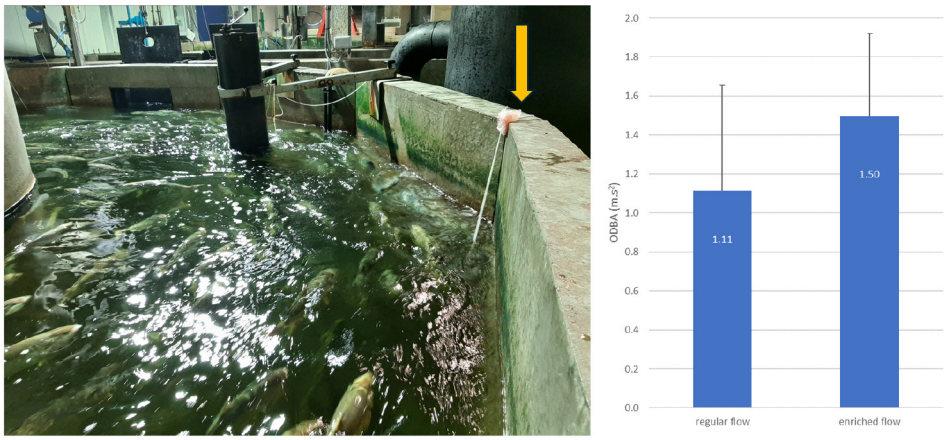

Figure 1. The picture illustrates the experimental fish swimming in the tank with inner ring under enriched flow conditions. The arrow indicates the position of the receiver for the sensortag signals. The graph shows the Overall Dynamic Body Acceleration (ODBA) values of experimental fish in the tank with regular flow and in the tank with enriched flow. Fish in the enriched flow tank showed an averaged value (± standard deviation) of $1.50 \pm 0.45$ m.s$^{-2}$ which was 34% higher than $1.12 \pm 0.54$ m.s$^{-2}$ for fish in the tank with regular flow ($P<0.001$).

**Introduction**
The influence of paternal effects on progeny quality, particularly during early developmental stages, has historically been underappreciated. Recently, sperm selection procedures like cryopreservation have been started to be used to identify paternal-effect genes (PEGs; Panda et al., 2024). The expression of these genes in the progeny under the paternal control, meaning their expression rely on paternally-derived factors such as epigenetic status and/or non-genetic inheritance factors (e.g., ncRNAs) contained in the sperm cell. Sperm cryopreservation is a leading and sophisticated process for sperm preservation, keeping the sperm cell viable and functional for artificial reproduction (Cabrita et al., 2010). It is also been reported that sperm cryopreservation may affect the transcriptomic profile of the progeny (Wang et al., 2022). In Eurasian perch (*Perca fluviatilis*), comparative analysis of transcriptomic profile of freshly hatched larvae obtained following usage of fresh or cryopreserved sperm for fertilization allowed to identify a panel of novel PEGs (Panda et al., 2024). These findings show that exposing sperm to a specific challenge is an excellent approach to identify PEGs.

It is specific feature of cryopreserved E. perch sperm that after thawing its motility decreases over a relatively short period of time, with significant reduction after already 30 min. Thus, post-thaw storage seems to be additional challenging factor for the sperm cells keeping the most robust cells viable. Therefore, the aim of this study was to compare progeny obtained following using freshly thawed (0 min; CON) and stored after thawing (post-thaw stored sperm; PTS) for 30 min through their zootechnical performance and transcriptomic analyses. We hypothesized, that such additional selection pressure will enable to reveal new paternally controlled traits and PEGs.

**Methods**
The semen from wild males (n=6) were stripped, checked for their motility and concentration; and cryopreserved as described by Judycka et al. (2021). Fertilizations were done with eggs coming from each female (n=3) portioned equally. Cryopreserved sperm straws were thawed at 40°C for 10 seconds in a water bath, and poured into an Eppendorf, stored at 4°C for 30 minutes (PTS), while the same thawing procedure was used for 0 min, CON without providing them a waiting period and taken into use directly. A total of six pairs were created, with two males used to fertilize eggs from single female. Advanced larviculture was carried out as described by Palińska-Żarska et al. (2020) till 27 days post hatch (dph), while noting zootechnical parameters. Larvae at mouth opening (MO) stage, when larvae started weaning and at end (27 DPH) were sampled for transcriptomic and gene expression analysis.

Transcriptomic profile larvae at MO from both groups were compared using RStudio (version 4.1.3) using the package DESeq2 (Love et al., 2014). Differences were considered significant when corrected p-values were inferior to α (α=0.05).
Quantitative real-time PCRs (RT-qPCR) were performed to validate the chosen differentially expressed genes (DEGs), normalized using 5 housekeeping genes, to verify expression levels of those genes at MO stage; weaning stage and end stage if positively validated.

**Results**
Notably, larvae from the PTS group exhibited higher mortality rates compared to the CON group, with minor or none differences in terms of other zootechnical parameters. Transcriptomic analysis of larvae at the mouth-opening stage revealed 49 DEGs, many of which associated with immune-related functional pathways. Several genes, including *mfap*, *gimap*, *hlag*, *pigr*, *pde6g*, and *neo1*, emerged as promising candidates for PEGs.

*(Continued on next page)*

**Discussion**

High mortality in PTS group is a very strong phenotype and directed the study's focus towards paternal effects. This finding suggests that paternity may compromise immune functions to promote larval survival. Alongside, the gene *pde6g*, which plays a crucial role in phototransduction, can be confirmed to be a strong candidate as PEG, given its steep downregulation in the PTS group and occurrence in our previous studies identify PEGs.

Overall, this study challenges the long-held view that maternal effects predominantly govern larval development and phenotype. It also represents a significant step towards disentangling individual parental contributions, thereby advancing our understanding of the effect of reproductive techniques in aquaculture which may lead us toward fine-tuning the hatchery protocols. Besides, it broader our knowledge in the field of reproductive and developmental biology bringing us closer to understanding non-genetic inheritance in finfishes.

# DOES BETA-GLUCAN FROM MUSHROOMS SOLVE SERIOUS BOTTLENECK IN COMMON CARP (*Cyprinus carpio*) PRODUCTION?

Remigiusz Panicz[1]*, Piotr Eljasik[1], Sławomir Lisiecki[1], Małgorzata Sobczak[1], Maria Luisa Tello Martín[1], Arkadiusz Nędzarek[1], Przemysław Śmietana[1], Mateusz Gzyl[3]

**Introduction**

Production of common carp (*Cyprinus carpio*, hereafter referred to as carp) takes approximately 33 months and includes several stages performed in different types of ponds. The key challenges alongside the production process include carp translocations from one pond to another as fish grow, and the several-month (October-April) wintering period when water temperature drops significantly to 4°C and farmers cease feeding. Among the two wintering periods, the first one, which includes carp fingerlings, is the key bottleneck since fish mortality during this stage can reach up to 50% or more. One of the circular-based solutions that approach this issue of high mortalities is feeding carp fingerlings before wintering with beta-glucan retrieved from another agricultural sector, i.e. mushroom production. Oyster mushrooms (*Pleurotus ostreatus*) production in Europe is mainly localised in Spain, followed by Poland and Italy, and ends with the edible cap directed for human consumption and the by-product stem that is usually wasted or composted and re-enter the process of mushroom production as part of the medium. However, a high content of beta-glucan (up to 35%), a potent immune booster, can serve as an ingredient that can potentially influence the condition of carp fingerlings during wintering and improve survival rates. Therefore, the study aimed to improve survival rates and the condition of carp fingerlings during the wintering period by feeding them with feed enriched with beta-glucan from the mushroom stalls.

Material and methods

The fish trial included two main stages. First, for 8 weeks before wintering, 50 carp fingerlings with an average weight of 40 g were randomly distributed into 12 floating cages (triplicated variants) and fed four feeds enriched with 0% (control, var. A), 0.1% (var. B), 0.2% (var. C), and 0.4% (var. D) of beta-glucan powder from oyster mushroom stems. After that period, fish were translocated into wintering ponds for 6 months. Before the first and second stage, and after the wintering period, fish were sampled and a series of zootechnical parameters were assessed, e.g. total weight, Fulton's condition factor, viscerosomatic (VSI) and hepatosomatic (HSI) indices. Moreover, skin and proximal intestine samples were secured for histological analysis. Results were also compared to traditional practices at the carp farm (var. E), i.e. carp were cultured in fingerling ponds and transferred into the typical wintering ponds until sampled. The timing of the first and last sampling, and the transfer time for the wintering phase of fish in the cages, has been correlated with the typical farm practices for carp fingerlings.

**Results and discussion**

Compared to the traditional wintering of carp fingerlings (60% mortality rate), the survival rate of fish in the cages ranged from 100% to 82%, and the direct effect of the beta-glucan on this zootechnical parameter was not observed. The main findings for the other zootechnical parameters showed no significant loss of total weight of fingerlings after wintering, and an increase in the average weight of the fish from the traditional wintering, which might be attributed to more natural food resources accessible to carps freely swimming in the wintering pond. The other condition parameters (VSI, HIS) were significantly lower in fish from the wintering pond (var. E), and the lower values may indicate the lower condition of these fish, presumably due to the cumulative effect of low energy reserves before wintering and compromised nutrient availability during winter. The findings are also confirmed by the laboratory analyses, which mainly showed that the skin of the fish from cages was thicker and included more *dermis stratum compactum* that supports better adaptation for the wintering period. In the case of the intestine, histomorphological studies showed that fish fed with the highest level of beta-glucan (var. C and D) had the longest intestinal villi and the lowest number of Goblet cells. The morphological changes in the intestine may indicate that a higher inclusion of beta-glucan in the feeds leads to the development of the absorption area and more efficient uptake of nutrients. The study showed that feeding carp fry before the wintering period solves the severe bottleneck in common carp farming. However, further studies are needed to characterise the intrinsic mechanism behind the influence of beta-glucan on the common carp performance.

**Introduction**

The aquaculture industry currently relies heavily on marine and land-based protein sources to meet the nutritional requirements of farmed fish and livestock. However, the rising cost of these raw materials, along with the environmental impact of their overexploitation, present a significant challenge to sustainable aquaculture production [1]. In response, there is growing interest in exploring more sustainable alternatives. These include plant by-products, macro- and microalgae, single-cell proteins, insect meal, and other unconventional sources [2]. As part of the CIPROMED project (PRIMA 2022,section 1), innovative feed ingredients such as insect meal (*Hermetia illucens*) and a blend of insect meal and microalgae (*Arthrospira platensis*) have been tested on European seabass (*Dicentrarchus labrax*) at the AquaBioTech testing facility in Malta to assess growth performance and somatic indices.

**Materials and Methods**

The trial was conducted in a 21 x 300L RAS system continuously monitored through an OxyGuard Pacific unit (DO, T, pH, ORP). A control diet and six experimental diets were formulated to be isonitrogenous, isolipidic and isoenergetic, replacing 100% of fishmeal with black soldier fly and spirulina meal (HI100 and SPI100 respectively), and a blend of both; Mix1 (80/20), Mix2 (60/40), Mix3 (40/60), Mix4 (20/80), and tested in triplicate. The diets were manufactured by Sparos Lda (Portugal).

European seabass, *Dicentrarchus labrax* (80 fish/tank; initial weight of 17.33 ± 0.05g), were randomly distributed at an initial stocking density of 4.6kg/$m^3$.

Fish were fed twice a day until satiation for 56 days. Bulk weighing of each replicate was performed at the end of the trial, and 3 fish from each tank were randomly selected and euthanized with an overdose of anesthetic to record biometrics such as total weight and length, liver and viscera weight. Growth performance (FCR, SGR, SFR%, feed intake) and somatic indexes (K, VSI, HIS), were evaluated and compared among diets.

**Results**

The results showed significant differences among the seven dietary treatments (CTRL, Hi100, MIX1, MIX2, MIX3, MIX4, and SPI100) across growth performance and somatic indexes.

Final body weight (FW) was highest in Mix1 (59.12 ± 1.33 g), followed by Hi100 (58.57 ± 0.68 g) and CTRL (57.36 ± 1.12 g), while significantly different to Mix3, Mix4 and SPI100, which exhibited the lowest FBW (46.31 ± 1.59 g). Feed conversion ratio (FCR) was significantly improved in Hi100 and Mix1 (1.05 ± 0.01, and 1.04 ± 0.02, respectively), while SPI100 had the poorest FCR (1.15 ± 0.06). Specific feeding rate (SFR) was highest in CTRL, Hi100, and Mix1 (ranging from 2.28–2.34%), and significantly lower in Mix3, Mix4 and SPI100 (ranging from 2.02–2.16%). Total feed intake showed significant variation, with CTRL, Hi100, and Mix1 consuming the most feed (3.40± 0.06 kg), while SPI100 consumed significantly less (2.41 ± 0.04 kg).

*(Continued on next page)*

Among the somatic indexes, condition factor (K), viscerosomatic index (VSI), and hepatosomatic index (HSI) did not exhibit consistent significant trends across treatments, though HSI was significantly higher in Hi100 (1.75 ± 0.25%) and Mix3 (1.79 ± 0.10%) compared to SPI100 (1.13 ± 0.27%).

The evaluation of both ingredients proved to be an efficient alternative to conventional fishmeal even at complete replacement.

**Objectives:**
Polyphenols derived from agri-food by-products are recognized for their diverse biological activities; however, their interaction with probiotic yeasts in synbiotic formulations remains insufficiently investigated. This study evaluates the effects of polyphenol-rich extracts from mulberry, olive, pomegranate leaves, and chestnut shells, on *Saccharomyces boulardii*, a probiotic yeast of emerging interest in aquaculture for promoting host health and reducing antibiotic dependency.

**Methods:**
Hydroethanolic extracts were obtained using a microwave-assisted extraction technique and subsequently characterized for their phytochemical profile and antioxidant capacity. The prebiotic potential of these extracts on *S. boulardii* was evaluated through a yeast fitness assay. At specific time points during incubation, both extracellular and intracellular postbiotic fractions were isolated. Extracellular postbiotics, recovered from the cell-free supernatants, were analyzed for polyphenol content, antioxidant activity, and soluble protein concentration. Intracellular constituents were extracted via cell lysis and subjected to the same analytical assessments.

**Results:**
All tested extracts exhibited significant total polyphenol content and antioxidant activity. Among them, olive and pomegranate leaf extracts notably enhanced the growth of *S. boulardii* in a glucose-free medium over a 7-day incubation, indicating strong prebiotic potential. Both extracellular and intracellular postbiotic fractions showed elevated levels of polyphenols, antioxidant activity, and soluble proteins compared to the control. Notably, the highest bioactivity in extracellular metabolites was observed with pomegranate leaf extracts, while intracellular fractions were particularly enriched following exposure to mulberry and olive leaf extracts.

**Conclusions:**
This study underscores the potential of polyphenol-rich agri-food wastes to promote *S. boulardii* growth and enhance postbiotic production under nutrient-limited conditions. These findings highlight their promising application in sustainable synbiotic formulations aimed at advancing eco-friendly aquaculture practices.

# A GAME FOR TWO: GENETIC PARAMETERS OF OBSERVED AND LATENT PARAMETERS OF FERTILITY IN SELECTIVELY BRED ARCTIC CHARR

F. Pappas[1], M. Johnsson[1], P.V. Debes[2], C. Palaiokostas[1]

[1]Department of Animal Biosciences, Swedish University of Agricultural Sciences, Uppsala, Sweden
[2]Department of Aquaculture and Fish Biology, Hólar University, Sauðárkrókur, Iceland
Email: fotis.pappas@slu.se

**Information**
Fertility is an important prerequisite directly affecting the success of selective breeding programs. Unlike livestock species, where unfavourable genetic correlations between production and reproduction have been reported, this relationship has been understudied in aquatic animals. In this study we investigate genetic parameters and correlations for a series of milt quality traits and growth in Arctic charr (Salvelinus alpinus) from the closed nucleus of the Swedish national breeding program. This population has been subject to selection for approximately 40 years (nine non-overlapping generations), with notable genetic gains for growth rate but also low and variable fertilization success rates (Palaiokostas et al., 2021) that make breeding practice challenging.

**Materials and Methods**
Using state-of-the-art, fluorescence-based cell counting and a standardized protocol for Computer Assisted Sperm Analysis (CASA) we recorded sperm concentration and kinematic parameters from 1,106 male charrs over two spawning seasons. Variance components estimation was performed in a multi-trait fashion with REML using either pedigree information alone or a combination of pedigree and genomic information from ~1/4 of the individuals using single step methodology. Our models adjusted for effects of year and water temperature at the day of sampling when applicable. A similar multivariate analysis was also applied to assess covariance components across two sex-limited traits, namely egg-count and sperm concentration, together with female and male growth proxies.

In addition, using retrospective data from 576 crosses we developed a statistical framework to disentangle latent fertility traits and their respective genetic parameters under two Bayesian hierarchical models. Unobserved male and female fertility factors were considered in non-linear functions describing the fraction of spawned eggs that were fertilized and reached the eyed stage. Animal models for the underlying factors were used as sub-models and genetic variances were partitioned utilizing additive genetic relationships.

**Results**
The phenotypic variation in the studied traits was extensive and could explain part of the variation in fertilization success rates. Heritability estimates for milt phenotypes appear relatively low to moderate spanning from ~0.1 to ~0.3. At the same time, fork length, a phenotype used as a proxy of growth rate, had a relatively moderate to high heritability of ~0.6 and revealed negative genetic covariance with male fertility proxies. More specifically, genetic correlations of -0.4 to -0.5 (depending on model) were yielded between sperm concentration and fork length while estimates around -0.2 were computed for between the latter and most sperm motility/velocity parameters. Lastly, fecundity, which is moderately heritable (h2 of ~0.4) showed positive genetic covariance with female and male growth but weak negative genetic correlation with sperm concentration.

Genetic variance posterior estimates corresponding to the female and male fertility variables converged at high levels explaining from around half and up to ~90% of the total variance (though characterized by relatively large standard errors).

**Discussion**
Our analysis suggests low to moderate heritability estimates for sperm quality traits. While this is in line with preliminary studies in the same populations (Kurta et al., 2022), here we extend by examining additional parameters to obtain insights on the genetic architecture of reproductive success in Swedish Arctic charr. Such parameters are egg count, latent variables for female and male fertility and the genetic covariance of growth rate with fertility. Opposing genetic correlation signs between fertility and growth for females and males reveal a likely complex genetic architecture governed by trade-offs and sex-specific genetic interactions with possible implications for the future of selective breeding practice in the closed nucleus.

*(Continued on next page)*

Latent fertility variables seem to have a strong heritable component, with estimates notably higher than the heritabilities for fertility proxies. That said, the respective estimated breeding values for male fertility were positively correlated with those for key sperm phenotypes. Despite a certain level of uncertainty due to limited data dimensions, this might reflect that fertility is a non-linear composite of underlying factors, with only a subset of which having been used as proxies in this study.

# A NOVEL METHOD FOR STURGEON SEXING BASED ON REAL TIME PCR

Miguel Ángel Pardo

## Introduction

The sturgeon is known as a 'living fossil', estimated to have existed for more than 250 million years, and is known primarily for its eggs, which are used to produce caviar, although its meat is also eaten. Virtually all caviar marketed today can be considered to come from aquaculture (EUMOFA, 2021). There are 25 sturgeon species belonging to the family *Acipenseridae*, among which the best known and most appreciated species belong to the genus *Huso* and *Acipenser*, the latter including the largest number of species.

At present, cytogenetical studies have not revealed any presence of sex heteromorphic chromosomes in sturgeons (Havelka et al., 2011). Due to their lack of secondary sexual characteristics, sturgeon sexing cannot be directly distinguished by their appearance.

It is noteworthy that caviar results from the processing of sturgeon eggs, so therefore requires the rearing of female fish. Thus, exploitation of sturgeons is highly costly, as females take many years to reach reproductive maturity. In fact, the process of selecting females for caviar production can be done after an average of 8 years of rearing, depending on the species, through an ultrasound examination to differentiate between male and female sturgeons. During this period, it is necessary to breed both males and females, with the consequent production (EUMOFA, 2021).

In recent years, new sex identification methods of sturgeons are based on specific genes or molecular markers. For example, it has been reported the amplification by PCR of the specific molecular marker fragments of sturgeon, and the subsequently detection of amplified fragments by gel agarose electrophoresis, for sex identification (Kuhl et al., 2021; Ruan et al., 2021). However, this methodology cannot meet the needs of current gender identification of sturgeons for the lack of accuracy and reproducibility.

For this reason, the industry needs accurate and robust sexing systems for sturgeon at an early age to adapt the feeding and needs of the animals as early as possible to optimise the maturation of the females and the final production of caviar.

## Material and Methods

Reference tissue samples of 296 adult sturgeons (*Acipenser baerii*, *A. gueldenstaedtii*, *A. naccarii* and *A. naccarii x A. baerii* (ANB)), were taken and stored at -20 °C until use. DNA extraction is performed using Wizard® Genomic DNA Purification Kit. All adults were previously sexed by visualization of the gonads (ovaries or testes) by ultrasounds in the facilities of Caviar Riofrío (Granada, Spain).
The amplification and detection of a 65 bp sex specific fragment is carried out by real time PCR amplification. Amplification is performed in MicroAmp Optical 96-well reaction plate. Each reaction mixture contained 0.3 μM of each forward and reverse primer*, 2.5 μM of specific FAM labeled probe* and 1-10 ng of template DNA. Amplification reactions are carried out employing TaqMan™ Universal Master Mix (Applied Biosystems, Thermo Fisher Scientific, USA). The analysis was carried out using the fluorescent signal level during the initial cycles of PCR. This baseline is used to accurately determine crossing point (Cp). Every sample is analyzed by triplicates and the average Cp is calculated for each sample.

* Primer and probe sequences are patent pending

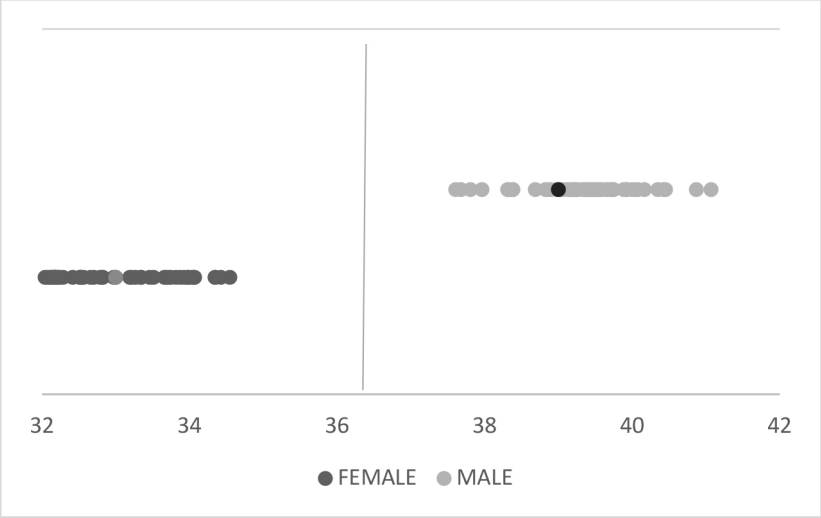

**Figure 1.** Validation of the sturgeon sexing method with the ANB species. The x-axis shows the Cp values. The vertical line represents the reference value of 36.52. Each point is the mean of the triplicates.

## Results and Conclusions

In the case of ANB species and after analyzing, at least, 50 male and 50 females, the real time PCR method has a 97,41 % correct male assignment (Figure 1). In other species, by far, the correct assignment is 100 % but, in the near future, a higher number of individuals are required to finish the complete validation with more sturgeon species.

In conclusion, the real time PCR method is suitable for sturgeon sexing of the most important commercial species. This molecular method has proven to be very accurate and reliable in comparison to other molecular methods previously described, holding the potential to become a routine methodology.

## Acknowledgments

Reference samples were kindly provided by Caviar Riofrio (Granada, Spain)

*Primer and probe sequences are patent pending

E-mail: yzpark@kiost.ac.kr

The swordtip squid, *Uroteuthis edulis*, is a commercially significant marine resource in Jeju Island, Korea. However, little is known about its immune mechanisms, particularly cellular immunity. This study aimed to characterize hemocytes of *U. edulis* using flow cytometry to elucidate their immunological roles and potential application in resource management. Hemolymph samples were collected from the cephalic artery of squids acclimated for four days post-capture. Hemocytes were morphologically categorized using light microscopy and subsequently analyzed for cellular functions including total hemocyte count, phagocytic activity, reactive oxygen species (ROS) production, and lysosomal content. Flow cytometric analysis revealed three distinct hemocyte populations: large granulocytes, small granulocytes, and blast-like cells, with small granulocytes being the predominant type (approximately 80%). Functional assays demonstrated significant variations among these populations. Large granulocytes exhibited high phagocytic activity (30–40%), robust ROS generation ($3.3 \times 10^6$ arbitrary units), and elevated lysosomal content ($5.8 \times 10^5$ arbitrary units), suggesting their pivotal role in innate immunity. Conversely, small granulocytes showed minimal phagocytosis but moderate ROS production, while blast-like cells displayed negligible phagocytic activity and lower lysosomal content. These findings provide critical insights into the immunological profile of *U. edulis*, underscoring large granulocytes as key effectors in immune defense. This characterization provides essential baseline information to support fisheries resource management and serves as a fundamental indicator of responses to environmental stressors.

# GROWTH AND SURVIVAL OF JUVENILE MANILA CLAMS *Ruditapes philippinarum* IN TWO SUSPENDED SYSTEMS IN A SARDINIAN LAGOON (SOUTH ITALY)

## Introduction

Bivalve mollusks play a vital role in coastal ecosystems and global aquaculture, contributing significantly to food security, nutrient cycling, and seafood-related economies. Among them, two clam species hold particular ecological and commercial importance: *Ruditapes decussatus* (the grooved carpet shell), native to the European Atlantic coasts and the Mediterranean, and *Ruditapes philippinarum* (the Manila clam), native to the Indo-Pacific region now naturalized in the Mediterranean Sea. Over recent decades, and increasingly in recent years, the clams' populations have undergone significant changes and are threatened by the growing frequency and intensity of extreme events (e.g., heatwaves and flash flood) in lagoon ecosystems coupled with the expansion of invasive species, such as the blue crab *Callinectes sapidus*. Indeed, a recent study reported that the blue crab shows a feeding preference for *R. decussatus* under mesocosm condition. According to FAO data, bivalves are among the most produced mollusks in aquaculture, with *R. philippinarum* being the second most cultivated bivalve species after oysters. Historically, Italy has been the leading European producer of clams and one of the top global producers, accounting for over 90% of European clam production in 2010. On the other hand, the species R. decussatus is traditionally harvested using artisanal fishery methods in the Mediterranean Sea, particularly in brackish coastal lagoons.

The objective of this study is to develop a pre-fattening system for clams that ensures an optimal cost-benefit ratio to strengthen clam supply chains. Specifically, we explored the effect of 1) different pre-fattening systems (lanterns and poches), 2) the effect of the presence of sandy substrate in lanterns (S vs B), 3) the effect of the installation depth in poches (SP vs BP). We considered clam growth and survival as response variables. The trials were tested in a suitable production area within the Santa Gilla lagoon, in collaboration with the fishery cooperative Consorzio Ittico Santa Gilla.

## Material and methods

For the trials we considered a homogeneous starting density of 0.2g/cm$^2$ of clams (0.13g/ind) in both lanterns and poches. The trials started in March 2024 (t0) and lasted four months. Bottom poches (BP) were placed at a depth of around 1.5m, while lanterns (L) and suspended poches (SP) were positioned within the top 20 cm of the water column. Each system was arranged along a long-line setup, spaced approximately 50 cm apart from each another.

Every month environmental parameters (temperature °C, Salinity and dissolved oxygen) were recorded using a multiparametric probe (*In-Situ* SmarTROLL Multiparameter Handheld). Additionally, a HOBO pendant data logger for temperature was placed *in situ*. At the same time, specimens were sampled and measured to estimate growth. Water samples were also collected to analyze the concentration of some inorganic nutrients (nitrate, nitrite, ammonia, total phosphorus). At the end of the trials all specimens were collected to estimate the survival rates under different conditions. Differences in clams' growth were assessed with univariate permutational analyses of variance (PERMANOVA), considering treatment and time as sources of variation.

## Results and Discussion

Biometric data (weight, length, width, thickness) of *R. philippinarum* were monitored over four periods (t0–t3) and showed significant differences in treatments and time, but not in their interaction. Weight increased progressively in all systems, with the highest gains observed in the Lantern Sand treatment. Systems using Poches, particularly the BP type, showed lower weight gain. Pairwise tests confirmed significant differences between t0 and t1 across all treatments, and among most system combinations at later time points. Length and width followed similar trends, with steady increases over time, particularly in

*(Continued on next page)*

lantern systems. Significant differences were detected across most group comparisons, except between some Poches treatments at later stages. Thickness also increased steadily, with the highest gains again seen in Lantern Sand. In summary, Lantern systems, especially those with sand substrate, consistently outperformed Poches systems across all biometric parameters. Moreover, survival was higher in the Lantern system (75–78%) compared to the Poches (47–52%).

This pilot study evaluated the effectiveness of different pre-fattening systems for clams in the Santa Gilla lagoon, comparing two cages: lantern and poches, with and without sandy substrate. Results showed that lantern systems with sand significantly improved clam growth and survival, supporting previous findings. However, higher stocking densities negatively impacted survival rates, highlighting the need for thinning practices and regular biofouling removal. Lantern systems were more reliable in offering protection and stability to the juveniles. The lagoon's nutrient-rich but eutrophic environment showed oxygen and nutrient levels suitable for clam farming, although continuous monitoring is essential, especially during periods of environmental stress. The observed growth rates aligned with previous studies from other Italian lagoons and confirmed the suitability of Santa Gilla for clam aquaculture. Nevertheless, improved management strategies are needed, such as increasing cleaning frequency and optimizing stocking densities. These findings also emphasize the need for adaptive practices to face challenges such as extreme weather events and variable water quality.

## Introduction

Understanding the expression patterns of key regulatory genes is critical for elucidating their biological roles across different cell and tissue types. In fish species, such insights are especially important for advancing research in aquaculture, developmental biology, and environmental adaptation. Here, we leverage publicly available transcriptome datasets from the Gene Expression Omnibus (GEO) database to investigate both bulk and single-cell RNA sequencing (RNA-Seq) expression profiles of mucosa-associated lymphoid tissue lymphoma translocation protein (*malt*) gene orthologs in salmonid fish species, with a focus on rainbow trout (*Oncorhynchus mykiss*), a key salmonid representative. Utilizing a combination of bioinformatic pipelines, including transcript quantification, single-cell RNA-Seq methods, and differential expression analyses, we systematically mapped the expression landscapes of three malt paralogs present in rainbow trout across a range of tissues and cell types.

## Material and methods

The workflow followed in this study is as follows:

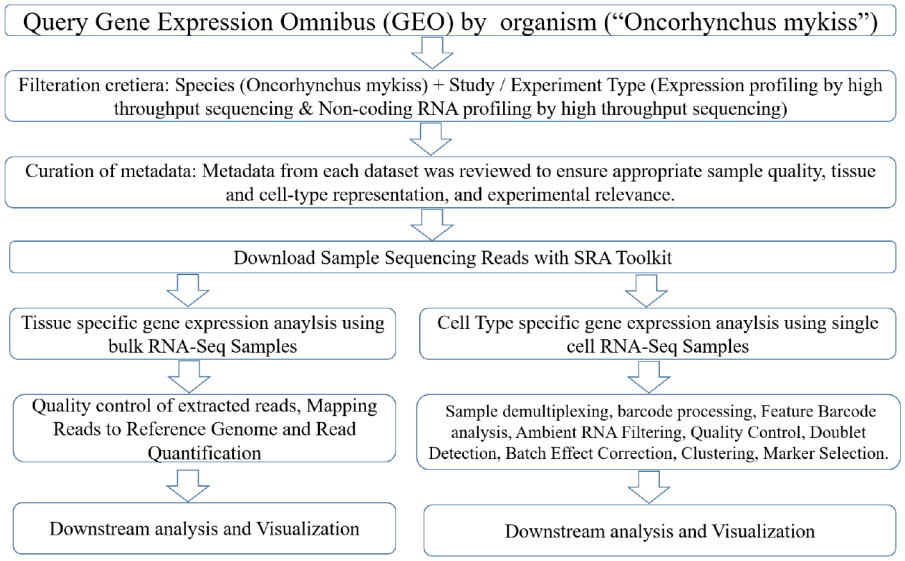

**Figure 1: Workflow for the meta-analysis of public datasets**

## Results and discussion

Initial quantitative RT-PCR validation revealed that *malt1* expression is predominant in the head kidney of rainbow trout, while *malt2* shows elevated levels in the spleen and trunk kidney. In contrast, *malt3* exhibits higher expression in the liver and intestine compared to other tissues. These findings highlight a functional diversification of MALT paralogs that may reflect specialized immune and metabolic roles across different tissue environments.

*(Continued on next page)*

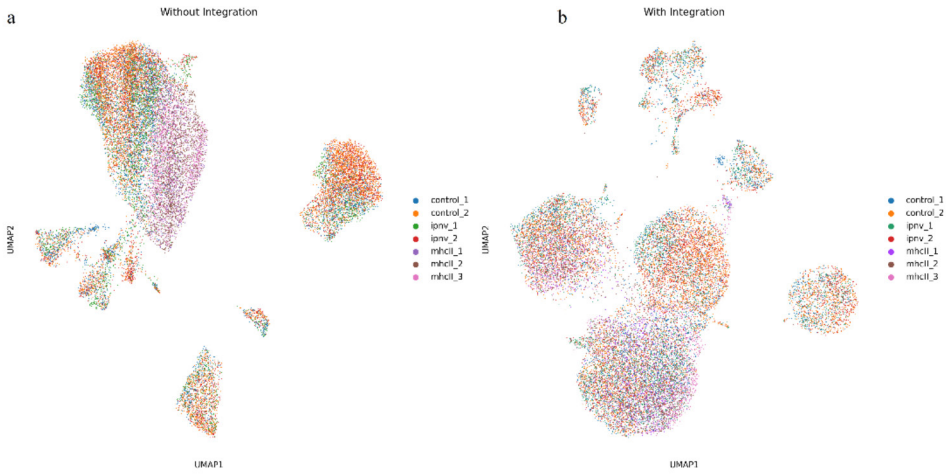

**Figure 2: Visualization of samples from merged GEO datasets (GSE260891 and GSE158102) (a) without integration and (b) with integration using scvi-tools.**

To further investigate these patterns, a meta-analysis combining bulk RNA-Seq and single-cell datasets is currently in progress. Integrating heterogeneous single-cell data, which encompasses diverse cell-type compositions, remains a considerable challenge. In this study, we demonstrate that the Single-cell Variational Inference (scvi) framework offers a more effective strategy for harmonizing diverse single-cell datasets (Lopez et. Al, 2018) (Figure 2).

Our results reveal distinct, tissue-specific expression patterns of the three *malt* paralogs in rainbow trout. By integrating public transcriptomic resources with targeted experimental validation, our study underscores both the opportunities and challenges of functional genomics in aquatic organisms.

Furthermore, these insights lay the foundation for a deeper exploration into the regulatory mechanisms of immune and stress-response pathways in salmonids, with potential applications in fish health management and aquaculture improvement.

## Introduction

Climate change, with its implications for agriculture and aquaculture, is the greatest environmental, economic, and social challenge of our time. In this context, aquaponics is an innovative and environmentally friendly farming system combining aquaculture and hydroponics, following circular economy principles (Goddek et al., 2015). In this study, we used European sea bass (*Dicentrarchus labrax*), a species of high commercial value that occupies an important place in Mediterranean aquaculture. It is resistant to changes in temperature and salinity (Yilmaz et al., 2020). Glassort (*Salicornia europea*) is an indigenous species of the Messolonghi lagoon, a Halophyte with tolerance to salinity changes, commercial value, and economic exploitation is recommended (Castagna et al. 2022). The aim of the present study was to investigate the effect of temperature on the food consumption of European sea bass when co-cultivated in a recirculated aquaponic system in combination with glasswort.

## Materials and Methods

The experiment was carried out in the Aquarium Laboratory of the Department of Fisheries and Aquaculture of the University of Patras in Messolonghi (West Greece). The experimental protocol was approved by the Ethics Committee of the University of Patras. Three autonomous aquaponic systems with a total volume of 432.2 L were used. Each aquaponic system consists of three cylindrical tanks of an 87.8 L/tank volume and two NFT (nutrient lmfilm technique) hydroponic subsystems of an 18.8 L total volume. Each aquaponics system was supported by a 150 L total volume filter, consisting of a mechanical, a biological, and a sump filter. The flow rate of the filter was designed to be upflow and downflow through the filter bed.

Three treatments took place based on temperature, namely at 20$^{o}$C, 25$^{o}$C and 30$^{o}$C, respectively. The temperature of 20$^{o}$C was selected as the optimum temperature for sea bass growth, 25$^{o}$C as the average temperature, and 30$^{o}$C as the maximum temperature for sea bass growth (Yilmaz et al. 2020). In total, 135 European sea bass with an average initial weight of 2.22 ± 0.06 g and an average initial length of 6.21 ± 0.07 cm were used (15 individuals per rearing tank). 24 salicornia plants were distributed in 6 sub-hydroponic subsystems/aquaponic systems. The duration of the experiment was 75 days, with a feeding ratio of 5% of body weight, three times per day. Abiotic parameters were measured every two days using a multimeter (HACK 40QH) to measure pH, nsalinity and temperature and a spectrophotometry analyzer (HACH3800) for TAN, $NO_2^-$, $NO_3^-$ and $PO^{4-3}$). At the end of the experiment, seabass final body weight, food consumption (FC) and specific growth rate (SGR) were calculated., The final height of the plants was also measured.

## Results and Discussion

At the beginning of the experiment, there were no significant differences between the initial boby weight and length of the European seabass and the initial height of glasswort between different temperature treatments (Table 1, ANOVA $p$>0.05). The results showed that an increase in temperature had a positive effect on food consumption and fish growth. Sea bass reared at 25 °C and 30 °C had higher FC and significantly higher SGR compared to those reared at 20 °C (ANOVA, p<0.05, Table 1), confirming that increasing temperature improves fish metabolism (Islam et al., 2020). Glasswort showed the lower growth in the 25°C treatment. In conclusion, a temperature of 25 °C is considered to be optimal for the balanced growth and FC of European sea bass, enhancing this way the performance in aquarium rearing systems under controlled climate change conditions (Goddek et al., 2015).

*(Continued on next page)*

# CURRENT BARRIERS, A NOVEL METHOD TO OPTIMIZE CURRENT SPEED IN FISH FARMING CAGES

Ø. Patursson*, J. J. Olsen

RAO
í Geilini 11
FO-175 Kirkjubøur
Faroe Islands
oystein@rao.fo

## Introduction

Salmon farming is an important industry in the Faroe Islands with a large production in a limited number of sites. The available sheltered farming sites are already in use and production has expanded into highly exposed sites. Further expansion is difficult and will most probably be in highly exposed sites. There has lately been a high focus on open ocean, but there are also possibilities in high current sites if the current speed inside the cages can be reduced to a suitable level for the farmed fish. In the Faroe islands salmon is farmed with high success at sites experiencing tidal currents up to 104 cm/s (measured currents). This is slightly higher than the reported maximum swimming speed of salmon from research (Hvas etal., 2021) even when the current reduction from the cagenets is included. Therefore, it is not expected that sites with much higher currents can be used with conventional equipment.

CFD (Computational Fluid Dynamics) is used to model flow through fish farming nets and the effect the nets have on the flow (Patursson, 2008 and Patursson etal., 2010). The present work presents the first phases of the project "Fish farming in Vestmannasund", where the use of current barriers is investigated in order to enable fish farming in high current sites previously not suitable for farming. The presented phases include 1) finding a suitable site, 2) using CFD to investigate a possible farm and current barrier design, and 3) the test of a small current barrier at the site to test the basic concept.

## Materials and methods

Initial measurements are used for description of the site and for boundary conditions for the CFD model. The measurements are from a bottom mounted ADCP and a boat mounted ADCP. Bottom mounted ADCP measurements provide timeseries of currents at a single location for statistical analysis, while boat mounted currents provide a transect along the boat path. By repeating the same path for just over 12 hours in a semi diurnal tidal site, an overview of the currents at the site through a tidal cycle can be provided.

CFD is used to investigate a full-size farm with a current barrier and a small current barrier. The CFD investigation is performed using steady state RANS, k-ω SST turbulence model and standard wall functions. The boundary conditions are based on the boat mounted current measurement at the time of the highest current speed at the site. The porous media coefficients to describe the nets are based on Patursson (2008). The coefficients for the cage nets are from Patursson etal., (2010), while the coefficients for the current barriers are chosen to provide a suitable current reduction.

The small current barrier was designed to facilitate field measurements of current reduction, mooring force and the vertical movement of the bottom of the current barrier. It was made from two barriers, each barrier was a flat net panel oriented across the flow, one downcurrent from the other.

The current reduction effect of the small current barrier was documented by measuring current upcurrent and downcurrent of the current barrier using two methods 1) One floating ADCP was moored on each side of the current barrier and 2) a boat mounted ADCP was used to measure current transects upcurrent and downcurrent of the barrier. In addition, mooring force in the major current direction was measured and the vertical position of the bottom of the barrier was measured using pressure sensors. The measurements were used to validate the CFD model and to evaluate the effect of the current barrier.

*(Continued on next page)*

## Results

The site experiences strong currents. The strongest currents (maximum during the measurement period is 220 cm/s) are aligned along the line from 280 to 100 degrees. Currents are fairly strong in the opposite direction but are low in other directions. Waves are expected to be low in the area, less than 2.5 m Hs.

The CFD results show that a current barrier, designed as a flat net across the flow slightly larger than the cross section of the cages, can shelter a row of at least 5 cages at the present site. The CFD results for the small current barrier show that the reduction is similar to the large barrier, and the wake is clear and long enough to be recognized in boat mounted ADCP measurements. The CFD work also shows that it is difficult to use measured current profiles from a boat mounted ADCP as inlet boundary conditions.

The measurement of current reduction with moored ADCPs gave the possibility to reevaluate the drag coefficient and the porous media coefficients of the net and the drag force gave another independent evaluation. The CFD results of the small barrier were validated against measurements with the boat mounted ADCP and showed good agreement.

The present work shows that it should be possible to have salmon farming in such high current sites as described above using current barriers. The present work also shows that the methods used for modeling and dimensioning were adequate to describe the small barrier and the effect of it. After the presented work was finished, the project has continued, and the farm is now in production. The next step is to improve the design of current barriers and to design current barriers that can withstand the forces from large waves as well. There is also ongoing work to investigate the difference between using steady state RANS and more detailed models like DES.

**Introduction**

Aquatic products are highly desirable in the human diet, as they provide essential omega-3 fatty acids, high-quality proteins, vitamins, and minerals. However, the growing commercialization of products derived from fisheries and aquaculture creates increasing opportunities for misrepresentation and fraud. Seafood is among the most vulnerable food categories globally, due to complex supply chains, high economic value, and frequent substitution and mislabeling. Aquaculture continues to grow as a sustainable source of animal protein, but robust tools are needed to verify the origin and production method of farmed and wild products. This study addresses these challenges by integrating stable isotope ratio analysis (SIRA), multi-elemental fingerprinting, and fatty acid profiling to differentiate between wild and farmed Gilthead seabream (*Sparus aurata*), determine geographical origin, and assess product quality based on fatty acid composition and the carbon stable isotope ratios of individual fatty acids. Obtained data are added into the IsoFoodTrack reference database which serves as a centralized repository for storing analytical data, supporting traceability and authenticity verification and food fraud prevention. To evaluate sample classification and discrimination by origin and production method, multivariate statistical models such as Orthogonal Partial Least Squares Discriminant Analysis (OPLS-DA) and Data-Driven Soft Independent Modelling of Class Analogy (DD-SIMCA) were applied, demonstrating the effectiveness of chemometric approaches in seafood authentication.

**Materials and Methods**

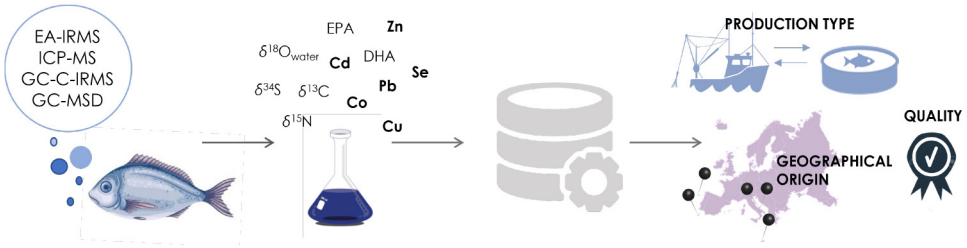
A total of 163 authentic and commercial samples of seabream were collected from various marine environments, including the Mediterranean Sea, Adriatic Sea, and the Atlantic Ocean. The stable isotope ratios of light elements ($\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$) were measured in defatted muscle tissues using IsoPrime100 – Vario PYRO Cube Isotope Ratio Mass Spectrometer (IRMS), while the measurements of oxygen ($\delta^{18}O$) isotopic composition in isolated water from the tissue were determined by IsoPrime MultiFlow system coupled to IRMS. Multi-elemental profiling of 30 elements was conducted by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Fatty acid methyl ester composition was determined by Gas Chromatography-Mass Spectrometry Detection (GC-MSD), while carbon isotope ratios of individual fatty acids were analyzed by Gas Chromatography–Combustion–Isotope Ratio Mass Spectrometry (GC-C-IRMS).

**Results and discussion**

Stable isotope ratios of $\delta^{13}C$, $\delta^{15}N$, and $\delta^{34}S$ effectively differentiated wild from farmed *Sparus aurata*, with wild samples showing enriched $\delta^{13}C$ and $\delta^{15}N$ values, consistent with a marine-based diet and higher trophic level. Elemental signatures, complemented the isotopic data and further supported the differentiation of geographic origin and production type. The most powerful variables for distinguishing samples from five different geographical locations were $\delta^{18}O$, K, P, Rb, $\delta^{13}C$, $\delta^{34}S$, Mg, Zn, $\delta^{15}N$, S, Co, Hg, and Se. Classification models using OPLS-DA achieved 94% accuracy for geographic origin and 100% accuracy for production method differentiation. The DD-SIMCA model was used for class modeling and verification of Portuguese-origin samples, achieving 96% accuracy, with 93% sensitivity and 98% specificity.

Fatty acid profiling revealed significantly higher concentrations of long-chain ω-3 polyunsaturated fatty acids (EPA and DHA) in wild seabream, as expected based on their natural diet and previous studies. EPA and DHA levels in wild fish reached 7.4% and 17.1%, respectively, compared to 2.1% and 5.3% in farmed seabream. These differences reflect dietary and environmental influences, including feed composition and production method. In addition, preliminary results from carbon isotope ratios of individual fatty acids suggest further potential for differentiating production origin and identifying biogenetic sources, highlighting the value of combining GC-MSD and GC-C-IRMS for assessing nutritional quality and feeding patterns.

*(Continued on next page)*



## Conclusion

This study demonstrates the effectiveness of an integrated analytical approach for seafood authentication and quality assessment. The resulting data contribute to the IsoFoodTrack database, supporting the development of reliable traceability systems and reinforcing efforts to prevent seafood fraud across the supply chain.

# BLOOD BIOCHEMISTRY AND TISSUE HEALTH OF EUROPEAN PERCH (*Perca fluviatilis*) FED DIETS CONTAINING VARYING LEVELS OF *Ganoderma spp.* COMPOSITE MYCELIUM MEAL

P. Pawlak*, V. Stejskal; F. Weirauch; J.B. Luce; T. Janssens

School of Agricultural, Forest and Food Sciences (HAFL)
Bern University of Applied Sciences (BFH)
Zollikofen, 3052, Switzerland

## Introduction

Proper nutrition is essential for maintaining fish health, supporting immune function, and enhancing aquaculture performance. With the increasing need for sustainable alternatives to fishmeal and soybean-based ingredients, novel feed additives are gaining attention. Composite mycelium meals (CMM) derived from Ganoderma spp. through solid-state fermentation (SSF) represent a promising innovation. Ganoderma spp. are rich in functional compounds like polysaccharides and triterpenoids, which may support fish health. While their potential has been demonstrated in species such as tilapia and carp, data on European perch (Perca fluviatilis), a key European aquaculture species, remain lacking. This study investigated the impact of dietary inclusion of Ganoderma-based CMM on blood biochemical parameters and tissue histology in juvenile European perch.

## Materials and methods

A 12-week feeding trial was conducted with juvenile European perch fed one of four diets: a control diet (CMM-0) and three experimental diets containing 5% (CMM-5), 7.5% (CMM-7.5), and 10% (CMM-10) Ganoderma spp. CMM. At the end of the trial, blood samples were collected via caudal venipuncture for biochemical analysis. Serum parameters included cholesterol (CHOL), alkaline phosphatase (ALP), phosphate (PHOS), and total protein (TP), among others. Data were analyzed using linear models in R, with estimated marginal means computed via the emmeans package.

Liver and mid-intestine samples were fixed in 10% buffered formalin, processed using standard paraffin embedding, and stained with hematoxylin and eosin (H&E). Histological sections were assessed using a semi-quantitative scoring system (0–4) to evaluate tissue alterations across five categories.

## Results

All fish fed CMM diets exhibited significantly higher cholesterol and alkaline phosphatase levels compared to controls. Phosphate levels were significantly elevated in the CMM-10 group when compared to the control group. Total protein was lowest in CMM-10 but differed significantly only in comparison to CMM-5. Other biochemical markers, including glucose, creatinine, and liver enzymes, showed no significant differences and remained within physiological ranges.

Histological analysis revealed no consistent or dose-dependent trends in tissue alterations across treatment groups.

## Conclusion

Diets containing Ganoderma spp.-based CMM influenced several blood biochemical markers, suggesting a systemic physiological response, particularly at higher inclusion levels. Elevated cholesterol and visceral fat (data not shown) may point toward shifts in lipid metabolism, what requires further investigation. The absence of major histopathological changes suggests that Ganoderma-based CMM may be safely included in perch diets up to 10%. From a practical perspective, moderate inclusion levels (5–7.5%) may offer a beneficial balance between functional effects and physiological stability. These findings support the potential of mycelium-based ingredients as sustainable feed additives in European aquaculture.

# CHARACTERIZING SKELETAL ONTONGENY AND ANOMALIES IN BALLAN WRASSE (*Labrus bergylta)* LARVAE

## Introduction

Challenges related to sea lice prevention and treatment remain major cost drivers in salmon farming (Abolofia et al., 2017). The deployment of cleaner fish, such as ballan wrasse (*Labrus bergylta*), has been used as one of several strategies to prevent and control sea lice infestations. Skeletal anomalies are amongst the most common challenges in farmed ballan wrasse (Fjelldal et al., 2021) compromising fish welfare by altering feeding and swimming behavior and increasing stress susceptibility (Boglione et al., 2013). These anomalies have multifactorial causes and are often linked to inadequate early nutrition (Lall and Lewis-McCrea, 2007; Fang et al., 2024). During the weaning phase, it is therefore crucial to use appropriate diets tailored to the species' nutritional needs. This study aimed to better understand the impact of early nutrition on growth performance, osteogenesis, and skeletal anomaly incidence in ballan wrasse larvae, using bone staining and comparative transcriptomic analyses.

## Material and methods

Ballan wrasse larvae (Mowi Stord, Norway) at two days post-hatching (dph) were stocked at a density of 115 larvae.$L^{-1}$ in 200 L tanks at SINTEF/NTNU SeaLab (Trondheim, Norway). Larvae were reared with a 24L:0D photoperiod, oxygen saturation was maintained above 90 %, salinity at 34psu and temperature was gradually increased from 11.8 ± 0.2 to 15.7 ±0.1 °C. The experiment was conducted in triplicates with four experimental feeding regimes differing in the weaning onset. The live feed protocol included *Acartia tonsa* copepodites (NII-III, 160–210 µm) from 4 to 12 dph, rotifers (*Brachionus ibericus*), enriched for 24 hours with Larviva Multigain (Biomar, Denmark), from 10 to 22 dph, and large barnacle nauplii (Cryo-L; *Semibalanus balanoides* NI, 320µm) from 18 to 44 dph. A formulated diet (WINWrasse, SPAROS) was introduced at 5, 17, 24 and 32 dph for Protocols 1, 2, 3 and 4, respectively. From 45 dph onwards, larvae were fed exclusively with the formulated diet. Larvae were sampled from each tank at 4, 16, 23, 31, 45 and 56 dph to determine standard length (SL), dry weight (DW), carbon and nitrogen content (CN), specific growth rate (SGR) and daily weight increase (%DWI). For gene expression analysis, 5-10 larvae per tank were collected at 16, 23, 31, 45, and 56 dph for sequencing. For the analyses the R package glmmSeq (Rivellese et al., 2022) was used to fit negative binomial mixed-effects models at the individual gene level. Additionally, 6–10 larvae per tank were sampled at 31, 45, and 56 dph for assessment of osteogenesis and skeletal anomalies, using a modified double-staining method (Gavaia et al., 2000) and an adapted scoring system (Sæle et al., 2004; Sørøy, 2012; Sæle et al., 2017).

All procedures complied with the Norwegian Animal Welfare Act of 20 December 1974, No. 73 (Sections 20–22, amended 19 June 2009). The experiment was approved by the Norwegian Food Safety Authority (FOTS ID 30573, reference number 23/243983).

## Results and Discussion

At 56 dph, significant differences were observed in DW between Protocols 3 and 4 ($p<0.05$; One-way ANOVA). A notable peak in mortality occurred across all groups between 21–26 dph, with Protocol 1 showing significantly higher cumulative mortality than Protocol 2 at 24 dph ($p<0.05$; One-way ANOVA). Growth patterns up to 30 dph were consistent with previous studies (Sørøy 2012; Høyland 2015) and both growth and mortality followed the tendency described by Malzahn et al. (2022) for a group fed copepod and Cirripedia nauplii. Possible contributing factors to the mortality peak may include appetite fluctuations, environmental conditions, and pathogen presence.

*(Continued on next page)*

Urostyle flexion was observed from 6.3 ± 0.10 mm SL and fully ossified vertebrae in larvae measuring 7 mm SL, which was consistent with previous studies in ballan wrasse larvae (Sørøy 2012; Høyland 2015; Malzahn et al., 2022). Protocol 4 had significantly more fully ossified vertebrae ($p < 0.05$; One-way ANOVA) compared to Protocols 1 and 2. At 45 dph, the most common anomaly in Protocols 2 and 3 was abnormal arches and/or spines (A/S) and lordosis was most prevalent in Protocol 1 (41.1%). In Protocol 4, twisted spines was the most frequent anomaly (30.3%) at 45 dph and increased across all Protocols by 56 dph. This increasing trend aligns with previous studies (Sørøy 2012; Høyland 2015), suggesting that twisted spines develop in later stages of ossification. The higher prevalence of this anomaly in Protocol 4 at 45 dph may be linked to its more advanced vertebral ossification at that time point. While anomalies in arches and spines are often not considered severe due to their minimal impact on external morphology, severe cases of spine anomalies can negatively impact fish performance.

Transcriptomic analysis revealed a significant upregulation of genes involved in the oxidative stress response, particularly in Protocol 1. Similar trends were observed for genes involved in the activation and response of the immune system against microbial infections, innate and adaptive immune response and stress resistance. We hypothesize that the introduction of formulated diets altered the bacterial load and community composition, thereby activating antibacterial immune responses.

**Conclusion**

In conclusion, the results of this trial emphasize the potential for refining rearing protocols for ballan wrasse larvae by incorporating advances in nutrition, environmental management, and developmental biology to enhance survival, growth, and skeletal development. Furthermore, we highlight the importance of better understanding ossification types and skeletal anomaly prevalence and integrating this knowledge with improvements in early-life-stage nutrition and longitudinal studies.

# MODULATORY EFFECTS OF TRYPTOPHAN SUPPLEMENTATION ON NEUROENDOCRINE AND MUCOSAL IMMUNE RESPONSES IN VACCINATED EUROPEAN SEABASS

Diogo Peixoto[1,2*]; Inês Carvalho[1,2]; André Cunha[1,2]; Rita Azeredo [1,2]; Benjamín Costas [1,2]

[1]CIIMAR - Centro Interdisciplinar de Investigação Marinha e Ambiental, Matosinhos, Portugal

*Presenter author: dpeixoto@ciimar.up.pt

**Introduction**
Tryptophan has been shown to play several roles in modulating stress and immune responses in fish, and it is hypothesized that may also serve as a complementary strategy to vaccination in aquaculture. This study evaluates the combined effects of dietary tryptophan supplementation and dip vaccination on skin and intestinal mucosal immunity of European seabass (*Dicentrarchus labrax*), as well as the complex interaction between neuroendocrine-immune systems.

**Materials and Methods**
European seabass juveniles (26.23 ± 7.22 g) were randomly distributed into two different recirculating seawater systems (temperature 20 ± 0.5 °C). In a complete randomized design, fish were fed either a control diet (CTRL) or one of two CTRL-based diets supplemented with tryptophan (TRP1 0.05 % DM and TRP2 0.5 % DM) in triplicate tanks *per* system. After 3 days of feeding, 3 fish *per* treatment from system 1 were euthanized by an overdose of 2-phenoxyethanol and skin mucus and blood (immune status), brain (diced in hypothalamus), pituitary gland, head-kidney (gene expression) and intestine (shotgun proteomics) samples were collected. The remaining fish were dip vaccinated, returning to their original tanks, and sampled after 1 hour, 6 hours, and 21 days post-vaccination. Following vaccination, fish were fed the same diets for 3 more days and after that, all fish were fed the CTRL diet until the end of the trial (21 days). Fish from system 2 were undisturbed following the same dietary regime of system 1.

**Results and Discussion**
Upon vaccination procedures, an expected inflammatory response was observed in fish fed CTRL and TRP2 diets 1 and 6 hours after, as shown by higher plasma cortisol levels, reduced total immunoglobulin M levels, and increased expression of neuroendocrine markers (*htr2a* and *tph1α*). In contrast, this inflammatory response was attenuated in dip-vaccinated fish fed TRP1, as evidenced by low transcription rates of serotonin-related genes, reduced plasma cortisol, and enhanced bactericidal activity in skin mucus - overall displaying a physiological profile similar to undisturbed control fish. Notably, dip-vaccinated fish fed TRP1 and sampled 6 hours post-vaccination exhibited a gut proteomic profile resembling also those of the undisturbed CTRL group. These findings suggest that tryptophan at low supplementation levels may mitigate the stress-related effects of dip vaccination and potentially enhance vaccine efficacy.

Regarding tryptophan supplementation's longstanding effects on fish vaccination efficacy, the lowest supplementation dose counteracted vaccine-mediated reduced gene expression (*c3*, *ido2*, *igm* and *il1β*), again mirroring the gene expression patterns observed in undisturbed fish. This suggests a sustained beneficial effect of tryptophan, even after a short administration period, with effects persisting up to 15 days after the end of the treatment.

**Conclusions**
Overall, the findings highlight a complex interplay between tryptophan supplementation and immune responses, supporting its potential as an effective dietary strategy to enhance vaccination outcomes in aquaculture.

## Introduction

Infections are common in nature but it is recognised that farming conditions can significantly influence the progression and severity of various diseases in aquatic animals. In this context, the study of host-pathogen interactions is essential to better understand the dynamics of waterborne transmission of pathogens. Enteric redmouth disease (ERM) is a serious septicaemic bacterial infection of salmonid fish species, caused by *Yersinia ruckeri*, a Gram-negative rod-shaped enterobacterium. ERM has a broad host range, widespread geographical distribution, and leads to considerable economic losses in the aquaculture industry. However, few studies focused on the use of a cohabitation mode of ERM exposure, and among them, shedders were intraperitoneally injected (i.p.) fish. In this context, the present study aimed to compare two inoculation routes, a less invasive oral gavage, and the more commonly used i.p. injection, in a ERM cohabitation challenge model using juvenile rainbow trout (*Oncorhynchus mykiss*) as host.

## Materials and Methods

Juvenile rainbow trout were randomly distributed to two separate recirculating seawater systems, each with 8 tanks (50 L water volume), maintained at a constant temperature (20 ± 0.5 °C). Both systems allowed to compare different ratios of shedder (i.e., infected fish) to healthy naïve fish, as well as two different bacterial inoculation routes into shedder fish. The numbers of shedders and healthy naïve fish were adjusted to maintain ratios of 1:3 and 1:5.

Designated shedder fish were anesthetized, marked in the peritoneal cavity using Alcian Blue, and *Y. ruckeri* strain QSP57.1 were i.p. injected or inoculated by oral gavage. In one system, each tank contained 9 or 10 trout (89.5 ± 8.5 g) and among them 3 or 2 fish (1:3 and 1:5, respectively) were i.p. injected with *Y. ruckeri* at a concentration of $7.3 \times 10^8$ CFU *per* fish. In the other system, each tank contained 36 fish (14.6 ± 5 g), with 9 or 6 fish (1:3 and 1:5, respectively) infected through oral gavage with $5.4 \times 10^9$ CFU *per* fish. Dead and moribund naïve fish were sampled for tissue collection (i.e., spleen, anus and gills) in order to quantify bacterial load by molecular methods (i.e., PCR).

## Results and Discussion

Preliminary results showed that different infection routes resulted in diverse onset times for ERM symptomatology. In both bacterial inoculation methods, shedders presented characteristic clinical signs of disease, such as exophthalmia, skin darkening, and subcutaneous haemorrhages around the mouth and throat. Additionally, the higher proportion of shedders-to-cohabitant fish (1:3) led to greater overall mortality compared to the 1:5 ratio in both inoculation routes.

In the oral gavage group, most shedders experienced high mortality within 7–8 days post-bacterial inoculation. Among fish exposed at a 1:3 ratio, 75% of the cohabitant trout survived up to 21 days, corresponding to a 25% mortality rate among naïve fish. In contrast, cohabitants in the 1:5 ratio group exhibited lower mortality, with cumulative losses of only 15% among naïve fish.

In the i.p. group, shedders showed higher and faster cumulative mortality compared to those inoculated by oral gavage with up to 100% mortality within 5 days. In those exposed to the 1:3 ratio, cohabitants showed a 14% cumulative mortality, whereas the their counterparts exposed to the 1:5 ratio, showed a 13% cumulative mortality among cohabitants up to 21 days.

These preliminary findings support the fact that infection pressure and inoculation route play a critical role in pathogen spread and disease dynamics, with increased pathogen load in the system likely facilitating faster and more extensive transmission to naïve individuals. Bacterial quantification in the sampled tissues will bring more insights regarding *Y. ruckeri* propagation during these cohabitation challenge models.

*(Continued on next page)*

**Conclusions**

Overall, these findings emphasize the importance of inoculation route and inoculum concentration during *Y. ruckeri* infection by cohabitation. While i.p. injection serves as a robust model for acute disease progression, oral gavage more closely replicates natural transmission dynamics.

Further research is needed to better understand the host immune response during infection by oral gavage inoculation, as this could significantly impact the development of new strategies for disease control and vaccination in aquaculture.

**Introduction**

Aquaculture is crucial for global food and livelihood, with over half of fish for human consumption coming from aquaculture in 2014 (FAO, 2022). By 2030, production is expected to reach 93.6 million tons, a 25% increase. Intensive aquaculture, using Recirculating Aquaculture Systems (RAS), ensures continuous quality fish production. RAS polyculture, cultivating multiple species together, improves resource utilization, waste management, and productivity (Verdegem et al., 2023; Zhang et al., 2011; Zhang et al., 2023). This study examines the impact of using a common pellet in RAS for breeding pikeperch (*Sander lucioperca*) and Russian sturgeon (*Acipenser gueldenstaedtii*), focusing on nutrient transfer efficiency, lipid, fatty acid, and amino acid utilization, and variations in nutrient absorption and flavor profiles.

**Materials and Methods**

All experimental groups were replicated three times. Juvenile pikeperch and Russian sturgeon were reared using pond and intensive aquaculture, respectively. A total of 1224 pikeperch and 576 sturgeons were divided into five groups: monoculture pikeperch (P100), monoculture sturgeon (P0), and three mixed stocks with varying pikeperch-to-sturgeon ratios (P90, P80, P70). Fifteen tanks, each containing 120 fish with an initial biomass of 5.75 kg/m³, were used. Fish were evenly distributed by age, with initial body weights of 18.17±2.65 g for pikeperch and 18.23±3.62 g for sturgeon.

Fish were fed Skretting Europa 15 F floating feed (2 mm pellets), containing 55% crude protein, 16% crude fat, and 4637 kcal/kg digestible energy. Feeding was administered three times daily using automatic feeders. A 12-hour photoperiod was maintained throughout the experiment. The introduction of sturgeon did not significantly affect water quality, demonstrating their compatibility with sustainable aquaculture.

Suspended solids were measured every 28 days, and tanks were cleaned and drained using aquatic nets. Fish were sedated with tricaine mesylate (MS-222) before biometric measurements. Samples, including fish fillets and suspended solids, were collected, filtered, and stored at -18°C for analysis. A total of 45 samples were analyzed using advanced laboratory instruments at the Laboratory of Nutrition.

Amino acid analysis involved protein digestion, derivatization with dansyl chloride, and HPLC-UV detection. Methionine and cysteine were quantified as methionine sulfate and cystic acid, respectively. Lipid extraction was conducted using hexane-isopropanol, and fatty acid composition was determined by gas chromatography. Acid-insoluble ash was used to assess lipid digestibility, providing a reliable alternative to traditional methods.

**Results**

The amino acid profile of pikeperch fillets in monoculture and polyculture with Russian sturgeon showed that lysine reserves were lower in polyculture, while methionine reserves increased. Non-essential amino acids like glycine and proline were highest in the P90 polyculture combination. Fillet lipid content and fatty acid profiles did not show significant changes between monoculture and polyculture. The DHA to EPA ratio almost doubled in flesh compared to food across all groups. Lipid digestibility of the common pellet was excellent, with the highest lipid-ADC in the P70 polyculture tank. EPA and DHA content in pikeperch fillets were lower than in Russian sturgeon, with no significant difference between monoculture and polyculture treatments.

*(Continued on next page)*

For Russian sturgeon, no significant changes in lysine or methionine reserves were observed between monoculture and polyculture. The fillet fat content increased significantly in polyculture, with higher MUFA oleic acid content. Lipid digestibility was excellent across all groups, with the highest lipid-ADC in monoculture tanks. EPA and DHA content in Russian sturgeon fillets were higher than in pikeperch, with the highest content in the P70 polyculture tank.

**Discussion**

The study examined the effects of polyculture on the amino acid and lipid profiles of pikeperch and Russian sturgeon in RAS. Key findings highlight the nutritional value, flavor, and texture of the fish. Acid-insoluble ash was found to accurately predict lipid digestibility, offering a reliable alternative to traditional methods. Pikeperch in polyculture showed decreased lysine and increased methionine reserves, while sturgeon amino acid profiles remained stable. Lipid content in pikeperch fillets was unchanged, but sturgeon fillets had higher fat content in polyculture. Lipid digestibility was excellent across all groups, with sturgeon showing robust lipid digestion. DHA and EPA content in pikeperch was similar in both monoculture and polyculture, while sturgeon in polyculture had higher MUFA and DHA content. The study demonstrates the benefits of RAS polyculture in enhancing nutrient utilization and improving fish nutritional quality. Further research is needed to explore the effects of polyculture on fish growth, health, and environmental sustainability in RAS systems.

# SUSTAINABLE AMMONIA MANAGEMENT IN AQUACULTURE USING CLAY MINERALS

I. Peppa [1,2]*, G. Artemiou [1,2], A. Katouni [1], P. Psofakis [1], C. Papadouli [1], T. Karatzinos, M. Kotsiri [1], P. Panagiotaki [1], E. Golomazou [1]

[1]Department of Ichthyology and Aquatic Environment - Aquaculture Laboratory, School of Agricultural Sciences, University of Thessaly, Fytokou str., 38446, Volos, Greece, e-mail: egolom@uth.gr
[2] Farmart Ltd, Athienou, Cyprus

## Introduction

Attapulgite is a natural clay mineral used in the industry of animal feed (EU 2023/1699) as an anti-caking and binding agent for mycotoxins and other substances. At the same time, it can perform zootechnical functions, affecting the gastrointestinal flora and improving the digestibility of feed in animals. It has been observed that it contributes to the reduction of ammonia during the composting process and effectively removes it from water (Xie et al., 2012, Teng et al., 2024). The purpose of this study was to evaluate the effectiveness of attapulgite in reducing ammonia excretion in the aquatic environment during fish farming.

## Materials and methods

All procedures followed the EU Directive 2010/63/EU for animal welfare and were conducted in licensed facilities (EL-43BIO/exp-01) at the Aquaculture Laboratory, University of Thessaly, Greece, by accredited scientists (FELASA, Functions A–D). 954 gilthead sea breams (*Sparus aurata*, B.W. 2.63 ± 0.46 g) were distributed into 18 aquaria (250 L; 53 fish each) with stable water conditions (salinity 33 ppt, temperature 21 ± 1 °C). Two experimental feeds were used: (1) a control diet and (2) a diet supplemented with attapulgite and 3% activated carbon (3 kg/ton). Six groups (three fed at 4% biomass and three fed *ad libitum*, each in triplicate) were constituted, and the biological filter in the recirculation systems was activated as shown in Table 1.

Fish were fed once daily, six days per week, for two weeks. Ammonia ($NH_3/NH_4^+$) and nitrite ($NO_2^-$) were measured daily at three time points: pre-feeding (PR-F), 2 h post-feeding (2h PST-F), and 9 h post-feeding (9h PST-F), using API commercial assays. No mortalities or injuries occurred. Data were analyzed separately for each feeding method using ANOVA (SPSS 26, $P < 0.05$).

## Results and discussion

In the case of feeding *ad libitum*, under conditions of inactivation of the biological filter, it was observed that the presence of attapulgite contributed to maintaining ammonia levels at significantly lower concentrations compared to the control group that received food without attapulgite (Fig. 1. B). Furthermore, these ammonia concentrations did not show statistically significant differences compared to those of the group in which the biological filter remained fully operational (Fig. 1. B). In contrast, the addition of attapulgite, in the absence of a biological filter, did not affect the levels of nitrite ions, which remained unchanged compared to the control group (Fig. 1. D). Attapulgite is a promising clay mineral with a wide range of applications in aquaculture and the aquatic environment, offering significant prospects in reducing the negative effects of ammonia on fish health. This readily available and economical material has a surface with excellent absorption capacities, acting catalytically in the degradation of ammonia (Xu et al., 2023).

**Table 1. Experimental groups and treatments**

| Experimental groups | Feeding | Biofilter | Experimental diet |
|---|---|---|---|
| CONTROL F-OFF | 4% biomass / *ad libitum* | OFF | CONTROL |
| ATTAPULGITE F-OFF | 4% biomass / *ad libitum* | OFF | ATTAPULGITE |
| ATTAPULGITE F-ON | 4% biomass / *ad libitum* | ON | ATTAPULGITE |

*(Continued on next page)*

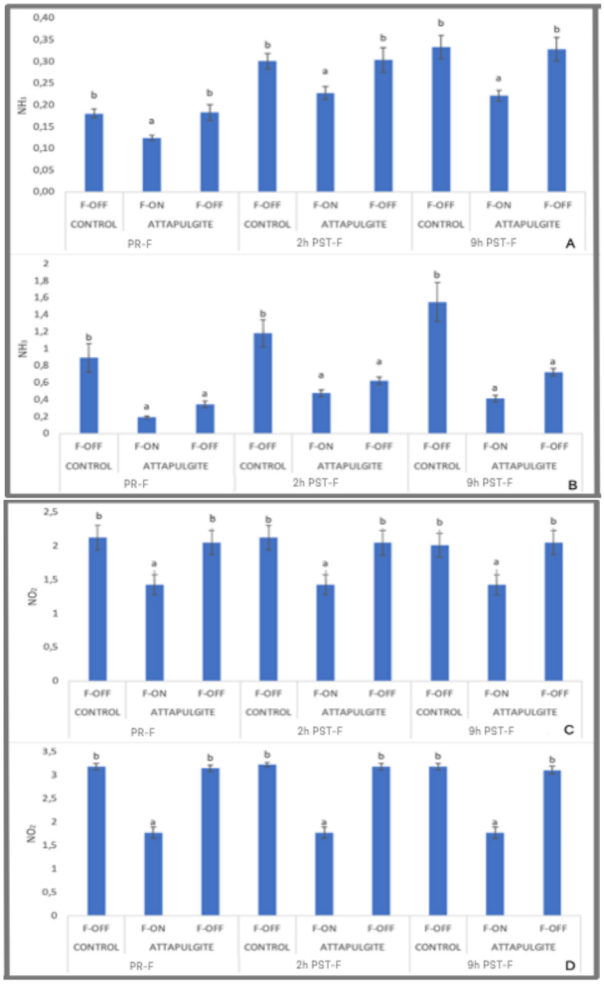

Figure 1. $NH_3$ and $NO_2^-$ values (mean ± standard error, A. C: 4% biomass, B. D: *ad libitum*) in treatment groups, measured before feeding, 2 hours post-feeding, and 9 hours post-feeding. Different letters indicate statistically significant differences among means within the same time point ($P < 0.05$). The absence of letters denotes no statistically significant differences between the tested groups.

# REDOX-DRIVEN VALORISATION OF MARINE RAS SLUDGE AND EFFLUENTS FOR NUTRIENT RECOVERY AND *ULVA SP.* CULTIVATION

S. Perché [a*], C. Espinal, C. Letelier-Gordo

[a] Department of Physiology

Recirculating aquaculture systems (RAS) offer a solution to counter eutrophication risk through the treatment or recycling of nutrient-rich effluents. Applying the residual resource concept improves these effluents by adding value through recovery and recirculation of nutrients. The objective of this study was to determine the optimal solubilization oxidation-reduction (redox) conditions for increased solubilization of nutrients produced from marine RAS sludge. Thus, increasing its bioavailability for seaweed development and optimizing the utilization of sludge. The solubilisation of relevant nutrients as nitrogen (N), phosphorus (P), iron (Fe), and manganese (Mn) were examined under three redox potentials: aerobic, intermittent aeration and anaerobic. The results showed that anaerobic conditions led to the highest solubilization degree (0,55 ± 0,06 g sCOD/g TCOD) compared to aerobic (0,45 ± 0,07 g sCOD/g TCOD) and intermittent aeration (0,34 ± 0,09 g sCOD/g TCOD). The optimum fermented sludge supernatant (FSS) obtained was subsequently mixed with RAS overflow water (OW). This mix was evaluated against two conditions: FSS+OW with trace elements (TE) and OW alone, in a 10-day growth trial for assessment of both Ulva sp. specific growth rate and nutrient uptake efficiency. In this test, Ulva cultivated with FSS+OW presented the highest specific growth rates (SGR) (9,07 ± 1,49 %/day) than those treated with FSS+OW+TE (6,71 ± 1,95 %/day) and OW alone (4,95 ± 1,11 %/day). This indicates that the supernatant derived from anaerobically treated marine RAS sludge, when mixed with OW, can stimulate Ulva growth more effectively than the mix supplement with TE and OW alone. While previous research has demonstrated the feasibility of using RAS water for seaweed growth, the current study indicates the role of sludge in supplying nutrients to OW, increasing seaweed growth. The sludge utilisation could reduce the reliance on chemical trace element supplementation in seaweed farming, enhancing sustainability and at the same time reduce the costs of saline sludge treatment. These findings highlight the potential of valorising marine RAS effluents as a sustainable nutrient source in a circular bioeconomy for seaweed production.

# LONG-TERM COMPARISON OF GREEN AND RED MACROALGAE EXTRACTS AND β-GLUCANS ON THE DISEASE RESISTANCE, GILLS INTEGRITY AND GROWTH PERFORMANCE OF NILE TILAPIA

Garcia-Suárez M.[1], Pereira R. T.[1*], Sutili F. J.[2], Battisti E. K.[2] , Rodriguez, M. A.[1], Marzin D.[1]

[1]OLMIX SA, ZA du Haut du Bois, 56 580 Bréhan, France
[2]ELOAQUA, Research Facility, Brazil
*rpereira@olmix.com

This study aimed to evaluate the efficacy of green and red macroalgae extracts and β-glucans on the disease resistance and growth performance of Nile tilapia (*Oreochromis niloticus*) in long-term dietary use. An algae-based marine sulphated polysaccharides (MSP) extracts, from Ulva sp. and Solieria chordalis, and 60% purified yeast-based β-glucans available in the market were used in the feeding trial. Fish weighting ~4 g were reared at 26-28 °C, and average dissolved oxygen 6 mg/L. Fish were assigned to 4 different dietary treatments and 6 replicates (tanks of 60 L): Control; Algae MSP 0.3%; β-Glucan A 0.1% and β-Glucan B 0.1%. Fish were stocked at a density of 15 fish/tank (90 fish/treatment) and fed twice a day for 110 days. At the end of the feeding period, all fish were weighed to assess growth, and 8 fish per treatment were sampled for innate immune response analysis. Another 6 fish per treatment were exposed via immersion to a bacterial solution containing *Aeromonas hydrophila* and *Streptococcus agalactiae*. Following 24 hours, gill samples were collected for histopathological evaluation using a diagnostic scoring system performed by a specialized laboratory. Additionally, a third group of 12 fish per treatment was intraperitoneally challenged with the same bacterial solution, and survival was monitored for 7 days. Data were analyzed using one-way ANOVA with means compared by Duncan's test ($p<0.10$) or Kaplan-Meier for survival data (SigmaPlot, Systat Software, San Jose, CA, USA). Tilapia fed Algae MSP showed the most consistent results overall: final weight gain was 3.4% higher than the control ($p = 0.071$); lysozyme activity was 109% higher ($p<0.001$); and superoxide anion production (NBT assay) was significantly higher in all supplemented groups compared to the control ($p<0.001$). Myeloperoxidase activity was highest in the β-Glucan B group, while hemolytic complement activity was greatest in the β-Glucan A group. Algae MSP was the only treatment that showed significantly higher survival after bacterial challenge (50% vs. 16.7%) compared to control. Although survival was numerically higher in fish fed β-Glucan A (33.3%) and B (25%), differences were not statistically significant. Gill histopathological scores were 1.15 (Control), 0.17 (Algae MSP), 0.42 *(β-Glucan A), and 0.*30 *(β-Glucan B), representing* a 85% reduction in tissue damage compared to the challenged control. In conclusion, Algae MSP demonstrated the most consistent overall performance, excelling in growth, innate immunity, gills protection, and survival meanwhile β-Glucans showed intermediate effects across evaluated parameters. The results highlighed the algae-based solution as a tool for strengthening natural defenses in aquaculture due to its broader benefits in long-term use.

# LIGHT, NUTRIENTS, AND GROWTH: MODELING *Ulva ohnoi* FOR SUSTAINABLE AQUACULTURE DESIGN

J. Pereira[1]*, G. Del Olmo Berenguer[2], J. Pintado[2] and E. Balsa-Canto[1]

## Introduction

Macroalgae (e.g. *Ulva* spp.) provide essential ecosystem services as biofiltration through the absorption of dissolved nutrients, such as nitrates. Among them, *Ulva ohnoi* (Linnaeus) is especially distinguished by its versatility, rapid growth rate, and high nutrient uptake efficiency, making it a worthwhile candidate for use in an Integrated Multi-Trophic Aquaculture with water recirculation system (IMTA-RAS). Designing and scaling-up such systems is usually complex and expensive. However, mathematical modeling is a useful tool to make the process easier, helping in the design and system optimization by enabling virtual simulations to identify optimal cultivation conditions and reduce the need for large-scale experimentation.

Here, we developed a mathematical model for *Ulva* growth and nutrient uptake under different light conditions. We carried out three independent batch-culture experiments in multi-well plates, measuring biomass production (dry weight) and nutrient dynamics (nitrate concentration) over time. A set of candidate models was established and evaluated using a multi-experiment parameter estimation approach, global optimization, and various goodness-of-fit criteria.

The selected model, based on Droop kinetics, incorporates nitrogen quota dynamics and explicitly accounts for light intensity effects. It achieves high predictive accuracy ($R^2 > 90\%$; NRMSE = 22%) and is capable of reproducing the observed growth patterns. Due to its strong precision, the model can now be used for simulation and numerical optimization to support the automated design of IMTA-RAS systems tailored to *Ulva* cultivation.

The GRINNAQUA project is dedicated to enhancing sustainable aquaculture practices through research, collaboration, and innovation. As part of this initiative, an event was organized, in collaboration with the MycoFish (*PTDC/CVT-CVT/2660/2021*) and AquaClimAdapt (*PTDC/CTA-AMB/0592/2021*) projects to gather together academia, aquaculture industry stakeholders, and policymakers, in equal representation. This event provided a platform for open discussions on both the broad challenges facing the aquaculture sector and the specific topics that are crucial for its future.

The conversations covered a range of topics, from the use of artificial intelligence in aquaculture and the role of functional feeds in fish health to concerns about food safety and animal welfare. Beyond these focused discussions, participants also tackled larger, industry-wide challenges such as sustainability, regulatory pressures, market access, and the need for innovation. A key point of focus was how different policies—from environmentally protective measures to more liberal market approaches—could influence the sector's growth and sustainability, either presenting opportunities or posing barriers.

The findings from these discussions served as the basis for developing position papers and policy briefs, which aim to guide future research and inform policy decisions. This poster summarizes the key takeaways from these events, focusing on the challenges identified, the policy recommendations proposed, and the strategies suggested to help the aquaculture sector grow in a sustainable and competitive way.

GRINNAQUA is co-funded by the European Union (GA 101079467) and the UK Research and Innovation (UKRI). Views and opinions expressed are however those of the authors only and do not necessarily reflect those of the European Union, the Research Executive Agency (REA) or the UKRI. Neither the European Union nor the granting authorities can be held responsible for them.

# GRINNAQUA PROJECT: BUILDING CAPACITY FOR A MORE SUSTAINABLE AQUACULTURE

* tania.pereira@ciimar.up.pt

The GRINNAQUA project, aligned with the EU's Farm-to-Fork Strategy, aims to strengthen CIIMAR's research capabilities and its leadership role in the aquaculture industry. In partnership with leading European institutions— Consejo Superior de Investigaciones Científicas (Spain), the University of Bergen (Norway), and the Roslin Institute at the University of Edinburgh (UK)—one of the project's focus is on enhancing expertise in fish health, genetics, and immunology.

A key part of GRINNAQUA's approach falls on its training program, designed to help early-career researchers and professionals to build the skills needed to address pressing challenges in aquaculture. Through a series of hands-on workshops and summer schools, participants have gained valuable insights into cutting-edge techniques and tools, particularly useful for the Aquatic Animal Health field. The learning materials developed during these events include:

- **Workshop 1:** *Theoretical-practical workshop about omics tools in aquaculture* – Led by the University of Edinburgh (UEDIN)
- **Workshop 2:** *Theoretical-practical workshop on fish vaccination* – Led by Consejo Superior de Investigaciones Científicas (CSIC)
- **Workshop 3:** *Theoretical-practical workshop on fish health and welfare in industrial aquaculture* – Led by the University of Bergen (UiB)
- **Summer School 1:** *Genomic and genetic tools for the blue revolution* – Led by UEDIN

These materials—such as presentations, practical guides, and interactive exercises—were designed for easy access and long-term use. They provide essential resources for both academic programs and professional development in the aquaculture sector.

This poster will highlight the key learning materials created throughout the project, showcasing how these resources support the ongoing development of aquaculture professionals and how these newfound skills can contribute to building a more sustainable and resilient aquaculture sector in Europe.

GRINNAQUA is co-funded by the European Union (GA 101079467) and the UK Research and Innovation (UKRI). # ELECTROCARDIOGRAPHIC ASSESSMENT OF ANAESTHESIA IN JUVENILE TAMBAQUI *Colossoma macropomum* USING MENTHOL

Brenda Maria Pereira Alho da Costa*[12], Moisés Hamoy[3], Luis André Luz Barbas[12]

[1]Postgraduate Program in Animal Science, Federal University of Pará, Castanhal, PA, Brazil

**Introduction**
In intensive aquaculture systems, fish are exposed to stressors that compromise welfare, and the use of anaesthetics is an effective strategy to reduce stress and preserve animal integrity (Abreu & Urbinati, 2009; Diniz & Honorato, 2012; Ross & Ross, 2008; De Souza et al., 2019). Synthetic compounds such as MS-222, benzocaine, and 2-phenoxyethanol present restrictions and adverse effects (Inoue et al., 2003; Sladky et al., 2001), encouraging the search for natural alternatives such as menthol ($C_{10}H_{20}O$), which is effective, accessible, and widely available (Façanha & Gomes, 2005). However, there is a lack of physiological data on its use (Cantanhêde et al., 2021; Da Costa et al., 2022), and electrocardiography (ECG) is an essential tool for assessing its safety (Ross & Ross, 2008; Da Fonseca et al., 2024). The tambaqui (*Colossoma macropomum*), the most farmed native species in Brazil (Valenti et al., 2021), requires such evaluations; therefore, this study investigated the effect of menthol (100 mg/L) on electrocardiographic activity to validate its safe use.

**Material and Methods**
Twenty-seven juvenile tambaqui (*Colossoma macropomum*) with a mean weight of 23.9 ± 4.2 g were distributed into three treatments: control, ethanol, and menthol 100 mg/L. Fish, sourced from a commercial farm, were acclimated for 30 days at LAET/IFPA – Campus Castanhal, in recirculating water systems with 250 L tanks, controlled photoperiod (12 h light/12 h dark), commercial feed (34% CP), and water quality maintained within recommended levels for the species. Fish were fasted for 24 h before trials. Menthol crystals (98% purity) were diluted in 70% ethanol at a 1:9 ratio, and the concentration of 100 mg/L was chosen based on previous studies indicating efficacy for the species (Cantanhêde et al., 2021; Da Costa et al., 2022). The experimental protocol was approved by the IFPA Animal Ethics and Welfare Committee (No. 4205150421).

ECG recordings followed methodologies from previous studies (Barbas et al., 2017; De Souza et al., 2019; Cantanhêde et al., 2021), using two stainless-steel electrodes positioned ventrally and below the pectoral fin, recording heart rate, QRS duration, and QT and RR intervals for 300 s during induction and recovery. Nine fish per treatment were analysed, each as an experimental unit. Signals were acquired by a high-impedance amplifier, filtered, amplified, and recorded on an oscilloscope inside a Faraday cage. Data normality and homogeneity were verified by Kolmogorov–Smirnov and Levene's tests and means compared using one-way ANOVA followed by Tukey's test, with significance set at $p < 0.05$.

**Results and Discussion**
During anaesthetic induction with menthol (100 mg/L), ECG recordings (Fig. 1) showed that in the first 120 s, heart rhythm and wave amplitudes remained stable and similar to controls ($P > 0.05$), maintaining a typical sinus rhythm. After this period, there was a progressive reduction in heart rate and signal intensity, although sinus rhythm was preserved.

In recovery (Fig. 2), initially low heart rate and amplitude were observed, with transient sinus arrhythmia, followed by a gradual increase in these parameters. However, the 5 min observation period was insufficient for full restoration of baseline cardiac activity. Quantitative analysis (Fig. 3) confirmed a marked decrease in heart rate and prolonged RR and QT intervals at the end of induction, along with partial reversal during recovery, with QRS returning to baseline and QT showing a reduction trend.

These findings are consistent with the expected depressant effect of anaesthetics on the central nervous system and cardiac conduction, as previously reported for compounds such as MS-222, propofol, thymol, and other essential oils (Barbas et al., 2017a; De Souza et al., 2019; Aydın & Orhan, 2021; Cantanhêde et al., 2021). Incomplete recovery within 5 min aligns with observations by Cantanhêde et al. (2021) for higher menthol concentrations. QT prolongation suggests slower ventricular repolarisation, possibly related to transient blockade of L-type calcium channels (Swandulla et al., 1987; Silva, 2020), a known effect in general anaesthesia (Wisely & Shipton, 2002), but reversible and without observed harmful consequences.

*(Continued on next page)*

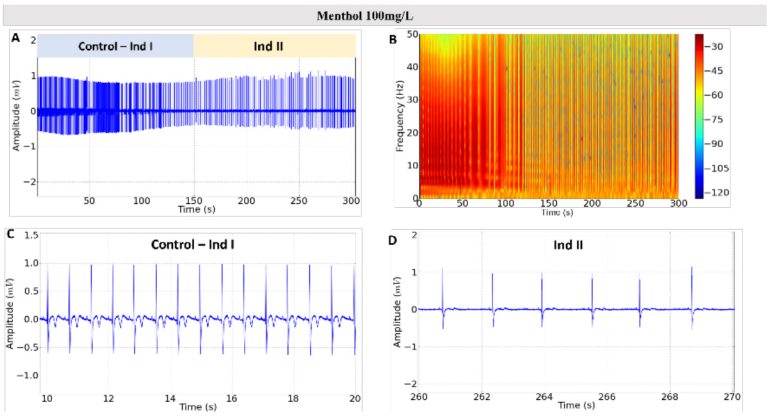

**Figure 1.** ECG of tambaqui (*Colossoma macropomum*) under menthol anaesthesia (100 mg/L): (A) 300 s induction with initial and final stages (Ind I, Ind II), (B) frequency spectrogram, (C) representative trace (Ind I), and (D) representative trace (Ind II).

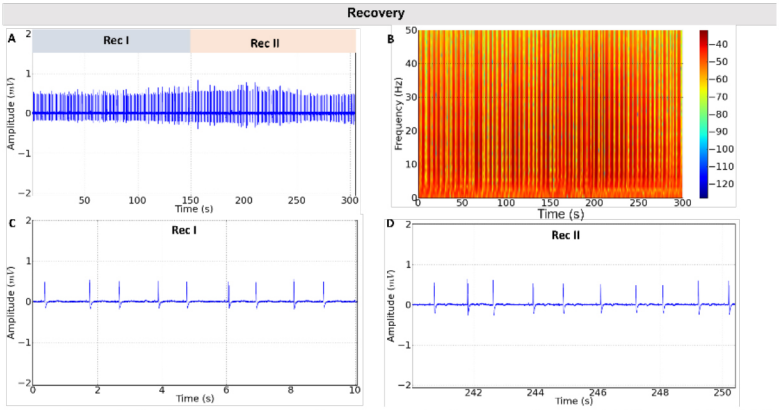

**Figure 2.** ECG of tambaqui during recovery from menthol anaesthesia (100 mg/L): (A) 300 s recording with initial (Rec I) and final (Rec II) stages, (B) frequency spectrogram, (C) 10 s trace at Rec I, and (D) 10 s trace at Rec II.

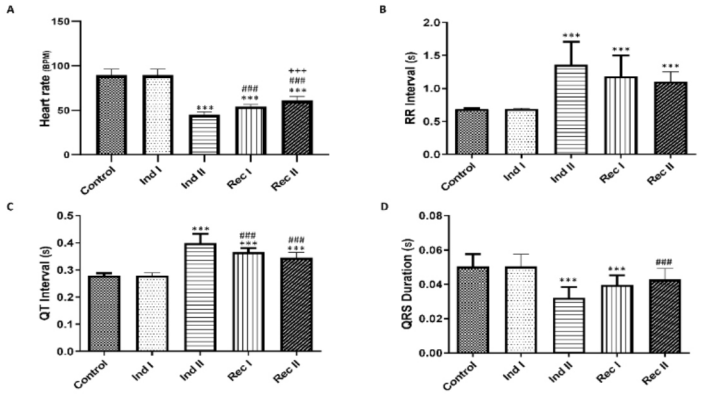

**Figure 3.** ECG parameters during induction and recovery from menthol anaesthesia (100 mg/L): (A) heart rate, (B) RR interval, (C) QT interval, and (D) QRS duration. Symbols indicate significant differences ($P < 0.05$).

## Conclusion

Menthol at 100 mg/L, for up to 5 min, proved effective and safe for juvenile tambaqui, inducing a reversible reduction in heart rate while preserving sinus rhythm and cardiac electrical function. These results indicate its suitability for invasive procedures with minimal risk to homeostasis, reinforcing ECG as a robust tool to validate the safety of anaesthetics in aquaculture.

**Introduction**

Infectious diseases represent a major challenge for aquaculture, leading to substantial economic losses and compromising fish welfare. Consequently, identifying viable and environmentally sustainable solutions is a key priority for the sector. Numerous efforts have been made and are continually being undertaken to develop efficient preventive and curative strategies to mitigate the impact of infectious diseases affecting fish while also seeking to avoid, or at least minimize, the use of antibiotics.

An effective approach for the implementation of selective breeding strategies or the development of novel preventive or control measures against infectious diseases involves deciphering the molecular differences between fish full-sibling families that exhibit differential degrees of resistance or susceptibility to a particular pathogen. In this regard, omics technologies, such as genomics, transcriptomics, and proteomics, have proven to be powerful tools to identify a wide range of molecular markers associated with disease resistance. However, the use of metabolomics for this purpose is not so widespread and, to the best of our knowledge, it has not previously been applied to compare the profiles of full-sibling fish families exhibiting different levels of susceptibility to a specific pathogen. This study aimed to identify metabolic markers associated with resistance to the bacterium *Aeromonas salmonicida* subsp. *salmonicida* in turbot (*Scophthalmus maximus*), with the ultimate goal of incorporating resistance-associated metabolites into functional diet formulations.

**Materials and methods**

Untargeted metabolomic analyses of the head kidney and liver from two full-sibling turbot families with differing susceptibility to the pathogen *A. salmonicida* subsp. *salmonicida* were conducted. Metabolites found in higher abundance in the resistant family were preliminarily screened in zebrafish (*Danio rerio*) larvae using an *A. hydrophila* infection model. Based on the promising results, two of these metabolites were incorporated into the diet at a concentration of 1.5% to further evaluate not only their protective effect in turbot against *A. salmonicida*, but also their palatability, impact on growth, and potential histopathological effects. In order to better understand the mechanisms underlying the protection induced by the resistance-associated metabolites, the modulation of the intestinal microbiota (via 16S rRNA amplicon sequencing) and transcriptomic changes (via RNA-Seq analysis) were assessed in response to the functional diet that demonstrated a significant protective effect.

**Results**

A comparative metabolomic analysis was conducted on two full-sibling turbot families with differing susceptibility to the pathogen, revealing a subset of metabolites with differential abundance in the head kidney and liver. Preliminary screening in zebrafish larvae identified 5-L-glutamyl-taurine as a promising protective compound. However, due to the high cost of this metabolite, its precursors—taurine and L-glutamic acid—were tested. Both showed protective effects in zebrafish larvae infected with *A. hydrophila*, leading to their selection for dietary trials in turbot. While dietary supplementation with L-glutamic acid did not significantly affect survival, the taurine-enriched diet significantly improved survival in turbot challenged with *A. salmonicida*, resulting in a 34% higher survival rate compared to controls, despite increased bacterial loads observed at 24 hours post-infection (hpi). Moreover, taurine supplementation had no negative effects on the evaluated parameters.

*(Continued on next page)*

Taurine also modulated the intestinal microbiota, reducing alpha diversity through the expansion of *Vibrionaceae* and *Marinobacteraceae*. RNA-Seq analysis of head kidney and intestinal tissues suggested that taurine's protective effect may involve attenuation of the early inflammatory response, potentially minimizing tissue damage. These changes emphasize the complex interplay between diet, immune response, and microbial communities. Overall, this study highlights taurine's potential as a functional dietary additive to enhance disease resistance in aquaculture, while underscoring the value of immunometabolism research in developing strategies to combat infectious diseases.

# THE REGULATION OF REDOX BALANCE UNDERLIES A CONSERVED ANTIVIRAL RESPONSE TO RNA VIRUSES IN FISH

Alejandro Romero, Beatriz Novoa, Antonio Figueras, Patricia Pereiro*

Instituto de Investigaciones Marinas (CSIC)
Eduardo Cabello 6, 36208, Vigo, Spain

**Introduction**
Reactive oxygen species (ROS) are byproducts of normal metabolism and play dual roles as both signaling molecules and mediators of oxidative stress. In fish, ROS are generated endogenously, mainly by mitochondria and NADPH oxidases, and influenced by environmental stressors such as pollutants, temperature shifts, and hypoxia. A sophisticated antioxidant system maintains redox homeostasis in fish. Viral infections can disrupt this balance, enhancing ROS production or impairing antioxidant defenses, with consequences ranging from antiviral signaling activation to facilitation of viral replication. The outcome depends on the virus, host, and infection stage. In turbot aquaculture, three major RNA viruses, viral hemorrhagic septicemia virus (VHSV), infectious pancreatic necrosis virus (IPNV), and red-spotted grouper nervous necrosis virus (RGNNV), cause high mortality, economic losses, and lack broadly effective treatments.

**Objective**
Identify conserved host responses in turbot to these three RNA viruses.

**Materials and Methods**
Turbot (*Scophthalmus maximus*) were experimentally infected with VHSV, IPNV, or RGNNV under standardized conditions. At 3 days post-infection, tissues were collected for label-free quantitative proteomics to identify differentially abundant proteins and define common antiviral response against all viruses. Functional assays using head kidney–derived leukocytes were conducted to assess ROS production by macrophages following viral challenge. Pharmacological inhibitors of NADPH oxidase and mitochondrial ROS were applied to evaluate their impact on viral replication in vitro.

**Results**
Mass spectrometry identified 4,499 proteins, with virus-specific sets of differentially expressed proteins (DEPs) in kidney and brain. Only neutrophil cytosol factor 4 (Ncf4) was common to all kidney infections. VHSV predominantly downregulated mitochondrial electron transport chain (ETC) components and the antioxidant superoxide dismutase 2 (Sod2); IPNV caused fewer changes, with modest immune protein modulation; RGNNV triggered the most extensive proteomic shifts, notably upregulating proteins linked to cytoskeleton, translation, metabolism, and ROS detoxification.

Across viruses, mitochondrial and cytoplasmic ROS-related proteins were altered, with VHSV generally reducing and RGNNV increasing their abundance; IPNV changes were milder. Gene expression analyses confirmed virus-specific temporal patterns in ROS-related genes. In vitro, all viruses tended to increase basal ROS production, with varying effects on PMA-induced ROS; in vivo, only VHSV significantly increased ROS in head kidney leukocytes.

Flow cytometry showed virus-dependent modulation of mitochondrial ROS (mitROS), particularly by RGNNV and IPNV. The release of neutrophil extracellular traps (NETs) was enhanced by some infections and interferon (IFN) stimulation, but reduced by IPNV in vivo and RGNNV in vitro. Pharmacological inhibition of ROS affected viral replication in a virus- and inhibitor-dependent manner, confirming ROS as a functional antiviral component.

**Conclusions**
Comparative proteomics of infected turbot revealed a conserved antiviral mechanism centered on ROS production and redox homeostasis.

*(Continued on next page)*

Mitochondrial and cytoplasmic ROS pathways are differentially modulated by each virus, with VHSV generally suppressing and RGNNV enhancing ROS-related proteins.

Pharmacological inhibition of NADPH oxidase– or mitochondria-derived ROS alters viral replication, confirming a direct antiviral role for ROS.

Findings provide a molecular basis for designing broad-spectrum antiviral strategies in aquaculture, including antioxidant-based adjuvants or immune modulators.

# EFFECTS OF FISH PROTEIN HYDROLYSATE FROM DISCARDED BLUE WHITING (*Micromesistius poutassou*) ON TURBOT (*Scophthalmus maximus*) GROWTH AND FEED INTAKE

## Introduction

One of the key challenges in making fish farming more sustainable is replacing fishmeal with alternative ingredients. While plant-based substitutes have been explored, they often fall short due to poor digestibility and amino acid imbalances that hinder fish growth (Hussain et al., 2024). Fish protein hydrolysates (FPH) offer a promising alternative, as their rich amino acid and bioactive peptide content improves growth and feed efficiency (Siddik et al., 2021). In Galicia, Northwest Spain, the fishing industry generates large volumes of discards that can be repurposed into FPH: a cleaner, more sustainable option than traditional fishmeal. This process not only reduces environmental impact but also yields valuable compounds such as proteins, oils, and minerals.

Blue whiting (*Micromesistius poutassou*), a commonly discarded species, has shown potential as raw material for FPH (Vázquez et al., 2024). Based on a previous work (Comesaña et al., unpublished), low molecular weight FPH from blue whiting (LBW FPH) produced comparable results to a commercial diet in turbot (*Scophthalmus maximus*)—a flatfish predominantly farmed in Galicia, Northwest Spain—regardless of the inclusion level (5, 10 and 15%), making it a viable alternative for replacing traditional fishmeal. Given the absence of adverse effects, the present research explores higher inclusion levels, completely replacing fishmeal. Over a three-month period, the effects of replacing fishmeal with 15 and 30% LBW FPH will be evaluated, focusing on growth performance. This approach supports circular and local economy principles and aims to enhance the sustainability and efficiency of turbot aquaculture.

## Materials and methods

Juvenile turbots (*Scophthalmus maximus*) were obtained from a local hatchery (Insuíña S.L., Oia, Pontevedra, Galicia, Spain) and transported to the facilities of the Oceanographic Center of Vigo. Experimental turbots (18.4 ± 0.18 g) were distributed into 9 tanks of 100 L each (n = 60 fish/tank). They were kept under natural photoperiod and a constant temperature of 16ºC. After an acclimation period, the feeding trial began and lasted for 3 months. Fish were fed ad libitum twice a day (9 am and 4 pm) up to a maximum of 3% of their body weight daily. Three different diets were used and tested in triplicate: i) Control with 30% fishmeal + 0% LBW FPH (LBW0), ii) 15% fishmeal + 15% LBW FPH (LBW15), and iii) 0% fishmeal + 30% LBW FPH (LBW30). The following zootechnical parameters were evaluated: daily feed intake, initial and final weight and total length, and liver weight. From these data, weight gain, specific growth rate (SGR), feed conversion ratio (FCR), condition factor, and hepatosomatic index (HSI) were calculated.

*(Continued on next page)*

**Table 1.** Growth performance, feed utilization, and biometric indices of juvenile turbot fed with control diet (LBW0) and LBW15 and LBW30 diets containing 15% and 30% respectively, of low molecular weight FPH of blue whiting.

| | LBW0 | LBW15 | LBW30 |
|---|---|---|---|
| **Growth performance** | | | |
| Inicial weight (g) | 18.5 ± 0.4 | 18.4 ± 0.1 | 18.5 ± 0.3 |
| Final weight (g) | 68.6 ± 2.0 a | 63.9 ± 0.7 ab | 57.4 ± 3.2 b |
| Weight gain (g) | 50.1 ± 1.7 a | 45.5 ± 0.5 ab | 38.9 ± 3.1 b |
| SGR, specific growth rate (%/day) | 1.45 ± 0.02 a | 1.38 ± 0.01 ab | 1.26 ± 0.06 b |
| **Feed utilization** | | | |
| Feed intake (% body weight/day) | 2.13 ± 0.12 | 2.45 ± 0.08 | 2.42 ± 0.04 |
| FCR, feed conversion ratio | 1.24 ± 0.11 | 1.78 ± 0.11 | 1.93 ± 0.13 |
| **Biometric indices** | | | |
| Condition factor, K | 2.02 ± 0.04 | 2.09 ± 0.02 | 2.18 ± 0.06 |
| HSI, hepatosomatic index (%) | 1.19 ± 0.04 a | 1.33 ± 0.01 ab | 1.52 ± 0.10 b |

The values are expressed as mean ± SEM of triplicate groups (n = 3). Data were analysed using one-way ANOVA and different letter indicates significant differences between diets ($p<0.05$).

## Results and discussion

Juvenile turbot fed with a diet in which fishmeal was completely replaced by LBW FPH (LBW30) exhibited reduced growth performance compared to control (LBW0), as evidenced by lower final weight, weight gain and SGR. No significant differences were observed in feed intake, FCR or condition factor. Moreover, HSI was significantly higher in fish fed the LBW30 diet compared to LBW0.

These findings suggest that full substitution of fishmeal with the LBW FPH may negatively affect growth in juvenile turbot. Further studies would be required to understand the physiological mechanisms behind the increased HSI and reduced growth, and to assess the broader implications of using this diet. In contrast, partial replacement (LBW15) showed comparable results to the control, indicating its potential as a sustainable alternative that could valorize previously discarded products and contribute to more environmentally friendly aquaculture practices.

# ANTIMICROBIAL STAINLESS-STEEL SURFACES FOR CONTROLLING *Pseudomonas* spp GROWTH IN FISH-PROCESSING FACILITIES

E. Pérez-Esteve*, O. Moumane, A. Rivas Soler, J.M. Barat Baviera, I. Fernández-Segovia

Instituto Universitario de Ingeniería de Alimentos – FoodUPV
Universitat Politècnica de València
Camino de Vera s/n, 46022, Valencia
E-mail: edpees@upv.es

## Introduction

The proliferation of *Pseudomonas* species presents a significant challenge in the fish industry, as these bacteria are among the most common spoilage organisms in refrigerated fish products. Capable of thriving at low temperatures, *Pseudomonas* produce enzymes that break down proteins and lipids, resulting in unpleasant odors, texture deterioration, and a markedly reduced shelf life (Ben Mhenni et al., 2023). Their presence not only compromises the sensory quality of fish but also raises serious concerns regarding food safety and economic losses. Therefore, in addition to conventional measures such as strict hygiene protocols, temperature control, and appropriate packaging, innovative strategies are needed to curb *Pseudomonas* growth. One promising approach is the functionalisation of stainless-steel surfaces with compounds that exhibit antimicrobial properties, which could serve as an effective barrier to bacterial contamination along the processing chain. The aim of this work was to study the antimicrobial effect of thymol and eugenol functionalised on stainless-steel plates.

## Materials and methods

In this study, 316L stainless-steel plates treated and functionalised with thymol and eugenol were prepared. These surfaces were evaluated against *E. coli* K12 CECT 433, a reference bacterium, as well as *Pseudomonas aeruginosa* CECT 108, a key bacteria in the seafood industry. A susceptibility test, using the microdilution method, of the studied strains against two essential oil compounds (EOCs), eugenol and thymol, in their free form was first performed to obtain the minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of both EOCs against both strains.

Functionalised plates were qualitatively characterised with Orange II and quantitatively using energy-dispersive X-ray spectroscopy (EDS) coupled to Field Emission Scanning Electron Microscope (FESEM) to confirm the proper anchoring of the compounds.

The antimicrobial activity of functionalised stainless-steel surfaces was evaluated by applying a bacterial inoculum ($10^5$ CFU/mL) on the surfaces. After 5 h of incubation at 30 °C, the microorganisms were recovered and quantified on TSA Petri dishes to determine microbial reduction.

## Results

*P. aeruginosa* was shown to be more resistant than *E. coli* K12 for both compounds, with a MIC of 2 mg/mL for eugenol and 0.5 mg/mL for thymol, while for *E. coli* K12 these values were 0.5 mg/mL and 0.25 mg/mL, respectively.

Orange II and FESEM results confirmed the functionalisation of the steel surfaces with the EOCs.

Furthermore, results showed that functionalised plates were able to reduce the microbial load by up to 4.5 log for *E. coli* K12 for both, thymol and eugenol. *P. aeruginosa* microbial load was reduced by 2.3 log on plates coated with thymol, but no significant reduction was observed with eugenol at our working concentration, due to the high MIC.

## Conclusion

The functionalisation of stainless-steel surfaces with thymol or eugenol has demonstrated high antimicrobial potential, which could contribute to improving food safety in fish processing plants.

# TOWARDS FULL GENOMIC REPRESENTATION OF THE BONY FISH PHYLOGENY

Noelia Pérez-Pereira*[1], Carmen Bouza[1], Paulino Martínez[1], Diego Robledo[1,2]

[1]Department of Genetics, University of Santiago de Compostela, Santiago de Compostela 15706, Spain
[2]The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh Easter Bush, EH25 9RG, Midlothian, United Kingdom
Email: noelia.perez.pereira@usc.es

## Introduction

Bony fish are an extremely diverse group in terms of morphology, evolutionary history and taxonomy, comprising more than 95% of all living fish and half of all known vertebrates. Additionally, this group comprises an important number of highly valuable species for global aquaculture and fisheries. Consequently, bony fish have been the subject of intensive research in multiple fields, including ecology, evolutionary biology, and fish production. The development of genomic sequencing technologies has enabled comparative studies within the group, providing powerful insights into the genetic basis of local adaptation, genome evolution, and the genetic architecture of production traits, knowledge needed for the sustainable management of farmed and wild genetic resources. However, in-depth biological and evolutionary studies require suitable genome assemblies to be available across multiple species and taxonomic groups. Here we provide a snapshot of the genomic resources currently available in the public databases, with a special focus on existing gaps throughout the fish phylogeny.

## Material and methods

The NCBI and Ensembl databases were scanned to record all bony fish species with available genomic data. Information on all available raw sequencing data was also retrieved from the Sequence Read Archive (SRA). Both the nomenclature and the taxonomic classification were taken from the NCBI, and the fish phylogeny by Betancur-R et al. (2017) was taken as reference of the phylogenetic relationships among taxa. The total number of recognized bony fish species was obtained from the Catalogue of Life.

## Results

Genome assemblies were found for a total of 1,744 bony fish species, mostly released in the last five years. Gene annotation has also experienced a boost, although only 16.49% of the current genomes are annotated. At the organism level, species of high commercial value in aquaculture, fisheries and sport fishing, were found to be particularly enriched with genomic data. Despite the accelerated rate of genome sequencing, the number of available genomes still represents only 5.36% of all recognized bony fish species. Nevertheless, they are well distributed throughout most of the bony fish phylogeny, with 93.05% of orders and 52.14% of families being represented. The five orders containing the largest number of assembled genomes are Cichliformes, Perciformes, Siluriformes, Cypriniformes and Cyprinodontiformes, where some of the species with the highest aquaculture production can be found, such as carp, catfish, perch and grouper. However, a fraction of the phylogenetic tree remains unrepresented, particularly within the Percomorpha clade. Despite the lack of fully assembled genomes, 19 out of the 20 gaps have associated high-throughput sequencing data in the SRA repository, so these gaps should not remain for too long.

## Conclusion

We are witnessing a genomic revolution, with exceptional efforts being dedicated to fish genomic resources in both commercial and non-commercial sectors. New sequencing efforts encompassing the full fish phylogeny, fuelled by the constant development of sequencing and assembly technologies, will provide an unprecedented array of genomic resources that can be used to address outstanding biological and evolutionary questions in bony fish.

## Introduction

The Pacific oyster *(Magallana gigas)*, introduced to New Zealand in the 1950s, is central to a major aquaculture industry producing nearly 2,000 tonnes annually. After a decline due to the OsHV-1 µvar virus outbreak in 2010, the industry has been recovering, aided by selective breeding. Growth rate variability among individuals offers both challenges and opportunities for optimization, driven by physiological and genetic factors. Studies have linked growth differences to food acquisition, metabolic costs, and gill morphology—especially surface area and ciliary structure.

In mussels, fast growers have denser ciliary networks and larger gills, while slow growers exhibit elevated antioxidant activity, potentially signalling higher oxidative stress (Pérez-Cebrecos et al., 2022). Immune function is influenced by haemocytes, which are involved in immune defence and other functions like shell formation. Gene expression studies suggest that slow growers may have immune inefficiencies, affecting overall fitness (Prieto et al., 2019). Reproductive energy demands can also influence growth. Triploid oysters, which allocate more energy to somatic growth, provide a model for investigating these trade-offs. Previous field studies suggest that growth-rate phenotypes in triploids correlate with reduced reproductive investment, leading to more efficient somatic growth.

This study investigates the physiological, histological, and immunological aspects of growth variation in M. gigas, exploring how triploidy influences growth, immune function, and oxidative stress. By examining these factors, the study aims to inform selective breeding strategies and improve oyster aquaculture sustainability.

## Materials and Methods

Triploid and diploid *M. gigas* oysters were produced from a biparental cross and reared under identical hatchery conditions. Growth phenotypes were classified into fast and slow growers within each ploidy group. Standard physiological measurements (clearance, ingestion, absorption, and respiration rates) were used to calculate scope for growth. Flow cytometry was applied to assess haemocyte activity, ROS production, and viability. Gill and digestive gland tissues were analysed for antioxidant enzyme activity (SOD, CAT), histopathology, and structural indices. Gametogenic stage was also evaluated histologically. All measurements were size-standardized and statistically analysed to test for effects of ploidy and growth phenotype.

## Results

Fast-growing oysters were 51% heavier and 87% larger than slow growers in both diploid and triploid groups. Clearance rates (CR) were 23% higher in fast growers ($3.60 \pm 0.86$ $L \cdot h^{-1} \cdot g^{-1}$) compared to slow growers ($2.76 \pm 0.48$ $L \cdot h^{-1} \cdot g^{-1}$), while absorption efficiency (AE) was 11% higher in slow-growing oysters ($0.74 \pm 0.06$) compared to fast-growing oysters ($0.66 \pm 0.15$). Scope for growth (SFG) was 37% higher in triploid oysters ($153.06 \pm 47.33$ $J \cdot h^{-1}$) compared to diploids ($96.05 \pm 48.56$ $J \cdot h^{-1}$), with fast growers showing a 51% higher SFG ($166.73 \pm 73.58$ $J \cdot h^{-1}$) than slow growers ($82.38 \pm 22.31$ $J \cdot h^{-1}$). In immune responses, fast-growing diploid oysters exhibited 62% higher reactive oxygen species (ROS) production compared to triploid fast growers, with significant reductions in immune cell viability, especially in slow-growing triploids.

*(Continued on next page)*

Catalase activity in the gills of triploid oysters (127.78 ± 9.88 μmol·min$^{-1}$·mg protein$^{-1}$) was 30% higher than in diploid oysters (89.80 ± 6.05 μmol·min$^{-1}$·mg protein$^{-1}$), while superoxide dismutase activity was 15% higher in fast-growing oysters (14.87 ± 1.75 U·min$^{-1}$·mg protein$^{-1}$) compared to slow-growing oysters (12.67 ± 2.03 U·min$^{-1}$·mg protein$^{-1}$).

Histopathological analysis revealed a higher prevalence of rickettsia-like organisms in triploid fast growers (0.88) compared to diploid fast growers (0.10). Slow growers exhibited a significantly lower gill structure index (0.66 ± 0.24) compared to fast growers (1.25 ± 0.23), and triploid oysters were more advanced in gamete development stages. Shell organic content was 27% higher in fast growers (15.31 ± 3.83) compared to slow growers (11.25 ± 3.05), while the shell-to-live weight ratio was 10% heavier in fast growers (0.48 ± 0.02) than slow growers (0.44 ± 0.05).

Discussion

Despite being from the same family and raised under identical conditions, fast-growing oysters were 52% heavier than slow growers, underscoring the importance of physiological traits in growth performance and aquaculture optimization.

Fast growers exhibited higher feeding rates without increased metabolic costs, suggesting enhanced metabolic efficiency, which supports their superior growth. This finding aligns with previous research showing that increased ingestion rates do not always correlate with higher metabolic costs (Babarro et al., 2000). Fast-growing oysters also had superior gill structure, a crucial factor in filtration efficiency. Their enhanced gill morphology likely supports their higher clearance rates and growth potential. In contrast, slow growers showed smaller, less viable haemocytes, and elevated ROS production, indicating compromised immune function and higher oxidative stress. This likely contributes to their lower SFG and reduced metabolic efficiency. The presence of basal cells in slow growers may reflect an increased immune turnover to compensate for the reduced viability of haemocytes.

Interestingly, triploid slow growers showed some compensatory advantages, with better gill structure and higher catalase activity than diploid slow growers. This suggests that triploids may invest more in antioxidant defences and somatic growth rather than reproduction. The higher organic shell content in slow-growing triploids, compared to diploid slow growers, further indicates a trade-off between growth and biomechanical protection. These oysters may allocate more energy to shell strengthening, enhancing resilience at the cost of slower growth.

Overall, the study demonstrates the complex trade-offs between growth, immune function, and oxidative stress. Fast-growing oysters exhibit superior growth, metabolic efficiency, and immune function, while slow growers are hampered by immune dysfunction and oxidative stress. Triploid oysters offer some advantages in immune defence. These findings emphasize the need to consider both physiological and immunological factors in aquaculture management and breeding programs aimed at optimizing oyster performance.

## Introduction

Fish farming requires a high supply of protein, ranging from 50 – 65% in weight of the diet for larval rearing, decreasing down to 45% for juvenile and adult individuals. The main source is fish meal, mainly obtained from herring, anchovy, and other lean fish species. The increasing demand of fish meal for aquaculture and pork farming has increased the prices of fish meal and oil. In this context, the formulation of novel aquaculture ingredients based on alternative proteins (e.g. insect, plant, biomass) has attached increasing interest over the past decade. Edible insects present variable protein content ranging from 40 – 65% of their dry weight and an amino acid composition equivalent to fish meal. Insect rearing is sustainable and economically feasible, due to their high feed-to-protein conversion rates. Zootechnical feeding trials are required to evaluate the effect of new dietary proteins on fish growth and survival, but they are expensive, time consuming and require high amounts of the dietary components. As an alternative, *in vitro* methods simulate the digestion of aquafeeds at lab scale, employing natural enzymes directly extracted from the aquatic species. Although they cannot fully reproduce the physiology of the fish digestive system, they can be easily implemented and are useful to evaluate the bioaccessibility of aquafeed ingredients.

The aim of this work is to evaluate the in vitro digestibility of different protein sources from insect (*Tenebrio molitor*) defatted meal, sunflower (*Helianthus annuus*) seed meal and microalgae (*Nannochlorosis gaditana*) powdered meals employing an INFOGEST protocol adapted for European seabass (*Dicentrarchus labrax*) as reference aquaculture species. The protein source showing the highest digestibility was then tested as protein ingredient in a commercial fish meal-based diet.

## Materials and Methods

Enzyme extracts were recovered from seabass stomach, intestin and caeca pylori after grinding and homogenization at 4ºC with 1:5 water for 2 h. The aqueous extracts were centrifuged and vacuum filtered, recovering the supernatants for determination of pepsin and trypsin activity. Firstly, protein suspensions from insect, sunflower and microalgae were prepared at 1.8 g of protein·100 mL-1 and heated at 85ºC for 15 min to inactivate endogenous enzymes. These suspensions were subjected to simulated digestion in a 200-mL jacketed rector. The digestion comprised two sequential stages—stomach and intestinal phase— of 2 h, both conducted at 25ºC and pH 2 and 8, respectively. The dried stomach and intestine extracts were added at 20 U of pepsin activity·mg-1 protein and 2 U of trypsin activity·mg-1. The extent of the digestion was evaluated by the pH stat method, using an automatic titration system (Metrohm, Switzerland). The protein source showing the highest digestibility (i.e. attaining the highest degree of hydrolysis after completing 4 h of digestion) was then tested as protein replacement in a commercial fish meal-based diet for European seabass (*Dicentrarchus labrax*). To this end, different levels of fish meal protein were substituted by the alternative protein partially hydrolysed (15% w/w of hydrolysate). Enzymatic hydrolysates were prepared from sustainable protein materials employing a mixture 1:1 of Alcalase and PTN at pH 8, 50ºC and enzyme-to-substrate ratio 3%. Response Surface Methodology was employed to optimize the formulation of the experimental meals, varying protein substitution (25, 50 and 75% w/w), and degree of hydrolysis (DH 10, 15 and 20%) through a factorial 3 x 3 design. The protein digestibility of the formulated diets was evaluated by the final degree of proteolysis attained after simulated digestion, which was estimated by the o-phthalaldehyde (OPA) spectrophotometric assay.

*(Continued on next page)*

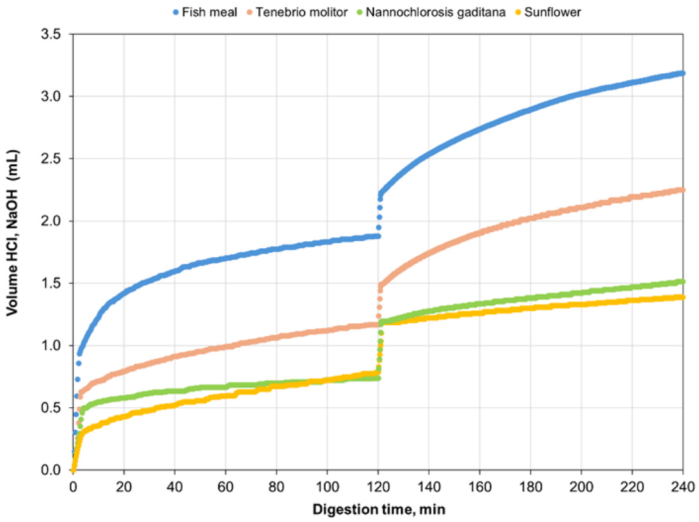

**Figure 1.** Digestion curves of the protein substrates with stomach extract (pH 2, 2 h) and intestine extract (pH 8, 2 h) from European seabass (*Dicentrarchus labrax*).

## Results

Fish meal presents the highest digestibility among the proteins assayed, followed by the insect protein from *Tenebrio molitor*, while sunflower seeds and microalgae were poorly digested. This was attributed to the presence of fibre and other insoluble impurities in the sunflower meal, or the resistance of microalgae membranes against enzyme attack. The digestibility of insect protein was then improved by the inclusion at 15% w/w of its protein hydrolysates. Supplementation of aquafeeds with enzyme hydrolysates improves their digestibility, as well as providing peptides and free amino acids with potential biological activities. A set of experimental diets containing *T. molitor* protein as replacement source were then formulated and subjected to in vitro digestion with European seabass enzymatic extracts. The maximal *in vitro* digestibility was observed for the experimental diet with 25% w/w of insect protein containing 15% w/w of enzymatic hydrolysate at DH 10%. After in vitro digestion, this formulation presented a final degree of hydrolysis of 13.4% (OPA), very similar to that of fish meal (14.2%).

## Conclusion

Insect protein can be used as protein ingredient to replace fish meal in aquaculture diets. Its digestibility can be further improved by partial hydrolysis of the insect meal, as confirmed by the INFOGEST assay adapted for European seabass. The degree of hydrolysis achieved after simulated digestion, which can be determined by the pH stat method or spectrophotometrically, can be used as index to evaluate protein digestibility.

# ENZYMATIC HYDROLYSIS AND MEMBRANE FRACTIONATION OF SKIPJACK TUNA BY-PRODUCTS TO OBTAIN FUNCTIONAL INGREDIENTS FOR AQUAFEEDS

R. Pérez Gálvez*, F.J. Espejo-Carpio, P.J. García-Moreno, A. Guadix, E.M. Guadix

## Introduction

Aquaculture industry faces increasing pressure to develop sustainable alternatives to fish meal, driven by the sharp increase in costs and decline in captures of some species intended for fish meal production (i.e. herring, anchovy). In Spain alone, aquafeed consumption reached 181,000 tonnes in 2023, with fish meal as main ingredient (86% w/w of fish meal production is intended for aquafeed).

In this context, by-products from fish industry represent a cost-effective and sustainable feed source. In the case of tuna canning industry, by-products can account for 60-70% of the weight of the processed fish. Heads are the main by-products resulting from tuna canning industry. They present on average 15% w/w proteins, 13.5% w/w lipids, and significant amounts of minerals which makes them suitable for their conversion into aquafeed ingredients. However, their inclusion in aquafeeds is restricted by their poor solubility and digestibility in larvae and juveniles. Digestibility can be improved by the inclusion of variable levels of fish protein hydrolysates. They not only improve the solubility, digestibility and palatability of the aquafeed, but also can display biological activities such as antimicrobial, anti-inflammatory or antioxidant, among others. The supplementation of aquafeeds with antioxidant peptides has a double purpose: (i) extend the self-life of aquafeeds, restraining oxidation of lipid ingredients (ii) help mitigate the oxidative stress generated by the environmental conditions of aquaculture systems.

This study aims to obtain antioxidant peptide fractions from Skipjack tuna (*Katsuwonus pelamis*) heads with application as functional ingredients in aquafeeds. Tuna heads were hydrolysed in an enzymatic reactor and fractionated by sequential ultrafiltration with ceramic membranes of 1, 3, and 8 kDa molecular weight cut-offs. The resulting fractions were tested for their *in vitro* antioxidant activity (i.e. DPPH radical scavenging and ferrous ion chelation). This procedure allows producing peptide fractions with antioxidant activity, which can be incorporated as natural antioxidants into aquafeed diets.

## Materials and Methods

Skipjack tuna (*Katsuwonus pelamis*) heads were obtained from a local canning factory, presenting 38.4% w/w of protein, 9.6% w/w of lipid and 11.5% w/w of mineral matter. The homogenized suspension was fed into an enzymatic reactor, employing two commercial proteases: Alcalase® and Flavourzyme® (Novozymes, Denmark) at pH 7.5, 55ºC and enzyme-to-substrate ratio of 3% w/w.

Tuna head hydrolysates were fractionated employing 3 ceramic ultrafiltration membranes (Tami, Nyons, France) of molecular weight cutoffs (MWCO) 8 kDa, 3 kDa, and 1 kDa, arranged into two sequential configurations (Figure 1). Every membrane unit operated at volume concentration factor of 1.6, crossflow velocity 3.3 $m \cdot s^{-1}$ and 1 bar of transmembrane pressure. Both permeate and retentate fractions were analysed for their soluble protein content and molecular weight (MW) distribution by Size Exclusion Chromatography. Two *in vitro* activities —DPPH radical scavenging and ferrous chelating activity— were determined on the peptide fractions.

## Results

A protein hydrolysate with degree of hydrolysis 18.5% was obtained after 4-h treatment with Alcalase and 1 h of combined proteolysis with Alcalase and Flavourzyme. The resulting hydrolysate was centrifuged to remove insoluble residues. The supernatant was submitted to membrane fractionation, following two separation sequences as shown in Figure 1. The MW distribution revealed that the final permeates F8F1 and F3F1 presented significant proportion of peptide species within the range 0.3–3 kDa, as well as 16% w/w of free amino acids. Their peptide profiles make them suitable for aquafeed formulation.

*(Continued on next page)*

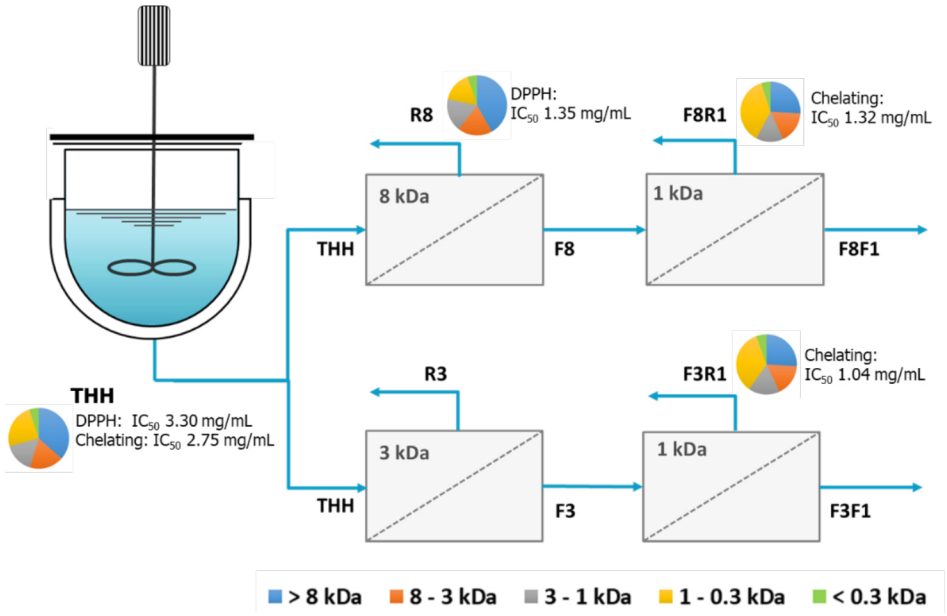

**Figure 1.** Layout of the enzyme hydrolysis and membrane fractionation sequence, showing the MW distribution and *in vitro* antioxidant activities of the peptide fractions.

DPPH radical scavenging and ferrous ion chelation of the tuna head hydrolysate ($IC_{50}$ = 3.30 mg·mL$^{-1}$ and 2.75 mg·mL$^{-1}$, respectively) were significantly improved by membrane fractionation. For instance, metal chelating activity was significantly favoured by the content of low MW peptides, as evidenced by the bioactivity displayed by the final membrane streams F8R1 and F3R1 ($IC_{50}$ = 1.04 and 1.32 mg·mL$^{-1}$, respectively).

## Conclusion

The integrated process proposed in this work allows the valorisation of tuna canning by-products to obtain membrane fractions rich in low MW peptides and free amino acids, as well as displaying antioxidant activities *in vitro*. These fractions could be used as functional ingredients in aquafeed formulation. Future research should focus on their validation through zootechnical experimentation.

# LOOKING FOR OYSTERS FROM THE SKY

Sara Pérez-Polo*[1], Daniel Jubera Piñero[2], Víctor Navarro Zurriaga[2], José Manuel Fernández Babarro[1] and Laura G. Peteiro[1].

[1]Instituto de Investigaciones Marinas (IIM), CSIC. Vigo, Spain

## Introduction

The Pacific oyster, *Magallana gigas*, has established stable populations in over 30 countries, becoming invasive in several of them due to its ecological impact (1). In Spain, specifically in Galicia, it was introduced in the 1980s and has since expanded southward, displacing native species (2). Despite its continued spread, no comprehensive monitoring efforts have been conducted since 2009. This lack of up-to-date data is concerning, especially in light of projected environmental changes that are likely to favor further expansion of this non-native species. Therefore, implementing an effective and continuous monitoring strategy is essential for understanding and managing its distribution. Long-term monitoring of this species is challenging in coastal areas, particularly in intertidal and shallow zones, due to the vast spatial extent, limited accessibility, and high resolution required, among other factors. In this work an approach to address such problems is presented through the use of UAVs (Unmanned Aerial Vehicles) and automated image analysis.

## Material and methods

Ten surveys at representative locations of the central and edge distribution of the Pacific oyster were selected at each of the 9 northern Rías in Galicia (Spain) where *M. gigas* is already naturalized (Ribadeo, Foz, Viveiro, O Barqueiro, Ortigueira, Cedeira, Ferrol, Ares-Betanzos and A Coruña). In each survey, a drone flew over the intertidal zone during the low-tide at a constant altitude of 16 m with a payload composed of an RGB and a multispectral camera to collect images with a maximum resolution of 0,3 cm/pixel. Ground-truth samples were also collected by placing 10-15 quadrats (20 x 20 cm). For each quadrat, GPS coordinates and digital photographs were taken.

High-resolution orthorectified mosaics for the RGB and Multispectral images, as well as Digital Elevation Models (DEMs) were generated with the Agisoft PhotoScan Pro software. Supervised machine learning algorithms were trained based on the annotations made by an expert on the orthomosaics, identifying the objective species. Different deep learning models and techniques were tested to select the one which offers better classification metrics. To assess temporal changes, five of the original sites were re-surveyed one year later, in order to evaluate the algorithm's ability to detect expansion or contraction in oyster coverage over time.

Image 1. Example of oyster segmentation. From left to right: 1. Real image, where green marks indicate correct recognition by the model and red marks indicate false positives. 2. Segmentation mask created by specialists. 3. Segmentation mask generated by the model.

*(Continued on next page)*

## Results

The best performing model achieved an accuracy exceeding 90 % for the identification of oysters on both training and test sets created from the original orthomosaics (Image 1). The confusion matrix shows a good trade-off between false positives and false negatives. Furthermore, the comparison of the obtained metrics for different locations and substrates does not show relevant differences, indicating good classification success both in rocky and muddy areas. These classifications were subsequently used to estimate oyster coverage, where we find areas with coverage ranging from 5% to 90% throughout northern Galicia, which matches the expected results after the visual assessment of the locations.

## Discussion

The study combines a series of emerging techniques to complete gaps on population dynamics (AUVs for mapping distribution and numerical modelling), integrate available multidisciplinary information in a common framework (GIS) and deliver a toolbox to assist decision-makers on the management of a non-indigenous species. Results provide new and significant insights to understand the expansion pathways of pacific oysters from a multidisciplinary approach.

This methodology not only evidences the viability of efficient long-term monitoring of *M. gigas*, but also offers a promising tool for tracking other ecologically relevant or conservation-priority species and sets the basis for the implementation of connectivity information and graph theory on the management of sedentary resources, and particularly in the assignment of spatially explicit invasion risk indices for non-native species.

# IMPACT OF TREATMENT WITH A SECONDARY BILE ACID (LITHOCHOLIC ACID) ON THE HEPATIC METABOLISM OF RAINBOW TROUT (*Oncorhynchus mykiss*)

**Introduction**

The growing demand for aquaculture products requires innovative strategies to maximize feed efficiency while maintaining the health and homeostasis of fish. In this context, bile acids (BAs) play a central role in the emulsification and absorption of lipids, in addition to modulating metabolic pathways and physiological responses that remain poorly studied to date. Recently, we demonstrated the impact of secondary bile acids (SBAs) on appetite-regulating mechanisms in rainbow trout (*Oncorhynchus mykiss*) (Pérez-Tierra *et al.*, 2025); however, their role in energy metabolism remains entirely unknown. Therefore, the aim of this study was to investigate the effect of one of the main SBAs—lithocholic acid (LCA)—on the enzymatic activity and mRNA abundance of genes related to key factors controlling both glucose and lipid metabolism, as well as on the levels of key energy metabolites in the liver of rainbow trout.

**Materials and methods**

Juvenile rainbow trout were randomly distributed in five tanks (n=8 fish per tank) and maintained during an acclimation period of two weeks. On the day of the trial, fish were fasted for 24 hours prior to being anesthetized using 2-phenoxyethanol (0.02% v/v). Each fish was then individually weighed and administered an intragastric dose of either distilled water containing 1% dimethylsulfoxide (DMSO; vehicle control) or distilled water with 1% DMSO supplemented with 500 µM lithocholic acid (LCA), at a volume of 1 mL per 100 g body weight. Following treatment, fish were returned to their respective tanks and six hours post-administration, they were again anesthetized and euthanized to obtain liver tissue for quantification of mRNA abundance, levels of metabolites, and enzyme activities.

**Results and discussion**

The relative mRNA levels of key hepatic regulators of glucose and lipid metabolism were differentially affected by LCA administration (Fig. 1A). Regarding glycogen homeostasis, LCA treatment led to an upregulation of glycogen synthase kinase 3 beta (*gsk3b*) mRNAs, which encode an enzyme that phosphorylates and thereby inactivates glycogen synthase, at 6 h post-administration. However, this transcriptional increase did not translate into significant changes in glycogen synthase activity or hepatic glycogen content, suggesting limited functional impact at the time point studied. In relation to gluconeogenesis, LCA significantly reduced the activities of phosphoenolpyruvate carboxykinase (Pepck), fructose 1,6-bisphosphatase (Fbpase), and glucose-6-phosphatase (G6pase) —the three main enzymes constituting the gluconeogenic pathway in the liver (Fig. 1B). This coordinated decrease indicates a lower hepatic gluconeogenic capacity following LCA exposure. To our knowledge, this is the first report describing an effect of SBAs on gluconeogenesis in fish. Interestingly, despite these pronounced reductions in enzyme activity, no significant changes occurred in the mRNA abundance of *pck1, fbp1*, or *g6pc* (Fig. 1A), in contrast to findings reported in mammalian models (Yamagata *et al*., 2004).

In lipid metabolism, the role of BAs in fish has been studied in the context of their emulsifying properties and their contribution to improving lipid absorption. Most available studies have reported a positive impact of dietary bile acid supplementation under high-fat feeding conditions, where hepatic lipid accumulation and metabolic imbalance are common concerns. In this study, treatment with LCA did not result in significant changes in mRNA abundance (Fig.1A) or activity (Data not shown) of major hepatic enzymes involved in lipogenesis or lipolysis, suggesting that under the tested conditions, LCA does not influence hepatic lipid metabolic pathways in rainbow trout.

*(Continued on next page)*

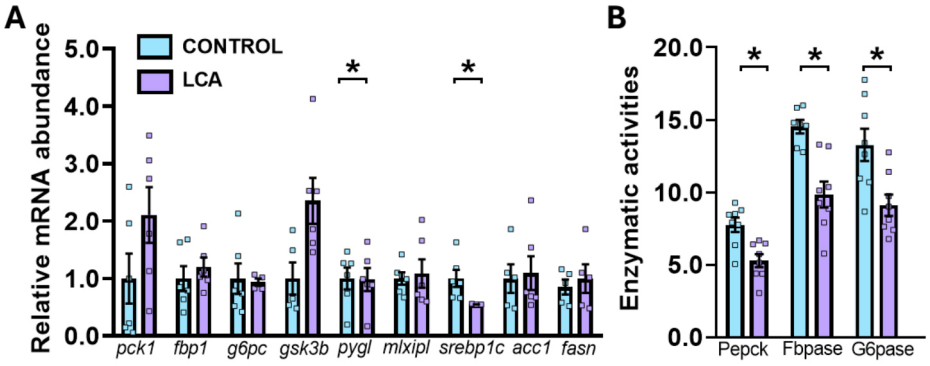

**Figure 1.** (A) Relative mRNA levels of genes encoding key components of hepatic glucose and lipid metabolism and (B) the enzymatic activities (mU·mg-1 protein) of key enzymes regulating gluconeogenesis, were analaysed in rainbow trout 6 hours after intragastric administration of distilled water with 1% DMSO (control) or containing 500 μM lithocholic acid (LCA) at a volume of 1 mL per 100 g body weight. RT-qPCR results were normalized to *actb* (encoding β-actin) and *eef1a1* (encoding elongation factor 1α) mRNA abundance and are presented as fold-change relative to the control group. Data are shown as mean ± SEM (n = 6). Statistical differences between control and LCA-treated group were determined using Student's t-test, with significant differences denoted by * ($p < 0.05$).

## Conclusions

The results of this study demonstrate that intragastrical administration of LCA leads to an apparent short-term inhibition of hepatic gluconeogenesis in rainbow trout, while it does not appear to affect lipid metabolism. Taken together, these findings provide fundamental insight into the short-term impact of SBAs—specifically lithocholic acid—on glucose and lipid metabolism in rainbow trout. This knowledge may serve as a basis for guiding future applications in the development of functional feed formulations for aquaculture.

# GENOME ANALYSIS OF *Vibrio alginolyticus* AND *Vibrio diabolicus* ISOLATES FROM BIVALVE AQUACULTURE ENVIRONMENT IN THE ADRIATIC SEA

L. Perić[1]*, V. Nerlović[2], D. Kapetanović[1], K. Orlić[1], S. Kazazić[1], I. Vardić Smrzlić[1], B. Kurtović[1]

[1]Ruđer Bošković Institute, 10000 Zagreb, Croatia
[2]University Department of Marine Studies, University of Split, 21000 Split, Croatia
*Lorena.Peric@irb.hr

**Introduction**

Bacteria of the genus Vibrio are ubiquitous in the marine environment. Vibrio species are also known to be opportunistic pathogens for farmed and wild marine organisms, including bivalves. As bivalves are able accumulate microorganisms by filtration, there is a risk of pathogen transmission along the food chain through the consumption of seafood products. Despite their diversity, knowledge about the pathogenic properties and the infection risks from non-cholera *Vibrio* species in the aquaculture of bivalve in the Adriatic Sea is currently very limited.

This aim of the study was to gain a deeper insight into the genome of potentially pathogenic *Vibrio* isolates from the Adriatic bivalve aquaculture environment through high resolution whole-genome sequencing and genome analysis. The study focussed on the presence of virulence factors and antibiotic resistance genes, as well as mobile genetic elements that mediate horizontal gene transfer related to the ability of bacteria to cause disease and survive in different environments. A set of isolates of *Vibrio alginolyticus* and *Vibrio diabolicus* were obtained from samples of farmed Mediterranean mussel *Mytilus galloprovincialis*. An exotic tunicate species *Clavelina oblonga*, which is usually closely associated with growing installations and dominates the biofouling community in the Northern Adriatic [1], was included in the investigation as a potentially relevant reservoir for *Vibrio* species with the capacity to cause infection in aquaculture areas, including the currently uninfected sites [2].

**Materials and methods**

Tissue homogenates of *M. galloprovincialis* and tunicate *C. oblonga* collected from bivalve farms in the northern and southern Adriatic were serially diluted and inoculated onto *Vibrio* selective media (thiosulphate–citrate–bile salts–sucrose agar). Representative overnight grown colonies were screened by matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF MS), as previously described [3]. Isolates that showed MALDI-TOF MS identity corresponding to *V. alginolyticus* were selected for confirmation of identity by sequencing of the RNA polymerase sigma factor gene (*rpo*D). A representative set of isolates identified as *V. alginolyticus* and *V. diabolicus* was selected for whole-genome sequencing performed on Illumina NovaSeq X Plus platform, to generate paired-end 150nt reads (Novogene, EU). Raw sequences were processed using online tools for quality checking, read trimming and assembly into contigs.

All sequences were scanned using the Virulence Factor Database - VFDB [4] with the full set of verified and potential virulence factors. The sequences were also screened for antibiotic resistance genes using the Comprehensive Antibiotic Resistance Database - CARD [5] and ResFinder *v* 4.7.2. [6,7]. Mobile genetic elements (MGEs), such as genomic islands, insertion sequence elements and prophages were predicted using IslandViewer 4 [8], ISEscan *v* 1.7.3. [9] and PHAge Search Tool Enhanced Release (PHASTER) [10], respectively.

**Results and discussion**

Our results show that *V. alginolyticus* and *V. diabolicus* from bivalve aquaculture in the Adriatic Sea share many of the genes encoding virulence factors with *Vibrio* species previously isolated from different environmental samples, that play a role in adherence, biofilm formation, evasion of phagocytosis, chemotaxis, motility, acquisition of iron, delivery of bacterial proteins, quorum sensing and haemolytic activity. Genes encoding for resistance to macrolides, fluoroquinolones, penicillin beta-lactams, tetracycline and fosfomycin were also identified. Several genomic islands were detected with genes encoding members of different transposase families, recombinases, phage proteins, lipid metabolism proteins, virulence factors, antibiotic resistance components and many hypothetical proteins, were detected in all isolates. A considerable number of insertion sequences and repeated regions as well as intact prophages were also found. These particular genetic features indicate the ability of bacteria to acquire new genetic information through horizontal gene transfer, which contributes to bacterial evolution, survival and pathogenesis. Overall, these results highlight the risk associated with the spread of bacteria in aquaculture which could have an impact on the profitability of production and the safety of public health.

Halifax, B3H 4R2 (Canada)
E-mail: Flavie.Perron@dal.ca

Mussels (*Mytilus edulis*) can show wide growth variability, even among same-aged individuals reared under similar conditions. Triploidy can influence growth rates as energy can be diverted from reproduction to somatic growth. Furthermore, the response of triploid mussels to heat stress remains poorly understood. This study investigated how growth phenotype (i.e., slow versus fast growers) and ploidy (i.e., diploids versus triploids) influence the response of mussels to thermal stress. Within each ploidy group, slow and fast growers (bottom and top 20% by size) were characterized across three mussel families. Each family was tested separately, where mussels were placed in individual respirometry chambers and exposed to thermal stress starting at an acclimation temperature of 18°C. The temperature was increased by 2°C every three days until it reached a sub-lethal temperature of 26°C. Shell lengths were measured at the start and end of the experiment, while feeding rates were assessed at 18, 22, and 26°C, and respiration rates were measured continually every 2h. Throughout the experiment, samples were collected for genotyping, RNA-sequencing, metabolomics, gill histology, and flow cytometry. This study aims to better understand how growth phenotype and ploidy influence mussel responses to thermal stress, with potential applications in mussel aquaculture through the selection of resilient growth lines.

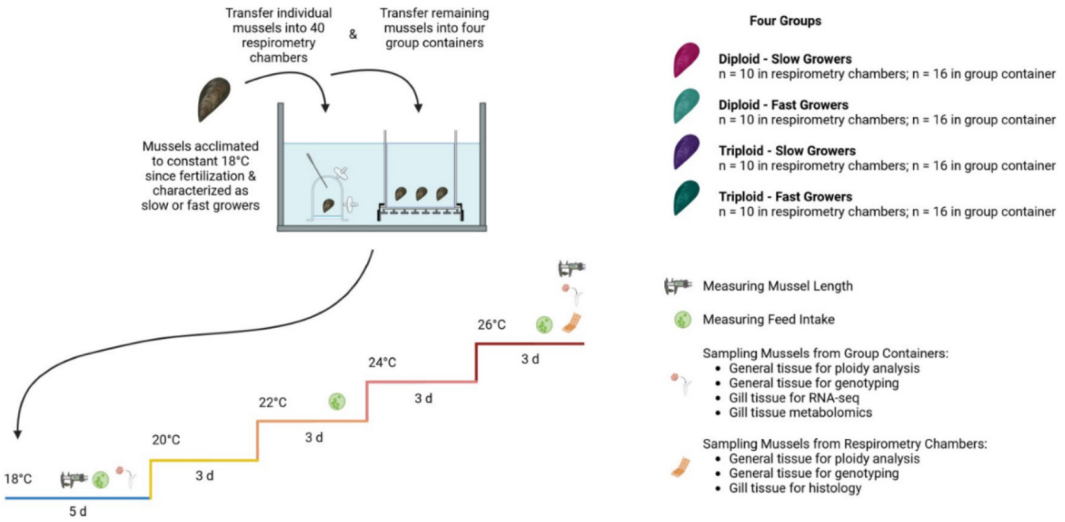

Figure 1. Experimental design of the temperature ramp (from 18 to 26°C) for slow and fast growers from both diploid and triploid mussels across 3 families, with morphological and tissue sampling denoted.

Bivalve aquaculture is an important activity able to provide healthy food with a low carbon footprint. This activity is threatened by climate extreme events such as marine heatwaves (MHWs), which are increasing their frequency, duration and intensity every year. In shellfish farming the scope for contrasting the impact of MHWs is limited. Selective breeding for organisms that are more resilient to MHW may be an effective solution against these stressful events and may, in turn, sustain the clam aquaculture sector. Within this framework, genome wide association studies (GWAS) supported by SNP array genotyping is a powerful tool to investigate the genetic basis of such complex (and possibly multigenic) traits.

For this task we initially designed a novel multi-species Axiom SNP array (60K) with ~45K SNPs for the Manila clam (*Ruditapes philippinarum*) and ~15K SNPs for the carpet shell clam (*R. decussatus*). The array was subsequently used aiming to identify quantitative trait loci (QTLs) significantly linked with the trait resistance to MHWs.

To fulfil our aim, we exposed a population of 1000 Manila clams, obtained from a mass spawning event at the Satmar hatchery, to a simulated MHW that mimicked a natural event which occurred in the Venice lagoon in 2015, with water temperatures fluctuating daily between 31 and 35 ˚ C. Animals were randomly split across 10 aquaria and the MHW was replicated across all the experimental tanks, lasting 15 days. After this period, we stopped the MHW and kept the remaining animals at 25 ˚ C until no more casualties were observed in the population. All samples were genotyped with the Axiom SNP-array. We evaluated the resistance to MHW as both a binary trait (i.e. resistant vs susceptible) and as a continuous trait (i.e. time to death). By identifying genetic markers associated with MHW resistance, this research paves the way for developing more resilient clam populations through genomic driven selective breeding, potentially revolutionizing the aquaculture industry's ability to adapt to climate change challenges.

# MARINE PROBIOTICS WATER SUPPLEMENTATION EFFECTS ON *Litopenaeus vannamei* AND ITS POSITIVE IMPACT ON SURVIVAL RATE AND MICROBIOTA AFTER AN AHPND STRESS

## Introduction

The aquaculture industry is continuously interested in innovative practices with the aim of improving farm practices while ensuring sustainable development. This is reflected in a global demand for shrimp quality and a minimal impact on the environment. One of the key strategic priorities is to improve resistance to pathogenic bacteria causing outbreaks and economic losses, and probiotics offer a potential strategy to achieve this goal. Probiotics are defined as microorganisms exerting a beneficial effect by modulating microbiota when they are ingested in adequate quantity. They are good candidate to improve shrimp immune resistance, to reduce the use of antibiotic and lead to a more sustainable aquaculture. In this study, we used probiotic strains which are native from the marine environment and are well adapted to the aquatic environment.

## Material and methods

A 7-week water supplementation with or without marine probiotics was performed in 800-liter ponds on *Litopenaeus vannamei* PL12 in triplicate (n = 1000, water temperature = 28°C). This supplementation was continued during a 15-day challenge test with *Vibrio parahaemolyticus* causing AHPND in 40L ponds (n = 60, 3 replicates, water temperature = 28°C). The capacity of the marine bacteria consortium on zootechnical parameters and shrimp survival rate was evaluated. A metabarcoding analysis was done on dead and alive shrimps to understand mechanisms involved at the microbiota level. Previously, an *in vitro* study was realized to understand the antibiofilm and antibacterial potential of one of these marine probiotic strains on pathogenic *V. harveyi* ORM4. Three different biofilms were realized by testing the activity of the probiotic supernatant as a curative or preventive solution and with a co-inoculation with the pathogen. Liquid chromatography coupled with a mass spectrophotometer was also performed on probiotic supernatant to investigate the production of antibiofilm compounds (Petit et al., 2024).

## Results

The results demonstrated a survival rate multiplied by 2.7 at the end of the challenge compared to the control group. The metabarcoding results showed that marine probiotics, added to the water, had a positive impact on the shrimp larvae gut. Indeed, the microbiota was marked by the presence of the *Pseudoruegeria* genus, known to be a defense mechanism against pathogens. This genus, coupled with marine probiotics, allowed shrimp larvae to have the therapeutic arsenal to fight the pathogen, explaining the better survival rate. The results show the ability of marine probiotics to influence the shrimp gut microbiota. Another characteristic of marine probiotics is their properties to have antibacterial and antibiofilm activity against pathogenic *V. harveyi* ORM4 when the probiotic is co-inoculated with the pathogen or used as a preventive or curative solution. We demonstrated in parallel the ability of this strain to synthesize lipopeptides which presented an antibiofilm activity against *V. harveyi* ORM4.

## Conclusion

These studies demonstrated the ability of marine probiotics to limit the development of pathogens thanks to their antibacterial and antibiofilm activity but also to help shrimp larvae fight against stress caused by *V. parahaemolyticus* by modulating the microbiota and improving the survival rate.

## Introduction

Aquaponics is a sustainable aquaculture method that combines fish farming and plant cultivation in a single closed recirculating system (FAO, 2019). Despite this being a well-acknowledged circular economy approach in RAS, the method is still under intensive development to increase its efficiency and sustainability. One common problem in aquaponic systems remains the accumulation of organic sludge, which can compromise water quality, lower system performance, and increase maintenance needs (Lenz et al., 2021). An integrated multi-trophic aquaculture approach by adding some filter feeders or detritivores to the standard aquaponics can help manage solid wastes and increase system productivity. In this study, we investigated whether incorporating detritivorous crustaceans could help reduce sludge production and improve system efficiency, compared to a standard aquaponic setup.

## Material and methods

Experimental cultivation of rainbow trout (*Oncorhynchus mykiss*), lettuce (*Lactuca sativa*), and noble crayfish (*Astacus astacus*) was performed in a small aquaponics system (a recirculating aquaculture system connected to three growth beds for plants) at Klaipeda University Marine Research Institute Fisheries and Aquaculture Laboratory. Three production cycles of 28-40 days were carried out. For 20 kg of rainbow trout biomass, 15-20 crayfish were added.

During each cycle, sludge production, water quality, and the growth of fish, crayfish and lettuce were monitored. Each cycle started with 19-20 three-week-old lettuce seedlings planted into the growth beds with clay pebbles. The average individual plant weight and total biomass were estimated. For fish and crayfish, biomass produced, average weight gain, feed consumption rate (FCR) and survival rate (%) were counted.

Sludge from the fish and crayfish tanks was collected once a week using a mesh bag and weighed. The total amount of sludge from the fish and crayfish tanks, the amount of sludge consumed by crayfish (g $h^{-1}$), and the efficiency (%) of sludge removal by crayfish were calculated. This study demonstrated that integrating crayfish into an aquaponics system maintained optimal water quality and had no negative impact on fish or lettuce growth.

## Results

Sludge collection revealed that crayfish tanks generated nearly half the sludge amount compared to fish tanks (82 g and 47 g, respectively). Crayfish actively consumed some sludge (on average, crayfish remove 3,5 ± 11,28 g of sludge per hour from the fish tank); however, the overall sludge removal efficiency was low.

## Conclusion

The study concludes that while crayfish can contribute to sludge reduction in aquaponic systems, optimizing crayfish density, feeding regimes, and tank design is essential for improving sludge removal efficiency and enhancing system sustainability. An integrated multi-trophic approach will be further tested with other crustacean species.

## Introduction

Current researchers offer some analysis of welfare trade-offs with individual sustainability pillars, or sustainability pillar(s) and welfare; but rarely consider sustainability and welfare together. The challenges in aquaculture are, for example, while welfare improvements, they often conflict with environmental sustainability goals like resource conservation or effluent reduction; while prioritizing environmental objectives can sometimes undermine welfare outcomes, although welfare and environmental sustainability are closely aligned goals (Albalat et al. 2022). This research investigated the interactions among sustainability pillars and welfare management across various shrimp farming intensities, from extensive to super-intensive systems.

## Materials and methods

Our work are conducted in the four main shrimp farming Mekong-delta Vietnamese provinces (Ca Mau, Bac Lieu, Soc Trang and Kien Giang, see Fig. 1). The surveys included 210 farmers who provided responses about their farms, with corresponding answers about their demographic and shrimp farm's details in the year 2024.

To analyze the data, we utilized Principal Component Analysis to develop composite indices for sustainability pillars and welfare, with each index standardized to range from 0 to 100. Structural Equation Modeling was then employed to explore the interactions between sustainability and welfare across varying shrimp farming intensities. Accordingly, we follow SEM with the inner model as below:

| | Hypothesis | Equation |
|---|---|---|
| $EiI = \beta_1 WI + \beta_2 EnI + \beta_3 SI + \in_1$ | (H1, H2, H3) | (Eq. 1) |
| $WI = \beta_4 EnI + \in_2$ | (H4) | (Eq. 2) |

where , are the path coefficients representing estimating the strength of each relationship and is the error term. The relationships are linear regressions within the structural model. In Eq.1, economic and welfare relationship by (H1) examinate how shrimp welfare affects economic efficiency. Besides, the model from Eq.1 also highlights other key relationships: the environment and economic relationship by (H2), and social influence economic performance by (H3). Additionally, the model from Eq. 2 assesses the interaction between shrimp welfare and environment sustainability relationship by (H4).

## Results

Fig. 1 illustrates the mean values (range 0 - 100) of the sustainability (economic, environmental, social), and welfare management indexes across three shrimp farming systems. Overall, intensive farms require higher input costs and rely less on natural ecological processes while increasing their dependence on intensive feed and aeration, leading to the lowest economic index (Ngoc et al. 2023). The environmental index is also less emphasized in intensive systems, as they focus more on maintaining pond water quality rather than promoting ecological balance. The shrimp welfare management index, however, is not much varied across all farming types, as econ-environmental priorities often take precedence over direct welfare investments.

Table 1 identified several important patterns in the interactions. In super-intensive and intensive farms, we observed a strong negative relationship between welfare improvements and economic performance, indicating that prioritizing welfare measures often incurs a financial trade-off. Across all farm types, environmental improvements were found to significantly reduce economic outcomes, with the most pronounced negative effect occurring in intensive farming systems. However, environmental enhancements were shown to significantly improve welfare outcomes across all shrimp farms, with the strongest positive impact observed in extensive and integrated systems.

**Discussion and Conclusion**

Extensive farming systems are often characterized by lower stocking densities and more natural rearing conditions, enabling shrimp to thrive in a more ecologically balanced environment. In contrast, intensive and semi-intensive systems typically prioritize productivity, which can increase disease susceptibility and stress for shrimp. As stocking densities rise, shrimp have less space to move, leading to reduced oxygen levels, higher waste accumulation, and greater pathogen transmission. These conditions ultimately increase the risk of shrimp to experiencing poor welfare if the systems are not well managed.

# SINGLE CELL TRANSCRIPTIONAL PROFILING OF GILTHEAD SEABREAM (*Sparus aurata*) GILLS. A USEFUL TOOL FOR MONITORING GILL HEALTH IN AQUACULTURE

M.C. Piazzon*, A. Sitjà-Bobadilla, I. Estensoro

Fish Pathology Group
Institute of Aquaculture Torre de la Sal (IATS, CSIC)
Spain
E-mail: carla.piazzon@csic.es

## Introduction

Teleost gill is a complex multifunctional organ essential for several physiological functions, such as gaseous exchange, osmoregulation, excretion of nitrogenous waste, pH regulation, immunity, and hormone production. Gill health is a key aspect in aquaculture and, due to the direct contact with the environment, it can be affected by different factors such as pathogens or environmental stressors.

Our current knowledge on the gill transcriptional responses in gilthead seabream is based on bulk transcriptomics of whole tissue, making it difficult, if not impossible, to link a response to a specific cell type or structure. In this work, we performed a single cell RNA-sequencing study to obtain a transcriptional atlas at single cell resolution that allowed us to define different cell types and subtypes in the healthy gill and find marker genes that can be used for monitoring gill health in aquaculture.

## Material and Methods

Two healthy gilthead seabream of 100 g were euthanized and bled completely to avoid erythrocyte contamination. Left gill arches were extracted and single cell suspension of gill filaments were obtained using a protocol based on incubation with EDTA, DTT, DNaseI and collagenase, and mechanical dissociation. Single cell suspensions were fixed with the Parse Biosciences Fixation Kit and 8,300 fixed cells were subjected to combinatorial barcoding and library preparation using the Evercode WT v3 kit.

After Illumina sequencing, quality filtering and data analysis was performed using Trailmaker. Mapping was performed using fSpaAur1.2 genome assembly from NCBI. Seurat was used for clustering and differential expression analysis. Marker genes for each cell cluster were used to perform gene ontology (GO) analyses and identify cell types.

## Results

After quality filtering, 3,000 cells per sample, with a median of 550 genes per cell were obtained. Cells were clustered into 15 groups that were broadly annotated by the differential expression of marker genes and enriched GO terms (Fig. 1a).

The largest clusters corresponded to epithelial, vascular and goblet cells, the latest with high expression of mucin 5ac and mucin 2 (Fig. 1b), and markers involved in epithelial cell differentiation and mucus layer. Epithelial cells expressed markers involved in cell junction and adhesion, desmosome or extracellular matrix organization (e.g. collagens, claudins or plakophilins). Transcriptional markers in the vascular cell cluster belonged to GO terms like collagen binding, cell adhesion, circulatory system, etc. Further subclustering of the vascular cell cluster allowed to identify the pavement cell population.

The expression of markers like *chga* or *notch1* allowed the classification of endocrine and neuroepithelial cells, respectively. Endothelial cells were enriched in markers involved in GO pathways related to the establishment of the endothelial barrier, such as *ppp1r16b*, *tjp2*, *krt19* and *cdh5*. A clearly separated cluster, with marker genes enriched for GO terms like ion transport was identified as ionocytes or mitochondrion-rich cells (MRCs), important cells in maintaining osmotic, ionic, and acid-base levels.

Regarding the immune system, three clusters were identified as myeloid cells by the expression, among others, of the cell markers *cd74* and *cd48* (Fig. 1c), and then further labeled as dendritic cells, macrophages and granulocytes. The lymphocyte population contained markers for both, B and T lymphocytes, such as *trbc*, *trac*, *cd40* and *pax5*.

*(Continued on next page)*

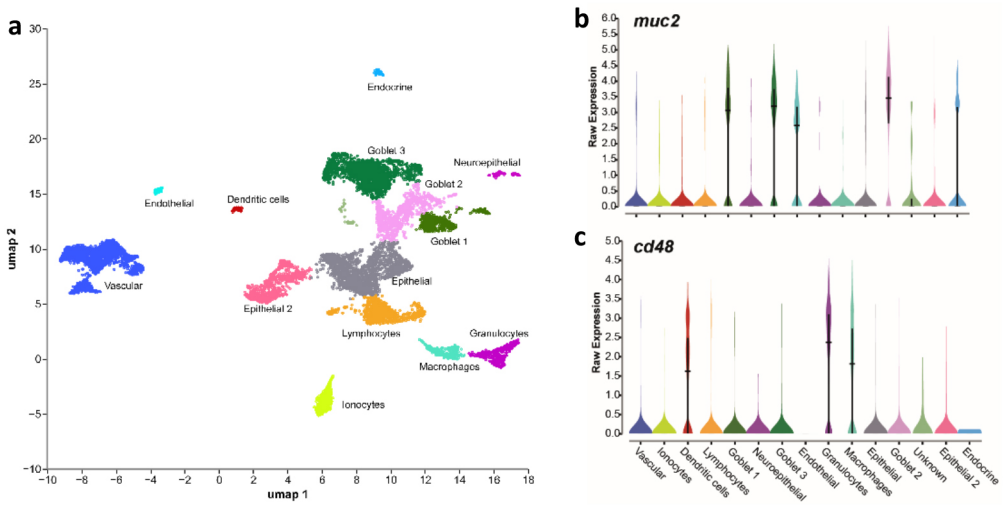

Figure 1: a) UMAP plot of pooled cell data. The plot shows the transcriptional distribution of 15 separate cell clusters. b, c) Violin plots showing the expression level of the goblet cell marker *mucin 2* (b) and the myeloid marker *cd48* (c).

**Conclusions**

This work provides the first transcriptional atlas at single cell resolution of the healthy gilthead seabream gill. We had broadly described 15 different populations based on marker gene expression and GO analysis. Further subclustering of the largest populations will provide markers and the transcriptional profiles for cell subtypes.

This dataset sets the baseline expression in healthy gills and provides a set of markers that will ease the interpretation of future studies aimed to determine gill status under different situations, pathogens or stressors.

victor.pierre@unicaen.fr

## Introduction

The industrialization of the aquaculture sector has been accompanied by a strong demand for raw materials to meet growing feed requirements. Fishmeal remains the main source of animal protein despite its high price and harmful impact on marine ecosystems. In this context, a substantial part of the fishmeal in aquaculture feeds has already been substituted by plant-based resources such as soy-based proteins. However, these alternatives also come with their sustainability issues and high environmental impact. Insect-based protein has more recently been proposed as a robust and more sustainable option, with a nutritional profile well adapted to aquatic species. The protein-rich larvae of the black soldier fly (*Hermetia illucens*) (BSF) are currently farmed industrially to produce meal. This study aims to assess the bioactive potential of the soluble fraction of insect meal – water soluble fraction (WSF) – potentially correlated with health and well-being claims.

## Materials and methods

Total RNA from *Hermetia illucens* larvae was extracted to construct a transcriptome. Sequencing was performed on an Ilumina NovaSeq 6000 sequencer using a cDNA library. Sequence cleaning and transcriptome assembly and annotation were carried out by the ABiMS platform (Roscoff biological station - CNRS). *In silico* analysis of the transcriptome was carried out using PepTraq software to identify the myotropic neuropeptides and antibacterial peptides expressed by BSF larvae. At the same time, peptides extracted from water soluble fraction (WSF) were used for functional tests. Myotropic activity tests were carried out on the proximal part of the intestine of rainbow trout (*Oncorhynchus mykiss*) using an electrophysiology system to measure intestinal contraction. Antibacterial activity tests were carried out through the growth of a wide range of pathogens of aquatic organisms – *Aeromonas salmonicida, Flavobacterium psychrophilum, Yersinia ruckeiri, Lactococcus garvieae, Vibrio parahaemolyticus, Vibrio alginolyticus, Vibrio splendidus, Vibrio anguillarum, Vibrio vulnificus, Vibrio harveyi, Vibrio fisheri, Vibrio penaeicida* – was assessed. Growth inhibition percentages were determined in triplicate by liquid growth inhibition tests using a Bioscreen system.

## Results

The *Hermetia illucens* larva transcriptome included 355,085 transcripts, 69,323 (19.5%) of which possessed a signal peptide. Twenty-six protein precursors corresponding to 22 families of neuropeptides with potential myotropic activity were identified. Seventy-two protein precursors of antibacterials grouped into 4 families were also identified: defensins (30), cecropins (27), attacins (3) and diptericins (12).

Functional tests of myotropic activity revealed that the amplitude and tone of contractions were proportional to the WSF concentration (Figure 1), highlighting a dose effect and a dose-dependent response.

Antibacterial activity measurements revealed three types of effect on the growth kinetics of the pathogens tested in the presence of crude WSF extracts (Figure 2): i) reduced growth, ii) a bacteriostatic effect, and iii) a bactericidal effect. Growth inhibition was observed on *Lactococcus gaerviae* and *Vibrio anguillarum*. A bacteriostatic effect was observed on *Flavobacterium psychrophilum*, *Vibrio fisheri,* and *Vibrio splendidus*. Finally, a bactericidal effect was observed on *Vibrio penaeicida* whatever the crude extract extraction method, which turned into a bacteriostatic effect from the dilution corresponding to 80 $OD_{214}$ units.

*(Continued on next page)*

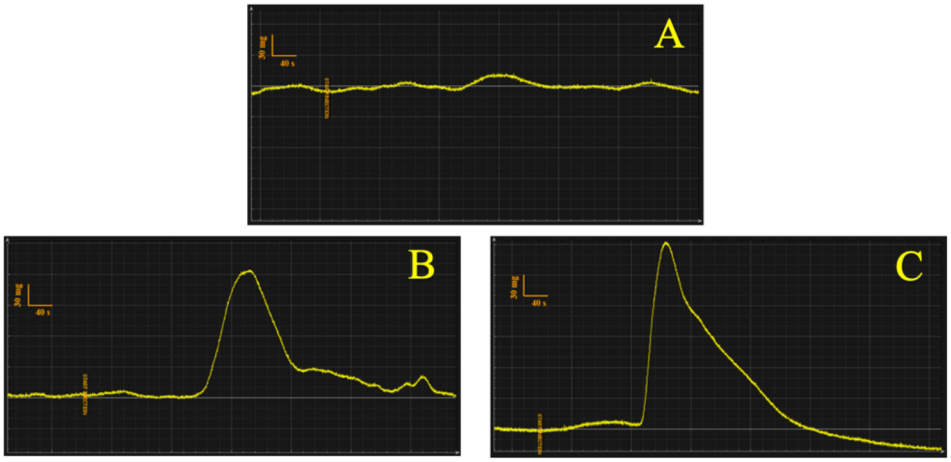

*Figure 1: Measurement of myotropic activity induced by the WSF extract at different concentrations resulting in contraction of the proximal intestine of Oncorhyncus mykiss. Dose effect: perfusion of an extract concentrated to 1 $OD_{214}$ unit (A), 40 $OD_{214}$ units (B), and injection of the crude solution (C).*

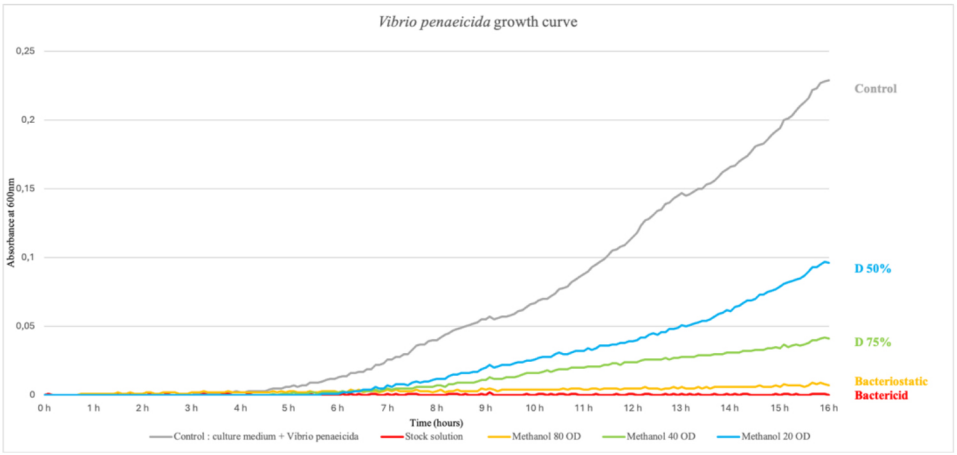

*Figure 3: Vibrio penaeicida growth curve: type of effect observed as a function of the WSF extract concentration (i, ii, iii)*

## Conclusion

This initial *in vitro* approach confirmed the bioactive potential of BSF meal. Its myotropic effects could lead to improved feed digestibility, and its antibacterial properties could significantly reduce the use of antibiotics at a time when antibiotic resistance is a growing concern.

# EFFECTS OF BLACK SOLDIER FLY (*Hermetia illucens*) PROTEIN EXTRACTS ON GROWTH PERFORMANCE AND INTESTINAL TRANSCRIPTOME IN RAINBOW TROUT (*Oncorhynchus mykiss*) UNDER FISHMEAL REPLACEMENT CONDITIONS

sandrine.skiba@inrae.fr

**Introduction**

Climate change and geopolitical instability are contributing to growing uncertainty regarding the availability of raw materials for animal feed, particularly protein sources used in aquaculture. This underscores the importance of continued research into alternative protein ingredients. In recent years, considerable attention has focused on assessing the nutritional value of insect-based products for farmed fish, especially carnivorous species such as salmonids (1). However, with ongoing advancements in the industrial processing of insects into protein meals, further evaluation is needed to determine the nutritional quality of these next-generation ingredients. This study aimed to assess the impact of partially and fully replacing fishmeal-derived proteins with insect-derived proteins in diets formulated for rainbow trout (Oncorhynchus mykiss). The insect proteins were sourced from three by-products of black soldier fly (BSF) processing: a crude insect meal (CIM), a refined insect meal (RIM) with reduced chitin content, and a protein extract derived from the aqueous fraction separated during the wet processing of BSF larvae into protein meal and oil, and commonly referred to as stickwater (SW). Due to its high content of water-soluble compounds, stickwater is particularly rich in low molecular weight proteins, peptides (including bioactive peptides), and micronutrients, notably minerals.

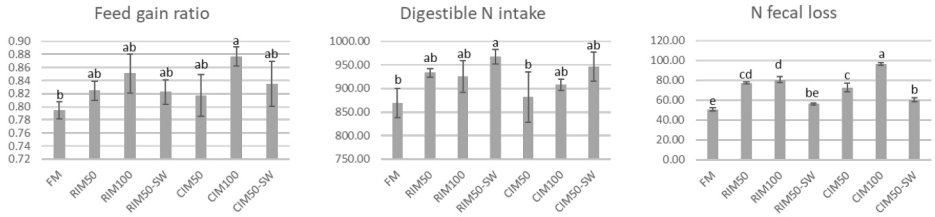
**Materials and methods**

A digestibility trial and a 12-week growth experiment were conducted on juvenile rainbow trout to evaluate seven experimental diets. The control diet included 17% fishmeal (FM). Two diets involved complete replacement of fishmeal protein with either crude (CIM100) or refined (RIM100) insect meal. Four additional diets replaced 50% of fishmeal protein with CIM (CIM50), RIM (RIM50), or a blend of 70% CIM or RIM and 30% stickwater (CIM-SW, RIM-SW). Diets, faeces, and whole fish were analyzed for proximate composition to calculate apparent digestibility coefficients (ADCs) and assess nutrient retention. Transcriptomic analysis of the distal intestine was performed to evaluate molecular responses to dietary treatments. Data were analyzed using a two-step approach: a two-way ANOVA assessed the effects of insect meal type and substitution level among the six insect-based diets, followed by a one-way ANOVA comparing all diets, including the control.

**Results**

Partial or total replacement of fishmeal with crude (CIM) or refined (RIM) insect meal reduced the apparent digestibility coefficients (ADCs) for protein, lipid, and energy compared to the fishmeal (FM) control, with the lowest values observed in the CIM-100 diet. However, supplementing 50% replacement diets with stickwater (SW) restored digestibility to control levels. Growth performance was not significantly affected by diet. Absolute feed intake increased with SW inclusion, and, when normalized to metabolic body weight, was also higher in CIM-50 and RIM-100 diets. Feed efficiency declined with full fishmeal replacement by CIM compared to control FM diet. Insect-based diets increased digestible nitrogen, fat, and energy intake, especially with SW. Fecal nutrient losses were also higher, particularly under full replacement, but were significantly reduced by SW in the 50% substitution diets. Nitrogen, fat, and energy gains and retentions were not significantly different among diets. Transcriptomic analysis of the distal intestine revealed limited changes between 50% and 100% substitution levels (2–3 differentially expressed genes, DEGs, per insect meal type). Comparing RIM-based diets revealed 27 DEGs, versus only 2 in CIM-based diets. Relative to the FM control, RIM diets showed 27 DEGs, and CIM diets 7, many associated with immune and inflammatory responses. Ladderlectin a and b were upregulated with insect diets, while samd9, an antiviral gene, was downregulated in CIM-100-fed fish.

*(Continued on next page)*



**Discussion**

Diets with partial or total replacement of fishmeal by insect proteins of varying quality supported growth performance comparable to that of the control diet containing 17% fishmeal. Chitin content did not appear to limit growth, but feed efficiency declined with insect-based diets. These insect-based diets led to higher nutrient intake and fecal losses, resulting in similar nutrient gains and retention. This potentially could reduced economic and environmental sustainability, particularly with crude insect meal, which showed the poorest efficiency when used in full replacement. Although stickwater improved digestibility in insect-based diets, its growth-promoting effect, as observed with stickwater issued from fishmeal production, in salmon (2), was less evident here. This may be attributed to the less balanced amino acid profile of insect meal compared to fishmeal. Overall, refined insect meal exerted a more pronounced effect on the intestinal transcriptome than crude insect meal. Notably, *ladderlectin a* and *b*, key components of fish innate immunity involved in defense against bacterial infections (3), were upregulated in trout fed insect-based proteins. This response may reflect the ability of ladderlectins, which possess sugar-binding domains, to recognize and bind chitin, a long-chain polymer of N-acetylglucosamine present in insect meals. In contrast, samd9, a gene linked to antiviral defense and potentially acting as a pattern-recognition receptor for microbial double-stranded DNA or RNA (4), was downregulated in trout fed the diet with full crude insect meal replacement. These immune-related transcriptomic shifts highlight the need for pathogen challenge trials to assess the health robustness of trout fed insect-based diets.

**Introduction**
Improving the welfare of fish in aquaculture is an essential step towards creating a healthier and more sustainable industry. Healthy fish are more resilient to disease, which means less reliance on chemical treatments. The effect of stress on the immune system has been widely investigated and chronic stress is known to suppress or dysregulate immune function and increase susceptibility to disease. However, more efforts need to address the effects of acute stress in fish, which seem to have both stimulatory and inhibitory actions on immune functions. This study focuses on how acute stress, specifically from transportation, affects juvenile rainbow trout (*Oncorhynchus mykiss*), with particular focus on its impact on the immune system, the fish's ability to recover from these challenges and, by analyzing gene expression, attempt to identify potential welfare biomarkers.

**Material and Methods**
A trial was devised to evaluate the stress response in rainbow trout juveniles after transport. Fish (approx. 18 g) were randomly distributed into 9 tanks, with 12 individuals per tank and hand fed to satiation 2 times a day with a commercial diet. Following an acclimatization period, fish from three tanks (n=3) were sampled to serve as a non-stressed control. The fish of each remaining tanks were transferred, to a plastic container (≈25 kg/m$^3$) with an $O_2$ saturated atmosphere and transported for 2 h. Upon arrival, 3 groups of transported fish were immediately sampled. The others were accommodated in the original system and sampled 24 h post-arrival. Plasma was used for cortisol, metabolites and humoral immune parameters. Liver was sampled for the analysis of metabolites and oxidative stress responses. Brain and head kidney were collected for gene expression analysis.

**Results**
Results showed a significant increase in plasma cortisol and glucose levels with a simultaneous decrease of hepatic glycogen and glucose immediately after transport for 2h. Plasma immune parameters showed a significant increase of nitric oxide levels immediately after stress-induced transport. Regarding metabolites, triglycerides increased in plasma whereas lactate decreased in the liver 24 h after stress. In regard to gene expression in the brain an increase in the level of mRNA expression of *crhbp* immediately after transport was observed, as well as its decrease 24h after stress. A similar pattern was observed in the levels of gene expression in the head-kidney, in relation to the genes *hsp70*, *il10* and *arg2*.

**Discussion**
Preliminary results suggested a stress induced response with a primary and secondary response pattern, specifically an increase in plasma cortisol and the rapid release of energy from hepatic carbohydrate reserves. An increase in plasma triglycerides during recovery might suggest a shift in energy use, with the fish relying more on fats as a longer-term energy source. The increase of level of expression of *crhbp* in the brain and *hsp70*, *il 10* and *arg2* immediately after stress, and their subsequent decrease 24 h after stress indicate a well-regulated response of fish to the transport stress, that successfully manage the cellular and inflammatory challenges, and that by 24 hours, had largely returned to a state of physiological homeostasis.

In conclusion, besides plasma cortisol, the expression of genes such as brain *crhbp*, and head-kidney *hsp70*, *il10* and *arg2* seem to be good markers of both stress-induced transport episodes and following its recovery.

## Introduction

Although freshwater aquaponics is the most practiced and studied, integrating the cultivation with halophyte plants (salt-tolerant) can be an alternative to the limited use of water for food production and soil salinization. Species such as *Salicornia neei*—commonly known as salicornia or sea asparagus—are of great interest in the global market for gourmet cuisine. The design of aquaponic systems often varies based on production objectives and the species being cultivated. To optimize performance, it is essential to understand the dynamics of solids production and manage nutrient-rich wastewater effectively, ensuring its efficient reuse for plant growth. Given the importance of managing residual nutrients and protecting plant roots from possible negative effects caused by suspended solids, this study aimed to evaluate the use of a settling chamber in a biofloc-based aquaponic system for the production of marine shrimp *Penaeus vannamei* and the halophyte *Salicornia neei*, and to assess its effects on sludge production.

## Material and methods

The experiment was conducted over a 54-day period, at the Marine Shrimp Laboratory (LCM) of the Federal University of Santa Catarina, southern Brazil.

To evaluate the effects of using a settling chamber in the aquaponic system, two treatments were tested: one with settling and one without settling. Each aquaponic experimental unit comprised a circular polyethylene tank (800 L useful volume) for shrimp cultivation and a hydroponic bench for plant growth. The shrimp tanks were equipped with a heater, aeration hose, and four vertical artificial substrates. In the treatment with settling, a cylindrical fiberglass settling chamber with a conical bottom (90 L capacity) was attached.

The aquaponics structure was constructed based on the design by Pinheiro et al. (2017), with modifications. The hydroponic bench consisted of four PVC pipes arranged side by side on wooden supports. Each bench had 0.33 m² of planting area, with 28 seedlings of *S. neei* per experimental unit. In the treatment without settling, water was continuously pumped from the shrimp tank to the hydroponic bench at a flow rate of 3.0 L $min^{-1}$ using a submerged pump and returned to the tank by gravity. In the treatment with settling, water was pumped continuously to the center of the settling chamber, allowing solids to settle along the chamber's conical bottom. Overflow water was then distributed into each irrigation channel and returned to the shrimp tank by gravity. To maintain the proper concentration of suspended solids, every thirty minutes the solids accumulated in the settling chamber were pumped back to the tank for 40 seconds using an electric pump connected to the bottom outlet of the settling chamber, at a flow rate of 15 L $min^{-1}$.

One day before the beginning of the experiment, the tanks and settling chambers were filled with biofloc water from a shrimp nursery tank. Each tank was stocked with 300 shrimp (average weight of 1.20 ± 0.08 g), representing a stocking density of 375 shrimp $m^{-3}$.

## Results and discussion

During the 54-day trial, the reduction of suspended solids in the treatment with settling led to an increase in TAN and $NO_2$ levels, while the concentration of $NO_3$ remained stable. Although water quality parameters were more stable in the treatment without settling, no significant differences were observed between the treatments regarding plant and shrimp production indices (Table 1).

*(Continued on next page)*

**Table 1.** Production indices of *Penaeus vannamei* and *Salicornia neei* cultivated in an aquaponic system with and without the use of a settling chamber for 54 days. Data are presented as a mean ± standard deviation.

| Parameters | Treatment | | *p*-value |
|---|---|---|---|
| | With settling | Without settling | |
| *Performance of* P. vannamei | | | |
| Survival (%) | 88.7 ± 6.7 | 86.8 ± 5.1 | 0.6745 |
| Mean final weight (g) | 10.2 ± 0.3 | 10.1 ± 0.3 | 0.6431 |
| Weekly weight gain (g week$^{-1}$) | 1.17 ± 0.04 | 1.15 ± 0.04 | 0.6283 |
| Final biomass (kg tank$^{-1}$) | 2.71 ± 0.14 | 2.62 ± 0.07 | 0.3936 |
| Productivity (kg m$^{-3}$) | 3.04 ± 0.16 | 3.27 ± 0.09 | 0.1125 |
| Feed conversion ratio (FCR) | 1.54 ± 0.11 | 1.61 ± 0.07 | 0.3757 |
| *Performance of* S. neei | | | |
| Mean final weight (g) | 14.5 ± 5.9 | 12.8 ± 4.8 | 0.3597 |
| Final biomass (g tank$^{-1}$) | 383.3 ± 58.4 | 338.2 ± 33.0 | 0.4510 |
| Survival (%) | 93.8 ± 1.8 | 94.0 ± 2.1 | 0.6964 |
| Productivity (kg m$^{-2}$) | 1.26 ± 0.24 | 1.13 ± 0.11 | 0.4510 |

One of the concerns of growing plants in aquaponics with BFT is the management of the solids concentration in the water, as these can severely affect the roots and impact the absorption of nutrients. However, the continuous use of the settling chamber can break the microbial aggregates into small non-settleable particles, more difficult to control. In the treatment with settling, there was a thick layer of floating solids probably broken during the water pumping and sludge return to the tank. Thus, the reduction in the concentration of total suspended solids and settleable solids may be responsible for decreasing the biomass of nitrifying bacteria in this treatment (Hu et al., 2015; Pinheiro et al., 2017). In the treatment with settling, the reduction of the TSS concentration led to the gradual increase of TAN and $NO_2$ in the water, since lower solids levels may disrupt the nitrification process, leading to an accumulation of these compounds (Schveitzer et al., 2024).

This study demonstrated, under the experimental conditions presented, the viability of aquaponic cultivation of *P. vannamei* and *S. neei* in biofloc systems without the need for a settling chamber to reduce solids before the water passes through the hydroponic bench, thereby simplifying the system. Moreover, the absence of a settling chamber before the hydroponic bed resulted in more stable water quality parameters. Although the system without the settling chamber exhibited higher concentrations of suspended solids, this did not hinder the growth of either the plants or the shrimp. Nevertheless, the eventual use of a settling chamber remains necessary to maintain suspended solid levels within a range suitable for marine shrimp cultivation, particularly in aquaponic systems with longer production cycles.

## Introduction

Flatfish species such as Senegalese sole (*Solea senegalensis*) and turbot (*Scophthalmus maximus*) have emerged as valuable niche species in Southern-European aquaculture, primarily due to their high-quality white flesh and elevated market value. Nonetheless, these species have some significant behavioural, anatomical and physiological variations. Namely, both present differences in feeding behaviour and digestive tract anatomy, already noticeable from the post-larval stage, with sole being more passive, feeding on the bottom of the tanks and displaying an elongated digestive tract typical of an omnivorous species. Contrarily, turbot actively feeds on water surface and exhibits a well-developed stomach and a shorter intestine, typical traits of a carnivorous species. Moreover, considerable research and development efforts over the past two decades have led to notable advancements in sole larval rearing techniques, including the refinement of weaning protocols, improvements in microdiet quality, and optimization of zootechnical procedures (Pinto et al., 2018). In contrast, the literature on nutritional strategies and feeding protocols during the early developmental stages of turbot remains relatively scarce. The present study aims at reviewing the latest efforts conducted on the road to create specific microdiets for sole and turbot larvae. To this end, this study aims at demonstrating how tailored microdiets can help tackling the nutritional challenges faced by each species during the early developmental stages.

## Materials and methods

Experimental trials were conducted during the first weeks of development of sole and turbot, ranging from 25 to 70 days after hatching (DAH). In these trials, larvae were reared in triplicate tanks under standard zootechnical conditions and fed *ad libitum* on experimental diets comprising of each trial. Trials focusing on macronutrients evaluated sources (marine vs plant-based) and levels of protein (55-61%) and lipids (12-17%). In terms of micronutrients, dietary calcium to phosphorous (Ca:P) ratio was investigated to understand its effect on skeletal malformations and body conformation of sole (e.g. slender vs round phenotype). In addition, the adequacy of feed additives (e.g. binder levels) and functional ingredients (e.g. curcumin) were also evaluated for both species. At the end of experimental trials fish were analysed for growth parameters (weight, length and relative growth rate), survival, and feed conversion ratio, to evaluate the biological efficacy of dietary treatments. The physical properties of microdiets (e.g. floatability) and leaching of water-soluble nutrients were also monitored on the different experimental trials to ensure their adequacy for the feeding behaviour of each species.

## Results

Results from the experimental trials showed different scenarios for sole and turbot, not only in terms of preferential ingredients to be included in microdiets, but also on sources and levels of macro/micronutrient to be adopted. Sole showed no preference between dietary protein sources (fish, squid, krill and plant-based diets), increasing growth performance when high levels of protein and medium levels of lipids were included in the diet. In addition, graded levels of dietary Ca:P ratios did not affect sole development in terms of growth performance, skeletal malformations or body conformation. The inclusion of high binder levels also increased sole growth performance, with these being negatively correlated to leaching of dietary water-soluble nutrients. In terms of functional ingredients, it was observed that dietary curcumin supplementation boosted sole growth performance. Diet physical properties were also shown to be extremely relevant for sole, as depressed growth and low survival was found when fish were fed a commercial diet with high floatability and residence properties at water surface.

*(Continued on next page)*

On the other hand, turbot did not tolerate high levels (>30 %; feed basis) of squid meal in the diet, exhibiting good growth performances when the main protein sources were fishmeal, krill meal or a mixture of marine and plant-based proteins. Contrarily to sole, turbot growth was not affected by diets with protein levels equal or above 55 %, or when dietary lipids were at medium or high levels. Opposed to sole, diet binder levels did not play a key role in turbot growth, with fish showing similar performances at low and high levels. Dietary curcumin supplementation did not play a significant role in boosting turbot growth but had a positive effect on larval total antioxidant capacity.

**Discussion**

Senegalese sole and turbot showed a different response to the nutritional composition of microdiets during the early developmental stages. As an omnivorous species, sole is apparently more eclectic in its dietary preference, showing a good response to several sources of dietary protein. However, continuous research showed by this study on the effects of different dietary nutritional compositions indicates the species tends to prefer high-protein diets and moderate lipid levels, benefiting from diets with a high binder inclusion level that retains water-soluble nutrients for a prolonged period. This feature is particularly important due to its passive feeding behaviour, with a positive effect on water quality. These clear nutritional preferences justify the considerable amount of research conducted during the past two decades to optimise the nutritional composition of sole diets (e.g. Pinto et al., 2016; Canada et al. 2017; Pinto et al., 2018). On the other hand, turbot seems to require a diet with a lower degree of specialization during the early developmental stages, as it is more tolerant to nutritional changes without a significant loss of performance. Combined with its voracity and active feeding behaviour, it is also perceptible why a lower research effort has been conducted on nutritional preferences and weaning of the species. Nonetheless, it is clear that a unique diet will not be optimised for both species, as nutritional composition and diet physical properties such as floatability have a preponderant role on the performance of sole and turbot during the early developmental stages. To this end, this work supports that tailoring the nutritional composition and physical properties of diets for marine fish larvae will contribute to produce high quality juveniles in aquaculture.

# ASSESSING PUBLIC SUPPORT FOR AQUATIC ANIMAL WELFARE: INSIGHTS FROM A MULTI-NATIONAL SURVEY

S. Pintos, K. Tietge and N. Boyland

Compassion in World Farming International
River Court, Mill Lane
Godalming, Surrey, GU7 1EZ, United Kingdom
Email: santiago.pintos@ciwf.org

An estimated 133 billion fish and 630 billion crustaceans are farmed for human consumption annually. Despite their vast numbers, scientific knowledge about the welfare needs of aquatic species remains limited, and their welfare is often severely compromised in aquaculture.

Public attitudes play a crucial role in shaping welfare policies. To understand citizens' awareness, perceptions, and values regarding aquatic animals, an online survey of 12,301 respondents from 12 countries was conducted. Descriptive statistics were employed to study participants' responses, and statistical models were applied to identify the factors modulating support for fish-welfare legislation. Results indicate strong preferences for welfare protection, with many supporting better protections for farmed fish. Many respondents also indicated they would pay premium prices for such products, highlighting the potential for market-driven welfare improvements. Additionally, statistical modelling revealed that the strongest predictors of participants' support were the country of residence, knowledge of fish farming practices, and beliefs about fish sentience and cognitive capacities.

Nevertheless, challenges persist: many citizens remain unaware of aquaculture and welfare issues, and there are discrepancies in perceptions of aquatic versus land animals. Addressing these barriers is crucial for fostering greater concern for aquatic animal welfare.

# CATCHES AS A TOOL FOR ESTIMATING AQUACULTURE ESCAPES. THE CASE OF THE CANARY ISLANDS BETWEEN 2006 AND 2020

Pitarch-Font, D., Fernández-del-Campo, J., Toledo-Guedes, K.

Department of Marine Sciences and Applied Biology
University of Alicante, Carretera San Vicente del Raspeig s/n
03690, Alicante, Spain
E-mail: david.pitarch@.ua.es

## Introduction

Marine cage aquaculture establishes multiple interactions with its environment, which can have an impact on the local fishing sector, both ecologically and socioeconomically, and can affect the dynamics and sustainability of fishing activity. One of the main impacts on the marine environment is the escape of organisms (Toledo Guedes et al., 2024).

The Canary Islands are a volcanic archipelago located in the Atlantic Ocean, northwest of Africa, consisting of eight main islands and with a subtropical climate. Aquaculture on these islands has been taking place mainly since the 1990s, with the farming of non-native species in the area such as sea bream (*Sparus aurata*) and sea bass (*Dicentrachus labrax*).
The best method to combat escapes is for the professional fleet to capture these escaped individuals. As time passes since an escape, there is greater dispersion of these organisms (Atalah et al., 2024). The capture of escaped organisms usually occurs in shallow areas near aquaculture facilities (Toledo-Guedes et al., 2014).

## Objectives

This study has two main objectives. The first is to assess whether the increase in sea bream and sea bass production in the Canary Islands is reflected in the number of catches reported by commercial vessels. The second objective is to analyze whether the geographical distribution of aquaculture activity affects the quantity of these species caught in the region.

## Materials and methods

Data on aquaculture production and catches of sea bream (*Sparus aurata*) and sea bass (*Dicentrachus labrax*) in the Canary Islands were used. The catch data came from the General Secretariat for Fisheries, while the production data were obtained from APROMAR's annual reports.

Regarding the data processing for the first objective, the annual production and extractive fishing data for the islands as a whole were analyzed jointly for the period 2006–2020. Initially, a simple linear regression model was fitted. Since the relationship showed a poor fit and was not statistically significant, a logarithmic transformation was applied to both variables to improve the linearity and homoscedasticity of the residuals. The performance of the models was evaluated using the Akaike (AIC) and Bayesian (BIC) information criteria, selecting the former as optimal.

Regarding the second objective, sea bream and sea bass catches broken down by island and year (2006–2020) were used. The data were grouped by island and year, and Bray–Curtis distances were then calculated to estimate the dissimilarity in catch composition between islands. A PERMANOVA analysis was then applied to evaluate significant differences between years and islands. Post hoc comparisons were then made between pairs of islands using the Bonferroni correction to control for type I error.

## Results and discussion

Regarding the first analysis, the logarithmic linear regression model (R2= 0.543) explains 54.3% of the variability. There is a strong and positive relationship between production and catch: higher production leads to higher catch, in a significant and non-linear way. Despite this, with the increase in production, the explained variability is not excessively high, as other very decisive factors such as storms or sabotage may influence it. Storms can have a major effect on variability, as cages are more likely to break and allow organisms to escape after such extreme events (Toledo-Guedes et al., 2014 a,b) or acts of sabotage (Atalah et al., 2024).

*(Continued on next page)*

As for the second analysis, the results indicated that there were no significant differences in the composition of the catch between the different years analyzed (2006–2020) ($F = 0.76$, $p = 1.00$). However, significant differences were found between the islands ($F = 4.78$, $p = 0.001$), suggesting that the total catch of escaped individuals varies significantly between the different islands. Despite this, this model explains 14.7% of the variation, with the remaining 85.3% of the variability attributed to residual variability not explained by the factors included. These results indicate that geographical location, i.e., the islands, is a determining factor in the difference in the catch of escaped organisms. The results of the post-hoc tests with Bonferroni correction revealed significant differences in the composition of catches between most of the pairs of islands analyzed. The most notable differences were observed between Gran Canaria and La Palma ($F = 7.27$, adjusted $p = 0.015$), as well as between La Palma and Lanzarote ($F = 7.00$, adjusted $p = 0.015$). In addition, Fuerteventura showed significant differences with all islands. However, no significant differences were found between Gran Canaria and La Gomera after correction (adjusted $p = 0.09$). These results indicate significant spatial variability in catch composition across the archipelago.

These differences may be due to the distribution of aquaculture facilities throughout the archipelago. During the years analyzed, La Palma, Tenerife, Gran Canaria, and Lanzarote have farmed sea bream and sea bass in marine cages. Fuerteventura and La Gomera are the only two islands that have catches and have not farmed these species on the island, mainly due to the presence of these organisms from marine cages. Fuerteventura shows significant differences from all the other islands, which may be due to the absence of aquaculture and its greater distance from all the other western islands. These results reinforce the existence of clear spatial differences in the composition and quantity of catches between most of the islands in the archipelago.

## Introduction

Marine cage aquaculture establishes multiple interactions with its environment, which can have an impact on the local fishing sector, both ecologically and socioeconomically, and can affect the dynamics and sustainability of fishing activity. One of the main impacts on the marine environment is the escape of organisms (Toledo Guedes et al., 2024).

The Canary Islands are a volcanic archipelago located in the Atlantic Ocean, northwest of Africa, consisting of eight main islands and with a subtropical climate. Aquaculture on these islands has been taking place mainly since the 1990s, with the farming of non-native species in the area such as sea bream (*Sparus aurata*) and sea bass (*Dicentrachus labrax*).
The best method to combat escapes is for the professional fleet to capture these escaped individuals. As time passes since an escape, there is greater dispersion of these organisms (Atalah et al., 2024). The capture of escaped organisms usually occurs in shallow areas near aquaculture facilities (Toledo-Guedes et al., 2014).

## Objectives

This study has two main objectives. The first is to assess whether the increase in sea bream and sea bass production in the Canary Islands is reflected in the number of catches reported by commercial vessels. The second objective is to analyze whether the geographical distribution of aquaculture activity affects the quantity of these species caught in the region.

## Materials and methods

Data on aquaculture production and catches of sea bream (*Sparus aurata*) and sea bass (*Dicentrachus labrax*) in the Canary Islands were used. The catch data came from the General Secretariat for Fisheries, while the production data were obtained from APROMAR's annual reports.

Regarding the data processing for the first objective, the annual production and extractive fishing data for the islands as a whole were analyzed jointly for the period 2006–2020. Initially, a simple linear regression model was fitted. Since the relationship showed a poor fit and was not statistically significant, a logarithmic transformation was applied to both variables to improve the linearity and homoscedasticity of the residuals. The performance of the models was evaluated using the Akaike (AIC) and Bayesian (BIC) information criteria, selecting the former as optimal.

Regarding the second objective, sea bream and sea bass catches broken down by island and year (2006–2020) were used. The data were grouped by island and year, and Bray–Curtis distances were then calculated to estimate the dissimilarity in catch composition between islands. A PERMANOVA analysis was then applied to evaluate significant differences between years and islands. Post hoc comparisons were then made between pairs of islands using the Bonferroni correction to control for type I error.

## Results and discussion

Regarding the first analysis, the logarithmic linear regression model (R2= 0.543) explains 54.3% of the variability. There is a strong and positive relationship between production and catch: higher production leads to higher catch, in a significant and non-linear way. Despite this, with the increase in production, the explained variability is not excessively high, as other very decisive factors such as storms or sabotage may influence it. Storms can have a major effect on variability, as cages are more likely to break and allow organisms to escape after such extreme events (Toledo-Guedes et al., 2014 a,b) or acts of sabotage (Atalah et al., 2024).

*(Continued on next page)*

As for the second analysis, the results indicated that there were no significant differences in the composition of the catch between the different years analyzed (2006–2020) ($F = 0.76$, $p = 1.00$). However, significant differences were found between the islands ($F = 4.78$, $p = 0.001$), suggesting that the total catch of escaped individuals varies significantly between the different islands. Despite this, this model explains 14.7% of the variation, with the remaining 85.3% of the variability attributed to residual variability not explained by the factors included. These results indicate that geographical location, i.e., the islands, is a determining factor in the difference in the catch of escaped organisms. The results of the post-hoc tests with Bonferroni correction revealed significant differences in the composition of catches between most of the pairs of islands analyzed. The most notable differences were observed between Gran Canaria and La Palma ($F = 7.27$, adjusted $p = 0.015$), as well as between La Palma and Lanzarote ($F = 7.00$, adjusted $p = 0.015$). In addition, Fuerteventura showed significant differences with all islands. However, no significant differences were found between Gran Canaria and La Gomera after correction (adjusted $p = 0.09$). These results indicate significant spatial variability in catch composition across the archipelago.

These differences may be due to the distribution of aquaculture facilities throughout the archipelago. During the years analyzed, La Palma, Tenerife, Gran Canaria, and Lanzarote have farmed sea bream and sea bass in marine cages. Fuerteventura and La Gomera are the only two islands that have catches and have not farmed these species on the island, mainly due to the presence of these organisms from marine cages. Fuerteventura shows significant differences from all the other islands, which may be due to the absence of aquaculture and its greater distance from all the other western islands. These results reinforce the existence of clear spatial differences in the composition and quantity of catches between most of the islands in the archipelago.

## Introduction

Today's seafood sector operates within a highly intricate ecosystem where sustainability encompasses a broad spectrum of interconnected dimensions, including environmental impact, social equity, economic viability, and nutritional value. Understanding and effectively communicating these multifaceted aspects are crucial for encouraging responsible practices, safeguarding marine resources, and ensuring equitable benefits for all stakeholders. In this context, the Horizon Europe VeriFish project[1] is providing an innovative system based on existing EU and global sources to meet the growing need for transparent, standardised, and actionable metrics for communication in the aquafood sector.

## The VeriFish Indicator Framework

The VeriFish Indicator Framework[2] addresses key challenges in data accessibility, communication and informed decision-making by supporting provision of trustworthy and verifiable information on the sustainability of aquafood products. It is structured around three pillars: (a) environmental, (b) nutrition and health and (c) social and economic. The framework is supported by a rich collection of trustworthy data sources, each contributing verifiable information aligned with the indicators defined under the three pillars.

## Key Indicators for Fisheries and Aquaculture

The environmental pillar focuses on minimising ecological impacts and promoting sustainable use of resources in both capture fisheries and aquaculture. It encompasses a broad range of indicators that reflect climate and ecological impacts, such as bycatch, gear loss, and carbon footprint, as well as stock status, animal welfare, and resource use efficiency. These indicators are informed by a variety of established and credible data sources, including the FAO Global Record of Stocks and Fisheries (GRSF), FishBase and SeaLifeBase, the IUCN Red List of Threatened Species, EMODNET Biology datasets, and WISE-Marine, among others.

**Assessing Nutritional Value in Sustainable Seafood**

The nutrition and health pillar underpins the role of aquafood in supporting human health and meeting dietary needs. Indicators are based on nutrients selected for their relevance to public health including protein content, omega-3 fatty acid, sodium, and micronutrients. These indicators not only reflect the nutritional significance of aquafood, but are also broadly applicable across a wide range of species. The primary data source supporting these indicators are drawn from EuroFIR's FoodEXplorer, which provides harmonized food composition data. Additional data sources- including the FAO/INFOODS Global Food Composition Database for Fish and Shellfish (uFish), various data collections from the World Health Organisation (WHO), and others- complement indicators for this pillar.

**Labour, Governance, and Equity in Aquafood**

The social and economic pillar underscores the importance of fair, inclusive and responsible practices across all stages of fisheries and aquafood production. Its indicators are organized into thematic sub-pillars: governance, labour practices and rights, health and safety of workers and issues related to discrimination and indigenous peoples. These indicators are primarily grounded in the conventions of the International Labour Organization (ILO), and their ratification status by individual countries. In addition, complementary data sources- such as the Global Slavery Index, Transparency International Corruption Perceptions Index, Flags of Convenience lists, and others- are leveraged to enhance the depth and contextual relevance of the indicators.

**VeriFish prototype mobile application**

The VeriFish framework provides measurable indicators for capture fisheries, aquaculture, and nutrition, enabling assessment of key sustainability metrics such as biodiversity conservation, carbon emissions, resource efficiency, and public health. These indicators form the basis of a prototype web application[3] that serves as a user-centric gateway to the VeriFish framework of indicators. It facilitates communication of sustainability by actors and enables consumers to make more informed decisions based on their priorities.

**Conclusions**

By standardising sustainability reporting and enhancing value-chain communication, the VeriFish framework can foster consumer trust and empowerment, promote responsible 'advertising' practices, and pave the way for diverse, sustainable consumption.

# EXPLORING ROBUSTNESS BIOMARKERS THROUGH FIN OMICS IN THREE EUROPEAN SEA BASS POPULATIONS

A. Pizzagalli*, F. Allal, D. Crestel, A.Vergnet, D. J. McKenzie, M. Vandeputte and N. Sánchez-Baizán

MARBEC Université de Montpellier

Palavas-les-Flots, France
*Email: Alexandra.Pizzagalli@partenaire-exterieur.ifremer.fr

## Introduction

Environmentally induced changes in DNA methylation have been proposed as potential contributors to short-term adaptive responses to changing environments. To investigate whether epigenetic changes are involved in the resistance to temperature as an environmental stressor, we analyzed three genetically distinct European sea bass populations—Atlantic (AT), Western Mediterranean (WM), and Eastern Mediterranean (EM)—produced by artificial fertilization and reared under common garden conditions in a relatively warm thermal regime representative of the Eastern Mediterranean (rEM). The primary objective of this study was to characterize the fin transcriptome and methylome to determine whether population-level differentiation is evident in these two omic layers. We then aimed to assess associations between omic patterns and phenotypic traits related to robustness, defined here as the capacity to resist environmental stressors and mitigate negative impacts on physiological performance and overall well-being.

## Materials and Methods

After one year of exposure to the rEM thermal regime, 612 fish were slaughtered, and phenotypic data were collected, including body weight, body length, liver and gonad weight. Photographs of whole animals were also taken to allow later scoring of fin erosion level. From these, 72 individuals were randomly selected for transcriptome and methylome analyses. RNA and DNA were co-extracted from the same fin tissue using the Quick DNA/RNA Mini Prep Plus Kit. For transcriptomic analysis, RNA from these individuals was equimolarly pooled into 18 libraries (six per population), stratified by sex and population. For DNA methylation analysis, 12 equimolar pools (four per population) were prepared using only high-quality DNA. RNA-seq libraries were sequenced at ~30× coverage, while whole-genome DNA methylation was assessed using Enzymatic Methyl-seq (EM-seq) at ~25× coverage. Following quality control and bioinformatic processing, principal component analysis (PCA) was performed, differentially expressed genes (DEGs) were identified using DESeq2, and differentially methylated regions (DMRs) were detected using the MethylKit package in R.

General linear models are being used to assess whether expression and methylation biomarkers can be associated with phenotypic traits of interest linked to robustness. Additionally, we are working to determine which of these DMRs are influenced by underlying single nucleotide polymorphisms (SNPs) and which may constitute environmentally-driven epigenetic markers.

## Results and Discussion

We observed significant differences among populations for several phenotypic traits, including condition factor and hepatosomatic index, which are associated with fish robustness. Transcriptome analysis identified 140 DEGs between EM and AT, 135 between WM and AT, and 119 between EM and WM (adjusted $P < 0.05$; $|\log_2 \text{fold change}| \geq 0.5$). Genes upregulated in the Mediterranean populations (EM and WM) were mainly associated with basal stress responses, whereas those upregulated in the Atlantic population (AT) were related to rapid stress response mechanisms, indicating population-specific molecular strategies to cope with warm environments. PCA of the methylome revealed significant differences between populations along the first three principal components. Differential methylation analysis identified 14,993 DMRs (EM vs AT), 8,391 (WM vs AT), and 4,983 (EM vs WM).

*(Continued on next page)*

Further downstream analyses—linking DMRs and DEGs and phenotypic traits—will help pinpoint candidate biomarkers of robustness under the relatively warm regime representative of the species' environmental range.

**Conclusions**

This study identifies candidate biomarkers of robustness from non-lethal fin tissue, contributing to the assessment of population vulnerability and promoting more sustainable aquaculture practices. It also enhances our understanding of genotype–environment interactions, local adaptation, and the potential impact of climate change on European sea bass populations.

# BEYOND THE DOCK: CULTIVATING EARLY STAGES OF THE ASCIDIAN *Styela plicata* FOR A SUSTAINABLE MARINE ECONOMY

Raz Platin*[1] and Noa Shenkar [1,2]

1 School of Zoology, George S. Wise Faculty of Life Sciences, Tel-Aviv University, Tel- Aviv, Israel
2 The Steinhardt Museum of Natural History, Israel National Center for Biodiversity Studies, Tel Aviv University, Tel-Aviv, Israel
Email: razplatin@gmail.com

## Introduction

The necessity for novel sources of natural products is increasing, positioning marine organisms as promising sources of sustainable food and biomaterials. Ascidians (Phylum: Chordata, Subphylum: Tunicata), or 'sea squirts', are marine filter-feeding invertebrates known for their rich chemical diversity and potential biotechnological applications (Palanisamy et al., 2017). Notably, they are the only known animals capable of producing cellulose (Xiaoyu et al., 2023). *Styela plicata* is a solitary, cosmopolitan ascidian often found in high densities on artificial structures in harbors and marinas. It is also recognized as a species that can interfere with aquaculture operations by fouling equipment and competing with farmed or native filter feeders (Pineda et al., 2013). It thrives in a wide range of environmental conditions, including high temperatures, salinity, and pollution (Platin & Shenkar, 2023), making it a strong candidate for aquaculture. In South Korea, *S. plicata* is consumed as a traditional seafood, valued for its high protein content and bioactive compounds with antioxidant and antimicrobial properties (Lambert et al., 2016). However, cultivation practices remain limited, and no standardized inland protocol has been established for this species to date. Moreover, individuals are often collected from highly polluted areas, which may affect their nutritional value. During a previous study (Platin, 2022), *S. plicata* demonstrated rapid growth and high reproductive output in a closed-water system, supporting its feasibility for scalable aquaculture. Notably, *S. plicata* produces a thick outer tunic (an external layer that protects the animal's soft body) composed of approximately 60% cellulose. Their cellulose is highly crystalline and exhibits exceptional mechanical, electrical, and magneto-responsive properties, positioning it as a promising source of tunicate nanocellulose (t-CNC) for industrial applications (Xiaoyu et al., 2023). This study introduces a controlled cultivation protocol for the early life stages of *S. plicata*, providing a basis for evaluating its potential in future applications related to food production and biomaterials. Given its physiological resilience and ability to grow in nutrient-poor conditions, *S. plicata* emerges as a promising candidate for resource-efficient marine cultivation targeting food and industrial biomaterials.

## Materials and methods

This study consisted of a series of controlled experiments designed to evaluate the growth performance and survival of *Styela plicata* juveniles under various rearing conditions, including food type (two algae and their mix), light intensity (low light *vs.* complete darkness), feeding frequency, and five different temperatures. All experiments were conducted in both Closed Water Systems (CWS) and Running Seawater Systems (RSS), except for the temperature experiment, which was performed exclusively in RSS. At the beginning of each trial, 5 to 13 adult individuals were collected from the field. Artificial fertilization was performed to produce same-age juveniles from the same parents, ensuring synchronized feeding across replicates. Survival and growth rate were measured weekly and served as the primary performance parameters, with 180 to 360 juveniles per experiment, depending on the trial. Each experiment lasted one month, except for the food type and concentration trial, which was conducted over a period of three and a half months.

## Results and discussion

Juveniles of *Styela plicata* showed high survival in RSS when fed *Nannochloropsis* at the lowest concentration, with 75 ± 8.3% survival and an average size of 2.9 ± 0.2 mm after three and a half months. A mixed diet of *Isochrysis galbana* and *Nannochloropsis* at the highest concentration resulted in 83.3 ± 14.4% survival and a larger size of 3.3 ± 0.6 mm. For subsequent experiments, *Nannochloropsis* at the lowest concentration was selected as the standard feed due to its favorable survival rates and cost-efficiency. After one month, survival with *Nannochloropsis* X reached 100% in CWS and 77.7 ± 9.6% in RSS. Temperature had a clear effect on growth. The highest average size was recorded at 26 °C (840 ± 94 µm), with significantly larger individuals ($p < 0.05$) compared to 16 °C (581 ± 40 µm), 20 °C (501 ± 175 µm), and 30 °C (585 ± 65 µm). Survival was

*(Continued on next page)*

highest at 16 °C (72.2 ± 33.6%) and declined sharply at both 20 °C (38.9 ± 17.3%) and 24 °C (38.9 ± 5.3%). These results highlight a trade-off between growth and survival, emphasizing the need to adjust rearing conditions to production goals. *S. plicata* demonstrates strong potential for controlled aquaculture, with feeding regime and temperature identified as key factors. The use of *Nannochloropsis* as a single-species feed supports both biological efficacy and economic feasibility for scalable cultivation.

**Conclusion**

The protocol developed in this study is optimized for the early stages of *S. plicata* and provides a solid foundation for its future use in aquaculture as a source of dietary supplements and cellulose for industrial applications. Although additional research is needed to refine long-term rearing strategies and evaluate later life stages, our results highlight the species' high reproductive capacity and its compatibility with open seawater systems. Notably, *S. plicata* was successfully cultivated in nutrient-poor Eastern Mediterranean seawater, demonstrating its robustness and potential for low-input marine production. Future studies should explore the species' value as a dietary supplement and as a sustainable source of tunicate cellulose following controlled aquaculture.

# MACRO- AND MICROELEMENT CONTENT IN OYSTERS (*Ostrea Edulis* L.) CULTIVATED IN THE MALI STON BAY, ADRIATIC SEA

Pleadin J.*, Skendrović H., Zrnčić S., Kudumija N., Listeš E., Krešić G.

Croatian Veterinary Institute
Savska Cesta 143
10000 Zagreb, Croatia
E-mail: pleadin@veinst.hr

## Introduction

Oysters are among the most commonly farmed marine species and are native to almost all ocean regions with the exception of the polar regions. They are prized as a delicacy and play an important role in global seafood consumption. In recent years, growing awareness of their nutritional value has led to an increase in demand, with oyster production increasing by an average of 7.8% per year over the last three decades. Compared to finfish, shellfish generally contain a higher protein content, and oysters are no exception. They are also rich in macroelements (Na, K, Ca, P and Mg) and trace elements (Cr, Co, Cu, F, Br, I, Fe, Se, Zn and Mn), some of which, such as iron, copper and zinc, play a crucial role in various biological systems. The aim of this study was to investigate the seasonal variations in the mineral composition of shallow oysters (*Ostrea edulis* L.) from the Bay of Mali Ston in the Adriatic Sea.

## Materials and methods

Samples were taken each month over a seven-month period and analyzed by flame atomic absorption spectroscopy (200 Series A4 with SPS 4 Auto-Sampler, Agilent Technologies, USA) to determine the content of selected macro- and micro- elements.

## Results

The results show that the macroelements (Figure 1) exhibit greater seasonal fluctuations, while the microelements (Figure 2) remain relatively constant. The average content of minerals in all samples was as follows: 6011 mg/kg for Na, 2613 mg/kg for Ca, 3533 mg/kg for K, 858 mg/kg for Mg, 275 mg/kg for Zn, 44 mg/kg for Fe, 17 mg/kg for Cu and 1586 mg/kg for P. Although specific fluctuations were observed in individual months, the overall constancy of the microelements indicates consistency in mineral content despite environmental changes.

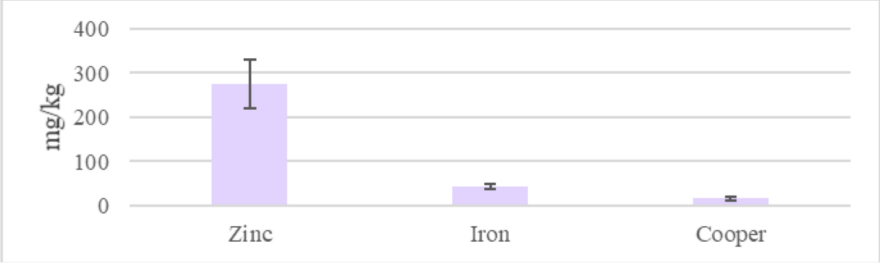

Figure 2. Microelements in oysters - mean concentrations with standard deviations

# LOW OR HIGH, WHERE DO REDCLAWS LIE? SHELTER USE IN CRAYFISH CULTURE

A. Plovie, J. Claeyé, H. Arnouts, L. Mariman, T. Abeel

Odisee University of Applied Sciences
Aquaculture Education and Research Facility (Aqua-ERF)
Ottergemsesteenweg Zuid 713
9000 Ghent, Belgium
E-mail: aaron.plovie@odisee.be

## Introduction

The redclaw crayfish (*Cherax quadricarinatus*) is a freshwater crayfish native to northern Australia and southern Papua New Guinea. It has gained increasing attention in global aquaculture due to its fast growth, high market value, and adaptability to a wide range of environmental conditions.

In confined environments, shelter plays a key role in reducing aggression, improving survival, and enhancing overall welfare. Redclaw crayfish are naturally territorial and exhibit increased aggressive interactions when shelter is limited, especially after molting. This can lead to injuries, stress, reduced growth performance, and decreased survival.

Can redclaw crayfish be cultured in higher tanks with less surface area, containing vertical shelter places? This study investigates the use of vertical shelter, when provided, and the effects on the behavior, growth, and survival of redclaw crayfish reared in indoor systems, with the aim of optimizing culture conditions for sustainable and productive aquaculture operations with attention to animal welfare.

## Materials and methods

Crayfish were kept at 27°C in six 800 L flat-bottomed square tanks. A photoperiod of 16h light/8h dark was applied. All tanks were connected to a RAS system with mechanical and biofiltration. 15 and 30 crayfish were stocked in tanks with low (five layers) and high (ten layers) tube bioblock shelter types respectively, in order to provide each animal with the same number of shelter tubes. Crayfish were fed once daily with a feeding level of 4% of total biomass. The trial ran 12 weeks and both treatments were performed in triplicate.

Every three weeks, all live animals were counted and weighted. Average Body Weight (ABW) and survival percentage were calculated.

During the first nine weeks, shelter occupation was recorded on three days per week. During each of these 27 observation moments, shelter occupation in one low shelter and one high shelter tank was recorded by counting the number of crayfish in each tube.

## Results

Redclaw crayfish prefer to occupy the lower tube layers, with a clear preference for the bottom layer. During the 27 observation moments in total, 75 and 36 crayfish were observed in the lowest tube layer in high and low shelters respectively. Note that the stocking numbers of crayfish in the high shelter tanks were twice the numbers in the low shelter tanks. The three top layers in the high shelter tanks had a low occupation rate. The heat map below (right) shows how many crayfish were observed per layer during the 27 observations in total in high and low shelter tanks.

The graph below (left) shows that the Average Body Weight (ABW) evolved from 7.91g ± 0.18g and 8.09g ± 0.12g in low and high shelter tanks respectively on week 0 to 23.52g ± 0.37g and 20.70g ± 1.97g in low and high shelter respectively on week 12. From the sampling on week 6 onwards, the ABW was significantly higher in low shelter tanks compared to high shelter tanks ($p$-value $< 0.05$).

Surprisingly, no significant effect of low and high shelter on survival rate could be shown

*(Continued on next page)*

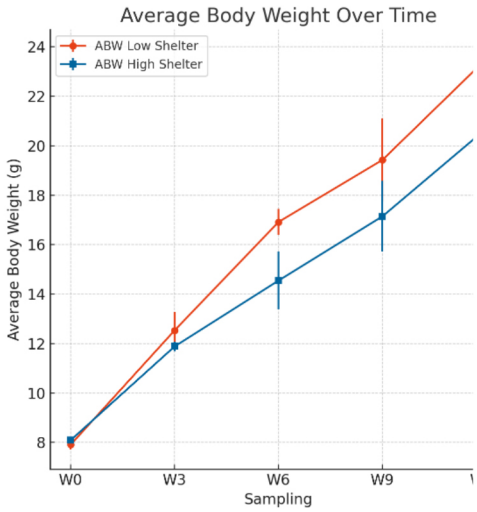

Fig. 1 Average body weight of crayfish in high and low shelter tanks. Error bars indicate standard deviation between tank replicates.

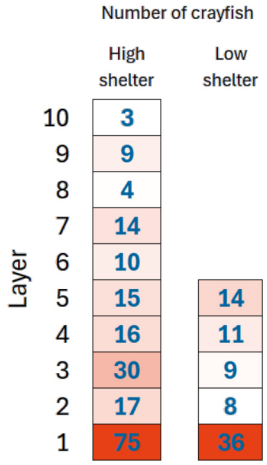

Fig. 2 Heat map showing total number of crayfish observed per layer of tubes in high and low shelter tanks during all observations.

**Discussion**

To provide an equal number of shelter tubes per crayfish, high shelter tanks contained twice the crayfish density per square meter bottom surface compared to low shelter tanks.

However, due to the low occupancy of upper tubes in high shelter tanks, competition was concentrated at the lower levels, likely intensifying interactions over limited bottom surface area and shelter tubes close to the bottom.

Increased competition in high shelter tanks may have led to more frequent and complex dominance interactions, potentially suppressing growth in subordinate individuals. In contrast, crayfish in low shelter tanks likely experienced more consistent access to feed and more efficient shelter use, facilitating simpler spatial dynamics and improved growth. However, no significant difference in mortality, primarily attributed to aggressive interactions and cannibalism, was observed between treatments.

These findings indicate that reducing bottom surface area by increasing vertical shelter complexity can negatively affect growth performance in indoor redclaw crayfish culture. Further research is recommended to evaluate alternative shelter designs and stocking strategies that optimize bottom space utilization and support growth.

# SUPLEMENTATION OF THE MICROALGAE *Arthrospira platensis* IN THE NURSERY PHASE OF PACIFIC WHITE SHRIMP (*Penaeus vannamei*, BOONE 1931) IN A BIOFLOC SYSTEM

Poersch, L.*, Rungo, N., Ribeiro, V., Carvalho, A., Cardozo, A., Tesser, M. and Wasielesky, W.

Federal University of Rio Grande – FURG
Marine Aquaculture Station
Rua do Hotel
02, Rio Grande, RS, Brazil. CP96210-030
lpoersch@gmail.com

This study evaluated the effect of adding dry biomass of the microalgae *Arthrospira platensis* (*Spirulina*) in to the water on shrimp growth, water quality and proximal composition of *Penaeus vannamei* post-larvae in a biofloc system. Four treatments were tested: (BFT) control without *A. platensis*; (*Sp40*) biofloc with 40 mg $L^{-1}$ mg/L of *A. platensis*; (*Sp50*) biofloc with 50 mg $L^{-1}$ of *A. platensis*; and (*Sp60*) biofloc with mg $L^{-1}$ of *A. platensis*. The shrimp with an initial average weight of 0.015 ± 0.009 were stocked at a density of 2000 post-larvae $m^3$ in polyethylene tanks with a useful volume of 50L and fed commercial feed. The experiment lasted 35 days and assessed zootechnical parameters, water quality and the proximal composition of the shrimp and the biofloc. Treatments with *A. platensis* showed improved biomass gain, better survival, and feed conversation rate, with a higher protein content in the shrimps when compared to control. The water quality parameters were significantly influenced by *A. platensis*, with reductions in pH and alkalinity in the treatments with the additions of *Spirulina*, particularly in *Sp60*, which showed the lowest values. Nitrate and phosphate concentrations increased in all *Spirulina* treatments compared to the control, with the highest values observed in the *Sp50* and *Sp60* treatments. However, all water quality parameters remained within tolerance levels for shrimp growth. Thus, among the treatments tested, the treatment with addition of 50 mg $L^{-1}$ of *A. platensis* powder positively influenced the survival and growth of the shrimp and improved their nutritional composition in the nursery phase of *P. vannamei* in the biofloc system.

# INFLUENCE OF MALE GENETIC BACKGROUND ON TEMPERATURE-DRIVEN DEVELOPMENTAL OUTCOMES IN ATLANTIC SALMON *salmo salar*

Manon Poignet*, Valérie Cornet, François D'halluin, Julie Hetru, Patrick Kestemont

Research Unit in Environmental and Evolutionary Biology (URBE)
Institute of Life Earth and Environment
University of Namur
61 Rue de Bruxelles
B-5000, Namur, Belgium.
Email : manon.poignet@unamur.be

## Introduction

Climate change is a major anthropogenic driver of biodiversity loss, intensifying extreme weather events such as floods and heatwaves (Heino et al., 2009). In freshwater systems, rising temperatures threaten cold-water species like Atlantic salmon (*Salmo salar*) (Buisson et al., 2008; Comte & Grenouillet, 2013). As ectothermic stenotherms, salmon are highly sensitive to temperature, especially during embryogenesis, which is optimal between 7–8 °C (Angilletta et al., 2002; Fraser et al., 2015). Hence, even slight thermal deviations can disrupt biochemical and metabolic processes, affecting growth, reproduction, and behaviour (Jonsson & Jonsson, 2009). Elevated incubation temperatures (>8 °C) have been linked to reduced survival, altered development, and increased abnormalities in salmon larvae (Kamler, 2002).

In Atlantic salmon populations, two male reproductive strategies are observed: migratory (anadromous) males, and precociously maturing males that reproduce in freshwater during their first (age 0+) or second (age 1+) year without seaward migration. This alternative tactic enhances resilience in harsh environments and is thought to result from interactions between genetic predisposition and environmental factors such as temperature-driven growth (Vladic et al., 2010; Martinez et al., 2000). With projected river warming, increased frequencies of precocious maturation may shift population structure toward freshwater residency, potentially altering genetic dynamics. These dynamics are particularly relevant for conservation aquaculture and the design of effective restocking strategies that aim to preserve genetic diversity and ensure the long-term viability of restored populations.

This study aims to evaluate how male genetic background modulates the effects of elevated water temperatures during embryonic development on key traits critical to Atlantic salmon restoration. Specifically, it will assess the impact of increased incubation temperatures on: (i) juvenile stress-related behaviour and (ii) immune system functionality.

## Material and Methods

Six wild anadromous male Atlantic salmon (*Salmo salar*, 5–6 years old) were captured during their 2024 upstream migration using a trapping system at the Lith fish ladder on the Meuse River (Netherlands). They were held in all-male tanks at the CoSMOS (Conservatoire du saumon mosan) hatchery in Érezée, Belgium (50°18'21.78"N, 5°32'33.61"E) until the breeding season. Additionally, six hatchery-reared precocious parr males (age 1+) raised at CoSMOS were used for reproduction.

Eggs were collected from farmed females (age 4+), pooled, and divided into batches of 300 eggs. Each batch was fertilized using fresh sperm from one of the 12 males to obtain a standard sperm-to-egg ratio of $10^6$. Fertilized eggs were incubated at the University of Namur in a dark, temperature-controlled room at 11 °C. After yolk sac resorption, larvae were transferred to larger tanks for free swimming and feeding to apparent satiation. Following two weeks of feeding, the juveniles underwent a standardized startle response test. Subsequently, half of the individuals were exposed to a bath infection with *Aeromonas salmonicida* achromogenes at a concentration of $1.41 \times 10^9$ CFU/mL for 12 hours at 11°C, while the other half served as an uninfected control group. Fish were then euthanized for liver and brain tissue collection.

RNA-seq was performed to identify differentially expressed genes (DEGs) between paternal origins. Selected genes related to immunity and stress were further analysed using RT-qPCR. In addition, RT-qPCR on telomere will be performed to assess the impact of genetic on chronic stress.

*(Continued on next page)*

**Results and discussion**

Preliminary results indicate generally low survival rates across all groups, with an average of 37.6 (min: 25.9, max: 57.5) for from anadromous males and 33.5 (min: 25.7, max: 42.8) f or offspring from precociously maturing parr. In the behavioural trials, we anticipate that juveniles fathered by anadromous males will demonstrate faster escape responses under stress. Finally, transcriptomic analyses are still underway, however, we expect to identify distinct gene expression patterns between offspring from the two male types, particularly in pathways related to stress response and immune function. These results would suggest that paternal reproductive strategy influences offspring resilience to early-life thermal stress, with implications for Atlantic salmon adaptation under future climate change scenarios.

# REGULATORY READINESS IN AQUAFEED INNOVATION: BRIDGING NUTRITION, POLICY AND PRACTICE

Tatiana Poletto*, Jorge Dias

*SPAROS Lda.
Área Empresarial de Marim
Lote C, 8700-221 Olhão, Portugal
tatianapoletto@sparos.pt

**Introduction:**
Aquafeed innovation is increasingly shaped by sustainability goals and the search for alternatives to traditional protein sources such as fishmeal. New ingredients — including agro-industrial by-products, insect meals, microalgae, single cell proteins (SCPs), and fermentation-derived biomass — offer promising nutritional and environmental advantages. However, their integration into commercial aquafeeds is often constrained by regulatory bottlenecks and unclear legal classifications under the European Union feed legislation.

One key barrier lies in the classification of feed ingredients within the EU regulatory framework. While placing a new feed material on the market may not require EFSA evaluation, this changes when the product is either considered a feed additive — subject to mandatory EFSA authorisation — or may be interpreted as a "novel" feed material under current regulatory practice, due to lack of historical use or innovative processing. Although no formal EU definition of "Novel Feed" exists, such cases will trigger an EFSA authorisation process. In both cases, authorisation processes can be complex and time-consuming, delaying innovation in feed formulation.

This presentation draws on internal formulation work conducted at SPAROS during the CIPROMED project, sharing lessons learned from the screening and evaluation of novel ingredients under real-world regulatory and nutritional constraints. The approach aligns with CIPROMED's mission to valorise local biomass and develop circular, sustainable protein sources within Mediterranean food systems.

**Internal approach**
To contextualize regulatory constraints, it is important to distinguish two common bottlenecks: (1) ingredients not listed in the EU Catalogue of Feed Materials (Reg. (EU) 68/2013) for aquaculture species — which may be permitted for terrestrial animals but not for fish — and (2) ingredients without documented history of use in aquafeed, or which involve new production processes, thus triggering additional legal scrutiny.

A structured, practice-oriented screening process was implemented to support internal ingredient triage and early-stage formulation planning, aiming to reduce regulatory and technical risk. Although scientific assessment typically begins with nutritional suitability, regulatory feasibility was screened early in this case to avoid investment in ingredients unlikely to reach market approval. The process included five sequential filters:

(1) Regulatory status (Catalogue listing, Registration process (if new ingredient), species and substrate restrictions);
(2) Nutritional suitability (composition, literature-based digestibility, anti-nutritional factors);
(3) Feed safety (compliance with legal undesirable substances thresholds);
(4) Technical feasibility (process compatibility, ingredient stability);
(5) Strategic relevance (alignment with sustainability and product innovation goals).

Ingredient performance modelling was supported by FEEDNETICS™, a nutritional simulation tool that estimates growth and nutrient retention using user-defined inputs such as feed intake, digestibility coefficients, proximate composition, fatty acid, and amino acid composition. This supported decision-making when in vivo data were limited or unavailable.

*(Continued on next page)*

**Results and Discussion**

This framework enabled risk-based screening in early formulation stages:

- Oriental fruit fly larvae (*Bactrocera dorsalis*) reared on mixed vegetal waste:

  This ingredient shows promising nutritional value but is currently not authorised under Regulation (EU) 2017/893, which limits insect feed use to specific species and approved substrates. Both the insect species and the vegetal substrate fall outside current regulatory allowances. However, this case underscores the importance of aligning insect rearing practices with existing approvals or supporting novel applications through EFSA dossiers.
  (Filters 1 and 5 – Regulatory status, Strategic relevance)

- Mediterranean fruit fly (*Ceratitis capitata*) larvae reared on olive pomace:

  Olive pomace is a sustainable agro-industrial by-product, widely studied and legally acceptable as a substrate. However, this insect species is not among the seven approved for feed use in aquaculture. Historical data on its safe use is lacking, which would necessitate a full EFSA safety assessment under Regulation (EC) 767/2009 before commercial inclusion. This highlights an opportunity for further research and regulatory engagement. (Filters 1, 2, and 3 – Regulatory status, Nutritional suitability, Feed safety)

- Schizochytrium sp., dried biomass:

  Both dried and fermented biomass forms are listed as feed materials in the EU Catalogue (e.g. 13.1.5) and can be used in aquafeeds under general feed law. Oil extracts — such as those commercialised in the aquafeed market — are treated as feed materials, not feed additives, and thus do not require pre-market EFSA authorisation. Their inclusion depends on meeting safety criteria (e.g. contaminant limits) and being properly labeled. These products represent successful examples of regulatory-compatible innovation in DHA supplementation. (Filter 1 – Regulatory status; Filter 2 – Nutritional suitability)

- Spirulina (*Arthrospira platensis*):

  A well-established microalga in aquafeeds, Spirulina is listed in the EU Feed Catalogue and supported by extensive research confirming its nutritional and antioxidant properties. As aquafeed innovation evolves, claims beyond nutrition (e.g., immune modulation) or use of novel strains or extraction techniques may require further validation. (Filters 1, 2, and 4 – Regulatory status, Nutritional suitability, Technical feasibility)

- Yeast-based SCP (*Cyberlindnera jadinii*):

  A non-GMO protein-rich biomass already present in the EU Feed Catalogue (sections 13.8.1 and 13.8.3), and widely used in commercial aquafeeds. Its established safety, nutritional value, and processing consistency position it as a low-risk ingredient for inclusion in formulation pipelines. (Filters 1, 2, and 4 – Regulatory status, Nutritional suitability, Technical feasibility)

This approach helped avoid investment in ingredients with low regulatory feasibility and supported early alignment between legal, nutritional, and technical considerations.

**Conclusion**

A paradox emerges: ingredients with the highest sustainability and circularity potential — such as insect meals on alternative substrates or agro-industrial residues — are often the most constrained by regulatory frameworks. By integrating legal feasibility into early-stage formulation, this framework improves internal decision-making and enhances support for clients developing experimental feeds. These insights directly support CIPROMED's mission to foster responsible innovation and valorise underused biomass in Mediterranean aquaculture systems.

# TOWARDS SUSTAINABLE SEA URCHIN AQUACULTURE: IMTA APPLICATION WITH POLYCHAETES AND MACROALGAE

P.M. Santos [a], J.L. Costa [b], T. Mouga [a], D. Teles [a], F. Jerónimo [a], A. Pombo [a*]

Email: pedro.c.santos@ipleiria.pt

## Introduction

Integrated Multi-Trophic Aquaculture (IMTA) promotes sustainability by combining species from different trophic levels to optimise nutrient utilisation. The sea urchin *Paracentrotus lividus*, highly valued in Southern Europe, presents slow growth rates that continue to limit its aquaculture potential. The inclusion of extractive species such as the polychaete *Hediste diversicolor* and the macroalga *Ulva rigida* may enhance system efficiency through the recycling of organic and dissolved nutrients. This study evaluated the survival and growth of *H. diversicolor* and *U. rigida* in a three-level IMTA with *P. lividus* as the fed species.

## Materials and methods

To evaluate the growth of extractive species under different IMTA configurations with *P. lividus*, a six-week trial was conducted with three treatments in triplicate, designed to compare the performance of *U. rigida* and *H. diversicolor* under separate and combined co-culture conditions: (1) *U. rigida* cultivated in static kreisel tanks (3 L available volume; 1 g $L^{-1}$ initial density) supplemented with culture medium; (2) co-culture of adult *P. lividus* and juvenile *H. diversicolor* in a recirculating aquaculture system (RAS); and (3) a full three-level IMTA integrating all species. *U. rigida* density was reset to 1 g $L^{-1}$ at the beginning of week 4. *H. diversicolor* (50 individuals per tank) was reared in a sediment layer at the bottom of 32 L tanks, with *P. lividus* (15 individuals per tank) held above in mesh containers. Sea urchins were fed a formulated dry diet. Mean environmental parameters across treatments were 18.2 °C, pH 8.5, and salinity 33.9. All organisms were weighed at the beginning and end of the trial. Growth was evaluated as specific growth rate (SGR).

## Results

Survival was 86% in polychaetes across both RAS treatments. Polychaete initial weights were 25.27 ± 3.97 mg (2) and 21.40 ± 2.62 mg (3), increasing to 0.37 ± 0.05 g and 0.39 ± 0.09 g, respectively, by the end of the trial. Polychaete SGR was 7.09 ± 0.45% $day^{-1}$ in the co-culture (2) and 7.81 ± 0.77% $day^{-1}$ in the full IMTA (3), with no significant differences between treatments. *U. rigida* showed an overall SGR of 4.06 ± 1.68% $day^{-1}$ in the control (1) and 2.01 ± 0.47% $day^{-1}$ in the IMTA system (3), although growth differences were not statistically significant. The peak weekly SGR occurred in week 2 for the static culture (5.95 ± 1.04% $day^{-1}$) and in week 6 for the IMTA treatment (3.20 ± 2.09% $day^{-1}$).

## Discussion

This study confirms the feasibility of integrating *H. diversicolor* and *U. rigida* with *P. lividus* in a three-level IMTA system. Polychaetes exhibited high survival and SGR values exceeding 7% $day^{-1}$, among the highest reported and comparable to those obtained using waste from carnivorous fish or high-protein diets. These findings highlight the nutritional suitability of sea urchin-derived organic waste for detritivorous species. Slightly higher polychaete growth under IMTA conditions may reflect indirect benefits from improved water quality, as *U. rigida* is known for its capacity to assimilate dissolved nitrogen compounds. Conversely, macroalgal growth was lower in the IMTA system compared to the static control, potentially due to limited nutrient availability and suboptimal flow conditions. *Ulva* productivity in IMTA systems depends not only on total nutrient concentrations, but also on the ratio and form of available nitrogen and phosphorus, as well as the presence of trace elements, which may limit uptake even when macronutrients are not limiting. Despite these limitations, biological performance across all components remained stable, supporting the use of low-trophic IMTA for integrated nutrient recovery and sustainable biomass production.

# INTEGRATED AQUACULTURE OF *Paracentrotus lividus* AND *Chondracanthus acicularis*: DOES URCHIN DENSITY MATTER?

## Introduction

Integrated Multi-Trophic Aquaculture (IMTA) is recognized as a sustainable method in aquaculture, bringing together species from various trophic levels to enhance nutrient utilization, minimize environmental impact, and transform waste materials into valuable, edible products. Therefore, IMTA has the potential to promote sustainable farming by improving efficiency while reducing waste, ultimately enhancing ecological, social, and economic sustainability of aquaculture. In this study, we evaluated the feasibility of cultivating the red seaweed *Chondracanthus acicularis* in IMTA with the sea urchin *Paracentrotus lividus*.

## Materials and methods

Three experimental systems were designed and monitored over a 4-week period: (S1) a monoculture of 40 sea urchins, (S2) a co-culture of 20 sea urchins with 1 g of *C. acicularis*, and (S3) a co-culture of 40 sea urchins with 1 g of *C. acicularis*. Both the seaweed and the sea-urchins were collected in Peniche, in the centre of Portugal (39° 19' 21.8" N, 9° 21' 31.2" W). Each system consisted of an independent sump connected to three flat-bottom tanks (50 L each) used to house the sea urchins (two with 40 individuals (S1, S3), and one with 20 individuals (S2). Each sump was connected to three kreisel tanks (2.9 L capacity each). In the IMTA systems, the kreisels contained *C. acicularis* at a density of 1 $g \cdot L^{-1}$, while the control system featured empty kreisels, serving as a baseline without macroalgae. The kreisels were illuminated by white LED lamps under a 12:12 h light:dark photoperiod, with an intensity of approximately 1000 lux, and were constantly aerated.

Twice a week, physicochemical parameters including temperature, salinity, pH, ammonia, nitrites, and nitrates ($NH_3$, $NO^-_2$ and $NO^-_3$, respectively) were regularly monitored and the seaweed Relative Growth Rate (RGR, $\%.day^{-1}$) was calculated weekly to assess biomass growth.

## Results

The systems showed generally stable environmental conditions, with small variations in temperature (ranging from 18.6 to 22.3°C), pH (7.57 to 8.14), and salinity (33.84 to 37.02). Ammonia concentrations were low across all treatments, though slightly higher in the monoculture system (S1). Notably, the nitrate and nitrite concentrations in S3 were consistently higher compared to S2, suggesting enhanced nutrient availability likely derived from sea urchin excretions.

Seaweed growth data revealed a striking contrast between the two IMTA setups. In S2 (IMTA with 20 sea urchins), *C. acicularis* showed a consistent decrease in biomass, with RGR values ranging from -1.34% to -6.32% per day, indicating a net biomass loss. Conversely, in S3 (IMTA with 40 sea urchins), the seaweed exhibited positive growth throughout the experiment, with RGR values ranging from 0.32% to 1.29% per day.

## Discussion

Seaweeds are widely recognized for their high capacity to absorb dissolved nutrients, particularly nitrogen compounds, making them valuable components in IMTA systems. However, the effectiveness of seaweeds in IMTA also depends on their growth dynamics. *C. acicularis*, in particular, is known for its relatively slow growth. In a previous study, the species reached a maximum relative growth rate (RGR) of 0.945% $day^{-1}$ under optimized conditions. In the present trial, this value was surpassed in the IMTA system with 40 sea urchins (S3), which showed a peak RGR of 1.29% $day^{-1}$ during the fourth week, while the system with 20 sea urchins consistently showed negative RGR. These contrasting results suggest that nutrient input from the sea urchins through excretion was insufficient in the lower-density system to support algal growth, while the higher-density setup provided adequate dissolved nutrients to sustain and promote biomass accumulation. Thus, this study highlights the critical importance of animal stocking density and nutrient load when designing effective IMTA configurations.

# COMPOSITION AND BIOACTIVITY OF SULPHATED POLYSACCHARIDES EXTRACTED FROM *Rugulopteryx okamurae*

## Introduction

Seaweeds are a source of bioactive compounds, including proteins, amino acids, polysaccharides fatty acids, vitamins, pigments and polyphenols with antioxidant, antimicrobial and antiviral functions. In recent years, there has been a growing interest in the research of polysaccharides of marine origin obtained from macroalgae being the most investigated for their potential applications in the fields of biomedicine and biotechnology: fucoidan, alginate and laminarin, present in brown macroalgae; ulvan obtained from green macroalgae; agar and carrageenan from red macroalgae (Salehi et al., 2019). Recently, the role of ulvan extracted from *Ulva ohnoi* as immunonutrient in *Solea senegalensis*, a species of great interest in aquaculture, has been reported (Ponce et al., 2024). Fucoidan is formed mainly by L-fucose and sulfate groups, although monosaccharides such as xylose, mannose, galactose, rhamnose and glucose, uronic acids and proteins may also be part of its structure. Like other macroalgae polysaccharides, fucoidan has a broad spectrum of biological properties, including antioxidant, immunomodulatory, antimicrobial, antiviral, anticancer and anticoagulant properties (Luthuli et al., 2019). The aim of this study was to characterize a sulphated polysaccharides extract obtained from the brown macroalgae *Rugulopteryx okamurae* and evaluate its antioxidant and immune activity. For this reason, sulphated polysaccharides extract was obtained using the hot water method and isolated by precipitation with ethanol. Chemical characterization and *in vitro* antioxidant and immunomodulatory activity was evaluated. Finally, the antimicrobial activity against *Photobacterium damselae* subsp. *piscicida*, an important fish pathogen, was determined.

## Material and methods

*R. okamurae* from Faro de Punta Carnero (Algeciras) was collected in spring. After washed, lyophilised, and milled, algal powder was mixed with ethanol 80% and stirred overnight at room temperature. The solution was centrifuged, the sediment was dried at 45ºC for 24 h and thereafter, it was treated with hot water (70ºC) for 2 h. The extract was centrifuged, and this process was repeated twice. The supernatant was collected and precipitated with ethanol overnight at 4ºC. The precipitated extract was recovered by centrifugation and freeze-dried. Total protein concentration was determined using the Bradford reagent following the manufacturer´s instructions for the 96 well plate assay. Sulfate, L-fucose, fucoidan and uronic acid content were determined as described previously by (January et al., 2019). Total phenolic assay was performed by the Folin- Ciocalteu method. For *in vitro* assays, macrophages from head kidney of 9 *S. senegalensis* juveniles obtained from facilities of IFAPA Centro El Toruño were extracted and cultured as described by Secombes and Fletcher, (1992). After 24 h of incubation with the sulphated polysaccharides extract (0.05, 0.5 y 1 mg $ml^{-1}$), cells were collected. Total RNA was isolated using the RNeasy® Mini Kit (Qiagen) and expression analyses were performed by RT-qPCR.

**Table 1.** Total phenolic compounds (TPC) and antioxidant activity

| TPC | | Antioxidant activity | | |
|---|---|---|---|---|
| Phloroglucinol (mg/g DW) | Gallic acid (mg/g DW) | DPPH (%) | $ABTS^{\bullet+}$ (µmol Trolox/g DW) | Reducing power (mg AA/ g DW) |
| 37.04 ± 0.75 | 22.96 ± 0.48 | 79.92 ± 1.31 | 352.74 ± 3.46 | 65.63 ± 1.85 |

*(Continued on next page)*

## Results and discussion

The yield of lyophilised sulphated polysaccharides extract obtained from *R. okamurae* was 3.16 ± 1.31% of the algal dry weight. High levels of L-fucose, a high sulphate content and low levels of contaminants such as uronic acid and protein are considered characteristics of good quality fucoidan (Ale et al., 2011). The sulphated polysaccharides extract obtained in this study contained 13.33 ± 2.92%, 5.34 ± 0.93% and 11.45 ± 2.14% of sulphate, L-fucose and fucoidan, respectively. Moreover, protein and uronic acid content was 2.34 ± 0.20 and 15.70 ± 0.81%, respectively. The protein content was lower than 3% indicating the purity of the sulphated polysaccharides extract. The main sugars were fucose (23.55 ± 0.03%), mannose (21.14 ± 1.0%) and xylose (15.17 ± 0.91) followed by galactose (13.78 ± 1.44%), glucuronic acid (10.19 ± 0.74%), glucose (8.58 ± 0.9) and rhamnose (8.01 ± 0.93%).

The results obtained in this study indicate that the sulphated polysaccharides extract has antioxidant activity (Table 1). The polyphenol content of macroalgae contributes significantly to their antioxidant and immunomodulatory properties. Therefore, these results could be explained by the higher content of phenolic compounds associated with the sulphated polysaccharides extract. To investigate the effects of the sulphated polysaccharides extract on the defence system, the expression level of a panel of genes related to the immune system was evaluated in Senegalese sole macrophages. The selected genes were as follows: lysozyme g (*lyg*), interleukin 1b (*il1b*), interleukin 6 (*il6*), interleukin 10 (*il10*), complement C3 (*c3*), hepcidin (*hamp*) and transferrin (*tf*). A significant coordinated increase in the mRNA levels of *il1b*, *il6*, *il10, hamp* and *tf* were observed in macrophages incubated with the sulphated polysaccharides extract at all concentrations assayed (0.05, 0.5 and 1 mg $ml^{-1}$) with respect to the control groups whereas no significant differences were observed in *c3* expression levels. All these results together with the antibacterial activity of the sulphated polysaccharides extract will be presented and discussed in depth during the oral presentation.

## Introduction

For the first time, aquaculture surpassed fisheries in aquatic animal production with 94.4 million tonnes. Aquaculture has the potential to significantly meet the rising global demand for aquatic foods although future expansion must prioritize sustainability (FAO, 2024). Researchers are exploring alternative preventive methods to reduce reliance on antibiotics and chemotherapeutics for infectious disease control. In this way, there has been a growing interest in the research of marine-derived polysaccharides (MDPs) due to their potential to enhance the immune responses of aquatic animals (Mohan et al., 2019). Specifically, ulvan is a sulphated MDP present in the cell wall of green macroalgae of the genus *Ulva* that has immunomodulating and antioxidant activities among others (Kidgell et al., 2019). Recently, the role of ulvan extracted from *Ulva ohnoi* as immunonutrient in Senegalese sole (*Solea senegalensis*) has been reported (Ponce et al., 2024). This study highlights the importance of considering the dosage, the time of administration and the prolonged effects after a withdrawal period. However, dietary ulvan effects in European seabass (*Dicentrarchus labrax*) remain largely unexplored. The aim of this study was to evaluate the influence of different dosages of dietary ulvan on immune gene expression, disease resistance and the prolonged effects after a withdrawal period in *D. labrax*. For this reason, European seabass juveniles were fed control, 0.5 and 1% ulvan supplemented diets for 15 days followed by 60 days post withdrawal (dpw). Finally, the disease resistance against *Photobacterium damselae* subsp. *piscicida*, an important fish pathogen, was determined at 60 dpw.

## Material and methods

*Ulva ohnoi* biomass was supplied by Ulva Natura S.L. and ulvan extraction was performed as described previously by Ponce et al. (2024). Briefly, after washed, lyophilised, and milled, algal powder was treated with hot water (80ºC) for 2 h. The extract was centrifuged, and this process was repeated twice. The supernatant was collected and precipitated with ethanol overnight at 4ºC. The precipitated ulvan-rich extract was recovered by centrifugation and freeze-dried. European seabass juveniles (average weight 14.26 ± 1.55 g) were provided by Cupibar S.L. (Cádiz, Spain) and three experimental groups were stablished in triplicate: control, 0.5 and 1% ulvan supplemented diets. The feeds were developed by LifeBioencapsulation S.L. (Almería, Spain). Juveniles were fed the experimental diets for 15 days followed by 60 days of withdrawal. At 15 days post-treatment (dpt), as well as at 30 and 60 days post-withdrawal (dpw), spleen samples were collected, transferred to RNAlater™ Stabilization Solution (Invitrogen), and stored at -80°C until further analysis. Total RNA from spleen was isolated using the RNeasy® Mini Kit (Qiagen) and treated twice with DNase I using the RNase-Free DNase kit (Qiagen). Total RNA was reverse transcribed using the iScript™ cDNA Synthesis kit (Bio-Rad). Expression analyses of a set of genes related to immune system were performed by RT-qPCR using specific primers: lysozyme g (*lyg*), interleukin 1b (*il1b*), interleukin 6 (*il6*), interleukin 10 (*il10*), tumor necrosis factor alpha (*tnfa*), hepcidin (*hamp*) and transferrin (*tf*). At 60 dpw *D. labrax* juveniles were challenged with *P. damselae* subsp. piscicida ($2\ 10^7$ cfu $g^{-1}$), and mortality was recorded each day.

## Results and discussion

To assess the effects of dietary ulvan on the immune system of European seabass, the expression profiles of seven genes were evaluated. No significant differences were observed for the expression levels of *il1b*, *il10* and *tf* in any case. When juveniles were fed the experimental diets supplemented with 0.5% ulvan, mRNA levels of *il6* and *hamp* were significantly upregulated with respect to the control groups only at 60 dpw. In the case of 1% ulvan treated groups, only expression levels of *il6* were significantly downregulated with respect to the controls at 15 dpt. Nevertheless, expression levels of *lyg*, *il6*, *tnfa* and *hamp* increased significantly with respect to the control groups at both, 30 and 60 dpw. Moreover, when juveniles were challenged with *P. damselae* subsp. *piscicida* at 60 dpw, the relative percentage survival (RPS) in juveniles from 0.5% and 1% ulvan treated

*(Continued on next page)*

groups was 31.58 and 42.11%, respectively at 7 days post challenge (dpc). Indeed, survival of 1% (54.17%) was signifcantly higher than controls (20.83%). No mortality was observed in juveniles from PBS injected groups throughtout the challenge period. Similar results were observed previously by Ponce et al., 2024 in Senegalese sole. In their study, administration of 1% dietary ulvan for 30 days resulted in an enhanced immune status and increased resistance against *P. damselae* subsp. *piscicida* and these effects were prolonged over time. Overall, these results demonstrate that dietary ulvan modulates the inmune gene expression levels and increases the disease resistance against *P. damselae* subsp. *piscicida* in *D. labrax* juveniles when is administered for 15 days at 1%. Moreover, these results highlight the importance of dosage, timing and target species for establishing a suitable protocol for the administration of immunomodulators such as ulvan in aquaculture.

UMR 241 SECOPOL
B.P. 6570 - 98702 Faa'a - Tahiti - Polynésie française
E-mail: anastasia.bestin@inrae.fr

## Introduction

The blue shrimp *Litopenaeus stylirostris* is naturally found on the Pacific East coast from northern Mexico to Peru. In the 1970s this species was identified as a good candidate for domestication. It was thus introduced straightaway in French Polynesia, New-Caledonia and Hawaï (Haffray et al., 2025). Nowadays, selective breeding programs are implemented in French Polynesia and New Caledonia. Manual fertilization to ensure controlled mating is common practice. To do so, the sperm mass contained in the spermatophores of the males is sampled and placed on the gonopores of the females for fertilization to occur. In order to ease that process, the aim would be to sample the desirable males whenever they are mature and store their spermatophore in the fridge, waiting for the wanted females to be about to spawn and fertilized thanks to these chilled spermatophores.

## Material and Method

The males used in this study were 10 months of age (~ 40 g) and were reared and prepared as breeders according to the practices of the commercial hatchery VAIA (Vairao, Tahiti). Only mature males with two spermatophores (non-melanized) were sampled. In total, 88 spermatophores from 88 different males were placed in a tube within a preservation solution for storage in the fridge (4°C). This solution was a saline calcium-free solution containing antibiotics, as inspired by Nimrat et al., 2020. Spermatophores were assessed for viability every day, starting the next day of the sampling and for two weeks. To do so, a suspension of spermatozoa obtained from the sperm mass from the spermatophores was stained with the pink dye eosine and observed under a light microscope. Unstained cells were considered alive whereas pink-colored cells were considered non-viable.

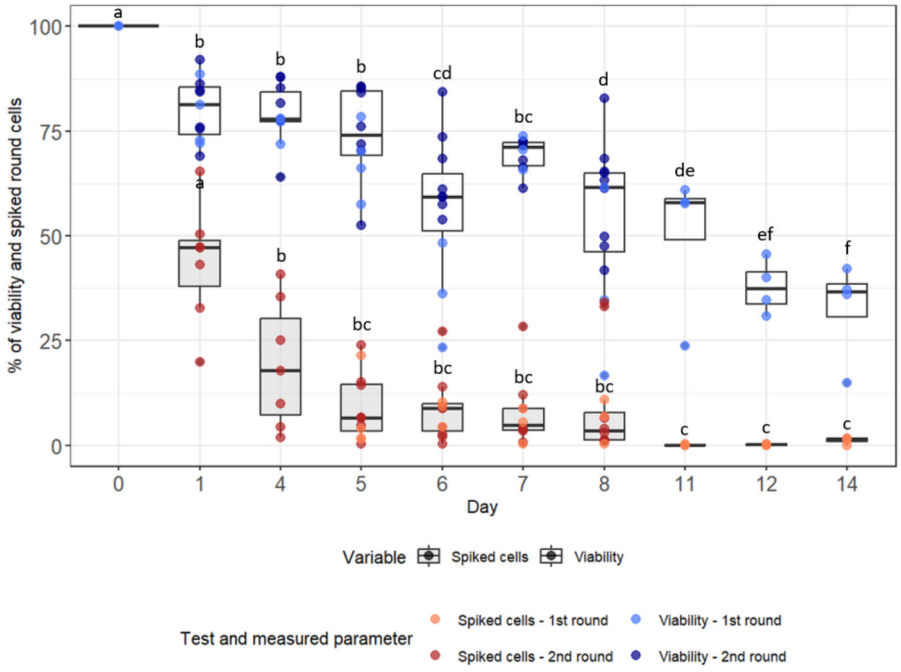

Figure 1: Assessment of sperm viability during chill storage of spermatophores

*(Continued on next page)*

**Results**

Statistically, as shown in Figure 1, there was a significative difference in mean viability since the first day of chilled-storage compared to the perfect full viability of the control. However, during the first 5 days, the viability remained stable above around 78% in mean. The viability dropped more noticeably after 8 days of chilled-storage and reached a mean of 37%.

**Conclusions**

Future work will aim at optimizing the current protocol to sample and preserve the spermatophore (*e.g.* composition of the solution) so that to keep viability more stable over time and at an even higher level.

As such, these results are promising to facilitate the use of *Litopenaeus stylirostris* males for artificial fertilization in hatcheries, as it provides some flexibility in the operational organization of the mating plans. It can also be a very interesting way to easily provide some male genetic resources to other hatcheries if transportation in chilled conditions does not exceed one week.

**Acknowledgements**

We feel very indebted towards the DRM who owns the shrimp line and VAIA hatchery in Tahiti financing 100% of the blue shrimp production through a public market with the CAPF: they let us use part of their broodstock in order to conduct the experiment. We warmly thank IsBlue for the mobility grant, the UPF for the training grant, OSO farming, Blue Genetics, Aquapesca and UPRA-NC Crevette for their financial support. We also thank also Ifremer (Vairao) for the place allocated to achieve the sampling of the animals.

# FEEDING TOMORROW'S SHRIMP: UK-SOURCED, LOW-EMISSION AQUAFEEDS TO DRIVE SUSTAINABLE RAS-SECTOR GROWTH

N. Pontefract*, H.E Mance, H Wong, and J.M. James

Pontus Research Ltd
Pembrokeshire, UK
nmp@pontusresearch.com

## Introduction

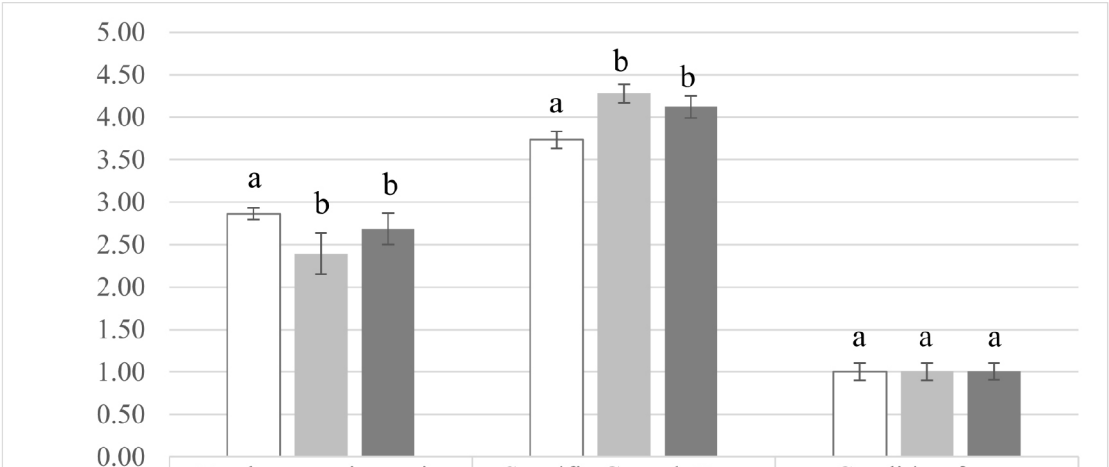
The UK shrimp recirculating aquaculture system (RAS) sector is still in its early stages of development and remains heavily dependent on imported aquafeeds. This reliance not only increases the sector's carbon footprint and feed costs but also exposes it to supply chain vulnerabilities. To address these challenges, the InSuRAFeed project was launched in 2023 with the aim of developing cost-effective, nutritionally balanced diets for Litopenaeus vannamei, formulated exclusively from UK-sourced, sustainably produced ingredients. By focusing on locally available raw materials and innovative feed formulations, the project seeks to enhance the sustainability, resilience, and economic viability of UK shrimp RAS operations.

## Methods

Twenty-two candidate ingredients were evaluated for nutrient profile, sustainability, and cost. Two experimental diets were formulated: high animal/low plant protein (HA/LP; 19 %:71 % animal-to-plant) and low animal/high plant protein (LA/HP; 13 %:76 %), both iso-nitrogenous, iso-lipidic, and iso-calorific with a commercial control. Diets were produced in-house and trialed in vivo over 50 days. Growth performance, feed conversion ratio (FCR), specific growth rate (SGR), condition factor (K), carcass composition, and apparent digestibility coefficients (ADCs) were measured.

## Results

Initial weights (1.47–1.50 g) were comparable across treatments. Final weights increased 8.15-fold (HA/LP) and 7.54-fold (LA/HP) versus 6.2-fold for the control ($p < 0.05$). SGR was significantly higher in both experimental groups; FCR was lowest for HA/LP but not significantly different from the control. K-factors (1.0–1.5) indicated optimal condition in all groups. Carcass protein (76.0–77.1% DM) was consistent, lipids slightly lower in LA/HP (4.68% DM), and ash higher in experimental diets. Protein ADCs were 78.8–83.9%, lipid 90.0–92.6%, phosphorus 96.5–97.1%, with moderate ash digestibility (36.8–44.9%). Cannibalism during molting likely affected feed metrics.



| | Feed conversion ratio | Specific Growth Rate | Condition factor |
|---|---|---|---|
| Control | 2.86 | 3.73 | 1.01 |
| HA/LP | 2.39 | 4.28 | 1.01 |
| LA/HP | 2.68 | 4.12 | 1.01 |

Figure 1. Average Feed Conversion Ratio, Specific Growth Rate, and Condition factor for *Litopenaeus vannamei* administered the different experimental aquafeeds for 50 days. Data presented as mean ± SD. Different letters above the columns denote significant differences.

*(Continued on next page)*

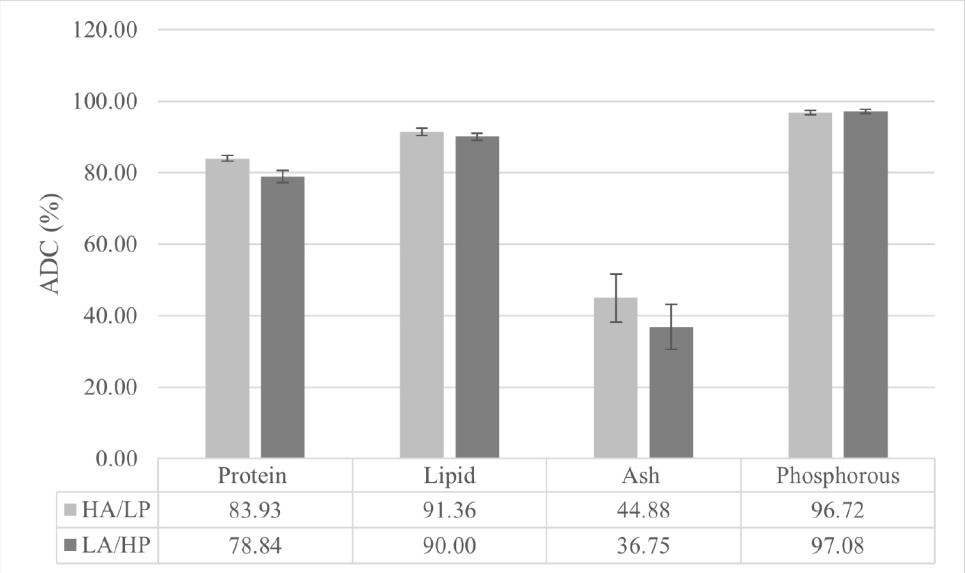


Figure 2. Apparent Digestibility Coefficients of the different experimental feeds when fed to *Litopenaeus vannamei.*

**Discussion and future work**

UK-sourced, soy-free diets can match or exceed the performance of imported feeds while maintaining product quality and nutrient digestibility. Future work will refine formulations to reduce cost, mitigate cannibalism impacts, and enhance scalability. Ongoing analyses include hepatopancreas histology, haematology, life cycle assessment (LCA), and waste particle characterisation to further optimise sustainable UK shrimp production. These findings demonstrate the feasibility of producing high-performance, UK-sourced diets for shrimp RAS without soy or imported proteins. Ongoing work includes hepatopancreas histology, haematological profiling, life cycle assessment (LCA) of ingredient sourcing, and waste characterisation for RAS optimisation. Refinement of formulations aims to reduce costs and enhance scalability, supporting sustainable UK shrimp production.

# INNOVATIVE SUSTAINABLE RECIRCULATING AQAUACULTRE SYSTEM AQUAFEEDS (InSuRAFeeds) FOR MIRROR CARP *Cyprinus carpio* UTILISING EXCLUSIVLEY UK-SOURCED, NON-SOY, LOW-EMISSION INGREDIENTS

[a]Pontefract, NM.*, [a]Mance, HE., [a]James, JM

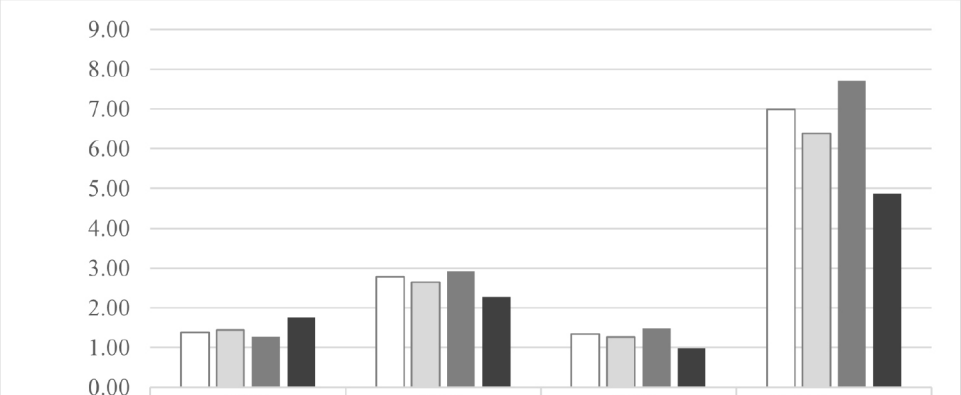
*nmp@pontusresearch.com
[a]Pontus Research Ltd., Unit E, Hirwaun Industrial Estate, Aberdare, Wales, UK. CF44 9UP

**Introduction**

Within the industry, there is a growing demand for sustainable and resource-efficient aquaculture feed, particularly for Recirculating Aquaculture Systems (RAS), while minimizing environmental impacts and ensuring healthy and sustainable diets. This research aimed to produce novel experimental RAS diet formulations, utilising non-soy, sustainably sourced, low-emission, UK-produced ingredients, exclusively, that are comparable to current commercially available aquafeeds, in terms of fish growth and nutrient digestibility.

**Methodology**

Of the 30 ingredient suppliers who were approach to participate in the project, 22 fully engaged. Following comprehensive proximate composition analysis, 3 iso-lipidic and iso-nitrogenous experimental feeds were formulated to meet the known minimum nutritional requirements of mirror carp, and manufactured in-house using a Clextral twin-screw extruder. The *in vivo* feeding trial (70-days: $BW_i = 8.64 \pm 0.02$g) was conducted in a RAS at Pontus Research's research facility, with dietary regimes assigned randomly in quadruplicate. Standard health and growth metrics (WG, % survival, FCR, SGR, and K-factor, were monitored, and faeces collected for digestibility analysis.



| | FCR | SGR | PER | Fold increase |
|---|---|---|---|---|
| Control | 1.38 | 2.77 | 1.35 | 6.98 |
| Diet 1 | 1.45 | 2.65 | 1.26 | 6.39 |
| Diet 2 | 1.28 | 2.92 | 1.48 | 7.71 |
| Diet 3 | 1.75 | 2.28 | 0.99 | 4.87 |

Figure 1. Growth parameters (FCR = Feed conversion ration, SGR = Specific Growth Rate, PER = Protein Efficiency Ratio) of mirror carp administerd the different experimental aquafeeds for 70 days.

*(Continued on next page)*

**Results**

Final weights increased 6.98-, 6.39-, 7.71- and 4.87-fold, respectively, for Control, and Diets- 1, 2 and 3. The SGR for fish administered Diet 2was significantly higher than the of the control-fed fish, which also demonstrated a significantly lower FCR.

Carcass composition and digestibility analysis, histological examination of the gills, skin and gut, haematology parameter analysis, and Life Cycle Analysis of the experimental diets all remain ongoing. We hope to have the data ready in time to present on the poster, should we be successfully chosen to present.

**Discussion**

From the results collated so far, we have demonstrated the potential for carp, raised in RAS, to be administered aquafeeds comprised exclusively of UK-sourced ingredients, decreasing industry dependency on soy and the associated carbon footprint of aquafeeds. We aim to demonstrate that diets formulated from UK-sourced, soy-free ingredients can achieve performance comparable to—or even exceeding—that of imported feeds, while maintaining high product quality and nutrient digestibility. Future research will focus on refining formulations to lower costs and improve scalability.

# DEVELOPING SUSTAINABLE, UK-SOURCED, LOW-EMISSION RAS DIETS FOR RAINBOW TROUT (*Oncorhynchus mykiss*)

Nicola M. Pontefract*, Hannah E. Mance, Jack M. James

Pontus Research
Unit E, Hirwaun Industrial Restate
Aberdare, Rhondda Cynon Taf
Correspondent email: nmp@pontusresearch.com

## Introduction

As the aquaculture sector continues to expand, there is a growing need for feeds that are not only nutritionally effective but also sustainable and resource-efficient, particularly within Recirculating Aquaculture Systems (RAS). Reducing the environmental footprint of aquafeeds while maintaining fish health and growth is a key challenge for the industry. In response, this research focused on the development of innovative RAS diet formulations made entirely from non-soy, sustainably sourced, low-emission, UK-produced ingredients. The aim was to produce diets that are comparable—or superior—to existing commercial feeds in terms of growth performance, nutrient digestibility, and feed efficiency, demonstrating a practical pathway toward locally sourced, environmentally responsible aquaculture nutrition.

## Methodology

Of the 30 ingredient suppliers approached to participate in the project, 22 fully engaged. Based on comprehensive proximate composition analysis, three iso-lipidic and iso-nitrogenous experimental feeds were formulated to meet the known minimum nutritional requirements of Rainbow trout and were manufactured in-house using a Clextral twin-screw extruder. The *in vivo* feeding trial (initial body weight = 27.64 ± 0.15 g) is being conducted at Pontus Research and remains on-going, with a scheduled end date of the 19th August.

Over the course of the 63-day trial, growth parameters and indices (FCR, SGR, WG, PER, survival and K-factor) have been closely monitored and will be presented in the conference poster. In addition, data on apparent digestibility coefficients, carcass composition, waste particle characterisation, epidermal mucous quality, and a range of haematological parameters will be included, providing a comprehensive assessment of the effects of the experimental diets on both growth performance and overall fish health. Gut, gill and skin samples will also be taken for histological examination at the conclusion of the trial but it is unclear whether these analysis will be completed in tie for inclusion in the poster.

## Significance

The InSuRAFeed project addresses a critical challenge in the UK aquaculture sector: the heavy reliance on imported feeds, which increases production costs, supply chain vulnerability, and the environmental footprint of farming operations. By developing nutritionally balanced, cost-effective diets formulated exclusively from UK-sourced, sustainably produced ingredients, the project aims to demonstrate that local feed resources can support high growth performance and fish health while reducing carbon emissions.

For the industry, the outcomes of InSuRAFeed are highly impactful. The project will provide evidence-based formulations that allow farmers to reduce dependency on imported ingredients, lower operational costs, and improve sustainability credentials. Additionally, by optimizing diet composition for recirculating aquaculture systems (RAS), the project supports efficient resource use, waste reduction, and improved animal welfare, setting a new benchmark for sustainable UK aquaculture. Ultimately, InSuRAFeed has the potential to transform industry practice, strengthen domestic feed production, and position the UK as a leader in low-emission, sustainable aquaculture.

# CENTRAL INFLAMMATORY RESPONSE IN RAINBOW TROUT AND ITS IMPLICATIONS IN APPETITE REGULATION

L. Portela-Couñago*, R. Paladea Rojo, C. Fernández-Maestú, J. L. Soengas and M. Conde-Sieira

Centro de Investigación Mariña

## Introduction

Increased dietary fat has been used in aquafeeds to enhance fish growth while reducing costs, as fats are energy rich and cheap (Naiel *et al.*, 2023). However, in mammals, high-fat diets (HFD) seem to trigger a generalized inflammatory response that alters feed intake regulation mechanisms (Le Thuc *et al.*, 2017), leading to hyperphagia (Lee *et al.*, 2020), linking inflammation and feed intake processes. In mammals, dietary fat triggers a rapid hypothalamic inflammatory response 24 h after the first feeding of HFD and reaches a peak around the third day, descending for 2-3 weeks, and rising again becoming chronic and systemic (Thaler *et al.*, 2013; Jais y Brüning, 2017, Lee *et al.*, 2020). Mechanistically, two major inflammatory pathways are activated: those mediated by JNK and NF-κB. As a result, proinflammatory cytokines are produced (Le Thuc *et al.*, 2017). Additionally, oxidative stress seems to be impaired because of toxic lipidic species accumulation (Cavaliere *et al.*). Saturated fatty acids seem to be the trigger of this complex response (Chataigner *et al.*, 2021). In fish, little is known about the relationship of feeding with inflammatory response associated to dietary fat. The inflammatory response has been mostly studied at peripheral levels and central effects have been demonstrated in fish (Dai *et al.*, 2018; Ghaddar *et al.*, 2020). The purpose of this study was to determine if the central inflammatory response to dietary fat observed in mammals is conserved in a teleost fish and if it is also related with feed intake.

## Materials and methods

60 rainbow trout (*Oncorhynchus mykiss*) were randomly distributed into 4 equal tanks and fed a commercial diet (Biomar, Spain) during the acclimatation period. Then, two tanks were fed the control diet (CD), whereas the other two were fed the high-fat diet (HFD), with a 24 and 32 (% DM) of fat content, respectively. Fish were fed until visual satiety once a day and feed intake levels were recorded. 3 and 17 days after eating the experimental diets (Sparos, Portugal), fish were anaesthetized and euthanized to collect blood, hypothalamus and telencephalon, that were immediately frozen in dry ice and stored at -80 ºC until further analysis. Glucose, lactate, fatty acids and triglycerides concentrations were measured in plasma. The relative amount of mRNA from genes related with inflammatory response, oxidative stress and feed intake regulation in hypothalamus and telencephalon was quantified by RT-PCR. Statistical analysis was performed to all data using R and RStudio software. ANOVA, Tukey tests and non-parametric Kruskall-Wallis tests were done as needed.

## Results

HFD led to a significantly higher plasmatic fatty acid concentration. An increasing trend was also observed in plasmatic triglycerides concentration. Antiinflammatory cytokines (*tgf-β1*and *il-10*) mRNA relative abundance showed a general tendency to increase over time in both (hypothalamus and telencephalon) (***Fig. 1A-D)***. Regarding proinflammatory cytokines, *tnf-α* mRNA relative abundance increased at long term in HFD group in telencephalon, whereas in hypothalamus, there is a decreasing trend in short term (***Fig. 1E-F)***. Genes related to inflammatory pathways (*ikkα* and *ikkβ*) showed an increasing tendency at 17 days in both tissues in HFD group. All three oxidative stress related genes mRNA relative abundance showed an increasing trend in both tissues at long term (data not shown). As for feed intake regulation, hypothalamic anorexigenic neuropeptides (*pomca1, cartpt*) mRNA relative abundance tended to increase at long term in HFD. Orexigenic neuropeptides (*npy* and *agrp*) mRNA abundance showed an increasing trend in those animals fed the HFD at short term in the hypothalamus (data not shown).

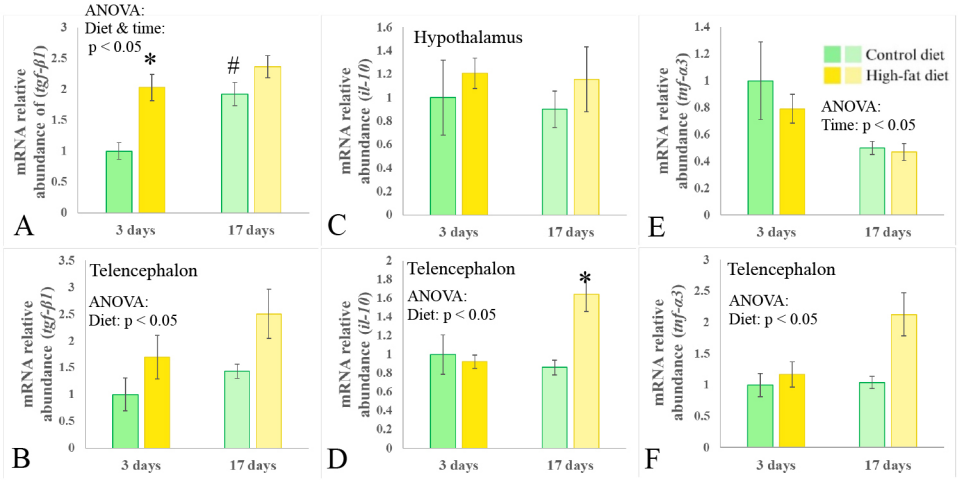

***Figure 1***.-mRNA relative abundance for 3 of the measured genes, in hypothalamus and telencephalon from rainbow trout after feeding with control or high fat diet at short and long term. A: *tgf-β1* in hypothalamus. B: *tgf-β1* in telencephalon. C: *il-10* in hypothalamus. D: *il-10* in telencephalon. E: *tnf-α3* in hypothalamus. F: *tnf-α3* in telencephalon. Bars are mean ± standard error of mean (n = 5-6). Results were analysed using ANOVA and Tukey test for post-hoc comparisons. *: significantly different from the group fed control diet at the same time ($p < 0.05$). #: significantly different from the group fed the same diet at 3 days ($p < 0.05$).

***Figure 1***.-mRNA relative abundance for 3 of the measured genes, in hypothalamus and telencephalon from rainbow trout after feeding with control or high fat diet at short and long term. A: *tgf-β1* in hypothalamus. B: *tgf-β1* in telencephalon. C: *il-10* in hypothalamus. D: *il-10* in telencephalon. E: *tnf-α3* in hypothalamus. F: *tnf-α3* in telencephalon. Bars are mean ± standard error of mean (n = 5-6). Results were analysed using ANOVA and Tukey test for post-hoc comparisons. *: significantly different from the group fed control diet at the same time ($p < 0.05$). #: significantly different from the group fed the same diet at 3 days ($p < 0.05$).

**Discussion and conclusions**

Inflammatory response seemed to be stronger and more consistent at telencephalon level attending to mRNA relative abundance variations. The increasing tendency observed in genes involved in inflammatory pathways along with the changes observed in pro- and anti-inflammatory genes support the hypothesis of a conserved inflammatory response to HFD at central level in teleost fish as observed previously in mammals (Souza *et al.*, 2016; Cavaliere *et al.*, 2018). Additionally, the pattern of variation displayed suggests that the sampling times, selected in accordance with the pattern observed in mammals, were not the optimal to catch the peak of inflammation, that could be due to immune responses being slower in fish (Watts *et al.*, 2001). On the other hand, a long-term orexigenic response was observed.

In summary, results suggest the existence of an inflammatory response against high fat diets that develops slower than in mammals. Moreover, this response seems to be related with homeostatic regulation of feeding, and could also be related to hedonic control, since telencephalon is the main brain area affected. Further studies are needed to address both the implication of hedonic control and the temporal pattern of inflammatory response.

# EVALUATION OF THE WELFARE OF RAINBOW TROUT (*Oncorhynchus mykiss*) IN AQUACULTURE: IDENTIFICATION AND VALIDATION OF RELEVANT HEALTH AND BEHAVIORAL INDICATORS

M. Poupon, A. Warin, M. Stomp

Bureau Bankiva
4 rue de la fin de chêne
21410 Gergueil, France
E-mail : maella.poupon@bankiva.fr

**Introduction**

Supported by the evolution of scientific knowledge and by a growing societal sensitivity towards animal welfare, the welfare of farmed fish is today a major issue. However, its assessment remains difficult due to the biological particularities specific to each aquatic species and the specificities of their environment. The indicators usually used for terrestrial animals are not directly transposable to fish.

In this context, a study was carried out by the consulting firm Bankiva, at the request of a French retailer, in order to identify and validate relevant indicators to assess the welfare of rainbow trout (*Oncorhynchus mykiss*) farmed in aquaculture.

The protocol implemented was based on the evaluation of thirteen health indicators (related to the state of health) and twelve behavioral indicators. Each indicator was examined with regard to five validation criteria: prevalence (Number of fish affected by a disease or expressing certain behaviors. The indicator must be observed frequently enough to validate this criterion.), specificity (Ensures that the indicator measures what we want to evaluate and not another factor. Specificity can be evaluated by taking two situations, one where the level of welfare is good and one where the level of welfare is degraded.), feasibility (Property allowing an indicator to be used in a farming context in the greatest possible number of situations and by the greatest possible number of observers.), sensitivity (Property of an indicator that makes it possible to detect early variations in welfare. Thus an indicator that only shows a variation in welfare very late or as a last resort would not be considered relevant.) and reproducibility (This consists of testing whether the same results are obtained after observing the same situation (here the same tank) by two different people.).

**Materials and methods**

The study was carried out on a large sample: 22,230 trout distributed in 18 tanks from 5 different fish farms, with varied practices (stocking densities, water recirculation systems, feeding strategies). The observations concerned three categories:

- Portion trout (250 g)
- Large trout (1–2 kg)
- Very large trout (2–3 kg)

Health observations were carried out individually on all the fish. Behavioral observations, on the other hand, focused on 54 groups (three areas per tank: head, middle, and tail). The indicators were observed according to a specific protocol:

- For behavior, visual scans every 5 minutes.
- For health, samples of 30 fish per area, observed directly in the water.

In total, 13 health indicators and 12 behavioral indicators were evaluated in each area. Their validation was based on:

- Prevalence: frequency of observation sufficient to be useful.
- Specificity: ability to measure a specific aspect of welfare, independently of other factors.
- Feasibility: applicability in the field, in different contexts.
- Sensitivity: early detection of variations in welfare.
- Reproducibility: consistency of results between observers.

*(Continued on next page)*

**Results**

The first results show that eight health indicators and six behavioral indicators meet all the validation criteria and can therefore be considered reliable for assessing the welfare of rainbow trout in aquaculture. However, five health indicators and six behavioral indicators did not meet all the criteria, revealing the difficulty of identifying robust and universal tools in fish farming.

Some non-validated indicators (e.g., vertebral deformities, hyperventilation) are rare but may indicate serious problems and act as sentinel indicators. Others, such as fin erosion, vary according to the physiological stage, suggesting a differentiated application. Observer training proved essential to improve reproducibility, notably through the use of standardized scoring grids.

**Conclusion**

In conclusion, this exploratory study highlights the complexity of selecting indicators and the challenges related to their practical application under production conditions. It paves the way for the development of protocols better suited to the specific needs of the species and to the realities of aquaculture farms. It also emphasizes the importance of continuing research to strengthen and refine fish welfare assessment tools, with the aim of continuously improving farming practices.

# SELECTIVE BREEDING OF AMUR MIRROR CARP: GENETIC VARIATION, CURRENT STATUS AND FUTURE CHALLENGES

M. Prchal[1]*, D. Gela[1], M. Kocour[1]

[1]University of South Bohemia in České Budějovice
Faculty of Fisheries and Protection of Waters
South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses
Zátiší 728/II
*Email: mprchal@frov.jcu.cz

## Introduction

Common carp is the dominant fish species in the Czech pond aquaculture, but no systematic selective breeding program has been realised until recently. The Amur mirror carp (AMC), a new Czech mirror carp breed established in 2014, has been used as a model fish species for a long-term study to estimate the genetic, practical, ecological and economical potential of using common carp for selective breeding under traditional pond aquaculture (Prchal et al., 2018, 2021, 2024; Kocour et al., 2025). Across various studies, different genetic parameters of performance and morphological traits were estimated from the yearlings to the market size fish. Moreover, attempts to shorten the generation interval in selective breeding program of common carp were performed, genetic markers for an effective pedigree reconstruction were designed and tested and the economic and ecological impacts of genetically improved carp stocks cultured under traditional pond aquaculture were evaluated to obtain comprehensive information for assessment of effectivity, sustainability and feasibility of selective breeding program in common carp under semi-intensive pond culture management.

## Materials and methods

For most studies, AMC stocks were used. The stocks were established by a partial factorial design to obtain up to 200 full-sib families within each study. All stocks were always reared communally under semi-intensive pond conditions or in combination with a RAS system to shorten the generation interval. The parentage assignment was done using microsatellite markers (Prchal et al., 2018) or SNP markers identified by RAD sequencing (Palaiokostas et al., 2018a). The fish were phenotyped after each growing and winter period until market size. The main performance traits were, for example, body weight, Fulton's condition factor, morphological indicators, muscle fat content, slaughter yields and their predictors, scale pattern quality or flesh colour traits (CIE System). The genetic and genomic parameters were estimated using pedigree or genomic markers using an animal model and relevant fixed effects. GWASs have also been performed to study the potential of using marker-assisted selection for KHV resistance and juvenile growth (Palaiokostas et al., 2018ab). The effect of stocks with higher performance potential on production and water quality parameters in fishponds was evaluated using two stocks (M2 represented the standard population, and M2 x AMC represented the one with higher performance potential) with an internal control group. The selective breeding program in AMC was established in 2017 using a phenotypic selection on growth with a 10% selection pressure and suitable scaly patterns of the mirror scaliness phenotype. The breeding population has been reared till two years old in a fishpond and then transferred into the RAS to reach earlier sex maturation. In 2020, the first successful spawning of selected and early-matured broodstock was realised, and in 2023, so far, the last selected population (AMC-S3) has been established.

## Results

Mostly high heritability estimates were found for the main traits in common carp such as muscle fat content (0.62-0.67), morphological traits (0.93-0.98), flesh colour traits (0.16-0.39), slaughter yields (0.46-0.50) and their predictors (0.40-0.41), and for scaly patterns quality (0.62-0.89). The body weight showed high heritability both at the age of two years (0.51) and at market size (0.63). In addition, a high genetic correlation (0.74) between these age stages has been found. No undesirable genetic correlations were found in the case of selection for higher performance. Although no strong QTLs for KHV resistance and juvenile growth were found, genomic selection, even using a low-density SNP panel, was shown to be more accurate than one based on pedigree information. Based on the RAD-seq results, 270 SNPs are now used for parentage assignment in AMC (~90% assignment success). A pilot study of rearing AMC broodstock in a combination of fishpond and RAS showed the possibility of shortening the generation interval in the selective breeding program from five to three years. The selection challenge may be performed after two years of fishpond rearing, and the selected individuals are then reared at ~20 °C in RAS. The carp stock with higher performance potential achieved significantly higher mass yield by up to 59% than standard carp stocks (Prchal et al., 2024). In addition, no effect of higher mass yields of common carp on water quality parameters in fishponds was observed (Kocour et al., 2025).

*(Continued on next page)*

**Conclusion and future challenges**

Results indicate that AMC displays very good heritability estimates for the most important performance traits. Still, the ongoing breeding program only focuses on the rapid growth and standard mirror scaly phenotype using phenotypic mass selection. Incorporation of i) other important traits (e.g. slaughter yields, resistance), ii) using a multi-trait selection index method, iii) selection based on the estimated breeding values using pedigree or genomic information into the selection process are future challenges. On the other hand, the current breeding strategy in AMC is based on a three-year cycle to speed up the cumulation of genetic gain. We are unaware of any similar common carp selective breeding program in temperate climatic conditions. Also, there is a hypothetical possibility of shortening the generation interval to two years, and the realised heritability of AMC populations in fishponds shall be verified in a broad-scale performance test.

# STURGEON GERM PLASM SEPARATED FROM OTHER GERM LINEAGES AS A UNIQUE MODEL FOR STUDYING PRIMORDIAL GERM CELLS IN FISH

Martin Pšenička*, Taiju Saito, Linan Gao, Mujahid Ali Shah, Roman Franěk, Marek Rodina, David Gela

## Introduction

Primordial germ cells (PGCs) in fish are typically specified through maternally inherited germ plasm. In sturgeons (Acipenseridae), this localization is spatially and developmentally distinct, resulting in a unique natural separation of germ cells from somatic lineages during early embryogenesis. Unlike most fish species, sturgeons exhibit holoblastic cleavage and an embryonic development pattern that more closely resembles amphibians rather than typical teleost fishes. This distinctive embryonic architecture establishes sturgeon embryos as a powerful model for studying PGC biology, mitochondrial contributions to germline development, and evolutionary transitions in cleavage patterns.

## Methods

We combined PGC visualization using FITC-dextran and GFP-nos3 3'UTR mRNA microinjections, targeted UV irradiation to eliminate vegetal germ plasm, and mitochondrial transplantation experiments in different sturgeon species. Recent findings on the role of vegetal blastomeres and novel techniques for selective blastomere inhibition were integrated. Histological and gene expression analyses (qPCR tomography) were performed to distinguish embryonic and extra-embryonic contributions.

## Results

Our data confirmed that sturgeon vegetal blastomeres primarily contribute to PGC formation, while the majority differentiate into transcriptionally inactive yolk cells serving as an extra-embryonic nutritional source. UV irradiation of the vegetal pole effectively ablated PGCs without disrupting somatic development, verifying the independence of early somatic patterning from germ plasm. Mitochondrial transplantation successfully restored PGC formation even when endogenous germ plasm was destroyed, suggesting mitochondria contribute critically to germline specification. Fate-mapping studies indicated that vegetal yolk cells do not integrate into embryonic tissues, supporting a model where sturgeons exhibit an evolutionary transition between holoblastic and meroblastic cleavage.

## Conclusion

Sturgeon embryos, with their naturally separated germ plasm and somatic territories, provide an exceptional in vivo system to study fundamental questions of germline development, mitochondrial function, and evolutionary developmental biology in fish. These insights not only advance basic understanding but also have implications for biotechnological applications, including germline conservation strategies for endangered sturgeon species.

# *IN VITRO* FERTILISATION OF NATURALLY OVULATED SENEGALESE SOLE (SOLEA SENEGALENSIS) EGGS FOR ORGANIC AQUACULTURE THAT INCORPORATES COMPUTER VISION PREDICTION MODELS

A. Qadir*[12], S. Salcedo-Martínez[1], F. Serratosa[2], N. Duncan[1]

**Introduction**

Senegalese sole (*Solea senegalensis*) is a valuable aquaculture species, which has reproductive challenges in captivity that hinder large-scale production (APROMAR, 2022; Morais et al., 2016). The reproductive challenges are linked to the absence of natural spawning in cultured Senegalese sole (hatched and raised in captivity) and the only method to obtain viable eggs is through *in vitro* fertilization (IVF). IVF circumvents the limitations of natural spawning by ensuring viable gametes are obtained for fertilization (Ramos-Júdez et al., 2021). However, these IVF protocols require the use of hormones to program the ovulation of viable eggs. The use of hormones in organic aquaculture is not permitted (European Commission, 2021) and, therefore, organic aquaculture necessitates hormone-free methods for predicting natural ovulation. Recent advancements in machine learning offer tools to analyse fish behaviour, potentially enabling non-invasive prediction of reproductive readiness (Zhao et al., 2021). This study aims to demonstrate the feasibility of hormone-free IVF using naturally ovulated eggs and to develop a machine learning model for predicting ovulation based on specific behavioural cues. This approach seeks to provide a sustainable and ethical alternative for enhancing reproductive outcomes for organic Senegalese sole aquaculture.

**Material and Methods**

Experimental data were collected at IRTA La Ràpita from March to May 2024, using two groups of Senegalese sole (Mix1 and Mix2) that combined wild and cultured fish. The two groups were held in 10 m³ recirculating aquaculture tanks under natural temperature and photoperiod, with specific temperature adjustments during spawning periods. Naturally spawned eggs were collected daily and assessed for viability and fertilization. For hormone-free IVF, gametes were collected between 14:00 and 24:00. Sperm was obtained via abdominal palpation, diluted with an extender (modified Leibovitz, Sigma, Spain), and assessed for quality using a Computer-Assisted Sperm Analysis (CASA) system (Microoptics, Barcelona, Spain). Females were checked for natural ovulation, and eggs were stripped for *in vitro* fertilization. Standard IVF protocols were followed using selected high-quality sperm and naturally ovulated eggs (Ramos-Júdez et al., 2021). Fertilized eggs were incubated at 16°C.

Reproductive behaviours, rest the head (RTH - an individual rests it's head on another sole) and Locomotor Activity (LA – movements that lasted more than 3 seconds) were monitored continuously using underwater aquaculture cameras. These behaviours, indicative of courtship and spawning readiness, served as inputs for the ovulation prediction model. Video footage was processed to classify behaviours using a trained behaviour detector. Fish tracking algorithms maintained individual fish IDs and calculated LA. The logistic regression model was developed and used to predict the probability of ovulation in Senegalese sole, by using RTH, LA counts and the time of behaviour occurrence as key inputs.

$$P(\text{Ovulation}) = \frac{1}{1+e^{-(\beta 0+\beta 1\cdot \text{RTH}+\beta 2\cdot \text{Locomotor Activity}+\beta 3\cdot \text{Time})}}$$

*Equation 1 Logistic regression model for predicting the probability of ovulation*

**Results and Discussion**

During the three-month spawning period, both experimental groups showed limited natural fertilization success, averaging 10-15% of all the spawns obtained. This highlights the challenges of natural spawning in captive Senegalese sole, reinforcing the need for controlled fertilization methods. In contrast, hormone-free IVF trials achieved up to 44% fertilization and 18% hatching, confirming the technical feasibility of this approach. Good quality sperm with high concentration of motile sperm per egg were used to ensure that sperm was not a limiting factor in the IVF protocol. Male gametes with superior motility (69.06 ± 13.24%), compared to low-quality sperm (39.52 ± 17.00% and 38.31 ± 13.79%, respectively) were selected and used for the IVF. This ensured fertilisation of eggs from females that had recently ovulated viable eggs to demonstrate that successful IVF of naturally ovulated eggs was possible and further highlighted the need to identify the time of natural ovulation to increase the efficacy.

*(Continued on next page)*

To support hormone-free IVF, an automated model was developed to detect and quantify key reproductive behaviours RTH and LA associated with ovulation. By classifying and tracking these behaviours, the system enabled the extraction of meaningful behavioural patterns that served as inputs to a logistic regression model for ovulation prediction. The integration of RTH and LA data, along with the time of behaviour occurrence, into a logistic regression model allowed for accurate prediction of ovulation timing, achieving 85% overall accuracy. The model scored 0.95 on the Area Under the Curve (AUC), a measure based on the Receiver Operating Characteristic (ROC) curve that indicates how well it distinguishes ovulatory from non-ovulatory nights. An AUC close to 1.0 means the model reliably separates these events across different thresholds, showing strong overall performance. The model correctly identified 17 out of 22 ovulatory nights and all 11 non-ovulatory nights in the test dataset, highlighting its strong performance in distinguishing ovulatory events. This suggests that non-invasive behavioural monitoring, combined with machine learning, can effectively replace hormone-induced ovulation, aligning with organic aquaculture principles. This research, for the first time, investigates that natural ovulation can produce fertilized eggs in Senegalese sole without the use of hormones, thereby pioneering a foundational concept for a more sustainable and ethical approach to control cultured sole reproduction. By strategically integrating targeted male selection for *in vitro* fertilization with an innovative automated behaviour-based ovulation prediction model, the reliance on hormonal treatments can be removed for organic aquaculture.

# A FUNCTIONAL RETROPOSON ENCODING DOUBLESEX (DSX) MEDIATES MALE SEXUAL DEVELOPMENT BY DIRECT INDUCING IAG IN THE PRAWN *Macrobrachium rosenbergii*

Gao-Feng Qiu*, Yao-Ting Dong, Xue Liu, Jie Chen

College of Fisheries and Life Science
Shanghai Ocean University
999 Huchenghuan Road
Pudong New Area

E-mail: gfqiu@shou.edu.cn

The giant freshwater prawn (*Macrobrachium rosenbergii*) is an important decapod species that is widely cultured in Asia and the western Pacific. Notably, the males grow faster to reach commercial size than the females and all-male cultures produce greater mean sizes, yields, and net benefits for production of the prawn. It is well known that the male sexual development is under direct control of the insulin-like androgenic gland hormone (IAG) in decapod crustaceans. However, the regulatory mechanism of IAG has remained a mystery for several decades. Here, we identified a novel *Dsx* (*MrDsx-a*) from the prawn *M. rosenbergii*. Unlike insect *Dsx* expressed via sex-specific alternative splicing in sexual development, *MrDsx-a* is a retrogene without intron and displayed male-specific expression in the testis and androgenic gland (Fig.1). RNAi-mediated knockdown of the *MrDsx-a* can significantly down-regulate *MrIAG* in the post-larvae and ultimately resulted in male-to-female sex reversal (Fig.2). The ZZ neofemales were capable of mating with normal ZZ males and producing all male progeny. The direct interaction between the MrDsx-a protein and *MrIAG* promoter was further confirmed by ChIP-qPCR analysis and dual-luciferase reporter assays. Together, we first demonstrated that *MrDsx-a* is a sex-determining gene mediating male sexual development by direct inducing the *MrIAG* in *M. rosenbergii*, which will provide an innovative way for mono-sex breeding in the prawn aquaculture.

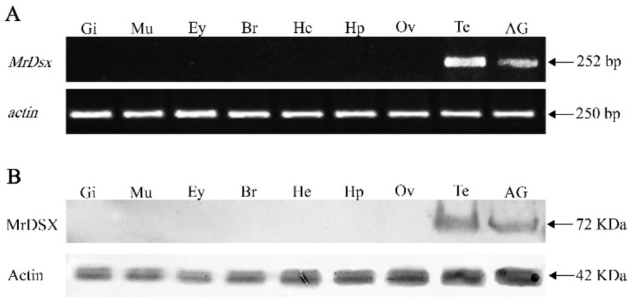

Figure 1 (A) RT-PCR (left) and Western blotting analysis (right) revealed the male-specific expression of *MrDsx-a* mRNA and protein in the adults, respectively. Marker, M; gill, Gi; muscle. Mu; eye, Ey; brain, Br; heart, He; hepatopancreas, Hp; ovary, Ov; testis, Te; androgenic gland, AG;

*E-mail: martina.quagliardi@unicam.it

## Introduction

In recent years, commercial farming of Atlantic cod (*Gadus morhua*) has resumed in Norway. However, the industry continues to face significant challenges related to fish welfare and economic losses, primarily due to intestinal disorders recently identified as strangulating obstruction (Skedsmo et al., 2024). Contemporary cod diets still rely heavily on marine-derived ingredients, in contrast to the plant-based formulations used in salmonid aquaculture, despite the growing global scarcity of marine resources. The natural diet of Atlantic cod is rich in chitin-containing organisms such as crustaceans and echinoderms, including crabs and shrimps (Lall and Nanton, 2002). This suggests that marine shell meals may represent promising side-stream candidates for inclusion in cod feeds (Tibbetts et al., 2006). Given the critical role of gastrointestinal function in overall health and nutrient absorption, a deeper understanding of cod gut physiology is necessary to identify the underlying causes of intestinal pathologies. In this context, dietary chitin has previously been reported to exert immune- and microbial modulatory effects with positive outcomes for fish gut health. The primary objective of this study was to enhance our knowledge of the Atlantic cod gastrointestinal system by evaluating two experimental diets incorporating crab and shrimp shell meals, assessing fish gut health and the digestibility of the formulated diets.

## Materials and methods

The present study evaluated the nutritional digestibility and gastrointestinal health and function of Atlantic cod with an average body weight of 300 g, fed isoenergetic diets incorporating alternative feed ingredients. Three experimental diets were formulated to be isoenergetic (20–21 kJ/g) with a digestible protein-to-energy ratio of 2.5 and approximately 50% crude protein and 17% lipid content. The control diet included 15% sunflower meal, while the other two substituted this fraction with 15% crab shell meal or 10% shrimp shell meal. Following a 27-day feeding period, fish were sampled for growth performance evaluation. Individual body weight and length, liver weight and pooled intestinal contents were recorded to determine dry matter and amino acid digestibility, and growth performance indices calculated. An additional subset of six fish per diet group was sampled for comprehensive physiological assessments. These included macroscopic examination of the digestive system in the abdominal cavity, histological analysis of intestinal tissue, gene expression profiling of the gastrointestinal tract (focusing on immunological, osmoregulatory and digestive markers), measurement of intestinal length and organ indices, bile salt and digestive enzyme assays and plasma biomarker analysis. The entire digestive system was dissected, and the intestine was sectioned into distinct anatomical regions: stomach, pyloric region with caeca, midgut (subdivided into three segments) and distal intestine. Statistical analyses were performed to assess the effects of dietary treatments and differences between anatomical segment differences, with significance determined at $p < 0.05$.

## Results and discussion

In addition to assessing digestive capacity and morphological characteristics, this study provided new insights into the spatial expression of gut-associated gene transcripts related to immune response, osmoregulation and digestion along the gastrointestinal tract of farmed Atlantic cod. A positive correlation was observed between fish body size and relative intestinal length, which may have implications for the development of digestive complications later in life. Fish fed the shrimp shell meal diet exhibited a tendency toward increased feed intake during the initial phase of the trial, resulting in a higher feed conversion ratio compared to the other dietary groups, despite overall comparable growth rates and total feed intake. The group fed crab

*(Continued on next page)*

shell meal demonstrated significantly higher amino acid digestibility than the other groups. However, elevated ash and calcium levels in the shell meal were associated with increased faecal output and reduced dry matter digestibility, in line with findings by Albrektsen et al. (2009). Biochemical analyses revealed elevated levels of maltase activity and bile salts in the pyloric caeca of fish fed the crab meal diet compared to the control group. No significant differences were observed among diet groups in terms of mortality or blood biomarkers associated with nutrient metabolism and only one case of strangulating obstruction occurred during the trial. Histological examination revealed increased lamina propria cellularity in the distal intestine of fish fed the control diet containing 15% sunflower meal, suggesting a potential adverse effect of sunflower meal not observed in the shell meal diets. Overall, the intestinal health of the experimental fish was assessed as normal, functional and free of significant pathological alterations.

**Conclusions**

This study provided new insights into the mapping of functional gut gene transcripts in relation to intestinal morphology and digestive capacity, serving as a reference for future research addressing intestinal strangulation in farmed Atlantic cod. Although further investigation is needed to determine whether this condition is genetically determined, diet-induced or specific to farmed populations, the present findings are essential for improving our understanding of normal gastrointestinal structure and function in this species. Shell meal from marine raw materials represents a side stream that can be used as ingredients in cod feed, helping to reduce reliance on fish meal from wild stocks and contribute to increased sustainable use of local resources.

*E-mail: martina.quagliardi@unicam.it

## Introduction

The seismic events that struck central Italy in 2016–2017 had a severe impact on inland areas of the 'Alto Maceratese' in central-northern Italy (the Marche region), leading to significant economic setbacks, particularly in the local agri-food sectors (Aleffi & Cavicchi, 2020; Dottori, 2024). In order to revitalise the area, various initiatives promoting a sustainable circular economy have been implemented. In this context, the European AgrI-fiSh project (financed by PRIMA and available at agrifish.unicam.it) was conducted to recover agricultural waste. Grape by-products, such as grape seeds and pomace, can be used to create a new, high-quality, resilient aquaculture (Quagliardi et al., 2024). Two interconnected case studies were conducted in this context, involving the administration of two sets of questionnaires: a 12-question survey was given to 30 restaurant chefs, and an ongoing 4-question survey was given to consumers. Both surveys were conducted in popular tourist destinations in the Marche region, including coastal areas such as Senigallia and San Benedetto, as well as rural areas like Macerata. The aim was to assess local restaurant chefs' awareness of incorporating a regional fish species (rainbow trout) into their winter menus and to gain a better understanding of consumers' current and future perception of such species in their diets.

## Materials and Methods

The 12-question Survey Questions Administered to Restaurateurs:

1) What is the average quantity (in kilograms) of fish you purchase on a weekly basis during winter time?
2) What is the estimated total quantity (in kilograms) of fish you purchase annually?
3) Do you currently use salmon in your restaurant's menu offerings?
4) How do you typically serve salmon?
5) When purchasing salmon, do you consistently consider its origin and farming method or do you prioritize lower prices?
6) Have you ever had concerns or reservations regarding salmon farming practices?
7) Have you observed any seasonal variations in the consumption of salmon by your customers?
8) Have you ever included trout in your menu offerings?
9) Would you be open to offering trout to your customers in the future?
10) If informed that the trout is locally farmed in the Marche region, produced at near-zero food miles and without the use of antibiotics, would you consider adding it to your menu?
11) Are you aware that trout is among the most commonly consumed fish species in Northern Europe and that it can contribute to tourism-related culinary interest?
12) Based on available data indicating that trout is of higher quality and lower cost than comparable fish species, do you consider it a viable and sustainable alternative for your restaurant?

The results were collected and presented descriptively via percentages and Microsoft Excel graphs. The 4-question survey, divided by 4 age groups (0–20, 21–40, 41–60, >60), is the result of the capitalization of the first survey and has been expanded according to the scope of the AgrI-fiSh project.

## Results and discussion

During the winter period, the surveyed restaurateurs (n=29) purchased an average of 33.6 kg of fish per week, equating to 1.4 tonnes per year. However, one restaurant was excluded from the survey as it does not serve fish dishes. Nevertheless, freshwater fish remained largely absent from their menus, with 81.8% of respondents indicating that they had never served species such as rainbow trout. While 75.9% of respondents used salmon, preparation methods varied (40.9% marinated), as did awareness of sustainable sourcing. Notably, a significant proportion (77.3%) expressed interest in high-quality products, and 72.7%

*(Continued on next page)*

paid attention to breeding practices. Despite having limited prior experience with trout, 77.3% of restaurateurs were open to experimenting with it, though 22.7% remained sceptical even when its sustainable attributes were considered. Therefore, there is an opportunity to bridge the gap between supply and demand by informing restaurant operators about consumer expectations and the benefits of locally produced trout as an ideal seasonal alternative to commonly used species such as salmon. When comparing salmon and trout, younger participants tended to favour salmon due to taste and familiarity, while older respondents were more positive about trout, often due to habit or local availability. Many participants said they would eat more trout if it were more widely available, suggesting there is potential for increased acceptance through improved distribution. Regarding the use of by-products in trout feed, in line with the scope of the AgrI-fiSh project, most respondents were open to it or conditionally accepted it, depending on the type of by-product used. Those people aged 21–60 were most curious and open to innovation, while rejection was more frequent among the youngest group and may be linked to unfamiliarity or lack of information. In terms of sustainability, the majority of participants considered vegetable by-products to be more environmentally friendly than fish by-products, although many recognised the value of both. This indicates a growing awareness of circular practices and an informed, balanced approach to environmental choices. Overall, consumer attitudes reflected a combination of traditional values and a willingness to embrace sustainable innovations. However, differences across age groups suggest opportunities for targeted communication and education.

**Conclusions**

A revitalisation strategy that integrates the rainbow trout farming sector into coastal and inland gastronomy in central Italy seems promising. Substituting imported fish for rainbow trout in winter seafood dishes would encourage inland trout farmers to form a regional consortium and promote the highly nutritious and sustainable nature of the species. This strategy could ensure a consistent supply and maintain quality standards, as well as improving marketing efforts, particularly if a sustainable approach is adopted. This will contribute to the economic recovery of rural areas and align with contemporary food movements that emphasise local sourcing, biodiversity and environmental responsibility.

## Introduction

Nowadays, the aquaculture industry faces the challenge of reducing its dependence on fish oil and fishmeal. Therefore, it is of paramount importance to develop successful innovative aquafeeds which may contribute to achieving truly sustainable rearing practices. On such account, omnivorous low trophic level species like *Chelon labrosus* have been proved to provide optimal performance results when fed with alternative land-based protein diets (Sanz Latorre, 2024). What is more, novel diets have been also evidenced to influence the fish gut microbial community and its functionality, improving the fish nutrient utilization and enhancing their immune response (Agboola et al., 2023). For this reason, this research aims to formulate and test the impact of three alternative experimental diets on *C.labrosus* growth, microbial biodiversity and its functional role.

## Materials and methods

Three isolipidic and isoenergetic diets were formulated using alternative ingredients and containing a 40% protein inclusion. The first one was 100% plant-based (V), the second one was a mix of vegetal and animal protein (VA) and the last one had a mixture of fishmeal and plant protein (FM). Then, 300 *Chelon labrosus* were kept in triplicate tanks and subjected to a 153 day trial phase in which they were administered the experimental diets. Zootechnical parameters were measured every 30 days. At the end of the experiment, 60 fish were sacrificed to obtain gastrointestinal tract samples for microbiome analysis. Composition and structure of the microbial community was assessed through the amplification and sequencing of the 16S rRNA gene. The bioinformatic analysis of the microbial metagenome was conducted using the Integrated Microbial Genome database, and the microbial functional annotation was based on the KEGG and COGs databases.

Table 1: Growth performance and nutritional parameters of *Chelon labrosus* with experimental protein sources

| | V | VA | FM |
|---|---|---|---|
| **Initial weight (g)** | $71.9^{c} \pm 0.26$ | $72.4^{ab} \pm 0.25$ | $73.2^{a} \pm 0.28$ |
| **Final weight (g)** | $104.1^{a} \pm 1.20$ | $73.8^{c} \pm 1.21$ | $92.1^{b} \pm 0.92$ |
| **SGR (% day$^{-1}$)** | $0.24^{a} \pm 0.008$ | $0.01^{c} \pm 0.009$ | $0.15^{b} \pm 0.005$ |
| **Weight gain (%)** | $144.9^{a} \pm 1.05$ | $101.9^{c} \pm 1.44$ | $125.8^{b} \pm 1.04$ |

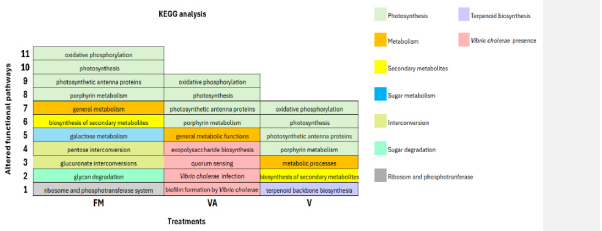

Figure 1. Number and types of altered functional pathways identified in the KEGG analysis after subjecting the fish to each of the experimental treatments.

*(Continued on next page)*

## Results and discussion

Growth performance and nutritional parameters of Chelon labrosus with experimental protein sources.

Individuals that were submitted to the V treatment showed an overall higher growth performance as well as more efficient nutritional rates, whereas the VA group provided the lowest zootechnical parameters values (Table 1). Furthermore, the alpha and beta diversity metrics confirmed the V diet had a significant impact on the fish microbiome, revealing distinct taxonomic differences compared to the other experimental groups.

As for the taxonomical groups found in the fish GIT, all experimental treatments modified the initial fish gut microbial community. However, slight biodiversity differences were observed between the three analyzed treatments (figure 1). Despite not having found any significant difference between the treatment's taxonomical biodiversity, the COGs and KEGGs terms analysis suggest that the experimental diets could have an effect in the fish gut microbial's community functionalities.

Although many previous works have studied the viability of providing innovative feeds with alternative protein sources to different intensive aquaculture species, little is known when *C.labrosus* becomes the target species of the nutritional study. Therefore, despite the lack of knowledge regarding this species' nutritional requirements, *C.labrosus* individuals reach optimal growth and zootechnical indexes when exclusively fed with vegetal protein-based diets. Such results could be due to the fact that inclusion of animal protein sources and hemoglobin affected the feed acceptability and palatability of the VA and FM pellets. This higher growth is aligned with a differential intestinal microbiota profile, as the *Pseudomonas, Methanobacter* and elusimicrobiaceae species that were exclusively found in the GIT from the V fish are known to have beneficial effects on nutrient digestion, fatty acids synthesis and immune defense boosting. In contrast*, Vibrio cholerae* proliferated in the fish gut of the VA specimens, which presence altered some physiological pathways (as observed in the KEGG analysis) and caused detrimental effects, having negative consequences to the fish growth and health.

## Conclusion

In summary, the manufacturing of plant-based diets for low trophic species like *C. labrosus* leads the aquaculture industry towards an optimistic future in which the sector reduces its dependency on fishmeal and fish oil, becoming truly sustainable.

## Introduction

Spontaneous fermentation of different food industry by-products has been proved to yield a product with enhanced nutritional value. What is more, this process is known to increase some substrate's protein and enrich their amino acids profile. Furthermore, it has also been confirmed that fermentation of cereals and legumes bioconverts their carbohydrates, making them more digestible (Adebo et al., 2022). Therefore, due to the current pursuit of a truly sustainable substitute for fishmeal in aquaculture emphasizes the need to find potential raw materials with high-nutritional value for aquafeed production.

## Materials and methods

Different by-products from animal and vegetal origin were prepared for spontaneous fermentation and kept at 22ºC for 7 days. Samples of each fermented material were taken after 1 and 7 days of fermentation in 5 ml aliquots and preserved frozen for further chemical analysis. Then, a proximal nutritional composition analysis was performed on every sample to determine their crude protein level. On the other hand, a metagenomic analysis was performed by extracting bacterial DNA from the fermented samples. Last, a high-throughput sequencing of the 16S rRNA gene was conducted with an Ilumina MiSeq platform in order to analyze the bacterial diversity by using Claudio Braulio shini program.

## Results and discussion

Most vegetal materials and yeasts increased their CP level after the spontaneous fermentation, whereas biofloc, all animal by-products and some cereals weren't enhanced by the process (Table 1). Alpha diversity metrics showed a gradual decline of the microbial biodiversity during the 7 days of the fermentation. Furthermore, shifts in diversity were observed between the fermented and unfermented bacterial communities, underscoring the impact of fermentation. Beta diversity metrics also showed significant differences in the fermented microbial communities and confirmed a restructuring of the microbial profile from the fermented and unfermented samples over time (Figure 1). The taxonomic composition analysis, dynamic changes at phylum and genera level were observed throughout the fermentation process.

Although fermentation of vegetal materials has been previously proved to enhance their nutritional value by making them more protein-rich, some of the tested cereals (rice, wheat gluten, corn and pea meal) experienced a decrease in their CP levels probably due to bacterial difficulties when digesting complex carbohydrate molecules. As for animal by-products, all tested substances rotted and suffered a decrease on their CP after just 24 hours of fermentation, maybe because bacteria cannot feed on matrixes with scarce carbohydrates. On the other hand, fermentation did cause an exponential rise of most plants and yeasts protein content. However, some vegetal materials performed better than others by reaching higher protein levels after 7 days of fermentation (soybean meal,flax), while the increase of bacterial protein in other substances stabilized or stopped after 24 hours of fermentation (cameline, beetroot). For this reason, further research needs to be done to optimize spontaneous fermentation, as many authors claim that the addition of exogenous bacteria may boost the process and enrich the resultant products with

*(Continued on next page)*

Table 1: Crude protein expressed as dry matter percentage (CP (dm%)) of the different tested materials before and after the fermentation process.

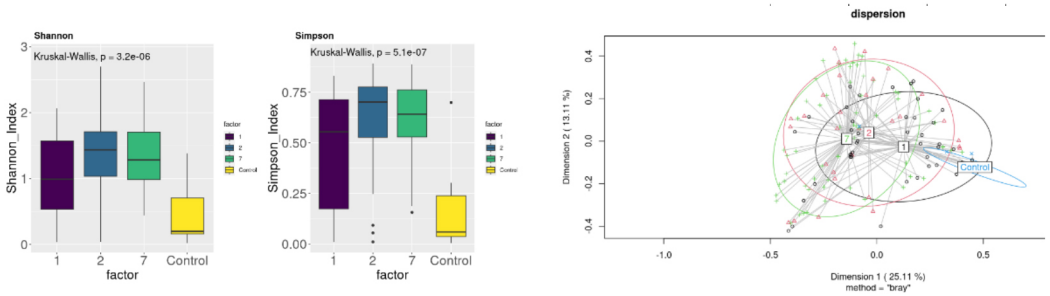

Figure 1. Alpha (left) and beta (right) diversity results of fermented materials at days 1, 2 and 7.

probiotics (Rajesh et al., 2010). As for the intestinal microflora population shifts, it is possible that the blooming of some taxons can also trigger the decline of others due to unsustainable competence for the same resources. Consequently, additional inquiry is required to determine how different microbial species may affect each other.

## Conclusion

Vegetal materials are more efficient at fermenting than other animal and biofloc by-products, yielding a product with enhanced protein content that can be used as a potential ingredient for aquafeeds. Nevertheless, further research needs to be done to optimize the fermentation process and test its potential to enhance alternative aquafeed ingredients.

## Introduction

Biofloc can be used as a source of live feed for farmed organisms. Furthermore, its excess and by-products have been also used successfully as a feeding source for insects, such as *Hermetia illucens* (Zhang et al., 2023). What is more, feeding larvae with biofloc waste may be a sustainable strategy which does not only help to recycle aquaculture's waste but that also converts it into a valuable alternative protein source (APS). Such approach would help lead aquaculture towards more sustainable practices that also align with the circular economy principles. Consequently, there is a current need to assess biofloc by-products as a potential feed for larvae to confirm if those insects can be turned into a nutritious protein-rich flour for aquafeed production.

## Materials and methods

*Tenebrio molitor* larvae were farmed in plastic containers for two weeks in a room with controlled environmental parameters. All experimental groups were fed wheat bran as dry feed. The control group received carrots twice a week as a source of hydration, while the other experimental groups were given biofloc 1, 2, or 3 times per week as substitute for the carrot. Larvae weight, non-eaten food weight and feces weight were measured weekly. At the end of the experimental trial, zootechnical parameters such as weight gain, mortality rate, feed conversion ratio (FCR) and frass production ratio (FPR) were calculated. Larvae were frozen and stored for their posterior nutritional composition analysis.

## Results and discussion

As shown in Table 1, control groups reached higher final biomass levels and provided lower FCR and FPR values during the first and second week of the experimental trial, reaching bigger larvae sizes too (Figure 1). In contrast, biofloc and wheat bran fed groups showed higher FCR and FPR values, indicating a lower feed conversion efficiency and confirming that some of the administered biofloc was not turned into biomass. However, biofloc was consumed at a higher rate when administered more frequently and no mortality rate could be observed in any of the experimental groups (Figure 2).

Although no literature has been found regarding biofloc's potential as a moisture source for insect feeding, one study evidenced that biofloc by-products mixed with wheat bran provided optimal growth results when tested as an alternative dry diet for blacksoldier fly larvae (Zhang et al., 2023). Despite the fact that fly larvae performed better than *T.molitor* when fed with the above-mentioned mix, our carrot-fed group provided similar results to other works in which mealworms were fed different moist raw materials (such as tangerine shells or mushroom spent substrate) (Kim et al., 2017). Therefore, even though biofloc may be a nutrient-rich substrate with probiotic effects, mealworm larvae seem to prefer, digest and assimilate better other moist ingredients like carrots. Nevertheless, biofloc may still be a promising dry ingredient when mixed with vegetal by-products.

## Conclusion

Although biolfoc by-products can be used as a suitable and safe ingredient for *T.molitor* larvae feeding, carrots were a more effective moisture source. Nevertheless, biofloc may still be a potential nutrient-rich ingredient for larvae feeding when mixed with other dry raw materials.

**Introduction**
Implementing an automated biomarker-based approach with machine learning model enables real-time assessment, early detection of health issues and timely interventions to reduce mortality and improve economic outcomes. This study aimed to develop automated machine learning models capable of predicting overall fish health as well as specific health challenges, including gill health, viral health and bacterial infections.

**Methods**
Blood biomarker data were collected biweekly from multiple pens across different fish farms by WellFish Tech laboratories, encompassing 8,846 individual fish samples. The data was annotated for use in models targeting general fish health, gill health, viral health, and bacterial infections.

The dataset underwent data curation to ensure quality and consistency. Outliers were filtered and exploration data analysis using box plots was conducted to assess the distribution of each biomarker. Further, selection of features for the modeling was conducted with correlation matrices to retain only one feature of identified highly correlated biomarkers. Standard scaling was applied to all features. To address class imbalance, multiple techniques were employed to generate 4 different modified datasets including no rebalancing, under sampling, oversampling and SMOTE. The dataset was split 80/20 for training and testing. Following this, both Logistic regression and random forest classification models were evaluated on the four datasets. Model performance was assessed using accuracy, precision, recall, and F1-score.

**Results**: Tables below summarize the results of the performance metrics for each health model:

**Table 1. Fish Health Classification**

**Conclusion**

Automated machine learning models using blood biomarker data effectively predict fish health and specific disease challenges. Summary results in Table 1 to 4, Random Forest models with oversampling demonstrated superior performance across all health categories. This approach facilitates early detection and intervention, reducing mortality and enhancing operational efficiency in aquaculture.

## Introduction

The pseudo kelp *Saccorhiza polyschides*, commonly known as furbelow, is a fast-growing, annual brown seaweed with potential applications in agriculture and human nutrition. In addition to its reported uses as a fertilizer and biostimulant (Nhhala *et al.*, 2024), it is also considered an edible species in Northern Portugal, Galicia, and other parts of the world (Pereira, 2016). Recent studies have shown that both wild and cultivated *S. polyschides* contain significant levels of essential nutrients, exhibit anti-inflammatory activity, and are rich in key mineral elements (Cardoso et al., 2023). Morphologically, *S. polyschides* is characterized by a large blade growing to over 2m long, with a flattened stipe with wavy frills, and a distinctive hollow bulbous holdfast. Its life cycle resembles that of the Laminarians, alternating between macroscopic diploid sporophytes and microscopic haploid gametophytes (FAO, 1970).

Within Vertical Algae project protocols for *S. polyschides* cultivation are being developed and optimised, in both nursery and at sea, in association with a seabream and seabass fish farm in the Southern coast of Portugal (Seaculture Lda. IMTA DEMO), exploring the potential of integrated multi-trophic aquaculture (IMTA) systems.

## Methods

Mature sori of *S. polyschides* were collected along the Portuguese coast between July and December of 2023 and 2024. Spore release and cultivation techniques were adapted from established protocols for kelp species (e.g., Edwards *et al.*, 2011). Twine seeding followed the direct seeding method from spores and seeded twine was deployed at Seaculture Lda. IMTA DEMO site.

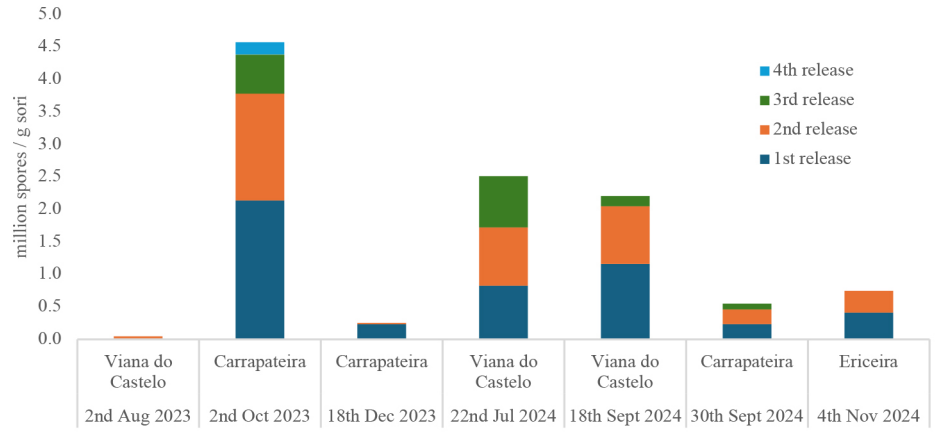

Figure 1 - Summary of *S. polyschides* spores release events during 2023 and 2024.

*(Continued on next page)*

**Results & Discussion**

Spore release for the several sori collection are presented in Figure 1, with the observed values of spores/g sori at a single re-hydration event varying between 17,316 and 2,137,394 spores/g sori.

Twine in spools was seeded with spores in October 2023, September, October and November 2024. Due to electrical failure and contamination at the nursery, spools seeded in September and October 2024 did not develop into healthy sporophytes and were discarded. In October 2023, the seeded twine was cultivated at 3 different temperatures (14, 16 and 18ºC), a closer monitoring at nursery was performed and it was observed the effect of temperature in the dramatic increase in contamination, with spools reared at 14ºC displayed the best resilience and lowest amount of contamination, being this the temperature chosen for all following cultivation. Also, sporophytes reached the minimum deployment size (~2-3mm) 29 days post-inoculation and remained healthy for 64 days. The twine seeded in October 2023 was deployed at sea mid-December 2023, and twine seeded in November 2024 was deployed at sea mid-February 2025.

While *S. polyschides* individual growth achieved at sea was promising, given the cultivation conditions and deployment, the density observed at harvest was below expectations, indicating the method needs further optimization. To address the challenges encountered, namely contamination in the nursery and low densities at sea, future work will focus on gametophyte cultivation and gametophyte/sporophyte seeding.

BLUEBOOST aims to demonstrate that co-culturing a wide range of low trophic species with established species can enhance European aquaculture production of blue foods and feeds, while reducing the environmental footprint and moving towards a carbon-neutral blue economy in aquaculture.

One of the six IMTA demonstration systems within BLUEBOOST is the cultivation of *Ulva* sp. integrated into a land-based pilot fish production system in the Algarve, South Portugal. In IMTA, species from different trophic levels are cultivated in proximity so that the waste from one species is recycled and becomes an input for another (Chopin *et al.*, 2001). This way, extractive species, such as seaweeds (macroalgae), can remove dissolved inorganic nutrients waste from fed culture and reduce its ecological impacts while providing the farmer with a new product. In parallel, seaweed biomass produced in IMTA has the potential to contribute directly to food security, as sustainable food, feed ingredients, or agricultural biofertilizers/biostimulants (e.g. Cai *et al.,* 2021; Craigie, 2011, Magnusson *et al.*, 2019). The genus Ulva (Ulvales, Ulvophyceae, Chlorophyta) shows a cosmopolitan distribution, including Portugal, and the Algarve , characterized by high growth rates and with a wide commercial interest. Several studies have focused on Ulva cultivation in IMTA and demonstrated its high, but very variable, potential for biomass production and nitrogen removal, besides most available data refers only to small-scale experimental production. Within this project the scale up of Ulva cultivation in earthen ponds in the South of Portugal will be tested and its productivity and bioremediation potential evaluated.

Initial biomass of *Ulva* sp. was harvested from EPPO-IPMA facilities (South Portugal) and transferred to a ~600m$^2$ earthen pond with aeration and receiving effluent from the research station fish production. Samples of the collected *Ulva* sp. were taken for molecular species identification, reproductive status, FW:DW ratio and C, N and P (CNP) composition. In the cultivation pond, temperature, pH, salinity and light measurements are taken every 10 mins via HOBO loggers, while turbidity and dissolved oxygen are measured daily (5 days per week). Water samples are collected twice a week at the inflow and outflow for dissolved nutrients analysis. Every 4 weeks *Ulva* sp. yield is assessed and excess biomass removed, with subsamples analyzed for reproductive status, FW:DW ratio and CNP content. With yield and CNP data, the bioremediation potential of *Ulva* sp. for nutrient removal will be quantified over the production period.

Overall, this study will provide insights into the feasibility of scaling up Ulva cultivation in IMTA systems, demonstrating its dual role as a biomass resource and a tool for nutrient bioremediation in land-based aquaculture

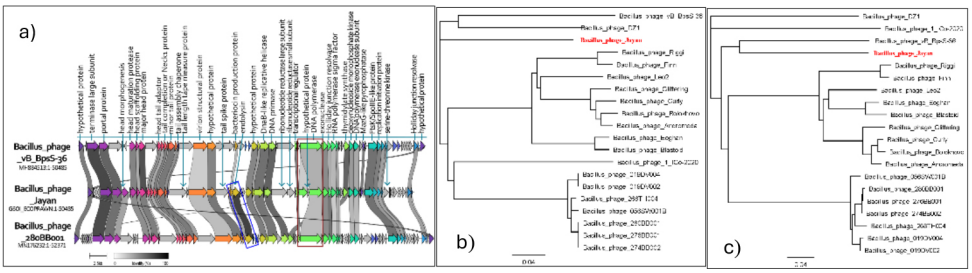
Introduction:
Commercial aquaculture probiotics commonly use *Bacillus licheniformis*, a probiotic strain, to boost beneficial microbial loads in prawn farms, thereby boosting productivity and providing safe food for consumers (Simmonds *et al.*, 2023). If commercial probiotics in aquaculture farms become infected by their specific phages, their population could eventually diminish instead of expanding. We are currently not sure to what degree phages threaten the effectiveness of probiotic bacteria. Phage isolation against probiotics is crucial for both understanding the viral ecology of probiotics and generating probiotic strains that are resistant to bacteriophage infection. Here we present a novel phage discovered against *Bacillus licheniformis*, Jayan.

Materials and Methods:
Aquaculture probiotic strains were isolated from three Bangladeshi commercial probiotic products using spread and streak plate methods. Genomic DNA extracted with the Beat-Beat Micro AXE kit and was sequenced on the Oxford Nanopore PromethION96 platform. Reads were trimmed (Porechop), assembled (Flye), annotated (PROKKA), and analysed using BV-BRC, TYGS, and visualized using iTOL. Phages were enriched from Danish wastewater and organic waste using a modified enrichment method (Van Twest and Kropinski, 2009), purified by repeated double agar overlay, amplified, and extracted DNA prepared with the NEBNext Ultra II FS kit for Illumina iSeq. Reads were processed with CLC Genomic Workbench, annotated with Pharokka, compared using VRIDIC and Clinker, then phylogenetically assessed with ViPTree. The spot test method was employed to evaluate the host range of phage Jayan against isolated commercial aquaculture probiotic strains.

Results and Discussion:
According to the TYGS phylogenetic analysis of these genomes, we identified ten morphologically distinct colonies belonging to the *Bacillus* and *Lysinibacillus* genus. These colonies encompass six distinct species, namely *Bacillus subtilis*, *Bacillus paranthracis*, *Bacillus paralicheniformis*, *Bacillus safensis*, *Bacillus licheniformis*, and *Lysinibacillus telephonicus*. For further confirmation of these results, a comprehensive genome analysis was conducted employing BV-BRC comprehensive genome analysis tools. The Jayan host strain *B. licheniformis* contains 4578 protein coding sequences (CDS), 80 transfer RNA (tRNA) genes, and 24 ribosomal RNA (rRNA) genes. This probiotic strain exhibited 97% query coverage and 99.93% identity with a 0.0 E value to the *B. licheniformis* DSM13 (NC_006322.1) strain during NCBI blastn with align two or more sequences option between isolated probiotic strain and GenBank *B. licheniformis* DSM13 strain.



*(Continued on next page)*

Figure 1. a) The Clinker map demonstrates the genomic synteny between the isolated phage and two highly closest relatives. The genome sizes, measured in base pairs (bp), of each phage are listed below. The maroon color rectangle indicates DNA polymerases of Jayan with closely related Bacillus phages, and dark yellow arrows in blue color rectangle denotes the endolysin; b) The phylogenetic tree of phage Jayan derived from terminase large subunit, and c) The phylogenetic tree of phage Jayan based on DNA polymerase.

Phage Jayan (PQ299153.1), isolated from organic waste, forms asymmetrical plaques on *B. licheniformis*, has a short latent period (10–15 min) and 25 min burst, and inhibits *B. licheniformis* DSM13 but not most other Bacillus spp. Genomically, Jayan (47,420 bp; 43.28% GC) shares only 20–27% intergenomic similarity with known phages , placing it as a novel species in a new *Herelleviridae* genus. Its DNA polymerase is disrupted by a unique 270 bp insertion (Figure 1a), while it retains an endolysin related to Bacillus phage 280BB001 (Loney *et al.*, 2023); phylogenetic analyses (Figure 1b & 1c) link conserved genes (TLS, primase) to phages DZ1 and vB_BpsS-36 (Akhwale *et al.*, 2019), but overall divergence confirms Jayan as a distinct lineage.

Conclusion:

Jayan is a novel virulent phage of *B. licheniformis* within a new *Herelleviridae* genus, isolated from organic waste in Copenhagen, with unique genetics and implications for probiotic ecology and phage-resistant strain development.

**Introduction**

Aquatic protein production plays a vital role in meeting the growing global demand for protein, which ensures food and nutrition security (Melenchón et al., 2022). According to FAO, more than 70% of aquaculture production currently depends on fishmeal (FM)-based feeds. As aquaculture expands rapidly, finding sustainable alternatives to traditional FM is becoming increasingly crucial (Fabrikov et al., 2021). The findings of Broeckx et al., (2021) and in line with the UNSDGs, insect meal (IM) has been emerged as promising and environmentally friendly substitute for aquafeeds (Quang et al., 2022). Studies reported that the novelty foods in many developed countries are insect-based and are now gaining attraction, particularly in Asia. This shift is supported by initiatives such as the establishment of the Asian Food and Feed Insect Association (AFFIA) in Bangkok, which promotes IM production across the region. Thus, IM has emerged as a promising and environmentally sustainable replacement for FM in aquafeeds (Quang et al., 2022), offering a renewable source of protein for food, feed, and biomaterials. In this context, sustainable and circular solutions required to ensure the long-term viability of aquafeeds. This study aimed to explore the potential of *Hermetia illucens* - black soldier fly larvae (BSFL) as an alternative protein source in fish diets through an integrated biowaste management approach using onion waste. The findings of the study focused on three primary objectives: (i) evaluating the feasibility of utilizing BSFL to upcycle onion waste, (ii) assessing the nutritional suitability of BSFL meal in fish feed, and (iii) comparing the environmental implications of BSFL meal inclusion versus conventional fishmeal.

**Materials and Methods**

In this study, BSFL were reared on a substrate composed of onion waste and poultry manure under controlled laboratory conditions. The bioconversion efficiency, larval growth, and compost quality were assessed through proximate analysis. Five isonitrogenous diets replacing fishmeal with BSFL meal at 0%-D0, 25%-D1, 50%-D2, 75%-D3, and 100%-D4 levels were formulated and analyzed for nutritional and physical properties, including sinking velocity and water stability. A feeding trial was conducted using *Cyprinus carpio* fingerlings for 30 days, during which growth performance, feed utilization, and survival were monitored. Blood samples were analyzed for hematological and biochemical parameters, while liver and intestinal tissues were examined for digestive enzymes (amylase, protease, trypsin) and antioxidant enzymes (SOD, CAT, GSH, GPx) activities. Histological analysis of the distal intestine was performed to observe structural changes due to BSFL inclusion. All tests were conducted in three biological triplicates. Data presented as mean ± standard deviation (SD). Data were compared using one-way analysis of variance (ANOVA) and post-hoc comparison test (DMRT) using GraphPad Prism version 9 (GraphPad Software, Inc., San Diego, CA, USA).

**Results**

BSFL were reared on a mixed substrate of onion waste and poultry manure under controlled laboratory conditions. Larval growth, bioconversion efficiency, survival rates, and compost quality were systematically evaluated. The rearing process demonstrated high larval survival (above 90%) and significant substrate degradation, highlighting the effectiveness of BSFL in waste valorization. Nutrient profiling confirmed that BSFL had high crude protein (38.47%) and lipid content (48.79%), making it a viable feed ingredient. Subsequently, five isonitrogenous diets (D0 to D4) were formulated by progressively replacing fishmeal with BSFL meal at 0%, 25%, 50%, 75%, and 100% levels, respectively. These diets were fed to *C. carpio* fingerlings over a 30-day period. Growth performance indicators such as weight gain, specific growth rate (SGR), feed conversion ratio (FCR), protein efficiency ratio (PER), and viscerosomatic index (VSI) were significantly improved in fish fed the 50% and 75% BSFL diets (D2 and D3), without compromising survival. Hematological and biochemical parameters remained within physiological ranges across all diets, suggesting that BSFL inclusion did not induce systemic stress. Digestive enzyme activities

*(Continued on next page)*

(amylase, protease, trypsin) and antioxidant enzyme levels (SOD, CAT, GSH, GPx) were also enhanced in BSFL-fed groups, particularly D2, indicating better digestion and oxidative stress management. Histopathological analysis of intestinal tissues revealed mild to moderate inflammation in higher inclusion groups (D3 and D4), warranting careful monitoring of gut health when formulating high-BSFL diets. Nevertheless, the overall findings validate the use of BSFL meal as a sustainable protein alternative, capable of replacing up to 50–75% of fishmeal without adverse effects on fish growth or health. Moreover, the frass (larval compost) generated post-bioremediation proved to be a nutrient-rich organic fertilizer, supporting soil sustainability.

## Introduction

Current animal welfare guidelines, based on the five-domain framework, state the need to prevent animal suffering, particularly during slaughter. The guidelines recommend that fish must be rendered unconscious through appropriate stunning methods such as live chilling, electronarcosis, or percussive stunning (OIE, 2019), but the effectiveness of these methods varies by species and requires validation. Consequently, turbot farmers have become interested in alternative methods to conventional live chilling, leading to studies that assessed electrical and percussive stunning using behavioural indicators. However, these indicators were found to be unreliable for determining consciousness due to their poor correlation with neurological activity (Morzel et al., 2003). In this context, electroencephalography (EEG) has been recommended as a preferred method to evaluate the effectiveness of stunning techniques (Bowman et al., 2019). The present study aimed to provide new evidence on the effects of electrical and live chilling stunning methods on turbot, using EEG to assess their effectiveness in industry settings.

## Materials and methods

Commercial-sized turbot (*Scophthalmus maximus*) weighing 1–2.5 kg from Stolt Sea Farm S.A. and CETGA (A Coruña, Spain) were used to evaluate the efficacy of industrial electric stunning and live chilling methods. Individually, each fish was anaesthetised with MS-222 (80 mg/L) prior to cranial placement of two stainless steel EEG electrodes over the telencephalon and optic lobe, with a reference electrode in the dorsal muscle. After recovery of the fish from anaesthesia, basal EEG recordings and strobe light-induced visual evoked responses (VERs) were collected for 10 min. For electrical stunning, the electrodes were removed prior to placing the fish in an industrial stunner (50 V, 50 Hz), and repositioned upon exit from the stunner, with brain activity being recorded for the next 15 min. For live chilling, recordings were taken at 10-min intervals before and during exposure to ice slurry, as well as after transfer to normal temperature water. EEG data were filtered to remove artefacts and analysed using Spike2 software, with power spectrum analysis (band pass filter 0.5-32 Hz, 10 Hz resolution) used to calculate total power (Ptot) and αβ power (Pαβ), both normalised to baseline. VERs were assessed by averaging twenty 1-second windows during light transitions.

## Results

This study evaluated the effect of two industrial stunning methods, electrical stunning and live chilling, on EEG activity in commercial-sized turbot. Our results showed that electrical stunning slightly increased power parameters values, although this was not significant due to the high variability of the recordings, especially towards the end of the post-stunning period studied. As for VERs, no attenuation or disappearance was evident following electrical stunning; on the contrary, a twofold increase in VER amplitude was noted during the early post-stunning recording.

Regarding live chilling, a progressive reduction in EEG power parameters was observed after immersion of fish in ice slurry. Significant decreases were observed within two minutes in ice slurry, reaching levels approximately 60% lower than those prior to cooling. VERs also showed a gradual decrease starting after two minutes of immersion in the ice mixture, disappearing complete after five minutes. Upon returning the fish to water of normal temperature, a gradual recovery of power parameters was observed, reaching pre-cooling levels after six min. The VERs also reappeared and gradually recovered to pre-cooling amplitude levels within two minutes of exposure to normal water temperature.

*(Continued on next page)*

**Discussion**

This study analysed and compared the EEG effects of electrical stunning and live chilling to assess their effectiveness in rendering turbot unconscious during industrial slaughter. We evaluated the electric stunning using the optimised set-up determined by previous operational indicator tests. The results showed that this method strongly immobilizes the fish by muscular blockage for a few min, but it does not cause reduction in brain activity and/or loss of VERs. This indicates that fish may remain conscious after stunning and highlights the poor correlation between behavioural signs and EEG-based measures of unconsciousness (Bowman et al., 2019).

On the other hand, live chilling resulted in a progressive decrease in brain activity, reaching a reduction of more than 50% in power parameters. In addition, a progressive disappearance of VERs within five minutes of live chilling was observed. These EEG findings are consistent with standards used in rainbow trout studies, where the absence of VERs is considered a reliable indicator of unconsciousness (Bowman et al., 2019), suggesting that this method could induce loss of consciousness in turbot. However, despite these results, live chilling also does not induce unconsciousness immediately, so with the current protocol it cannot be claimed to be an optimal method for stunning according to welfare guidelines (OIE, 2019).

Overall, our results show that the current method of electrical stunning is ineffective in rendering turbot unconscious, while live chilling appears more effective, although with time constraints that need to be considered. This study also highlights the limitations of operational indicators and emphasises the importance of using EEG techniques when assessing slaughter in turbot.

**Introduction**

This study presents a controlled experimental campaign to observe any possible momentary behavioral changes in adult captive bluefin tuna in a tank, exposed to boat noise playback for durations of fifteen minutes. The goal is to assess whether such stimuli elicit measurable alterations in swimming patterns or group dynamics, given the tuna have limited response options because of the confined space inside tank in contrast to the open sea.

**Materials and methods**

The experiment was conducted during four days in a circular tank (22 m diameter, 9–9.5 m depth) that housed 17 adult bluefin tuna fish ranging from 200 to 250 kg at the ICTS-ICAR, (www.icar.ieo.es) tuna fish facilities in Mazarrón, Spain. The fish have grown up in the same facilities over many years. The fish typically swam in group and in a clockwise direction, counter to the water current generated by two pumps. The sound used in the experiment was a playback of a recording of a passing by boat noise 21 second long, which was played repeatedly for fifteen minutes. During the daytime period, intervals of 15 minutes were interspersed with a test and rest signal. The boat playback sound was emitted by an underwater loudspeaker (Lubell VC2C sound source) with three different levels being played with a gap of around 2.5 hours between each emission level. The levels were chosen to ensure adequate sound pressure level inside the tank as compared to the ambient noise as well as not as high as to scare the tuna that may result in collision with the walls. Apart from the boat playback sound measurements, the ambient conditions inside the tank were also measured. The experiment was repeated for four days in a similar fashion. The sound field was recorded with 3 hydrophones (AQUARIAN AS-1) and an autonomous hydrophone NAUTA used as a reference. Two stereoscopic cameras were used to record the movements of tuna during the sound recordings. The proposed experimental setup is shown in figure 1.

The emitted levels were chosen to ensure adequate sound pressure level inside the tank as compared to the ambient noise. Figure 2 (left) shows the comparation between the SPL with hand without sound source. The cameras were installed on opposite sides of the tank at mid-depth to monitor fish behavior, ensuring synchronized visual and acoustic data collection and, on the right is showed the SPL in a period of fighting minutes when the test sample is emitting.

**Results and discussion**

An application has been developed through which the spectrogram, the temporal evolution of the SPL and a video of the tuna can be displayed at the same time for a set period (figure 3). The camera recording, though not covering the whole tank and hence fish not visible all the time, shows that the fish show slightly faster movement with the boat noise radiation as compared to the ambient conditions. The most obvious reactions in behavior occur in the transients of rising emissions where there is an increase in SPL of around 20 dB (depending on the position of the hydrophone).

**Conclusion**

The observed behavioral response of captive bluefin tuna to boat noise playback was subtle, characterized primarily by a slight increase in swimming speed rather than disorganized or erratic movement. This suggests a level of acoustic stimulation that does not cause a pronounced stress reaction, which may be influenced by the confined nature of the tank. However, clear reactions to some rising transients have been found, showing changes in the direction of turns and disorder in the group dynamics, which must be confirmed in future experiments with higher sound levels in the test signals.

[2]Universiad Politécnica de Valencia de Alicante. Campus de Gandía. Carrretera Nazaret-Oliva s/n.46730. Grao de Gandía, Spain

**Introduction**

This paper analyzes some key points in experimental configurations used to evaluate the behavior of juvenile vertebrate fish in tanks, taking as a reference an experience carried out in 2024 in which eight tanks were used, four control tanks and four that were subjected to an increasing level of sound exposure. Samples were taken at 30 minutes, 3 hours, 24 hours and 7 days. Biological issues are left aside for other work. This only affects some technical considerations/precautions to be considered.

**Materials and methods**

As mentioned above, eight tanks were used arranged as shown in Figure 1 (four control tanks and four experiment tanks).

Before starting the experiment, a series of operations have been carried out and some decisions have been made, which are discussed below. Some of these decisions/operations condition the others and have not been taken successively.

**Acoustic Analysis of the Tank.** A numerical model (FEM) with the same dimensions as the experimental tank. The tank was modeled using acoustic and shell (structure mechanics) module with a fluid-structure interaction boundary between the common boundaries. With this analysis, it was possible to obtain the response of the tank and compare it with experimental measurements.

**Selección de la señal de prueba**. In the experiment on fish six audio recordings of different approaching boats were played randomly. Four of the recordings were 2 minutes 45 seconds long, one was 2 minutes 25 seconds, and the last one was 3 minutes and 56 seconds long. All the audios are recordings of boats approaching and passing by.

**Selection/design of the sound source**. Figure 2 shows the parts of the DML (Distributed Mode Loudspeaker) radiant system designed. The figure on the left shows the actuator, the one on the center-right the container and the one on the center right the vibrating and radiating plate that is excited by the actuator. Figure 2 on the right shows the final aspect of the speaker. This speaker is designed to radiate from the surface of the water.

**Channel calibration and adjustment**. The calibration of the receiver transducers is described in standardized procedures. Often the channel setting in the broadcast part is not considered. In a cost-effective configuration such as the one described, the key point is in the connection between the board and the power amplifier since depending on the input sensitivity of the amplifier and the output level of the preamp, distortions of different types can occur.

**Conclusion**

The development of an experimental configuration for the study of the effect of noise on fish involves a series of operations among which it is not possible to avoid: a) the performance of prior numerical analyses to ensure that the contribution of the enclosure is known (acoustically speaking) and that the dynamic margin to carry out the experiment is known; and (b) the electroacoustic adjustment of the channel to ensure that the equipment is being used under conditions of minimum possible distortion.

# AQUASELF2. INTEGRAL ENERGY MANAGEMENT OF AQUACULTURE FACILITIES, GREEN HYDROGEN, ZERO DISCHARGE

J.A. Ramos*and F. de la Gándara

Centro oceanográfico de Murcia (IEO,CSIC)
Planta Cultivos Marinos
Mazarrón, Murcia, Spain
Email: juan.ramos@ieo.csic.es

## Introduction

Currently, there is a high level of awareness regarding the use of renewable energy and its optimization in production processes. In aquaculture, there is a vast field of application, especially in the use of energy-sustainable RAS (Recirculating Aquaculture Systems). By determining the energy needs, a method for energy-sustainable operation can be established, allowing the culture of sea bass (*Dicentrarchus labrax*) to be carried out solely with renewable energy. Once the needs are identified, the necessary solar field and automation system have been designed, along with the volumes of tanks and treatment systems required for the cultivation. Another interesting factor is the incorporation of electricity generated by green hydrogen, which will be produced via photovoltaic methods. Additionally, due to the environmental issues caused by nitrogen waste (urine, feed residues), the goal has been set to prevent water discharge outside the system, significantly reducing the required energy input. To achieve this, biopolymers have been used in downflow reactors operating under semi-anaerobic conditions. Our results show that it is possible to cultivate sea bass during the ongrowing phase without water discharge and with 100% renewable energy.

## Materials and methods

The experiment was conducted at the facility of the Murcia Oceanographic Center (IEO, CSIC), in Puerto de Mazarrón (Murcia, Spain) (37º34'35" N 1º14'02" W). Five tanks of 1,680 liters were used, connected at their base to a biological treatment tank with a capacity of 1,850 liters. Temperature and oxygen concentration in the tanks were monitored daily, and $NH_4^+$, $NO_2^-$, $NO_3^-$ and pH were measured weekly. To eliminate nitrogenous compounds, a 1,850 liter tank (Denitrification Tank – "Tank-Des") was used for denitrification (Alzate Marín, 2019). In addition, one 1,680 liter tank was used as an electrochemical purification tank ("Tank-Pur"), where purification was carried out using solar electricity and a Ti-Rh electrode. In the Tank-Des, four downflow reactors were installed, each divided into two compartments. The lower compartment contained a support medium for denitrifying bacteria (porous pumice), while the upper compartment contained a biopolymer (starch-derived) synthesized in the laboratory.

A total of 125 European seabass (*Dicentrarchus labrax*) weighing 53 ± 20 g were distributed among five culture tanks, with 25 fish per tank. Seabass were fed manually to apparent satiety twice a day, at 09:00 and 13:00, with commercial feed D-3 Alterna 3p from Skretting (44% protein content) on alternate days. The following parameters were estimated: weight gain, specific growth rate (SGR = (ln (final weight / initial weight)) * 100 / days), feed conversion ratio (feed intake / weight gain), individual feed consumption, and the coefficient of variation in live weight at the beginning and end of the experiment (standard deviation / mean weight).

Two water recirculation systems were used. The first system supplied water directly to the five tanks after passing through a ring filter, cartridge filter, skimmer, ultraviolet sterilizer, blower (biological filter), and heat pump. The minimum target for daily water renewal was set at 200% of the water treated in the biological filter. Once the renewal flow rate and its treatment were established, a theoretical minimum energy consumption of 10 $kWh^{-1}$ per day was calculated for the most unfavorable periods (winter). The second recirculation system (denitrification) operated at a flow rate of 2 liters per minute, passing through a ring filter to provide anaerobic conditions in certain parts of the reactors. A 0.4 kW pump with a potentiometer regulator was used to set this flow rate, resulting in a theoretical consumption of 3 $kWh^{-1}$ per day under the most unfavorable conditions (winter). The culture tanks were cleaned by collecting coarse solids in the ring filter and returning the water to the denitrification tank. The retained particles were removed by cleaning with fresh water. Subsequently, the denitrified water was purified electrochemically using a Ti-Rh electrode and added back to the culture tanks after neutralization. Due to the lack of energy for cooling during summer, a reactor was designed for the generation of green hydrogen and oxygen, both separately. The oxygen was supplied to the culture tanks, and the hydrogen to a generator to produce electricity.

*(Continued on next page)*

**Results and discussion**

As established by Timmons *et al*. (2009), the emission rate of nitrogenous compounds is given by PNAT = F × %protein × %protein. In a fully closed-loop system, all nitrogen introduced must ultimately end up as $NO_3^-$ thanks to the biological filter. Dissolved protein in the water should be removed by the skimmer, while faeces and feed waste are eliminated through filtration and retention in the ring filter. The results are shown in the following table:

| | $NH_4^+$ ppm | $NO_2^-$ ppm | $NO_3^-$ ppm | Feed g | N supplied g | N present g | Nitrogen compound removal | Solar consumption $kWh^{-1}$ |
|---|---|---|---|---|---|---|---|---|
| **January** | 0.5 | 0 | 0 | 250.0 | 30.0 | 4.1 | -25.9 | 185.9 |
| **February** | 0 | 0.5 | 15 | 810.5 | 97.3 | 127.9 | 30.6 | 438.8 |
| **March** | 0 | 0.5 | 20 | 1,074.8 | 129.0 | 169.1 | 40.2 | 419.0 |
| **April** | 0 | 0.5 | 35 | 1,941.9 | 233.0 | 292.9 | 59.9 | 459.0 |
| **May** | 0.35 | 0.8 | 25 | 2,975.6 | 357.1 | 215.7 | -141.3 | 398.0 |
| **June** | 0.35 | 0.8 | 30 | 3,252.0 | 390.2 | 257.0 | -133.3 | 741.0 |
| | | | | 10,304.8 | | | | |

The main forms of nitrogenous waste excretion include $NH_4^+$, as noted by Martínez López (2002). Currently, an adequate removal rate is expected to ensure proper operation of the culture system, with target values of $NO_3^- < 30$ ppm, $NO_2^- < 1$ ppm, and $NH_4^+ < 0.5$ ppm.

# IMPACT OF SHORTDURATION PRETREATMENTS ON DEWATERING EFFICIENCY OF BROWN SEAWEEDS

Abirami Ramu Ganesan*, Michael Streicher, Shanmugam Munisamy

Department of Biomarine Resource Valorisation
Division of Food Production and Society
Norwegian Institute of Bioeconomy Research
Kudalsveien 6, NO-8027 Bodø, Norway
Email:abirami.ganesan@nibio.no

Introduction

Seaweed biomass is an increasingly important sustainable resource for aquaculture feed. However, due to its *high-water content* (ranging between 74–89%) presents challenges by increasing transportation costs, spoilage, and reducing processing efficiency (Prahu et al., 2020). Mechanical dewatering complemented by pretreatment steps is therefore critical to improve dry matter content and biomass stability prior to downstream processing (Milledge and Harvey, 2016). Chemical pretreatments such as acid or alkali have been shown to alter seaweed tissue structure, affecting water binding and enhance biorefining process (Kadam et al., 2015). This work examines the short-term effects (< 5 min) of fresh water, alkaline (KOH), and acidic (HCl) soaking and mechanical pressing on seaweed dewatering performance, correcting for mass changes induced by pretreatment to provide an evaluation of pressing efficiency in moisture removal from fresh seaweed.

**Materials and Methods**

***Alaria esculenta*** *(AE)* and ***Saccharina latissima*** *(SL)* were farmed and harvested in June 2024 from Måsskjæra, Norway, and supplied by Seaweed Solutions used in this study. The fresh seaweed biomass was received as a block-frozen and transported to the processing facility. Prior to pretreatment, each seaweed sample was thawed to room temperature. Four pretreatment conditions were applied on the whole seaweed: control (untreated), freshwater soak, 0.1% KOH, and 0.1 M HCl, —at a sample-to-solution ratio of 1:4 w/v. Biomass were immersed in their respective solutions for <5 min, after which they were weighed to record changes in mass. Then they were mechanically pressed using a twin-screen to separate solid and liquid fractions. Water removal% was calculated based on the initial water content of the post-pretreatment biomass, normalizing for hydration effects to enable accurate comparison of pretreatment efficacy on dewatering. Dry matter (DM), moisture content (MC), and ash content% were determined for both fractions following standard procedures (Milledge and Harvey, 2016).

**Results**

**Figure 1a** reveals notable differences in post-treatment weights and mass variation among treatments in *S.latissima*, especially the higher weight and mass loss variation seen in freshwater soaking and pressing **(SL2)**: Causes strong water uptake, resulting in diluted solids and poorest dewatering performance. Alkali treated **(SL3)**: Also increases water content, but slightly better retention of dry matter than freshwater. Acid treated **(SL4)**: Promotes water loss, yielding higher solid DM% (13.29 DM%) and better dewatering efficiency. SL4 promoted greater liquid release, with SL4 also showing weight loss, possibly reflecting leaching or degradation processes. These outcomes suggest that the treatments alter not only mass balance but also the efficiency of solid–liquid separation and dry matter recovery. While control **(SL1):** Maintains natural balance with relatively high DM% in solid fraction (16.9 DM%) and liquid fraction of 8.7 DM%, serving as reference. Handling loss during pressing was 3.7 to ~8.0% across all treatments but can be brought down further in commercial scale.

**Figure 1b.** The dewatering efficiency of *Alaria esculenta* biomass following different pre-treatment strategies (control, freshwater, KOH, and HCl treatment) was assessed through mass balance analysis of solid and liquid fractions. AE1 (Control): biomass yielding 35.9 g solids and 52.0 g liquid, with a handling loss of 12.1%. The solid fraction exhibited a DM of 28.33%, while the liquid fraction contained 6.39% DM. This reflects efficient retention of dry matter in the pressed cake, serving as the baseline reference for treated samples.

Whereas the biomass gained 24.1% and 49.7% FW when treated with and AE3 (KOH treatment) and AE2 (Freshwater treatment). Handling losses were highest (19.7%), while solid DM% dropped markedly to 23.10% and liquid DM% to 2.51% in AE2 which demonstrates strong dilution of the biomass matrix, producing the poor dewatering performance among treatments compared to AE3.

*(Continued on next page)*

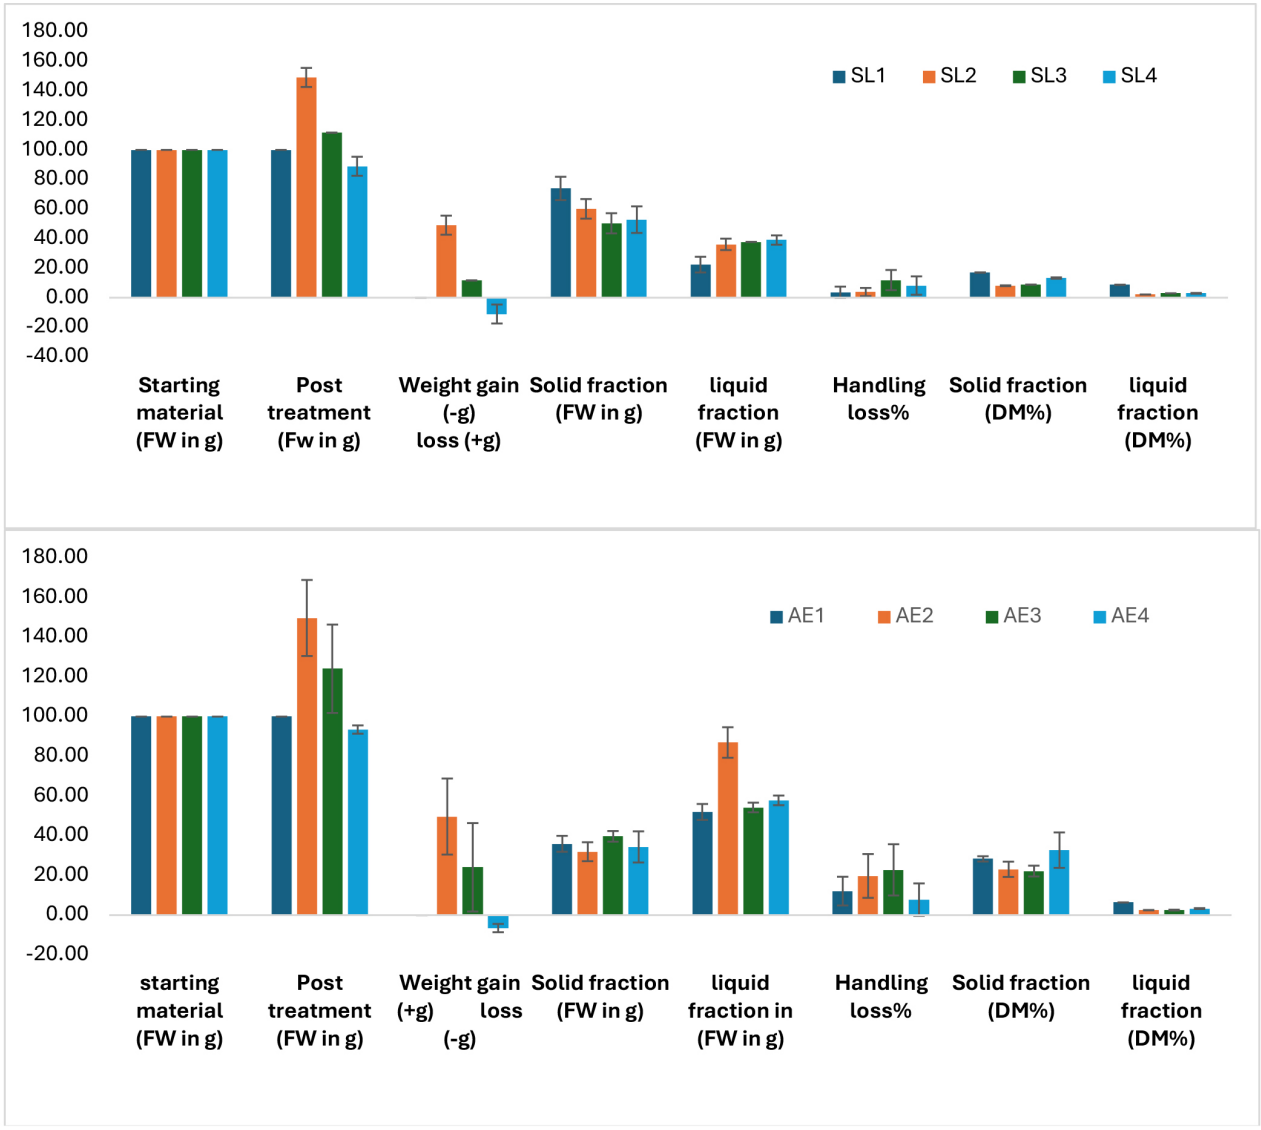

**Figure 1a.** Mass balance of pretreated and pressed *Saccharina latissima* (SL). **Figure 1b**. *Alaria esculenta* (AE) after pretreatment and pressing. The untreated whole biomass contained 13.15 % dry matter (DM) in SL and 20.5 % DM in AE, corresponding to a moisture content (MC) of 86.46 % in SL and 79.49 % in AE.

AE4 (HCl treatment): Biomass lost 6.5% FW, generating 34.4 g solids and 57.8 g liquid with the lowest handling loss (7.83%). The solid DM% increased to 32.73%, while liquid DM% was 3.31%. This treatment significantly enhanced solid concentration and improved water removal efficiency, making HCl soaking the most effective pre-treatment. Among treatments, HCl treated (AE4) was the most effective strategy, yielding the highest solid DM% and lowest handling loss, while freshwater treatment (AE2) was the least effective.

## Conclusion

Overall, acid treated on fresh seaweed found to be promising method to reduce the water content during pretreatment followed by pressing as a dewatering method is best suited both for downstream processing and stabilization of biomass. Whereas untreated seaweed during pressing liberated more dissolved solids and DM% in the liquid fraction. Meanwhile, the liquid fraction was rich in salt content and soluble solids which can be recovered and used for other purposes.

# INDUCTION OF POLYPLOIDY IN GREEN ALGA *Ulva fenestrata*: A NEW APPROACH FOR UPSCALING ITS BIOMASS PRODUCTIONS

Abirami Ramu Ganesan*, Shanmugam Munisamy, Leo Minini, Johan Johansen

Department of Biomarine Resource Valorization
Division of Food Production and Society Norwegian Institute of Bioeconomy Research (NIBIO)
Torggarden, Kudalsveien 6
No-8027, Bodø, Norway
*Corresponding author: shanmugam.munisamy@nibio.no

**Introduction**

*Ulva fenestrata* is a green seaweed commonly found in Norwegian waters, with strong potential for commercial-scale cultivation. Known as sea lettuce, Ulva spp. are a rich source of protein, vitamins and minerals, and hold strong promise for applications in food, feed, agriculture, bioremediation and biofuel production. Species of Ulva (commonly known as sea lettuce) is a rich source of protein, vitamin and mineral nutrients and it has huge commercial potential in application of food, feed, agriculture, bioremediation and biofuel production field. However, the industry is constrained by the unavailability of high-quality *Ulva* seeds. Polyploidy induction is a widely used technique in agriculture and aquaculture to enhance growth, yield and quality (Fig 1 & 2). Hence, this study aims at developing high vigor polyploid seedlings of *Ulva fenestrata* through treatments with anti-mitotic agents like colchicine and oryzalin.

**Methods**

To achieve this, protoplast isolation and chromosome counting methods are first optimized for this species. Chromosomes are counted in fresh tissue both before and after treatment with anti-mitotic agents at varying concentrations and durations, as well as in protoplasts isolated from these tissues, to assess the effectiveness of the treatments in doubling chromosome numbers via mitotic slippage. DNA content is also measured in isolated protoplasts through flow cytometry (Fig. 3). Once tetraploid *Ulva* cultures are obtained, their growth rate, reproductive traits, biochemical composition, and commercial potential will be compared with those of their wild counterparts. If successful, this approach could open new avenues for up-scaling *Ulva* production.

**Expected results**

- Methodologies to foster *U. fenestrata* breeding and polyploidization:
    - ► High-yield, high-quality protoplast isolation procedure
    - ► Chromosome counting and DNA quantification protocols
    - ► Optimized polyploidy induction method using anti-mitotic agents
- Established polyploid U. fenestrata cultures and sterile and/or fertile seedling production
- Comparative study of growth performance and biochemical composition between polyploid and wild type plants.

# EVALUATION OF THE MICROBIOLOGICAL QUALITY OF FROZEN, DRIED, AND SALTED-DRIED *Octopus vulgaris* : CASE STUDY OF MAHAJANGA

R. Ranjivah Frandley * J. D. Randriamialy * M. B. Cheikh * V. Razafitsalama * Astirfadhul

E-mail : randimbizakafrandley@gmail.com

**Introduction**

The common *Octopus* (*Octopus vulgaris*), also known as the common octopus, is the most commercially fished species of octopus in Europe (Common O., 2025). Conservation and processing techniques also play a crucial role in the distribution and marketing of aquatic products. These techniques include lowering the temperature of products (refrigeration and freezing), applying heat treatment (canning, boiling, and smoking), reducing water content (drying, salting, and smoking), and altering their storage environment (vacuum packaging, modified atmosphere packaging, and refrigeration) (Utilization and Transformation of Fisheries and Aquaculture Production, n.d.). The general objective of this research is to determine which type of conservation treatment is most effective for preservation. To achieve this, it is necessary to assess the effect of different conservation techniques on the microbiological quality of finished products and product stability.

**Materials and Methods**

Fresh octopus specimens were collected from various markets for processing. The specimens were categorized into three samples based on the type of treatment applied: freezing at -20°C for 10 hours, drying in a well-covered solar dryer for 3 to 5 days, and salting and drying. The latter involved immersing the octopus in boiling water for two to five minutes, followed by fermentation with salt for two to three days, and then drying under the sun for 2 to 3 days. Each product was weighed, and the temperature was recorded at each stage and day of processing to ensure treatment effectiveness and evaluate production yield. To ensure the quality of the finished products, the germ count of hygiene indicators such as FTM, total coliforms, *Escherichia coli*, staphylococcus, ASR, yeasts, and molds were performed. Additionally, pathogenic germs (salmonella) were also investigated.

**Results and Discussion**

The results obtained in this study on the microbiological quality evaluation of dried, salted, and frozen octopus showed interesting variations between the different conservation processes. Regarding treatment yield, the frozen octopus displayed high yields, ranging between 90% and 99%. These high yields can be attributed to the freezing process, which better preserves the product's characteristics, particularly by preventing excessive dehydration. In contrast, the salted and dried products showed lower yields (50-64% for salted-dried products and 54-63% for dried products). As (Zakhia, 1992) noted in their research, during 26 hours of drying, the water content of the fish decreased from 77% to 14%. Furthermore, the results from (El Kaouti, 2010) correspond with our findings on salting meat fillets, showing a 20% water loss.

The microbiological analysis of frozen, dried, and salted-dried octopus showed very satisfactory results. All analyzed samples met contamination levels well below critical limits. None of the hygiene indicator germs, such as total coliforms (CT), fecal coliforms (CF), *Escherichia coli* (EC), *Staphylococcus aureus*, and sulfite-reducing anaerobes (ASR), were detected. Additionally, no presence of *Salmonella* was observed. Our results were lower than those recorded by (Hafsa, n.d., 2019). However, we observed the presence of FTM in frozen octopus and a significant observation of molds for the salted-dried sample 2 (50 CFU/g). Nevertheless, this value did not exceed the target limit, indicating that our product was classified as satisfactory. During our experiments, we dried the octopus under the sun, where the temperature ranged between 30°C and 40°C theoretically. **(Zakhia, 1992)** explains that a product dried at 30°C has a risk of *L. monocytogenes* proliferation.

*(Continued on next page)*

## Conclusion

Food conservation techniques meet consumer demand. To ensure the effectiveness of these conservation techniques, it is crucial to evaluate the microbiological quality and stability of the product at the end of the process. The three methods chosen (freezing, drying, and salting-drying) for this study are among the most commonly practiced. Overall, our results indicate that freezing remains the easiest technique to master, considering the microbiological quality of the finished products and the yield obtained, although dried and salted-dried products show good results in terms of quality. However, the presence of certain germs, such as FTM, yeasts, and molds, requires improvements, especially in terms of water content and temperature control.

# OPTIFEESH PROJECT FOR OPTIMIZING FISH PRODUCTION PLANNING: A REAL-WORLD CASE STUDY

A. Raposo*, F. Soares, D. Vicente, L. Conceição, A. Sagia, K. Seferis, A. Glaropoulos, A. Nobre

* SPAROS Lda., Área Empresarial de Marim, Lote C, 8700-221 Olhão, Portugal.
Email: andreiaraposo@sparos.pt

**Introduction**

Optimizing fish feeding is essential to minimize on-farm trial-and-error and robust production planning, enabling aquaculture stakeholders to make informed decisions. Despite increasing digitalization in the aquaculture space and scientific advances on fish nutrition, there is no solution for fish farmers that effectively addresses the major challenge of optimizing feeding planning in aquaculture: The tools available so far do not integrate in-depth knowledge of fish nutrition. It is precisely this gap that OptiFeeSH project aims to fill by combining technical know-how in nutrition with digital intelligence, offering an innovative solution geared towards making informed and efficient decisions.

**OptiFeeSH approach**

The development of OptiFeeSH is driven by expertise in fish production and industrial R&D, integrating fish nutrition and farming technology within a user-friendly interface. Its Optimization module applies a biological approach based on a nutritional-based mathematical model, calibrated by species and sensitive to the feed energy and protein content. In a first step the system calculates four reference base plans:

- Maximum growth plan: feeding rates that ensure maximum growth.
- Lowest FCR plan: feeding rates that ensure the lowest FCR.
- Maximum profit plan: feeding rates that ensure the maximum profit.
- Meet requirements: fish feed requirements to ensure the user target weight.

In the second step, the engine creates interpolated plans, delivering a tailored set of feeding strategies aligned with the user's specific production goals (Table 1).

**Case study for a seabream cage farming**

Figure 1 shows a subset of the plans generated by OptiFeeSH for the bream case study (Table 1), which allows users to evaluate and choose according to their optimization targets: maximize profit, maximize growth, minimize FCR. All OptiFeeSH plans forecast improved profit and FCR compared to the current user plan (Figure 1). The Meet Requirements Plan, designed to meet nutritional needs for the user input target weight and production period, aligns closely with real production data (Figure 2) and as shown in Figure 1, outperforms current user plans in both profit (€0.84 vs. €0.64 per kg biomass) and economic FCR (1.69 vs. 1.83). Plan 8 delivers the fastest growth, while Plan 3 yields the highest profit for a 150,000-fish cage. Plan 3 provides a different feeding strategy, by increasing feeding rates for fish bigger than 250g, when comparing with the Meet Requirements, reaching the 450g target, 11 days earlier and increasing the profit of the cage from 50.9k € to 51.5 k €. The subset of plans listed in Figure 1 also shows that a lower economic FCR does not always translate to higher profitability.

**Conclusion**

OptiFeeSH provides a sound scientific approach to create multiple production plans that meet each farm target growth and allows the user to choose the optimal one according to their criteria: faster growth, minimum FCR, maximum profit, or a compromised solution. These tailored feeding and production plans help avoid overfeeding, fine-tune FCRs, and detect underfeeding early, providing a solid basis for daily feeding decisions.

This work is part of the E!2498 OptiFeeSH project, No. 17506, Operation No. MPr-2023-4-17506 (COMPETE2030-FEDER-01004100, ALGARVE-FEDER-01004100), supported by the EUROSTARS-3 program and co-financed by the European Union through the Algarve 2030 and COMPETE 2030 Operational Programs, in the framework of Portugal 2030, RESTART 2016-2020 Programme (Cyprus), and Participation of Greece in two calls for proposals of the co-funded European Partnership for Innovative SMEs of Horizon Europe.

[8]Aristotle University of Thessaloniki, Greece

Email: andreiaraposo@sparos.pt

**Introduction**

The FEEDNEXT initiative addresses the need for digital innovation and capacity building within Mediterranean aquaculture by equipping students, young professionals, unemployed workers, and industry stakeholders with essential skills in precision feeding, digital tools, and sustainable aquaculture practices. Implemented across Portugal, Greece, Tunisia, Turkey, and Egypt, the initiative fosters equal access to training through development of interactive learning modules, online resources, and practical applications that align with the green and digital transitions. By leveraging the expertise of research institutions, universities, and industry partners, FEEDNEXT aspires to establish a transnational platform to strengthen digital literacy and sustainable aquaculture practices. The initiative is dedicated to delivering scalable and transferable educational content that supports long-term skills development and sustainability in aquaculture.

**Methods and implementation**

FEEDNEXT aims to implement a capacity-building initiative that will address essential subjects like data digitization, aquaculture nutrition, precision feeding strategies, and circular economy principles, including Life Cycle Assessment (LCA) in aquaculture. The training materials will be translated into the languages of partner countries and made accessible via a Moodle platform, ensuring accessibility for a broad audience. The project will also create pilot actions designed to function as interactive training platforms, allowing participants to gain practical experience analyzing real-world data, applying advanced tools, and addressing sector-specific challenges. The training modules will also include practical tutorials with FEEDNETICS, allowing participants to gain experience on digital prediction tools. FEEDNEXT aims to equip the participants with the digital and technical skills necessary for sustainable aquaculture.

**Expected outcomes and impact**

FEEDNEXT expects to foster a new generation of aquaculture professionals by bridging the gap between research, industry, and education. The initiative aims to enhance digital skills, precision feeding knowledge, and sustainable practices/methods, equipping students, young professionals, and unemployed workers with the necessary tools for a greener and efficient aquaculture sector. By advocating for circular economy concepts, resource-efficient fish farming, and digital literacy, FEEDNEXT will contribute to the EU Green Deal objectives and the UN Sustainable Development Goals. Through capacity-building initiatives, e-learning materials, and hands-on training, the program will contribute to improving employability and strengthen industry-academia collaboration. FEEDNEXT will ensure its long-term scalability and adaptability by partnering with universities, research institutes, and industry stakeholders throughout the Mediterranean.

**Conclusion**

By integrating digital innovation, sustainability, and education, FEEDNEXT aims to strengthen the resilience and competitiveness of Mediterranean aquaculture. The initiative's approach will not only enhance skills development and employment opportunities but also supports the transition toward a more sustainable and eco-friendly blue economy.

# BACTERICIDAL AND BACTERIOSTATIC ACTIVITIES OF HALOPHYTE BASED BIOACTIVE COMPOUNDS AGAINST BACTERIAL PATHOGENS

## Introduction

The modern expansion of aquaculture is frequently accompanied by the emergence of diseases, leading to significant impacts on the production of various fish species, including the economically important European seabass (*Dicentrarchus labrax*). To address this challenge, and to combat antimicrobial resistance due to irresponsible and inappropriate use of antibiotics, exploring sustainable and eco-friendly strategies could have great potential for the industry. Bioactive compounds from halophytes have recently gained significant attention for use in the nutraceutical, pharmaceutical, and cosmetic industries. Phytochemicals including natural compounds, secondary metabolites, and their derivatives can play active roles in antibacterial, anti-inflammatory, and antioxidant activities (Giordano *et al*., 2021). This study aimed to evaluate the antimicrobial potential of bioactive compounds from *Salicornia ramosissima* residual biomass for applications in aquaculture while applying circular economy concepts.

## Materials and methods

The bactericidal and bacteriostatic potential of seven extracts (Ext1, Ext2, Ext3, XAD, XAD3, FERM, FRAC3) obtained from the halophyte *S. ramosissima* were tested at 0.125, 0.25, and 0.5 mg·mL$^{-1}$ against bacterial pathogens for fish and shrimp: *Aeromonas hydrophila, Edwardsiella piscicida, Photobacterium damselae piscicida, Tenacibaculum maritimum, Vibrio anguillarum, Vibrio parahaemolyticus, and Yersinia ruckeri*. The bactericidal activity of the extracts was determined by a colorimetric MTT assay (Machado *et al*., 2024) and expressed as % viability inhibition, while the bacteriostatic activity was measured as % growth inhibition at the 24-h endpoint, using $OD_{630}$ recorded at 13 time points from 0–24 h (Mai *et al*., 2023)

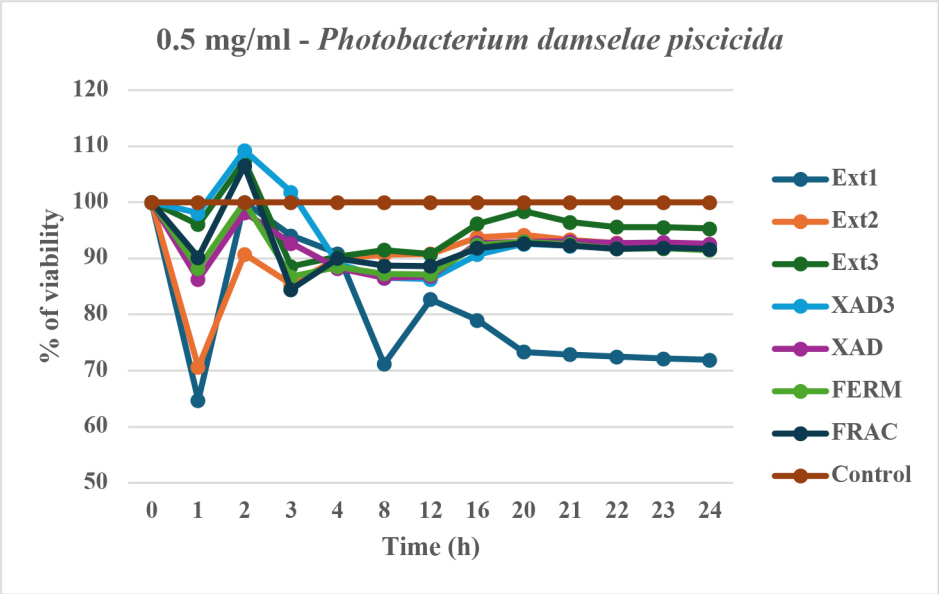

Figure 1. Bacteriostatic activity of extracts against *Photobacterium damselae piscicida* at 0.5mg/ml

*(Continued on next page)*

**Results**

Ext1, Ext2, Ext3, XAD, and FRAC3 showed modest bactericidal activity (31.42–40.55%) at the highest concentration (0.5 $mg \cdot mL^{-1}$) against *P. damselae piscicida* and *Y. ruckeri*, while XAD and FERM showed mild viability reductions (17.63–18.65%) against *T. maritimum*. In contrast, almost all extracts showed very weak to no inhibition of viability against *A. hydrophila, E. piscicida, V. anguillarum, and V. parahaemolyticus* at all concentrations tested. Overall, while most tested *S. ramosissima* extracts displayed a narrow-spectrum bacteriostatic profile, Ext1 showed a moderate bacteriostatic activity against *P. damselae piscicida*, which translates into aprox. 29% inhibition at concentration 0.5 $mg \cdot mL^{-1}$ (Figure1)

**Conclusion**

In conclusion, these findings indicate that some extracts could act as promising antibacterial agents. However, further studies are needed to increase the concentration range to examine dose–response/$IC_{50}$, as well as confirming killing via Minimum Inhibitory Concentration (MIC)/Minimum Bactericidal Concentration (MBC) or colony forming unit counts and assess potential synergies. Also, its therapeutic or prophylactic effect in vivo should be addressed to evaluate their potential as nutraceutical ingredient.

## Introduction

Bivalves have a complex life cycle, encompassing a planktonic free-swimming larvae and a benthonic phase[1]. Metamorphosis is responsible for the transition from larvae to the juvenile stage and represents a critical step in the bivalve life cycle. This process is one of the most challenging phases for bivalve hatcheries due to high mortality and a non-synchronous larval development within a cohort – not all the individuals are physiologically competent to metamorphose at the same time[2]. To achieve a greater, more rapid and efficient percentage of metamorphosis and consequently improve the production[3,4], hatcheries could use synthetic chemical inducers. Among the compounds with an inductive effect on metamorphosis, the amino acid derivative γ-aminobutyric acid (GABA) and the catecholamine epinephrine (EPI) are considered as the most efficient.

Grooved carpet shell (*Ruditapes decussatus*) and Pullet carpet shell (*Venerupis corrugata*) are species with high commercial and ecological importance, widely distributed in coastal and estuarine waters throughout Europe, the Mediterranean and North Africa[5–7]. In Portugal, while *R.* decussatus, which is produced and harvested mainly in Ria Formosa lagoon, is crucial for aquaculture revenue (representing 90% of the national production), *V. corrugata* is emerging as a relevant species to Portuguese bivalve aquaculture. Considering the relevance of these species and, in order to improve metamorphosis, with reduced mortality in bivalve hatcheries, the current work evaluated the effects of GABA and EPI, in terms of optimal concentrations, toxicity and exposure time.

## Material and methods

Larvae were exposed to three different concentrations ($10^{-2}$, $10^{-4}$ and $10^{-6}$ M) of EPI and GABA and filtered sea water (FSW) was used as control. EPI and GABA stock solutions were initially prepared at a concentration of $10^{-1}$ M and $10^{-3}$ M; stock solutions were then diluted in FSW to reach the experimental concentrations immediately before experiments.

Metamorphosis trials were conducted in glass beakers with 300 ml of FSW, under continuous aeration. Each beaker contained a sieve (150 $\mu$m mesh) with approximately 1000 larvae (3 larvae $mL^{-1}$). Larvae were exposed to different concentrations for 24, 48 and 72 hours. After the exposure period, larvae were rinsed with FSW and 3 aliquots with a minimum of 30 larvae of each beaker were analysed, to evaluate mortality and metamorphic stages. The developmental stages were characterized by the presence of velum, foot and velum, foot, or foot and branchial arches. A larva was considered to have undergone complete metamorphosis when it had lost its velum, was using its foot to crawl and had developed branchial arches. After evaluation, larvae were placed back into the beakers with clean FSW for an additional period of 5, 4 and 3 days, respectively. Metamorphosis rate and mortality were evaluated after each exposure time and at day 6 after the onset of exposure.

## Results and Discussion

Figure 1 shows the effects of EPI and GABA on the metamorphosis rate of *V. corrugata* and *R. decussatus* after each exposure time. In general, high concentrations of both EPI and GABA ($10^{-2}$ M and $10^{-4}$ M) revealed to be toxic to the larvae of both species, regardless of the exposure time (fig. 2). The higher metamorphic rate in *V. corrugata* and lower mortality were achieved after exposure to EPI $10^{-6}$ M (24h and 48h) and GABA $10^{-6}$ M (48h) (fig. 1). At 6$^{th}$ day, the 48h-exposure to GABA and EPI $10^{-6}$ M induced a higher metamorphosis rate, varying between 62.2% and 82.2%, respectively. Despite its effectiveness in inducing metamorphosis, *V. corrugata* appeared to be more sensitive to EPI, exhibiting higher mortality rates at certain concentrations.

*(Continued on next page)*

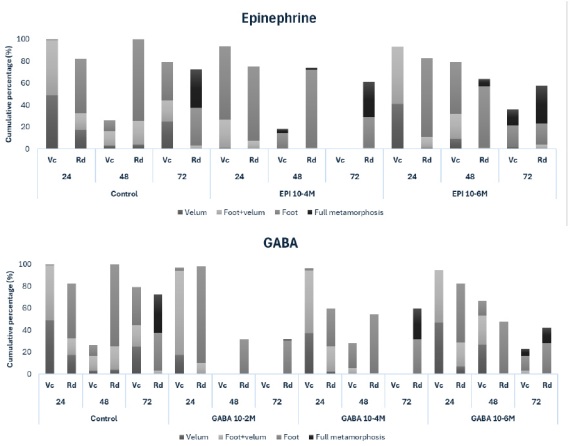

**Figure 1-** Metamorphic induction after exposure (24h, 48h and 72h) to epinephrine and GABA on larvae of *Venerupis corrugata* (Vc) and *Ruditapes decussatus* (Rd).

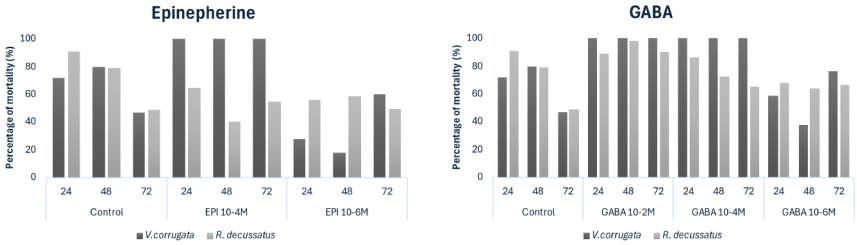

**Figure 2-** Percentage of mortality of larvae of *Venerupis corrugata* and *Ruditapes decussatus* observed at the end of the trial (6$^{th}$ day) after exposure to epinephrine and GABA.

In contrast, GABA failed to induce metamorphosis in *R. decussatus*, besides being toxic to the larvae. For this species, 72h-exposure to EPI $10^{-4}$ M and $10^{-6}$ M induced a higher metamorphic rate, varying between 32.2% and 34.3%, respectively (fig.1). At 6$^{th}$ day of the trial, metamorphosis reached 55.6% and 50.5% in larvae exposed to EPI $10^{-4}$ M (48h) and $10^{-6}$ M (72h).

These findings highlight the species-specific responses to chemical inducers. Optimal concentration and exposure time vary between species, emphasizing the need to adapt conditions accordingly. Adjusting these parameters may enhance hatchery production by improving metamorphosis efficiency while minimizing larval mortality.

# INTEGRATED MULTI-TROPHIC AQUACULTURE IN THE ATLANTIC: IS IMTA THE ANSWER FOR SUSTAINABLE, RESILIENT AND PROFITABLE AQUATIC VALUE CHAINS? FINAL RESULTS FROM THE ASTRAL PROJECT

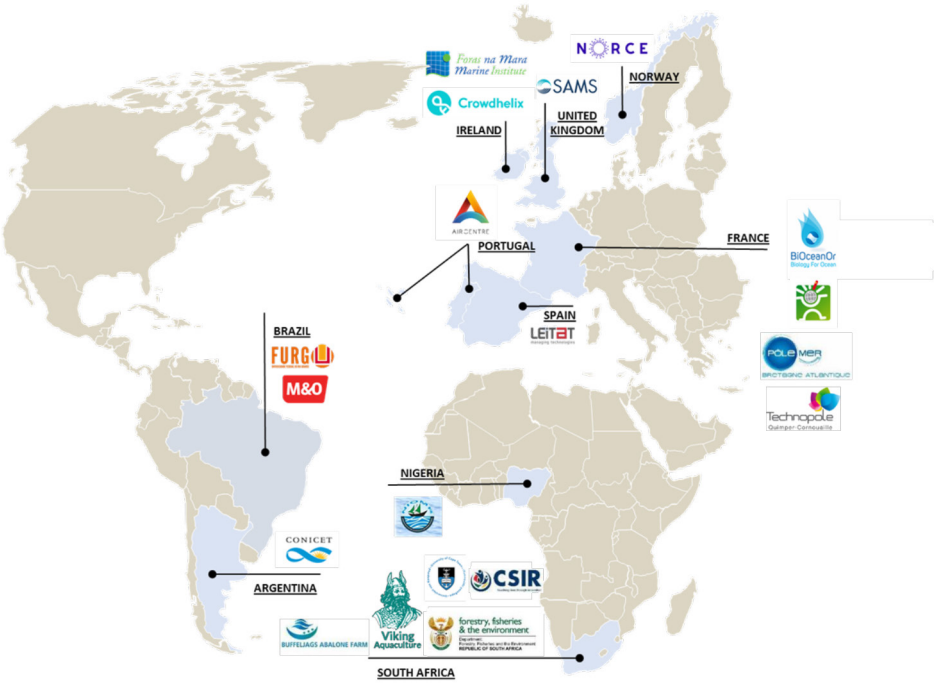
Elisa Ravagnan

NORCE Research AS
Nygårdsgaten 112
5008 Bergen, Norway
Email: elra@norceresearch.no

The EU-funded ASTRAL project has developed IMTA production chains for Atlantic markets. Focusing on a regional challenge-based perspective, it brought together labs in Ireland and Scotland (open offshore labs), South Africa (flow-through inshore, partially recirculating) and Brazil (recirculation inshore) as well as Argentina (prospective IMTA). The aim has been to increase circularity compared to monoculture baseline aquaculture and to boost revenue diversification for aquaculture producers. The ASTRAL project has also fostered a collaborative ecosystem along the Atlantic through shared, integrated, and co-generated knowledge, technology and best practices.

The conclusive results on increased circularity, best practices for zero waste, economic and social assessments will be presented.

Acknowledgment: The ASTRAL project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 863034.



# EVALUATION OF THE ANTIVIRAL ACTIVITY OF NATURAL SUBSTANCES OBTAINED FROM BACTERIA AND ALGAE AGAINST VIRAL HAEMORRHAGIC SEPTICEMIA VIRUS

## Introduction

Viral haemorrhagic septicaemia virus (VHSV) infects a wide range of freshwater and marine fish species, causing high mortality rates in susceptible cultured fish, mainly salmonids (Smail and Snow, 2011). A prophylactic practise to enhance the natural resistance of farmed fish to viral infections is the use of functional food. Extracellular polymers (ECPs) from probiotic bacteria are postbiotics that represent a valid and safe alternative for providing beneficial effects against microorganisms in fish (Domínguez-Maqueda *et al.*, 2024; García-Márquez *et al.*, 2023). Macroalgae and microalgae are also alternative sources of substances with potential activity to improve resistance to microbial infections (Abdala-Díaz *et al.*, 2021; Parra-Riofrio *et al.*, 2023). The objective of this study was to evaluate the antiviral activity of ECPs from the probiotic bacteria *Shewanella putrefaciens* Pdp11 and *Bacillus pumilus* UMA169, as well as extracts and/or polysaccharides from *Ulva rigida* and *Porphyridium cruentum*, against a freshwater VHSV isolate.

## Materials and methods

The protection conferred by each substance against a freshwater VHSV isolate (genotype 1) was evaluated *in vitro*, on RTG-2 cells, by quantifying the cellular survival rate after viral infection, using the MTT reduction assay. Cells were inoculated at 0.05 MOI, and, after an adsorption time of 1 hour, the viral suspension was removed, and replaced by cultured medium supplemented with the substances. Cells were cultured at the optimum temperature for viral replication, and the cellular survival rate was calculated 3 days post-infection. The substances tested were: (i) ECPs from *B. pumilus* UMA169, ECPs from S. *putrefaciens* Pdp11 (both bacteria cultured on TSAs at 15 ºC for 48 h) at 50 µg of protein·mL$^{-1}$, (ii) extracts of *U. rigida* at 100 and 500 µg·mL$^{-1}$, (iii) ulvan polysaccharides from *U. rigida* at 50 µg·mL$^{-1}$ and (iii) extracts of *P. cruentum* at 100 µg·mL$^{-1}$.

## Results

All substances tested exhibited antiviral activity against VHSV, except for ECPs from Pdp11, which showed the opposite effect (Figure 1). ECPs from *B. pumilus* UMA169 conferred full protection to the cells, whereas algal extracts and ulvan polysaccharides conferred a similar protection level to VHSV infected cells. Thus, these substances, excluding ECPs from Pdp11, are promising candidates to be used as protective substances against VHSV. Actually, their effect on viral replication and infective viral particles production will also be evaluated.

According to these results, a supplemented diet will be designed to test the anti-VHSV activity of these substances in the experimental model of zebrafish to evaluate their antiviral potential and relevance to aquaculture.

*(Continued on next page)*

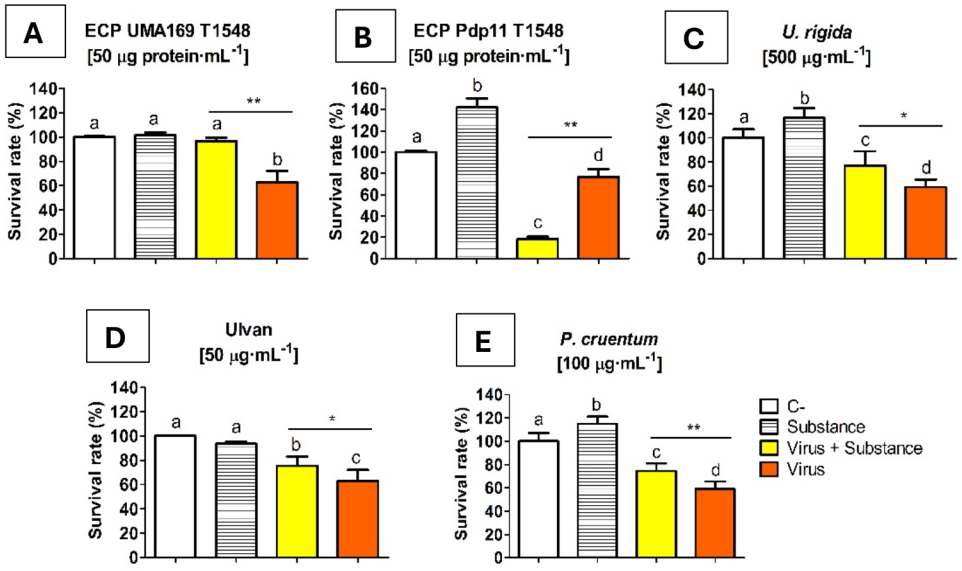

**Figure 1 :** Survival of RTG-2 cells exposed to ECP UMA169 (T1548) (A), ECP Pdp11 (T1548) (B), *U. rigida* extracts (C), ulvans (D) and *P. cruentum* extracts (E). Cells were inoculated with a freshwater VHSV isolate at 0.05 MOI. The survival rate was evaluated at 3 days post-infection. Data were statistically analysed with the two-way ANOVA test. Different letters denote significant differences between groups. Values of $P < 0.01$ (*) or $P < 0.001$ (**) were considered significant. Results are mean ± standard deviation (SD) (n = 8).

## Introduction

One of the main priorities for the aquaculture industry is the development and implementation of measures to prevent viral diseases. In this regard, the design of functional food is taking great relevance, since it may stimulate the unspecific antiviral immune system, protecting fish from different viral infections. The main unspecific antiviral immune system is the interferon I (IFN-I) system, responsible for the induction of hundreds of IFN-stimulated genes (ISGs), such as *mx*. The objective of this study was the *in vitro* evaluation of the immunostimulatory and antiviral activities of two marine amphipod species (*Caprella scaura* and *Gammarus insensibilis*), which have high nutritional value and great potential as new trophic resource in aquaculture (Guerra-García *et al*., 2016; Jiménez-Prada *et al*., 2018)

## Materials and methods

The stimulation of the IFN-I system was evaluated using two celular systems: (i) RTG-2 cells expressing luciferase under the control of the Senegalese sole (*Solea senegalensis*) *mx* promoter (p*ssmx*, RTG-2-p*ssmx-luciferase system*), and (ii) RTG-2 cells expressing luciferase under the control of the gilthead seabream (*Sparus aurata*) *mx2* promoter (p*saumx2*, RTG-2-p*saumx2-luciferase system*) (Alvarez-Torres *et al*., 2013; González-Mariscal *et al*., 2014). These cells were exposed to different concentrations of lyophilized amphipods during several periods, and subsequently washed, lysed and mixed with the luciferase substrate. Stimulation of p*ssmx* and/or p*saumx2* promoters was quantified as luciferase activity, which was measured as relative light units. Inducibility was calculated according Alvarez-Torres *et al.* (2013). The antiviral activity was evaluated against a marine viral haemorrhagic septicaemia virus (VHSV) isolate (genotype 3) on RTG-2 cells following three procedures: (i) viral neutralization assay, (ii) 1-h pre-adsorption assay, and (iii) post-adsorption assay (Moreno *et al*., 2023). Results were expressed as cellular survival rate, which was calculated 3 days after the viral infection by the MTT-reduction assay.

## Results

The Senegalese sole *mx* promoter was not induced by any of the amphipods tested, however both species induced gilthead seabream *mx2* promoter. Specifically, p*saumx2* was induced at 3 days after cell exposure to *G. insensibilis* (100 $\mu$M) and, at 3 and 4 days after *C. scaura* exposure (100 and 250 $\mu$M) (**Figure 1**). Nevertheless, only cells exposed to *G. insensibilis* (100 and 250 $\mu$M) after VHSV infection (post-adsorption assay) exhibited survival rates significantly higher than those obtained for the control non-exposed cells (**Figure 2**).

We can conclude that both species are able to activate the IFN-I signalling pathway in RTG-2 cells, although only *G. insensibilis* provides *in vitro* protection against VHSV. In consequence, these two species are promising candidates to be used as immunostimulants in aquaculture, and they may induce an antiviral state in the host, which probably is species dependent.

*(Continued on next page)*

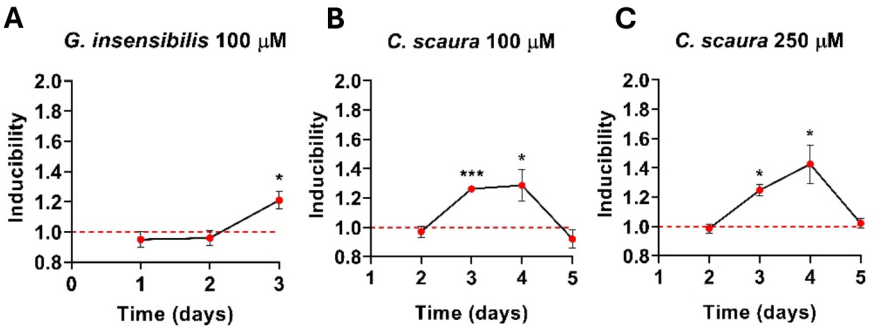

**Figure 1:** Inducibility of the RTG-2-p*saumx2-luciferase* system by exposure to *G. insensibilis* at 100 µM (A) or to *C. scaura* at 100 (B) and 250 (C) µM. Dashed-red line is the threshold of inducibility. Data were analysed with the Student's t-test. Asterisk denotes significant induction ($P$<0.05 *; $P$<0.001 ***). Results are mean ± standard deviation (SD) (n=3).

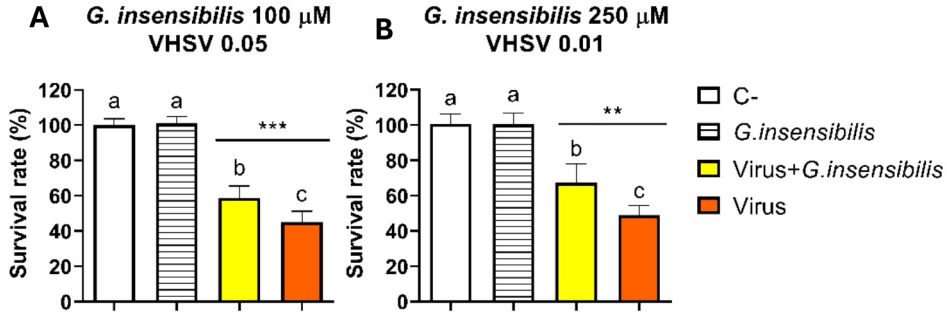

**Figure 2:** Survival of RTG-2 cells exposed to *G. insensibilis* at 100 (A) and 250 (B) µM after viral infection. Cells were inoculated with a marine VHSV isolate at 0.05 (A) and 0.01 (B) MOI. Data were analysed with the two-way ANOVA test. Different letters denote significant differences. Values of $P$<0.01(**) or $P$<0.001(***) were considered significant. Results are mean ± standard deviation (SD) (n=8).

Maintaining gut health is essential for optimal growth, feed efficiency, and disease resistance in aquaculture species. Inflammatory bowel conditions, whether caused by pathogens, diet, or environmental stressors, represent a major threat in intensive aquaculture systems. This study aims to investigate the effects of 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis in zebrafish as an *in-vivo* model for acute intestinal inflammation and assess the potential mitigating effects of dietary beta-glucans, as shown in Figure 1.

Beta-glucans are complex polysaccharides derived from yeast and other fungal cell walls. They are known immunomodulators and have demonstrated anti-inflammatory properties in various animal models. Beta-glucans can increase macrophage functionality and mobilise other immune cells including natural killer cells, which play a crucial role in controlling inflammation and infection. We hypothesize that dietary supplementation with beta-glucans can reduce TNBS-induced inflammation in the posterior intestine of zebrafish, potentially by modulating innate cellular responses and preserve intestinal integrity.

This model will serve as a foundation for developing functional feeds that support intestinal health in commercially important aquaculture species. Results from this research may contribute to sustainable health management strategies in fish farming.

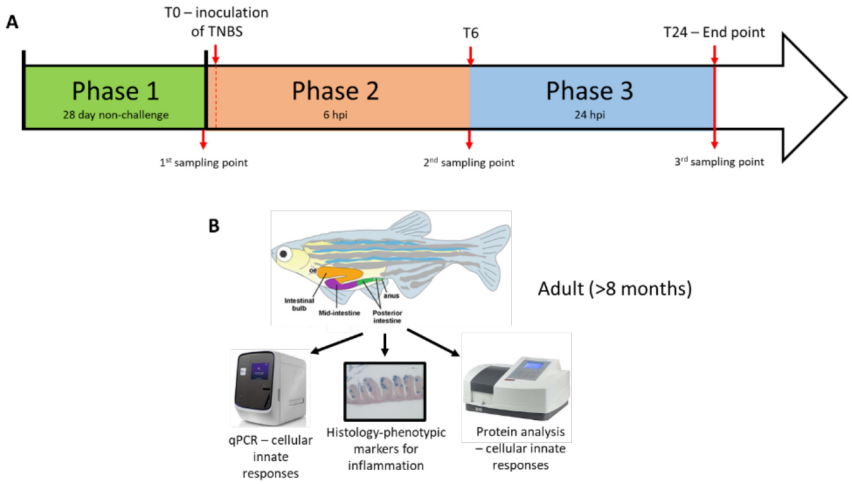

Figure 1. Schematic showing the trial (A) experimental design and (B) sampling endpoints. Figure B shows in green the posterior intestine, this intestinal region was sampled for analysis.

# GILLS, GENES AND GRADIENTS: INVESTIGATING SALINITY TOLERANCE IN MARAENA WHITEFISH (*Coregonus maraena*)

## Introduction

Fish employ a range of physiological mechanisms to acclimate to environmental salinity levels that differ from their internal osmotic conditions. Many of these adaptive responses are mediated by characteristic, teleost-specific gene expression patterns. Among the most studied are two isoforms of the *atp1a1* gene, which encode the α-subunit of the Na□/K□-ATPase, an essential enzyme for osmoregulation. These isoforms have become established transcriptional markers in aquaculture, particularly for predicting the seawater adaptability of Atlantic salmon *Salmo salar* (McGowan et al., 2021).

Despite the growing body of research on osmoregulatory markers in salmonids, transcriptional indicators of saltwater tolerance in coregonids remain largely unexplored. To address this gap, we profiled gene expression in selected tissues of maraena whitefish *Coregonus maraena* reared either in the Baltic Sea with naturally fluctuating salinities or in a freshwater facility (see Figure a). Acknowledging the influence of variable environmental conditions in these two open aquaculture systems, we also conducted a complementary salinity challenge under standardised conditions in a recirculating aquaculture system (RAS).

## Material and methods

To investigate the potential effects of salinity on the expression of genes associated with salinity adaptation, we analysed transcript levels in the gills, skin, head kidney, and liver of maraena whitefish over a 10-week period. Fish were reared either in a freshwater pond system (BiMES, Friedrichsruhe/Frauenmark, Germany) or in a net-cage facility located within an artificial reef in the Baltic Sea with fluctuating salinity levels between 8.6 and 12.0 PSU (see Figure a). To complement field data and account for potential confounding environmental variables in the open systems, a controlled follow-up experiment was conducted at the experimental aquaculture facility of the FBN (Dummerstorf, Germany). During this 9-day experiment, two RASs were used: one maintained with freshwater, and the other adjusted to 8 PSU and later to 20 PSU for 48 h, using sea salt (Sale Marino, LP20259B, Fino Margherita, Milano, Italy) (see Figure b).

Gene expression profiling was performed using the BioMark HD system (Standard BioTools, San Francisco, CA, USA). A total of 23 candidate genes associated with salinity tolerance, along with two reference genes, were selected based on prior work by Houde et al. (2019).

## Results and discussion

The *atp1a1a* isoform showed significantly higher expression in the gills of maraena whitefish reared in the freshwater pond compared to individuals from the brackish-water reef. In contrast, the seawater-associated isoform *atp1a1b* was significantly upregulated in the gills of whitefish from the reef relative to their pond-reared conspecifics (Figure c). Despite these differences, the overall expression profiles between the two groups were largely comparable. A PCA based on gene expression across all sampled tissues did not reveal clear separation between reef- and pond-reared individuals, indicating a high degree of similarity in their transcriptional profiles (Figure d). In the gills, as in the three other tissues analysed, only sporadic modulations in transcript abundances across time points were observed (Figures e and f).

*(Continued on next page)*

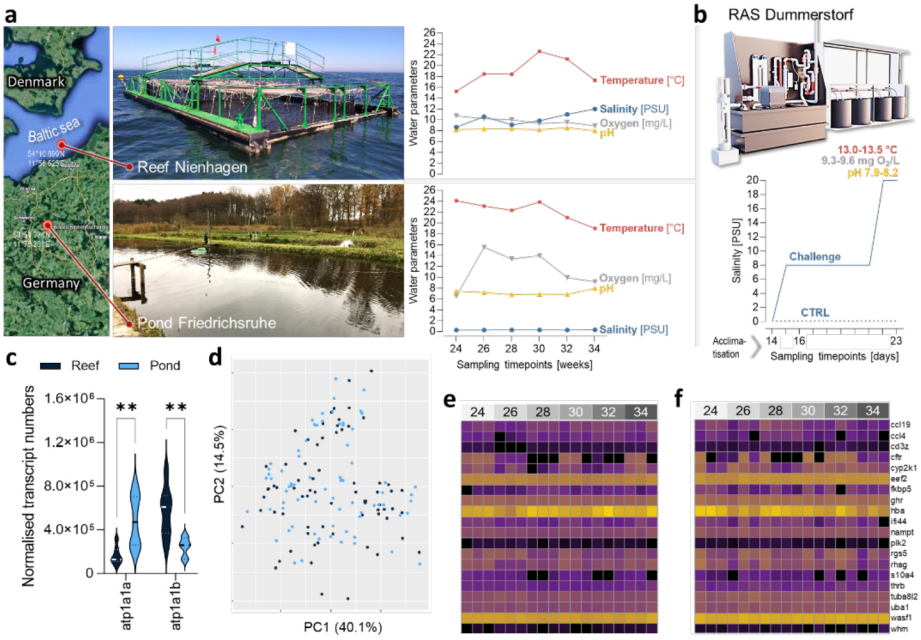

**Figure: Overview of experimental sites, environmental conditions and gene expression analyses in maraena whitefish.** (**a**) Map section (adapted from Google Maps) showing the locations of the two whitefish production facilities: the brackish-water reef (top left) and the freshwater pond system (bottom left). Temperature (red), salinity (blue), oxygen concentration (grey), and pH (yellow) are plotted over the 10-week observation period. (**b**) Schematic representation of the RAS (top) used for the 9-day salinity treatment illustrated over time (bottom). (**c**) Violin plots showing normalised expression levels of *atp1a1a* and *atp1a1b* in the gills of whitefish reared under reef (dark blue) and pond (light blue) conditions (n = 7). Asterisks indicate statistically significant differences (adjusted p = 0.005). (**d**) PCA plot showing the separation of gene expression profiles from whitefish reared in the reef (dark blue) and pond (light blue). (**e–f**) Heat maps of log10-transformed transcript counts for selected genes in gill tissue of whitefish from (**e**) the reef and (**f**) pond systems (n = 3 per condition). Sampling time is shown above each heat map; gene symbols are listed on the right.

In the follow-up experiment conducted in the RAS, an increase in salinity from 0 to 8 PSU led to significant decreased *atp1a1a* and increased *fkbp5* transcript levels in the gills. Elevation to 20 PSU was associated with further reduced levels of *atp1a1a* in the gills.

Overall, the data suggest that maraena whitefish tolerate salinities up to 20 PSU without showing signs of physiological stress. However, the limited transcriptional differentiation observed under natural rearing conditions indicates that the current set of candidate biomarkers may be less effective for evaluating open aquaculture systems. In contrast, gene expression responses in the RAS were more consistent and pronounced, highlighting the potential of these markers for controlled-environment applications.

# CLIMATE CHANGE ADAPTATIONS IN SALMON AQUACTULRUE: ECOSYSTEM SERVICE IMPACTS AND TRADE-OFFS

Megan Rector*
Lynne Falconer

Institute of Aquaculture
University of Stirling
Stirling UK FK9 4LA
megan.rector@stir.ac.uk

Marine aquaculture systems rely on services provided by the natural environment to support food production, but the marine environment and the ecosystem services it provides are increasingly affected by climate change. Climate change impacts including decreased oxygen levels, heat waves, increasing incidence of jellyfish and algal blooms, and extreme weather events and storm surges are affecting aquaculture production, fish health, and the welfare of farmed species. Coping strategies, transformational change, and technological solutions may allow farmers and companies to adapt to climate change, but the impact of these adaptations is unknown. We are developing a Bayesian Belief Model (BBN) based on expert elicitation to explore the impacts of climate change adaptations on ecosystem services. Using marine salmon farming as an example, this approach provides a means to explore potential aquaculture futures and identify trade-offs between ecosystem services under different climate change and adaptation scenarios.

## Introduction

Additives are widely used in aquaculture as proactive nutritional strategies to improve fish nutrient utilization and health, with some of their benefits potentially related to changes in intestinal microbiota composition and function. The intestinal microbiota plays region-specific roles in the digestion and synthesis of key metabolites, such as short-chain fatty acids (SCFAs), amino acids, and vitamins [1]. Pomegranate (*Punica granatum*), a fruit rich in polyphenols such as punicalagin, has shown functional potential by modulating microbial communities, suppressing pathogens, promoting commensals, and stimulating SCFAs synthesis [2]. Several studies have demonstrated that pomegranate-derived additives enhance the growth, immunity, and disease resistance of rainbow trout (*Oncorhynchus mykiss*) [3], rohu (*Labeo Rohita*) [4]it was observed that pomegranate peel ethanolic extract (PPEE, common carp (*Cyprinus carpio*) [5], and Nile tilapia (*Oreochromis niloticus*) [6]. However, no data are available on their effects on European sea bass (*Dicentrarchus labrax*), especially regarding the intestinal microbiota, using next-generation sequencing (NGS). This study aimed to evaluate the effect of pomegranate extract (PM) on the growth and intestinal microbiota of European sea bass juveniles, as a tool to promote productivity and microbial stability.

## Materials and methods

Juvenile sea bass (n = 200; 12.71 ± 0.08 g) were randomly distributed into six 0.5 m³ tanks (3 replicates per diet) in IRTAmar™ recirculation aquaculture systems (RAS). Fish were fed either a control diet (CTRL) or a pomegranate-supplemented diet (PM; 0.02%) for 12 weeks. At the end of the feeding trial, fish were individually weighed, and 12 fish per tank were sampled to collect the anterior (AI) and posterior intestine (PI) mucosa for microbiota analyses. DNA was extracted using the DNeasy® PowerSoil® Pro Kit, and the V3–V4 region of the 16S rRNA gene was sequenced on an Illumina MiSeq (2 × 300 bp). Sequence processing and taxonomic classification were performed in R using QIIME2, DADA2, and Microbiome packages and SILVA v138.1 database. Diversity indices were calculated using the microeco package. Statistical analyses included LMM for alpha diversity, PERMANOVA for beta diversity, and ANCOM-BC for differential abundance ($p \leq 0.05$), with diet and intestinal region as variables. For growth performance, a t-test ($p \leq 0.05$) was conducted after verifying the normality and homogeneity of variances.

## Results and discussion

After 12 weeks of dietary supplementation, PM dietary supplementation did not significantly affect growth performance ($p > 0.05$; average SGR of 1.93 ± 0.05%). According to the bioinformatic results, a total of 8.9 million clean reads and 895 ASVs were obtained. No significant differences were observed in alpha or beta diversity across diets or intestinal regions (LMM and PERMANOVA; $p > 0.05$). However, differential abundance analysis (ANCOM-BC; $p \leq 0.05$) revealed an effect of PM supplementation on 2 phyla and 22 genera; of intestinal region on 3 genera; and of the interaction of both variables on 1 phylum and 23 genera. Subsequent analyses stratified by intestinal region showed that in the AI, the dominant phyla (>5% relative abundance) were Proteobacteria, Actinobacteriota, and Firmicutes. Halobacterota, mainly represented by *Haloccocus*, was significantly enriched in fish fed the PM diet. Dominant genera included *Pelomonas*, *Cutibacterium, Corynebacterium, Staphylococcus, Vibrio,* and *Shewanella.* PM supplementation also increased the moderately abundant (1–5% relative abundance) *Planctomicrobium* and low-abundance (<1% relative abundance) genera such as *Francisella, Delftia,* and *Caulobacter*, while *Coxiella* was higher in fish fed the CTRL diet. In the PI, dominant phyla included Proteobacteria, Actinobacteriota, Firmicutes, Chloroflexi, and Bacteroidota. Fish fed the PM diet presented increased Halobacterota (*Halococcus*), as observed in the AI. Additionally, moderately abundant such as *Stenotrophomonas* and *Actinomyces,* increased, while *Knoellia* decreased. Low-abundance genera such as *Blastopirellula, Persicirhabdus,* and *Pir4 lineage* increased in fish fed the PM diet, whereas *Caulobacter* and *IMCC26207* were higher in fish fed the CTRL diet.

*(Continued on next page)*

Dietary supplementation with the PM extract did not affect growth performance or overall microbial diversity, consistent with previous findings in Nile tilapia [6], where the main effects were observed in the increase of immune responses against bacterial infection by *Aeromonas hydrophila*. However, differential abundance analysis revealed slight, microbiota region-specific modulations, particularly in the PI. The archaeal phylum Halobacteriota, represented by *Halococcus*, was significantly increased in both intestinal regions of fish fed the PM diet. Although typically associated with hypersaline environments, *Halococcus* has been reported in the intestine of other fish [7, 8]a rapidly expanding sector, meets the global surging demand for aquatic food. Pangasius, a highly valued freshwater species, has seen a significant increase in demand due to its adaptability and potential for high yields, making it a promising candidate for aquaculture in India. This study investigates the gut microbiome composition of Pangasius pangasius fish cultured in three different systems (biofloc, cage, and pond. Its enrichment may reflect selective pressure from polyphenols, which favors stress-tolerant taxa under oxidative or antimicrobial conditions [9]. Several moderately abundant genera were also affected by the PM diet. In the AI, *Planctomicrobium* increased; this genus, common in aquatic environments and other fish and shellfish species [10–12]genotoxic, and teratogenic damages. One consequence of this exposure is the dysbiosis of the gut microbiota, where the normal bacterial composition is modified. Herein, we assessed the effect of the exposure to water accommodated fraction (WAF, is involved in the degradation of complex organic matter [13]budding, non-pigmented and rosette-forming bacterium was isolated from a littoral wetland of a boreal lake located in Valaam Island, northern Russia, and designated strain P3T. Ellipsoidal to pear-shaped cells of this bacterium were covered with crateriform pits and possessed stalks suggesting a planctomycete morphotype. 16S rRNA gene sequence analysis confirmed that strain P3T was a member of the order Planctomycetales and belonged to a phylogenetic lineage defined by the genus Planctomyces, with 89 and 86 % sequence similarity to Planctomyces brasiliensis and Planctomyces maris, respectively. Strain P3T was a mildly acidophilic, mesophilic organism capable of growth at pH values between pH 4.2 and 7.1 (with an optimum at pH 6.0–6.5, pointing to a positive effect on the digestion of non-digestible compounds. In the PI, *Stenotrophomonas* and *Actinomyces* were more abundant in the PM-fed fish. *Stenotrophomonas,* reported as both pathogenic and commensal in fish, including in the core microbiota of European sea bass [14]and strongly modulated by host diet. In aquaculture, a current challenge is to feed carnivorous fish with plant-feedstuffs in substitution of fish meal, an unsustainable commodity. Plants have a limited nutritive value due to the presence of non-starch polysaccharides (NSP, produces extracellular enzymes relevant to digestion [15]; while *Actinomyces* is known for cellulose degradation and has been detected in fish intestine [16], supporting its potential digestive role. *Knoellia*, which decreased in response to the PM diet, has been linked to lipid and glucose metabolism via acetate production [17], and may indicate improved lipid utilization. In summary, dietary PM induced minor but functionally microbial shifts, enhancing the genera associated with digestion without compromising growth performance, which may have a potentially beneficial effect in medium- to long-term supplementation.

**Conclusions**

Dietary supplementation with PM extract did not affect growth performance or microbial diversity in juvenile European sea bass but induced subtle region-specific shifts in the intestinal microbiota. These changes included a higher abundance of Halobacterota and certain genera associated with digestive functions, such as *Planctomicrobium*, *Stenotrophomonas*, and *Actinomyces*. These results suggest a potential role for PM extract in modulating intestinal functionality. However, further studies are being conducted to explore its effects on immune response and disease resistance.

# BACTERIAL PATHOGENS AND MICROBIOME STRUCTURE IN *Arca noae* LINKED TO MORTALITY EVENTS IN THE EBRO RIVER DELTA

S. Reinoso[1*], J. López[1], M. Fernández-Tejedor[1], and D. Furones[1]

[1]Institute of Agrifood Research and Technology (IRTA)
Centre de la Rápita
La Rápita, Spain
E-mail: samira.reinoso@irta.cat

## Introduction

Noah's ark (*Arca noae*) is a commercially valuable marine bivalve distributed throughout the eastern Atlantic and the Mediterranean Sea [1]. Although not yet established as an aquaculture species, interest in its cultivation is increasing, as reflected by a growing number of publications [2–4]. Recently, mortality events have been reported in natural beds of A. noae, including areas adjacent to oyster and mussel farms, raising concerns about ecological impacts and potential risks to nearby shellfish production; however, a previous study did not identify causal agents [5]. Accordingly, we aimed to identify putative pathogens associated with A. noae mortality in the Ebro River Delta by integrating culture-based isolation and challenge assays with 16S rRNA microbiota profiling; to this end, organisms collected during a mortality event were compared with an adjacent non-mortality population.

## Materials and methods

Fifty-five specimens were collected in July 2022 from two areas near the Ebro Delta: Les Cases d'Alcanar, during a mortality episode (6M sampling), and L'Ampolla, where no mortality was observed (6N sampling). Samples from live and recently dead arks were cultured on marine agar, tryptic soy agar (TSA), and thiosulfate–citrate–bile salts–sucrose (TCBS) agar to isolate putative pathogens. Isolates were typed by ERIC-PCR fingerprinting, the 16S rRNA gene was sequenced, and pathogenicity was assessed in adult *Arca noae* under laboratory conditions (bacterial doses: $1.6x10^7$-$4.4x10^8$ cfu/ark). Additional samples were stored at −80 °C for microbiota analyses. DNA was extracted using the DNeasy® PowerSoil® Pro Kit, and the V3–V4 region of the 16S rRNA gene was sequenced on an Illumina MiSeq (2 × 300 bp). Reads were processed and taxonomy assigned with QIIME 2 and DADA2 using SILVA v138.1; downstream analyses were performed in R (microbiome package). Statistical analyses included t-tests for alpha diversity and PERMANOVA for beta diversity, using mortality status as the grouping factor ($p \leq 0.05$). For putative causal pathogenic genera, we generated a PCA contribution biplot based on relative abundances, ran LEfSe, and built Neighbor-Joining phylogenies aligning pathogenic isolates with microbiota ASVs.

## Results and discussion

***Isolation of potential pathogenic strains*:** From samples 6M and 6N, 166 isolates were obtained. ERIC-PCR typing of these isolates revealed two groups of isolates that were present only in the 6M samples. Based on 16S sequencing, these two groups were provisionally identified as *Acinetobacte*r sp. (*johnsonii)* and *Enterobacter* sp. Both groups were detected together in 83% of the 6M samples, comprising 14% and 12% of the isolates obtained from these samples. Virulence assays performed on representative isolates from these two groups (*Acinetobacter* sp. r499 and *Enterobacter* sp. r488) showed mortality rates of 80–90% and 80–83%, respectively. However, the control groups also showed high mortality (23–30%) over the 4 days of the assays.

***Microbiota profiling:*** Across 22 samples (each sample consists of a pool of 5 individuals), 1,019,430 clean reads yielded 7,326 ASVs; 766 ASVs were shared between mortality and non-mortality, accounting for 89.2% of total relative abundance (RA). Alpha diversity was lower in mortality than in non-mortality ($p \leq 0.05$): Observed richness 456 ± 107 vs 767 ± 2.21 ASVs; Shannon 2.56 ± 0.29 vs 3.85 ± 0.72; Faith's PD 25.75 ± 4.65 vs 38.56 ± 7.49. Beta diversity also differed significantly between groups ($p \leq 0.05$), indicating marked compositional dissimilarity.

*(Continued on next page)*

***Community composition:*** Mortality samples were dominated (relative abundance, RA > 5%) by Cyanobacteria (48%) and Proteobacteria (37%), whereas non-mortality samples were dominated by Cyanobacteria (31%), Spirochaetota (25%), Proteobacteria (16%), Firmicutes (9%), and Crenarchaeota (8%). At the genus level, mortality samples were dominated (RA > 3%) by *Synechococcus* CC9902 (45%), *Stenotrophomonas* (21%), *Acinetobacter* (4%), and *Spirochaeta* 2 (4%); *Enterobacter* was less abundant (1%). In contrast, non-mortality samples were dominated by *Synechococcus* CC9902 (25%), *Spirochaeta* 2 (25%), *Candidatus Nitrosopumilus* (8%), *Mycoplasma* (8%), and *Cyanobium* PCC-6307 (5%), with *Acinetobacter* (0.2%) and *Enterobacter* (0.01%) at very low abundance.

***Integration of culture and sequencing evidence:*** PCA (phylum/genus; Dim1 = 42.3%/45%) separated samples by mortality status: mortality aligned with potentially opportunistic taxa, Cyanobacteria (*Synechococcus* CC9902) and Proteobacteria (*Acinetobacter*, *Stenotrophomonas*, *Enterobacter*), whereas non-mortality associated with Bacteroidota, Firmicutes, Actinobacteriota, Verrucomicrobiota, and genera such as Sva0996 marine group, *Mycoplasma*, *Ruegeria*, *Blastocatella*, and *Cyanobium* PCC-6307. LEfSe (LDA > 3.5; $p \leq 0.05$) corroborated these patterns, identifying *Stenotrophomonas*, *Synechococcus* CC9902, *Acinetobacter*, and *Enterobacter* as mortality markers. Neighbor-Joining phylogenies were used to link pathogenic isolates to community ASVs; the ASVs most closely related to the isolates were more abundant in mortality (six *Acinetobacter*: ASV_15, ASV_30, ASV_414, ASV_77, ASV_122, ASV_21; two *Enterobacter*: ASV_78, ASV_29), consistent with genus-level relative abundances (*Acinetobacter* 4.1% vs 0.18%; *Enterobacter* 1.0% vs 0.01%).

Overall, in line with the PCA, LEfSe, and phylogenetic tree results, Acinetobacter and Enterobacter were consistently linked to the mortality event, and both have been reported in mollusk disease contexts [6, 7]. Stenotrophomonas and Synechococcus CC9902 also tracked the mortality state but were not recovered by culture, underscoring a limitation of culture-dependent approaches; Stenotrophomonas is typically an opportunistic, multidrug-resistant taxon in aquaculture microbiomes rather than a confirmed bivalve pathogen [9–11], whereas Synechococcus CC9902 is a ubiquitous coastal picocyanobacterium with no established pathogenicity in bivalves [12, 13].

## Conclusions

Mortality in *A. noae* was associated with marked microbiome shifts, lower alpha diversity and enrichment of Proteobacteria, with clear group separation by ordination and LEfSe. Challenge assays and phylogenetic mapping implicated *Acinetobacter* and *Enterobacter*. By contrast, *Stenotrophomonas* and *Synechococcus* CC9902 tracked mortality in sequencing data but were not recovered by culture; given reports of *Stenotrophomonas* as an opportunistic (occasionally pathogenic) taxon in aquaculture microbiomes, it remains a provisional candidate warranting targeted isolation and virulence testing. Collectively, these findings highlight *Acinetobacter* and *Enterobacter* as priority targets for surveillance and mechanistic studies in future mortality events.

# FISH MATTER: A DIGITAL ECOSYSTEM TO UNLOCK THE VALUE OF AQUACULTURE BY-PRODUCTS

J. Reis*, A.R.A. Ribeiro

*B2E Associação para a Bioeconomia Azul – Laboratório Colaborativo
Av. da Liberdade s/n 4450-718 Leça da Palmeira
E-mail: b2e@b2e.pt

## Introduction

Aquaculture and fisheries generate a large volume of by-products that are often discarded or underutilized, despite their high potential for valorisation in areas such as nutraceuticals, cosmetics, bioplastics, and animal feed. According to FAO (2022), improving the use of fish side-streams is a key pathway for increasing resource efficiency and sustainability in blue food systems. In the context of a circular bioeconomy, the effective valorisation of marine by-products is both an environmental and economic imperative (European Commission, 2020). Responding to this challenge, Fish Matter was developed as a digital platform to promote the sustainable and innovative use of marine by-products. Financed by Next Generation EU under the Blue Bioeconomy Pact, it aims to connect value chain actors and foster a knowledge-based innovation ecosystem. More information is available at https://fishmatter.pt.

## Objectives

Fish Matter aims to:

1. Serve as a unique virtual space connecting companies that generate marine by-products with those that transform them, along with technology providers.
2. Facilitate business matchmaking while promoting transparency and traceability.
3. Host a wider innovation ecosystem, integrating scientific networks, legislative frameworks, intellectual property resources, and funding opportunities.
4. Support the development of new projects and ideas, creating a dynamic knowledge base for collective intelligence and innovation.

## Material and methods

The platform was co-designed with actors from across the aquaculture and fisheries value chains, integrating feedback from industry, R&D institutions, and public agencies. It includes tools for registering available by-products, sharing technical and market data, and exploring potential applications across sectors such as nutraceuticals, cosmetics, animal feed, and biomaterials. A participatory approach involving surveys, pilot case studies, and stakeholder workshops guided the iterative development between 2023 and 2025.

## Results

Initial deployment in Portugal mapped a wide array of underutilized by-products and highlighted the need for digital tools to enhance connectivity, knowledge sharing, and trust. Early adopters will benefit from increased market visibility, and collaborations will be initiated through the platform. Stakeholders already registered valued the integrated access to scientific resources and regulatory guidance, recognizing Fish Matter not only as a marketplace, but as a catalyst for systemic innovation. With its integrated AI-powered chatbot, Fish Matter allows users to access tailored guidance, navigate legislation, identify funding opportunities, and explore suitable partners or technologies, significantly improving user experience and decision-making.

## Conclusions

Fish Matter exemplifies how digital innovation can drive circularity and value creation in aquaculture. Beyond matchmaking, it nurtures a collaborative environment for developing solutions, sharing knowledge, and scaling best practices. As interest in sustainable marine resources rises globally, Fish Matter positions Portugal as a pioneer in transforming marine co-products into engines of economic, environmental, and scientific impact, with potential for international replication.

E-mail: breis@ciimar.up.pt

## Introduction

Increasing water temperatures arising from heat waves and global warming can lead to stressful conditions for farmed fish. Fish have developed mechanisms to adapt to challenging external environments and the ability to cope with stress, is a major health trait that can determine fish susceptibility to opportunistic pathogens and disease. However, rapid temperature changes can exceed the organism capacity to adapt to new homeostatic states. Stress resilience and fish welfare, within a context of changing environmental conditions, is rapidly becoming a major research subject in aquaculture. The present work aimed to assess the effects of high temperature-induced chronic stress on stress resilience as well as immune and oxidative stress responses of rainbow trout (*Oncorhynchus mykiss*) juveniles.

## Material & Methods

A trial with rainbow trout juveniles was devised. Three different groups were created, namely: CTR (16 °C); MED (19 °C); HIGH (22 °C). In each group, fish were randomly distributed into 6 tanks with 20 fish each (approx. 20 g initial body weight). Following an acclimatization period, fish were hand fed a fixed amount of feed (3% body weight) 2 times a day with a commercial-like diet, for 4 weeks. After this period, blood samples were collected for hematological procedures while plasma was isolated and used for cortisol, metabolites and humoral immune parameters. Liver was sampled for the analysis of metabolites and oxidative stress responses. Head-kidney, brain and hypophysis were sampled for gene expression analysis. Skin mucus and water were sampled both for proteomics and transcriptomics (miRNA) analyses, while skin tissue was collected solely for RNAseq analysis.

## Results and Discussion

Results from the analysed plasma humoral parameters showed no differences between experimental groups regarding anti-proteases activity, after 4 weeks. However, the HIGH temperature group showed higher lysozyme activity than CTR. Regarding the head-kidney panel of selected genes, glucorticoid receptor 1 (gr1) and arginase 2 (arg2) showed significantly higher gene expression in HIGH temperature group in comparison to MED, although no differences were perceived relative to CTR.

Chronic stress is associated with glucocorticoid receptor loss of sensitivity, impairing corticosteroids regulatory effects, namely the anti-inflammatory function. It has also been linked with increased circulating pro-inflammatory biomarkers in blood. Ongoing data analysis on the above referred tissues and matrices will allow a better understanding of stress and health related mechanisms involved in chronic stress response, namely the relation between the HPI axis and the immune mechanisms. The integration of all the generated data, is expected to provide the establishment of reliable biomarkers under chronic stress conditions.

Work Co-funded by UKRI and by the European Union's Horizon Europe research and innovation programme (GA No. 101084651 - project IGNITION).

# IMPROVING GROWTH AND FEEDING BEHAVIOURS OF FARMED SHRIMP *Penaeus vannamei* IN COMMERCIAL CONDITIONS

L. Reverchon-Billot*, C. Bailly, A. Warin

Bureau Bankiva
4 impasse de la fin de chêne
21410 Gergueil, France
E-mail: lola.reverchon-billot@bankiva.fr

## Introduction

Over 400 billion shrimps are farmed each year worldwide, more than five times the total number of all farmed land animals. Despite these facts, our scientific knowledge on shrimp behaviour and welfare is quite weak.

This study focuses on the feeding behaviour of *Penaeus vannamei*. According to the literature, shrimp feed in small quantities; offering feed increases exploration, crawling and feed grabbing; while feed-deprivation and molt status influence the feeding behaviour. Nevertheless, there are controversial studies regarding the preferred feeding time by shrimps and the best feeding frequency. Moreover, the way shrimp behave in groups during feed distribution is still unknown.

## Material and methods

The study aimed to observe shrimp behaviour directly in raceways in commercial farms, with one raceway being fed every hour during daytime (from 7 am to 7 pm) and the other being fed every hour during day and night, with the same feed quantity per 24h in both raceways. The behaviour of shrimp has been recorded every three days, four times a day, for 15 minutes around feeding time via GoPro. These videos have been analyzed based on an ethogram designed for this study. Water quality has been recorded several times a day and 60 shrimp have been sampled every day to score eight health indicators to see how shrimp react to different feeding schedules. To estimate shrimp activity levels, we performed image scans every 30 seconds over the course of 15-minute video recordings. At each scan (i.e., video still frame), we counted the number of shrimps that were resting on the substrate versus those that were suspended in the water column. This snapshot-based approach allowed us to quantify temporal patterns of activity based on spatial positioning. Furthermore, weight has been recorded every two days based on a shrimp sample leading to a weight mean.

## Results

One of the main concerns of farmers was the water quality and the possible deterioration in case of frequent feeding. The results showed no difference in the two raceways which is good news for producers. Furthermore, concerning weight, shrimp fed day and night gain more weight than those fed only during the day.

The scan sampling based on videos revealed that shrimp fed only during the day were significantly more active—i.e., more frequently observed in suspension—during the feeding compared to shrimps fed day and night. This higher activity for shrimps fed during the day only was also observed before the first feeding of the day (7 am) suggesting an anticipatory response to food availability.. To conclude, feeding the shrimp every hour during night and day lead to have behaviours closer to natural shrimp behaviours which tend to rest more on the substrate.

## Conclusion

It is a pioneer study as it has never been done to observe and analyze shrimp behaviour in commercial farms without using AI. A better understanding of shrimp feeding behaviour will help many farmers and also improve the lives of many shrimps in commercial farms.

More similar studies would be a key to confirm the different results, especially concerning the weight to ensure that all shrimps gain more weight.

# SAMPLING SHRIMP (*Penaeus vannamei*) THE RIGHT WAY: A BETTER ANTICIPATION OF HEALTH ISSUES

L. Reverchon-Billot*, C. Bailly, A. Warin

Bureau Bankiva
4 impasse de la fin de chêne
21410 Gergueil, France
E-mail: lola.reverchon-billot@bankiva.fr

## Introduction

Over 400 billion shrimps are farmed each year worldwide, more than five times the total number of all farmed land animals. Despite these facts, our scientific knowledge on shrimp behaviour and welfare is quite weak.

Animal monitoring is typically conducted daily in terrestrial farms to assess the health of individuals and identify potential issues. In shrimp ponds, however, the main challenge lies in the brackish water, which hampers visibility and makes it difficult to observe the animals' behaviour. In many cases, farmers sow their pond with post-larvae and then sample a variable number of shrimps at different times during the grow-out stage. In ponds with automatic feeders, it is common for farmers to realize these samples around the feeders to catch enough shrimp to monitor. However, the risk is not only to have the biggest and healthiest shrimp but also to miss some information on the health status of the pond. Furthermore, a low number of indicators are usually recorded. According to the literature, more indicators can be used to have a clearer view of shrimp health with some indicators being linked indirectly to welfare (Pedrazzani et al. 2023). This study aimed to determine (i) where to sample shrimp in the pond, and (ii) how many and (iii) which indicators are useful to better detect health issues.

## Material and methods

To answer these questions, 350 shrimps (*Litopenaeus vannamei*) have been sampled with 50 per sampling point distributed at seven different areas of the pond, twice a week, at two different times (morning and afternoon) and in two commercial ponds. After 1 to 3 net throws in an area to obtain at least 50 shrimps, the farmer could move away and collect shrimp in a different location to avoid spending hours at the same spot. It leads to a total of 2,550 shrimp being sampled during the duration of the trial for one pond and 4,865 for the second pond. Eight health indicators have been scored (rostrum, eyes, antennae, gills, hepatopancreas, exoskeleton, uropods, musculature, motor appendages) based on the study from Pedrazzani (2023) with score 1 (good welfare), 2 (tolerable welfare) or 3 (critical welfare). The shrimp were sampled at the inlet, at the outlet, around 2 automatic feeders and close to 3 edges.

Moreover, oxygen, temperature and salinity were recorded once or twice a day in addition to weekly weight estimation, percentage of survival, biomass, quantity of feed distributed and usual notation of percentage of shrimp in good health. Scores were analyzed using linear models and non-linear models (generalized additive model) to evaluate the health variation of shrimps over the days in both ponds.

## Results

The results first show that the localization for global health monitoring is important (significant variations in health scores depending on the localization). In both ponds, the health deteriorates faster over the days in the grow-out pond at the edges and at the outlet of the pond. Some health indicators vary over time with certain indicators being more efficient than others to detect special events. For example, motor appendages seem to be a good indicator as we observed scores stabilizing after a potential weather event and a reliable indicator as score variation is largely explained by days, for both ponds.

This stabilization could be explained by a high mortality after the weather event, leading to have only the shrimp in better health staying in the pond. After some time, there is once again a deterioration of the health.

## Conclusion

This protocol not only encourages farmers to focus more on shrimp welfare but also allows to determine where samplings are more useful to better anticipate issues and thus, improve shrimp health and welfare by reacting faster. Implementing this monitoring would also contribute to increase productivity.

# METATRANSCRIPTOMIC TOOLS FOR THE DETECTION OF PATHOGENS IN MOLLUSCS

Magalí Rey-Campos*, Beatriz Novoa and Antonio Figueras

Institute of Marine Research (IIM-CSIC), National Research Council (CSIC), Vigo, Spain
E-mail: mrey@iim.csic.es

## Introduction

Metatranscriptomics has emerged as a very useful technology for the study of microbiomes from RNA-seq reads. This method provides additional information compared to the sequencing of ribosomal genes such as the possible detection of viral sequences or the gene expression evaluation of both, host and associated microorganisms (dual-transcriptomics). Moreover, the targeted search for specific and active pathogens is a valuable strength.

Molluscs industry, and especially bivalves' market is an economic sector of high potential in the Spanish coast, especially in Galicia. These species cope with highly variable environmental conditions in estuarine and intertidal regions. However, the current climate change scenario implies severe changes such as temperature increase, acidification, variations in water salinity or oxygen availability. This have a direct effect on the marine ecosystem and therefore on the species that are cultivated, which are fully adapted to specific conditions. Furthermore, there emerge additional risks such as the appearance of new pathogens, which may result in production problems.

In addition to the risk posed by the emergence of new diseases, there are a significant number of known bivalve pathogens that are already causing problems for cultures today. For instance, clams are susceptible to bacterial diseases (mainly vibriosis caused by *V. splendidus*, *V. alginolyticus* or *Vibrio tapetis*) and also multiple protozoan parasites such as *Bonamia*, *Perkinsus*, *Haplosporidium* or *Marteilia*, which invade tissues and have a negative impact on reproduction and growth. Another notable case is the high susceptibility of oysters to the OsHV-1 herpesvirus. Mollusc diseases have a common denominator, which is the absence of treatment, therefore the only possibility of control lies in prevention and monitoring of stocks.

## Material and methods

Datasets available in public databases were used to perform a meta-analysis. Prior to the analysis, raw reads (RNA-seq reads) were trimmed to remove sequencing adapters and short and low-quality sequences (quality score limit 0.01 = PHRED 20). Moreover, datasets were randomly subsampled to equal the lowest number of reads to compare microbial abundance in a more appropriate manner. To analyze the different microbiome profiles, a working plan consisting of mapping the reads to several reference databases was implemented. The microorganism reference databases were built with all the virus, protozoan, and fungal genomes deposited in RefSeq. Specifically, these databases contained a total of 2,396 bacterial sequences, 10,907 viral sequences, 93 protozoan assemblies, and 388 fungal assemblies. Available genome assemblies were used to filter putative host-specific reads. Mapping parameters used to classify read packages in different taxonomic groups were as follows: length fraction = 0.5, similarity fraction = 0.8, and minimum seed length = 50. This minimum seed length parameter defines the minimum perfect match length for a position in the reference to be considered a valid candidate when matching the read.

## Results

In this work, we used the metatranscriptomic approach to study a series of relevant mollusc pathogens in available transcriptomic data, to have a broad view of the prevalence of several pathogens in different geographical locations.

Moreover, we could also detect other associated microorganisms, being possible to stablish some relationships and interactions.

# EVALUATION OF ANTI-FOULING COATINGS AGAINST GOLDEN MUSSEL ON NETTING FOR CAGE AQUACULTURE

**Introduction**

Biofouling caused by the golden mussel (*Limnoperna fortunei*) compromises the integrity of cage aquaculture structures, increasing operational costs and sanitary risks. This study evaluated two types of antifouling coatings as alternatives to conventional biocides: a commercial hybrid resin of silicone and epoxy, and a biocidal paint containing lysoglycerophosphocholines (LGPCs), derived from soybean lecithins.

**Material and methods**

In September 2024, 36 metal frames (80 × 130 cm) were installed in the Chavantes Reservoir, Paranapanema River, at the Southeast–South border of Brazil. The frames were distributed across three sectors of a fish farming. Each frame, submerged at a depth of 0.5 m, contained three stainless steel mesh panels (20 × 20 cm): one uncoated (control), one coated with a hybrid silicone-epoxy resin, and one coated with biocidal paint.

From September 2024 to April 2025, monthly 1000 L water samples were collected, filtered (40 µm), and preserved for quantifying *Limnoperna fortunei* larvae. Each month, one mesh panel was randomly selected; individuals in a central 10 × 10 cm area were collected and counted. Larvae and juveniles were counted by stereomicroscopy (Sedgwick-Rafter method), and adults (>5 mm) by visual inspection. A two-way ANOVA assessed differences in total attached larvae and adult densities across sectors and materials.

The coatings were subjected to physical tests for blister formation and immersion in a specialized laboratory, as well as ecotoxicological tests, exposing *Daphnia similis* and *Ceriodaphnia dubia* to stainless steel wires coated with the tested materials and submerged in 10 mL of synthetic medium (SM).

**Results and Discussion**

*L. fortunei* larvae were detected throughout the study in the environment, with density peaks in November, February, and notably April, reflecting increased reproduction in warmer months. This was supported by higher larval and juvenile adhesion from December and increased adult presence from January (Table 1). The highest adult fouling on the mesh panels with the three materials was observed in Sector 3, in the month of April. (Figure 1).

The coatings did not reduce *L. fortunei* fouling compared to uncoated mesh ($F=0.13$; $p=0.87$), but differences were observed between sectors ($F=12.38$; $p=0.00$). Tukey's post hoc test showed that sector 1 differed from sectors 2 and 3. In sector 1, panels were covered by filamentous algae (Oscillatoriaceae), which may have hindered mussel attachment.

In the blistering test, paint peeling began after 880 hours. In the immersion test, gloss and color changes appeared after 240 hours, and resin peeling started after 760 hours. Ecotoxicological assays revealed acute toxicity of the paint to *D. similis* and chronic effects on *C. dubia*, while the resin caused chronic effects on *C. dubia*. These findings indicate coating degradation and/or toxic substance release, potentially compromising antifouling efficacy and posing environmental risks. Improving the durability and performance of these materials is recommended for future assessments.

# EFFECTS OF PARTICLE POLLUTANTS PRODUCED THROUGH IN-WATER HULL-CLEANING PROCESS ON PHYSIOLOGICAL AND BIOCHEMICAL PARAMETERS OF WHITELEG SHRIMP, *Litopenaeus vannamei*

Somyeong Lee, Jehee Kim, Jae-Sung Rhee*

[a] Department of Marine Science, College of Natural Sciences, Incheon National University, Incheon 22012, Republic of Korea
[b] Yellow Sea Research Institute, Incheon 22012, Republic of Korea

jsrhee@inu.ac.kr

We conducted a comprehensive assessment involving acute effects on 96-hour survival and biochemical parameters of the whiteleg shrimp, Litopenaeus vannamei exposed to different concentrations of particle pollutants produced through in-water hull-cleaning process to evaluate the potential impact of ship hull-cleaning wastewater on crustaceans. The analyzed particle pollutants contained high concentrations of metals and antifoulants. The results revealed dose-dependent reductions in survival rates, accompanied by a notable increase in oxidative stress and reduction in feeding rates. Molecular and biochemical responses were then analyzed at the transcriptomic, proteomic, and metabolomic levels, after integration with in silico bioinformatics. Our findings revealed that the primary toxic mechanism of particle pollutants involved the induction of oxidative stress and detoxification pathways, reduction in immune pathways, and increase endoplasmic reticulum stress, leading to cell death. Collectively, these findings underscore the potential harm posed by particle pollutants to the health of crustacean populations under aquaculture systems.

# EXPLORING SEX-DRIVEN EPIGENOMIC RESPONSES TO INFECTIONS

S. López-Chillarón, M. Mitsopoulou and L. Ribas*

Institute of Marine Sciences (ICM-CSIC)
Passeig Marítim de la Barceloneta
37-49, 08003 Barcelona (Spain)
Email: lribas@icm.csic.es

## Introduction

Bacterial infections are a major cause of disease outbreaks in fish, leading to reduced productivity in aquaculture. Understanding the molecular responses triggered in the gonads following infection is crucial for improving fish farming practices, optimizing disease control, and identifying the most resilient phenotypes (Caballero-Huertas et al., 2024). This study focuses on two key species: the commercially valuable European sea bass (*Dicentrarchus labrax*), widely farmed across Europe, and the extensively studied model organism zebrafish (*Danio rerio*). We investigated epigenomic alterations in both species following bacterial challenge. The epigenomic approach consisted on state-of the arts techniques such as Whole Genome Methylation sequencing (WGMS), microRNA-seq, and RNA-seq.

## Methodology

European sea bass and zebrafish were experimentally exposed to bacterial pathogens. In European sea bass, infections were administered via intraperitoneal injection, and gonadal tissues were collected 48 hours post-infection. For zebrafish, exposure occurred through bath immersion. Sequencing libraries were constructed according to standard manufacturer protocols for each specific sequencing technique. Additionally, the expression of selected key microRNAs (miRNAs) was analyzed using the miRCURY LNA SYBR Green PCR Kit.

## Results

Bacterial challenge led to substantial alterations in the gonadal epigenome, transcriptome, and miRNome. The most pronounced changes in DNA methylation were observed between male and female samples under the same treatment, with over 88,000 and 105,000 hypermethylated CpG sites, and approximately 3 million and 2.7 million hypomethylated CpG sites, respectively. Transcriptome profiling of European sea bass gonads indicated a higher number of differentially expressed genes (DEGs) in testes compared to ovaries. Four miRNAs were identified in testicular tissue as potential biomarkers of prior infection exposure. In zebrafish, analysis of gonadal miRNA expression revealed sex-dependent differences post-infection, including suppression of reproductive pathways such as oocyte meiosis, and activation of immune-related pathways.

## Discussion

As similarly reported by Gelderen et al. (2025a, 2025b), the sex-specific epigenetic differences observed may underlie the sexually dimorphic responses to infection. These results highlight the significance of incorporating sex as a biological variable in fish immunological and epigenetic research. Although sexual dimorphism is known to modulate immune function across vertebrates, its role in fish immunity remains barely underexplored (Caballero-Huertas et al., 2024). This study enhances our understanding of the sex-driven epigenomic basis in fish, with important implications for aquaculture practices and the development of disease-resistant phenotypes.

## Introduction

Vitamin D is essential for salmonids, yet its metabolism and physiological roles in these species remain incompletely understood. To exert its biological effects following absorption, dietary cholecalciferol ($D_3$) must be metabolized *in vivo* to calcifediol (25-OH-$D_3$), and subsequently to its active form, calcitriol (1,25-OH-$D_3$). Supplementing with 25-OH-$D_3$ can be effectively improve vitamin D status in fish by partially bypassing this metabolic process (Rider et al., 2024 & 2023). This study investigated the effects of oral intake of these plasma metabolites on vitamin D metabolism and calcium (Ca) and phosphorus (P) homeostasis by analysing their kinetics.

## Methods

Single 22 $\mu$g oral doses of $D_3$ or 25-OH-$D_3$, or a 2.54 $\mu$g dose of calcitriol-glycosides (1,25-OH-$D_3$-gly) were administered to rainbow trout fed a practical diet containing 2,817 IU/kg $D_3$. The kinetics of circulating vitamin D metabolites, calcium (Ca), and phosphorus (P) were monitored in plasma over six days by sampling at 6, 24, 48, 72 and 168 hours post-gavage. A 42-hour feed withdrawal period was associated with the administration of the single oral doses.

## Results

In fish receiving the baseline diet and prior to the gavage, neither $D_3$ nor 25-OH-$D_3$ were detectable in plasma, while 1,25-OH-$D_3$ was the most abundant vitamin D metabolite. A single dose of $D_3$ produced a plasma $D_3$ peak at 48 hours, whereas a single dose of 25-OH-$D_3$ resulted in a smaller 25-OH-$D_3$ peak at 72 hours. The $D_3$ peak did not alter baseline 25-OH-$D_3$ levels. A single dose of 1,25-OH-$D_3$-gly did not influence baseline 1,25-OH-$D_3$ levels. None of the single vitamin D doses significantly altered plasma levels of active vitamin D, Ca, or P.

Across all groups, plasma 1,25-OH-$D_3$ was significantly modulated over time. Plasma 1,25-OH-$D_3$ levels significantly declined reaching a minimum 24 hours after gavage and were not restored by any of the vitamin D treatments, see Figure 1. Circulating Ca, and especially P, also declined 24-hours after the drop in plasma 1,25-OH-$D_3$.

## Conclusions

These findings demonstrated that even at 1.7 times the NRC minimum of 1,600 IU/kg $D_3$, neither $D_3$ nor 25-OH-$D_3$ were detectable in plasma. Although both $D_3$ and 25-OH-$D_3$ were rapidly absorbed, they were also rapidly cleared. The observed kinetics also indicated that short-term feed deprivation significantly reduced active vitamin D levels, and this decline was not mitigated by the single doses of any of the vitamin D sources. The subsequent reductions in plasma Ca and P suggest a temporal link with declining plasma 1,25-OH-$D_3$ levels. This is the first study to connect circulating active vitamin D to feed intake in fish, pointing to a potential role of this vitamin in energy metabolism.

# HEALTH BENEFITS OF A NOVEL PREBIOTIC OLIGOSACCHARIDE FOR AQUACULTURE PRODUCTION

William W. Riley[1]*, Bradley A. Saville[2,3], Sandra Saville[2]

1. WWR and Associates. Ltd., Hong Kong, wmriley54@yahoo.com
2. GreenSage Prebiotics, Oakville, Canada, brad.saville@greensageprebiotics.com
3. University of Toronto, Toronto, Canada

## Introduction

Growth in aquaculture production is contingent upon strategies to manage and mitigate infections that reduce growth and harvest quality and that lead to premature mortality. Aquatic diseases caused by pathogenic bacteria, viruses, and parasites are the most pressing issues affecting aquaculture producers and the most acute within intensive aquaculture production systems.

Prebiotics – compounds that selectively feed beneficial bacteria within the body - can play an important role in supporting digestive and immune health in aquaculture species. GreenSage Prebiotics uses residues from coconut production to produce a novel prebiotic, Pretego™, that supports digestive and immune health in aquatic and terrestrial animals. Pretego™ is unique and distinct from other prebiotics, owing to its ability to directly inhibit the growth of several bacteria that have a material impact on aquaculture production, confirmed by MIC studies (Table 1).

In this presentation, we report on the impact of Pretego™ on the health and survival of shrimp and finfish (e.g., Atlantic salmon and sea bass).

## Materials and Methods

***Trial 1***: A 42-day feeding trial was conducted at the ShrimpVet Demonstration Farm (Vietnam), followed by a pathogen challenge with *Vibrio parahaemolyticus*. At the beginning of the trial, 60 SPF shrimp (*L. vannamei*) with an average body weight of 2.41 ± 0.49 g/shrimp were stocked into 22 tanks. The feeding trial consisted of 4 groups: (i) Control group (No Pretego™); (ii) 0.30 wt% Pretego™; (iii) 0.50 wt% Pretego™; and (iv) 0.65 wt% Pretego™. Following the feeding trial, the pathogen challenge trial was conducted by immersion in *Vibrio parahaemolyticus* for 8 days. The control group was subdivided into two subgroups, to include shrimp that were and were not exposed to the pathogen. Shrimp growth and survival data were collected.

***Trial 2***: Atlantic salmon (*Salmo salar*) parr (ca. 11.68 ± 0.11g) were fed either a control diet or diets supplemented with one of three levels of Pretego™ (0.25, 0.35 or 0.5%). Diets were manufactured by Skretting using commercially relevant formulations that met the nutritional requirements of Atlantic salmon. Fish were reared in a freshwater RAS system for 70 days, with 3 replicated tanks per treatment group. Fish growth performance was determined at the conclusion of the trial, and fish skin and intestinal samples underwent histological assessment.

## Results

***Trial 1***: Increasing the inclusion rate of Pretego™ was correlated with improved growth performance and feed efficiency in *L. vannamei*. Inclusion of Pretego™ at 0.5% and 0.65% led to significantly better outcomes, with up to 26% more biomass harvested (correlated with higher survival rates), higher average daily weight gain and specific growth rate, and a 24% lower feed conversion ratio compared to the control group that did not consume Pretego™. Following exposure to *Vibrio parahaemolyticus*, survival was dramatically higher in shrimp that consumed Pretego™ – increasing from 22% to 70% (Figure 1).

| | |
|---|---|
| *Vibrio parahaemolyticus, anguillarum* | *Tenacibaculum maritimum, finnmarkense* |
| *Moritella viscosa* | *Piscirickettsia salmonis* |
| *Aeromonas salmonicida* | *Yersinia ruckeri* |

Table 1: Aquaculture Pathogens Inhibited by Pretego™

*(Continued on next page)*

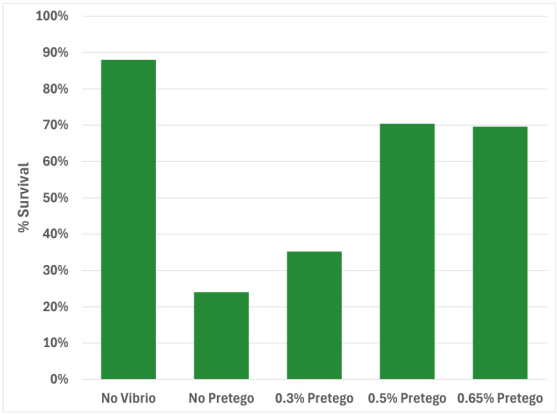

Figure 1: Impact of Pretego™ on Shrimp Survival Following an EMS Challenge

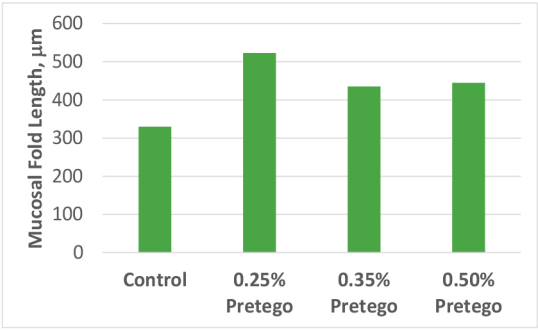

Figure 2: Impact of Pretego™ on Mucosal Fold Length

***Trial 2***: There were trends suggesting improvement in feed conversion and growth rate over the 70-day study, but these improvements were not statistically significant. Nonetheless, there were statistically significant increases in the mucosal fold length (an indicator of improved nutrient absorption; Figure 2), and the histological appraisal revealed that Pretego™ significantly increased goblet cell counts in the intestine and skin, which is indicative of improved disease barrier function. Samples from the trial mid-point revealed that benefits started to emerge from as early as day 35, with elevated mucosal fold length, intestinal goblet cell levels, and skin goblet cell levels compared to the control fish.

**Conclusions**

Pretego™, a novel prebiotic from coconut residue, supports the digestive and immune health of shrimp, salmon, and other aquaculture species. Pretego™ improves survival and growth when added to aquaculture feed at levels from 0.25% to 0.65%. Pretego™ supports aquaculture production during the grow-out phase and during periods when there is a high risk of infection.

# GENOME-WIDE MULTIPLEX AMPSEQ PROFILING OF *Neoparamoeba perurans*, MOLECULAR EPIDEMIOLOGY

[1]B. A. Robertson* & [1]M. S. Llewellyn

[1] School of Biodiversity
One Health and Veterinary Medicine

## Introduction

Amoebic gill disease (AGD) is a significant infection and health concern of farmed Atlantic salmon (*Salmo salar L.*), caused by the marine amphizoic amoeba *Neoparamoeba perurans*. Since its emergence in the mid-1980s, the disease has become a global challenge for aquaculture. Despite its impact, little is known about how *N. perurans* spreads between farms, production cycles, or across geographical regions – essential knowledge for effective control and fallowing strategies. Population-level genomic studies of *N. perurans* have been hindered by high levels of inter- and intracellular bacterial contamination that obscure parasite-derived sequence data. To date, only a few genetic markers have been sequenced, offering insufficient resolution to inform management practices and molecular epidemiological studies. To address this, a draft genome assembled by the Llewellyn lab enabled the development of 82 unique primer pairs targeting loci across nuclear, mitochondrial, and kinetoplastid genomes of *N. perurans*. These markers aim to address the gap by demonstrating that high-resolution genotyping can be achieved directly from field samples, supporting disease tracking and management.

## Materials and Methods

Gill swabs and gill tissue were analysed from 2019 to 2023, collected from multiple sites across Norway (n = 9), Scotland (n = 4) and Ireland (n = 1). Initially, a multiplex PCR panel comprising 201 individual primers was used to amplify loci across all targeted genomes (n =158). The resulting products were sequenced on an Illumina NGS platform following custom 3-round library preparation. Sequences from each sample were processed to remove orphan reads using fastq_pair, then mapped to the draft genome with BWA. Resulting SAM files were converted to BAM, sorted, and indexed using Samtools. BAM files were converted to BED format in Bedtools, sorted, and read counts per genomic contig were obtained using Linux cut and uniq commands. Mapping efficiency for each marker was then assessed in R using ggplot, dplyr, and tidyr.

Following initial sequencing, the primer pool was refined to 82 unique primer pairs targeting the genomes of *N. perurans* and kinetoplastid sequences. These markers were amplified individually via single-target PCR reactions, with products from each sample (n = 58) pooled and run on an agarose gel. Bands were gel-extracted using a custom protocol, then subjected to a custom library preparation involving 2$^{nd}$ and 3$^{rd}$ round PCRs to attach custom barcodes and sequencing adaptors. An ethanol precipitation step was performed after 3$^{rd}$ PCR, and the final products were pooled together and sequenced on an Illumina NGS platform. Bioinformatic analysis is ongoing.

## Results and Discussion

Following read mapping of the multiplex sequencing run, approximately 21.7 million reads were recovered across all samples (n = 158). Substantial dropout occurred across the amplicon panel, with many markers yielding zero reads, indicating reduced efficiency of amplification in a multiplex. After removing failed markers and duplicates, only 82 amplicons from the original panel were retained (Figure 1). Several biological samples were absent from the final dataset, suggesting inconsistencies in amplification. Read distribution was strongly biased: ~21 million mapped to kinetoplastid nuclear targets, none to the kinetoplastid mitochondrial, and only ~56,000 and 29 reads to *N. perurans* nuclear and mitochondrial genomes. Respectively. These results highlight an imbalance in primer performance and inefficient coverage across genomic targets. Therefore, the primers were reduced to 82 unique targets and run as single-target PCR reactions to improve coverage for unrepresented genomes of *N. perurans* and kinetoplastid mitochondrial targets. Analysis is currently ongoing to determine this approach's success.

*(Continued on next page)*

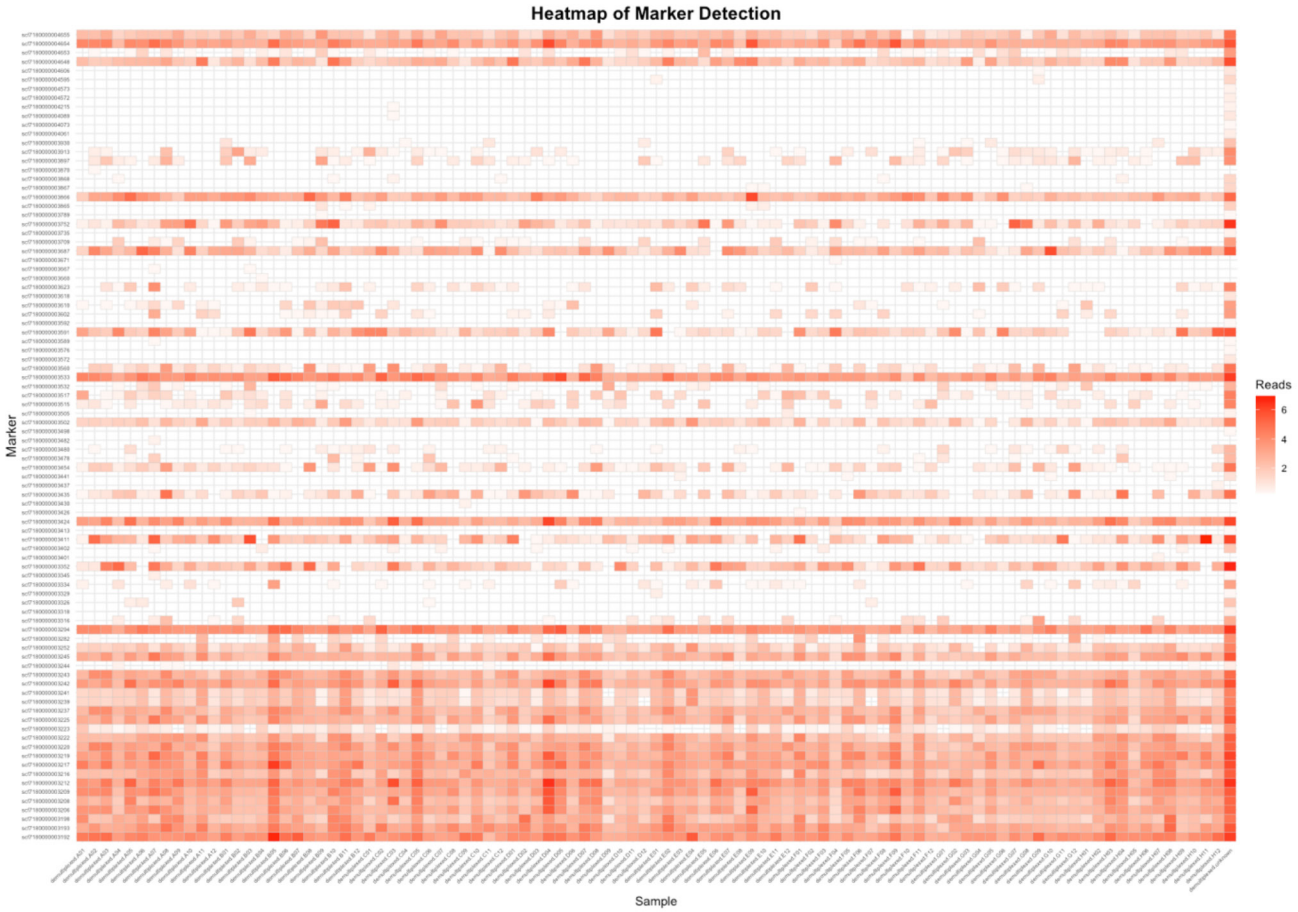

**Figure 1: Heatmap of amplicon marker detection across all biological samples.** Each cell represents the read count (log-transformed) for a given marker (y-axis) in a specific biological sample (x-axis).

## Conclusion and Future Work

To date, there is no reliable method to attribute AGD infections to a specific source, nor to effectively prevent parasite transmission between farms, production cycles, and the surrounding environment. This work takes a step toward addressing this gap by demonstrating that high-resolution genetic data can be derived directly from gill swab samples, providing valuable insights for the treatment and control of AGD. Future research will focus on delivering this information directly to farm managers through a web-based visualisation tool capable of tracking genotypes and their spread over time, enabling more targeted and timely responses to AGD outbreaks.

# BENCHMARKING OF HEALTH PROMOTING ADDITIVES TO SUPPORT HEAT STRESS TOLERANCE OF EUROPEAN SEABASS *Dicentrarchus labrax*

R. Robles-Arozarena*[1], I-T. Chen[2], L. Bermúdez[1], W. G. Nuez-Ortín[2].

[1]Testing Blue S.L., Puerto Real, Spain
[2]Adisseo, France
Email: rociorobles@testingblue.eu

## Introduction

Water temperature plays a crucial role in fish culture. In the context of climate change and extreme temperature events, the impact of increasing ocean temperature affects aquaculture production in general, and European aquaculture in particular. In the southern part of the Mediterranean, the temperature of shallow waterbodies may occasionally exceed 33–34 °C, especially during summer. European seabass, *Dicentrarchus labrax*, an important aquaculture species, is challenged with the increased frequency and intensity of heatwaves (Islam et al., 2025; Sáez-Arteaga et al., 2020) adding stress to farmed fish. Some of the strategies to mitigate thermal stress include feeding optimization, water quality control, culture density management and lately, dietary manipulations (Herrera et al., 2019). Feed additives have shown efficacy to counteract stress effects (including oxidative stress) and physiological functions in farmed fish (Zhang et al., 2020). In this study, we have done a benchmarking of different health additives to strengthen heat stress tolerance in European seabass.

## Material and methods

European seabass of 144 ± 3.23 g average individual body weight was distributed in 15 tanks of a marine RAS. A group of 14 animals was stocked per tank. Water temperature was controlled during the trial: 1st week at 26ºC; 9 weeks at 28ºC, 1 week at 32ºC and 10 days at 28ºC. Temperatures changes were applied progressively at 1ºC per day until the established temperature.

Five isonitrogenous and isolipidic diets (43 % CP/16% CF) were evaluated: 1) a control diet, 2)HeatPro (Adisseo), 3) Sanacore (Adisseo), 4) R2 and 5) K8. Fish were fed manually twice per day to apparent satiation 6 days per week. Feed intake was controlled daily. The trial lasted 12 weeks. After the 9 weeks at 28ºC seabass were sampled for SGR and FCR. At the end of the trial (12 weeks), fish were sampled to calculate SGR, FCR and somatic indexes. Plasma samples were also taken for cortisol, glucose, lactate, total proteins, TAG and cholesterol determinations. Liver samples were obtained and processed for proteomic analysis, histopathological analysis and for antioxidant enzymatic analysis (MDA, CAT, SOD, GPX and pNPB).

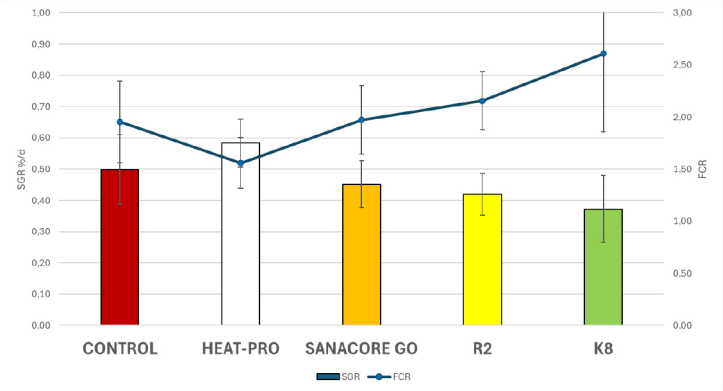

**Figure 1.** SGR and FCR values of seabass during the recuperation period (10 days) after the mortality caused by a heat stress period (one week at 32ºC).

*(Continued on next page)*

**Results & conclusions**

No difference among diets were found in SGR nor FCR during the 9 weeks that the seabass was cultured at 28ºC. However, after one week at 32ºC, mortality appeared in all the fish fed the experimental diets. Seabass fed diet HeatPro diet presented the highest survival, followed by the fish fed diet Sanacore and control diet (95,24%, 92,86% and 88.10 % respectively). After the mortality episode, fish was kept in the system for 10 more days at 28ºC. Although no significant difference was found for SGR nor FCR, seabass fed diet Sanacore showed a 17% better SGR and 20% lower FCR than the fish fed the control diet (Figure 1).

Plasma metabolites showed significant differences for cortisol, glucose and lactate (lowest values for fish fed the HeatPro diet). Histopathology analysis showed that all the fish were highly affected by the temperature increase during the trial; all groups presented a marked level of intracytoplasmic lipid-type vacuolation in the liver and the high temperature may have promoted direct or indirect liver damage at subclinical level. Enzymatic antioxidant analysis pointed out that fish fed Sanacore diet had significantly lower MDA values. No difference was found for CAT, SOD, GPX or pNPB, although fish fed Sanacore showed the lowest values, except for pNPB. Molecular (stress markers) analysis of the fish fed with HeatPro diet showed reduced HSP70 and PRDX3 level, indicating lower cellular stress, and increased IGF-1 expression, reflecting improved recovery and metabolic balance.

As conclusion of the study, it can be pointed out that seabass subjected to heat stress (temperature above 30ºC) and fed HeatPro diet showed better SGR, FCR, cortisol, lactate and glucose plasma levels than the fish fed control diet. On the other hand, fish fed Sanacore diet showed significantly lower MDA values than the fish fed control diet. Molecular findings suggest that the supplementation with HeatPro enhances stress tolerance and physiological resilience in seabass under high-temperature conditions.

# BIOCHAR AS A PROMISING FEED ADDITIVE IN DIETS FOR ATLANTIC SALMON PRE-SMOLTS

S. D. C. Rocha[1*], B. Djordjevic[1], J. Hooft, M. Øverland[1]

[1]Department of Animal and Aquacultural Sciences
Faculty of Biosciences
Norwegian University of Life Sciences
P. O. Box 5003
NO-1432, Aas, Norway
*E-mail: sergio.rocha@nmbu.no

## Introduction

The use of biochar as a feed additive has gained increasing attention in animal nutrition due to its potential benefits on digestion, nutrient absorption, and overall health. Biochar, a carbon-rich product derived from pyrolysis of organic materials, has been traditionally used in animal husbandry for toxin adsorption and digestive health enhancement, but recent studies have highlighted its broader applications, including improvements in feed efficiency, reduction of greenhouse gas emissions, and enhancement of animal welfare (Schmidt et al., 2019). However, the systematic evaluation of biochar's effects on aquaculture species, particularly Atlantic salmon, remains limited.

## Experimental set-up

A basal commercial-like diet (D1) was formulated to meet or exceed the nutritional requirements of Atlantic salmon according to NRC (2011), without any additional growth-promoting ingredients (Table 1). Biochar, either 0.25% (D2) or 0.50% (D3), was added to the basal diet. The biochar was provided by OBIO (Norway) and was ground to 1mm.

The diets were produced by extrusion at Fôrtek (Center for Feed Technology, NMBU, Aas, Norway), with a 2mm die and with a final diameter of ca. 2.4mm. After drying until 8-10% moisture, pellets were vacuum coated with fish oil and rapeseed oil.

A four-week experiment was conducted at the Center for Fish Trials (NMBU, Aas, Norway). A total of 315 pre-smolts Atlantic salmon with an initial average body weight of 31.7 g were randomly distributed into nine 300L fiberglass tanks (35 fish per tank). Fish received one of the three diets, *ad libitum*, with three replicate tanks per diet. Each tank had a capacity of 300 L. Uneaten feed was collected daily to calculate feed intake according to Helland et al. (1996).

## Results and Discussion

Physical pellet quality: The inclusion of biochar in diets for Atlantic salmon significantly affected the physical pellet quality. Pellets from diets D2 and D3 were harder ($p = 0.001$) and had slower sinking velocity ($p = 0.012$) compared to D1 pellets, which allowed the pellets to stay in the water column longer, providing more time for the fish to feed and thereby reducing feed waste. In addition, diet D3 had a significantly higher water stability index ($p = 0.039$), which is a desired characteristic for fish production in RAS systems.

Lastly, in accordance with the previous results, there was a lower waste output in fish fed diets containing biochar (Figure 1). There was a strong tendency for reduced total solid waste ($p = 0.065$) and a significant reduction in solid nitrogen waste ($p = 0.015$), suggesting that biochar improves nutrient utilization, potentially reducing nitrogen excretion. Overall, results suggest that the use of biochar in RAS systems can reduce solid wastes, reduce maintenance costs, and minimize environmental impact.

Growth performance: No significant differences were observed in the growth performance parameters such as specific growth rate (SGR), feed conversion ratio (FCR) and final body weight. However, there was a numerical increase in weight gain and specific growth rate (SGR) and a numerical decrease in FCR for fish fed diets D2 and D3 compared to D1.

Digestibility: The apparent digestibility coefficients of dry matter, crude protein, ash, and carbon increased significantly in fish fed diets D2 and D3 (Table 2). This improved digestibility suggests a better nutrient utilization when Atlantic salmon diets are supplemented with biochar.

*(Continued on next page)*

Table 1. Diet composition of D1

| Ingredients | (g/kg) |
|---|---|
| Fish meal | 244.4 |
| Soybean meal | 290.0 |
| Wheat gluten meal | 80.0 |
| Pea protein concentrate | 45.0 |
| Wheat flour | 120.0 |
| Rapeseed oil | 60.0 |
| Fish oil | 120.0 |
| Monocalcium phosphate | 20.0 |
| Vitamin and mineral premix | 5.0 |
| L-lysine | 9.0 |
| DL-methionine | 3.0 |
| L-threonine | 1.0 |
| Choline chloride | 1.5 |
| Yttrium oxide | 0.1 |
| Iron | 1.0 |

Table 2. Apparent digestibility coefficient (%) in Atlantic salmon (n=3 tanks per diet).

| ADC % | D1 | D2 | D3 | SEM | $P_{ANOVA}$ |
|---|---|---|---|---|---|
| Dry matter | $72.70^{A}$ | $74.55^{B}$ | $75.33^{B}$ | 0.43 | 0.0045 ** |
| Ash | $13.47^{A}$ | $19.83^{B}$ | $21.25^{B}$ | 1.26 | 0.0011 ** |
| Crude protein | $91.48^{A}$ | $92.76^{B}$ | $92.89^{B}$ | 0.26 | 0.0201* |
| Carbon (C) | $79.31^{A}$ | $80.22^{AB}$ | $80.98^{B}$ | 0.27 | 0.0094** |

Intestinal health and metabolism: Histological analysis of 12 fish/diet revealed that the inclusion of biochar did not have any effect on mucosal structure. No significant differences in enteritis or mucosal atrophy were observed. Analysis of plasma revealed no differences between dietary groups regarding their enzyme activity (e.g., ALP, AST, DGGR), metabolites (e.g., albumin, bile acid, glucose, cholesterol), vitamins (A, D and E) or minerals (K, Ca, Na, P). Biochar is commonly associated with a high absorption capacity and there was the possibility of some nutrients being retained by the biochar and not absorbed by the fish. The current results suggest that biochar did not impact intestinal structure nor plasmatic levels of metabolism-related compounds.

Microbiota: 16S rRNA sequencing in distal intestine digesta is currently being carried out to determine the effect of biochar in intestinal microbiota, as has been reported in other studies.

**Conclusion**

The current results suggest that biochar has potential as a sustainable feed additive in RAS aquaculture. Inclusion of biochar in diets not only reduced solid waste production, potentially improving system efficiency, but also resulted in improved nutrient utilization and had no adverse effects on fish health.

# IS *Phaeobacter inhibens* ABLE TO CONTROL *Vibrio* IN *Artemia salina* LIVE FEED CULTURE*?*

Ana Rodiles[1*], Dorothee Gotz[1], Alberto García[2], Gabriela Carril[2], Jeleel Opeyemi Agboola[2], Antonio Villanueva[2], Ragnhild I. Vestrum[2], Eric Leclercq[1]

[1]Lallemand Animal Nutrition (Blagnac, France)
[2]BioMar AS (Norway)
arodiles@lallemand.com

## Introduction

Live-feed cultures are a key vector of *Vibrio* contamination in larviculture. *Phaeobacter sp.* has been suggested as good biocontrol candidates by biosynthesis of the antibacterial secondary metabolite tropodithietic acid (TDA).

## Material and Methods

An *Artemia salina* trial was performed in a commercial facility within 5L static tanks. The trial tested three incremental doses of *P. inhibens* (live freeze-dried powder form; Lallemand, France) in triplicate against a Control. The test product was applied in the rearing media at the start of both the hatching- and the enrichment phases using LARVIVA Multigain (BioMar). Artemia rearing remained otherwise standard and followed commercial practices. At the end of both the hatching- and rearing-phase; artemia and water samples were collected to quantify *Vibrio* load in TCBS agar media and to perform 16S rRNA amplicon sequencing by Miseq, then analysed with DADA2 in QIIME2.

## Results

The addition of *P. inhibens* significantly reduced the artemia *Vibrio* load at the end of enrichment. The higher doses tested clearly modulated the composition of the artemia microbial community which was concomitant with a significantly higher Shannon-index. The relative abundance of *Phaeobacter* increased (and other interesting genera as *Exiguobacterium*) and of *Vibrio* decreased, with increasing inputs of *P. inhibens*. The Rhodobacteraceae/Vibrionales ratio was confirmed as a relevant index also in *Artemia salina* culture. This first *in vivo* trial using a live, freeze-dried form of *P. inhibens* confirms this candidate agent as a potential and practical *Vibrio* biocontrol strategy in marine fish hatchery.

# EFFECTS OF DIFFERENT PLANT-BASED DIETS ON THE FATTY ACID COMPOSITION OF THE MARINE AMPHIPOD *Gammarus locusta*

Daniela P. Rodrigues[1]*, Luísa Marques[1], João P. Sousa[1], Felisa Rey[2,3], M. Rosário Domingues[2,3], Ricardo Calado[1]

## Introduction

The use of sustainable aquafeed ingredients in aquaculture primarily aims to reduce pressures on marine ecosystems by minimizing the reliance on fish meal and fish oil production. Most sources of omega-3 fatty acids (FA) come from highly exploited marine resources; however, omega-3 FA display a pivotal role in marine aquaculture. In the search for environmentally friendly and economically viable feed ingredients, terrestrial plants sources have emerged as promising alternatives to traditional marine-based inputs, but feature several limitations (e.g., limits of incorporation, anti-nutritional effects…). The present study evaluated the effects of different plant-based diets on the fatty acid profile of the marine amphipod *Gammarus locusta*, a key species in marine trophic chains and a potential candidate for inclusion in marine aquafeeds due to its content in long-chain polyunsaturated fatty acids (PUFA). This approach aims to further merge green and blue food ecosystems.

## Material and methods

Offspring of *G. locusta* were fed with four different diets: *Ulva* sp. (Ul) (used as control), peas (Pe), green beans (GB), and carrots (Ca), until reaching sexual maturity. Subsequently, individuals were collected, and their fatty acid composition determined. Fatty acid methyl esters were analysed via gas chromatography- mass spectrometry (GC-MS). The absolute abundance of fatty acids was calculated in $\mu$g/mg dry weight (DW), and data were compared across different diets.

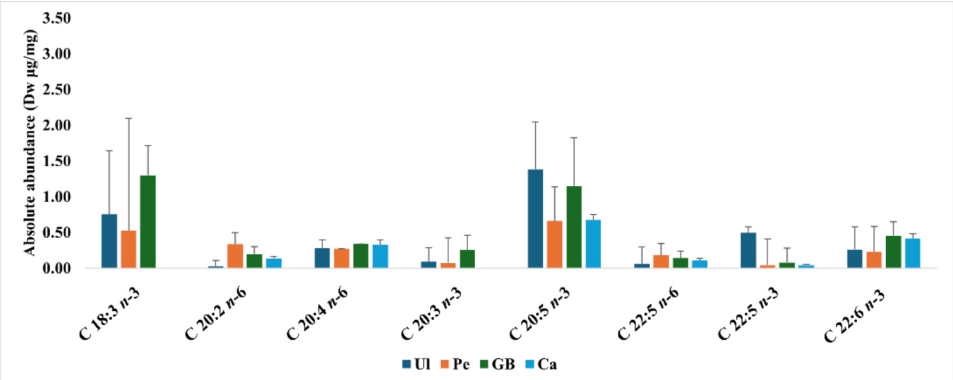

**Figure 1** – Mean abundance of polyunsaturated fatty acid composition of *Gammarus locusta* supplied with *Ulva* sp. (Ul), pea (Pe), green bean (GB) and carrot (Ca). Data expressed as µg.mg$^{-1}$ DW and representing the mean ± SE of 5 replicates ($n$ = 5), with exception for carrot (n=3).

*(Continued on next page)*

**Results**

The fatty acid composition of *G. locusta* clearly reflected their diets. Amphipods fed *Ulva* sp. showed higher levels of eicosapentaenoic acid (EPA) (C20:5*n*-3) (Ul: 1.39 ± 0.15, Pe: 0.70 ± 0.18, GB: 1.15 ± 0.32 and Ca: 0.68 ± 0.09, $\mu$g/mg DW) (Figure 1). However, in the case of docosahexaenoic acid (DHA) (C22:6*n*-3), amphipods fed *Ulva* displayed lower values when compared to conspecifics fed plant-based diets (Ul: 0.26 ±0.07, Pe: 0.28 ± 0.09, GB: 0.46 ± 0.08 and Ca: 0.41 ± 0.08 $\mu$g/mg DW) (Figure 1). It is worth highlighting that amphipods fed on terrestrial plant diets (Pe, GB, Ca) exhibited both EPA and DHA, despite the absence of these fatty acids in their diets

**Discussion**

These findings highlight the metabolic plasticity of *G. locusta* and its potential ability of synthesising long-chain omega-3 PUFAs, such as EPA and DHA from diets without these fatty acids. Although marine ingredients like *Ulva* sp. can directly supply EPA (in residual amounts), terrestrial diets enable biosynthesis of EPA and DHA, offering a sustainable strategy to farm *G. locusta*, whose biomass can eventually be used as an ingredient/supplement for aquafeeds. This approach is a promising pathway for converting low-cost, terrestrial inputs into high-value marine ingredients through bioconversion.

**Conclusion**

*G. locusta* can biosynthesise essential *n*-3 PUFAs (namely EPA and DHA) from terrestrial plant-based diets, making them viable and sustainable inputs for producing enriched live feeds. The use of terrestrial diets represents a novel and ecologically sound approach for generating DHA and EPA through trophic upgrading.

## Introduction

Aquaculture is the fastest growing food production system worldwide, having increased from 10 million tonnes in 1990 to 94.4 million tonnes in 2022 (FAO, 2024). While global aquaculture production continues to grow rapidly, the EU freshwater aquaculture sector has largely stagnated over the past two decades (Guillen *et al.*, 2025). This sector faces significant challenges including feed costs, environmental concerns such as nutrient loading and resource use in addition to inefficient waste management practices that fail to capitalize on circular economy opportunities. The SmartAqua4FuturE (SAFE) project aims to reverse the declining trend in European freshwater aquaculture through novel circular economy approaches to waste stream valorisation. Central to this initiative is the development of a comprehensive environmental sustainability assessment framework that can evaluate the environmental performance of different freshwater aquaculture systems (FWAS) and SAFE innovations. The project will evaluate the environmental performance of a number of approaches that can reduce the impacts of aquaculture – these include novel ingredients for feed production, approaches to aquaculture operation and methods for enabling valorisation of aquaculture waste. This abstract presents the work developed towards the advancement of a standardised methodological framework for conducting Life Cycle Assessment (LCA) of FWAS, with particular emphasis on integrating biodiversity elements. By developing these novel approaches, this work will contribute to the development of an LCI framework that can be extensively adopted by scientific organisations, industry and aquaculture operators. The boundaries of the analysis for these approaches are also presented.

## Methods

System boundaries were established for eight systems: carp polyculture in China, carp monoculture in Poland, flowthrough trout farming in Portugal, RAS/pond perch farming in Ireland, RAS salmonid farming in Denmark, and three SAFE innovations (mushroom cultivation, redworm meal production, and mealworm production). For each system, appropriate functional units were considered, such as kg of fish at the farm gate. The environmental sustainability assessment methodology follows ISO 14040/14044 standards for LCA and is aligned with EU Product Environmental Footprint Category Rules (PEFCR) and Environmental Product Declaration (EPD) guidelines.

The assessment covers three main systems: 1) EU FWAS including extensive pond-based operations and intensive recirculating aquaculture systems (RAS), 2) feed trials examining both conventional and novel feeds incorporating circular alternative ingredients and 3) SAFE innovations for waste stream valorisation. A structured data collection framework was developed to ensure methodological consistency and data quality. Primary data will be collected through tailored surveys targeting farm-level inputs (feed, energy, water, chemicals) and outputs (fish production, waste streams), while secondary data from scientific literature and databases will complement background processes. Several The pedigree matrix approach was incorporated to facilitate transparent assessment of data quality. Environmental impact categories selected for assessment include carbon footprint, acidification potential, eutrophication potential, freshwater consumption, land use requirements, and biotic resource use. Additionally, FWAS-specific indicators such as Fish In Fish Out (FIFO) ratio will be included to provide sector-relevant performance metrics. A novel aspect of the methodology is the integration of biodiversity indicators into the LCA framework through three complementary strategies: the Water Framework Directive (WFD) methodology, to assess impacts on water body ecological status; the integration of locally relevant species that could serve as context-specific bioindicators such as such as benthic macroinvertebrates and aquatic macrophytes, that reflect the unique ecological conditions of different aquatic ecosystems, through a structured self-reporting system for farmers to document species observed at their facilities; and lastly, the incorporation of land use metrics to assess effects of land use on water bodies health and aquatic biota.

*(Continued on next page)*

## Results and Discussion

The methodological framework presented establishes a foundation for comprehensive environmental sustainability assessment of freshwater aquaculture systems and innovations developed within the SAFE project. By adhering to standardized LCA protocols while adapting them to the specific challenges of aquaculture production, this framework enables meaningful comparison across different production systems and technologies. Preliminary work on integrating biodiversity indicators represents a significant advancement in addressing a fundamental gap in the environmental sustainability assessment of the aquaculture sector. The proposed approach combining WFD methodologies, bioindicator species monitoring, and land use metrics offers a more holistic evaluation of biodiversity impacts than the conventional LCA approaches, which typically focus solely on land use change.

The methodology developed will enable the evaluation of environmental performance and potential trade-offs associated with circular economy innovations in freshwater aquaculture. For instance, valorising aquaculture waste streams for novel feed ingredients might reduce dependence on marine-derived ingredients and lower the overall environmental footprint but could potentially introduce new challenges related to processing energy requirements or nutrient profiles.

## Conclusion

The standardized methodology developed within the SAFE project provides a robust framework for assessing the sustainability of freshwater aquaculture systems and circular economy innovations. By integrating conventional LCA approaches with aquaculture-specific indicators and enhanced biodiversity assessment, this methodology addresses key gaps in sustainability evaluation for the sector. When fully implemented, this framework will inform evidence-based decisions regarding the environmental performance of different production systems and technologies, ultimately supporting the European freshwater aquaculture sector's transition toward more sustainable and circular production methods. The approach developed has broader applications beyond the SAFE project and could contribute to standardizing environmental sustainability assessment methodologies for the global aquaculture sector.

# APPLICATION OF HYPERSPECTRAL IMAGING FOR THE CLASSIFICATION AND CHARACTERIZATION OF STURGEON CAVIAR AND TROUT ROE

Miriam Alonso[1], Beatriz Rodríguez[2], Vanesa Suárez[1], Paula Esquiroz[1], María-José Sáiz[1] and Diego Mendiola[2]*

[1] National Centre for Food Technology and Safety (CNTA) Crta.NA 134-km 53, 31570 San Adrian, Navarra, Spain

E-mail: malonso@cnta.es
diego.mendiola@caviarpirinea.com

## Introduction

The classification of a product such as caviar is crucial for ensuring its quality, authenticity, and market value. For Caviar Pirinea, this categorization is especially significant due to its unique characteristics and distinctive origin. Selecting the appropriate category helps differentiate between various qualities and types, protects consumers, and enhances the product's value both locally and internationally [1, 2] Additionally, proper classification helps preserve the tradition and sustainability of caviar production, both of which are essential for maintaining its reputation and competitiveness. [3]. The same applies to trout roe, which also needs proper classification and description to guarantee its quality and freshness and to increase its value in the gourmet market. Although trout roe is less expensive than sturgeon caviar, it is appreciated for its taste and uses in cooking. Clear categories help improve how it is sold and protect the consumer [4, 5].

Hyperspectral imaging is an advanced technology that allows rapid and non-destructive analysis of food, capturing detailed information about its chemical composition and physical characteristics. This technique uses multiple wavelengths to obtain images that reveal properties invisible to the human eye, facilitating the detection of defects, contaminants, or variations in product quality [6, 7]. Its application in food quality control is growing rapidly, as it provides accurate results and helps ensure safety and freshness, thereby increasing consumer confidence and optimizing production processes [8].

## Materials and methods

The hyperspectral imaging cameras used for this experiment were the FX10 (Specim, 400–1000 nm) and the FX17 (Specim, 900–1700 nm). Due to the glare and reflections caused by the product matrix itself, a diffuse lighting system was required to capture high-quality images.

For this study, samples from three sturgeon caviar varieties were selected: Baerii, Naccarii, and Osetra. As for the trout roe, all samples originated from rainbow trout. A total of 80 sturgeon caviar samples and 50 trout roe samples were analyzed.

The primary objectives of product classification were to assess the color, size, moisture, and firmness of sturgeon caviar and to separate trout roe into high and lower quality categories, and to measure salt content.

The methodology followed was based on the following work-flow: hyperspectral image acquisition, data processing to differentiate and ROI selection, extraction of the average spectrum per ROI or sample, and development of regression or classification models depending on the parameter of interest.

## Results and discussion

After applying various approaches and calibrating models according to the parameters of interest for each product, it was observed that the FX17 hyperspectral camera delivered better results than the FX10 for most of the evaluated parameters.

For sturgeon caviar, the models developed with the FX17 to estimate diameter and moisture content showed the best performance, outperforming the models related to firmness and color. The limited availability of samples in one of the firmness classes reduced the robustness of the results, making them inconclusive. Regarding color, the models were able to distinguish between light, dark, and bi-colored roe; however, the classification of intermediate shades could not be adequately trained with the available sample set.

*(Continued on next page)*

For trout roe, both quality classification (high or low) and salt content prediction yielded good results with both cameras. Nevertheless, it is important to note that the image quality of the FX10 is lower than that of the FX17, which significantly reduces the number of roe identified per sample. Therefore, the results obtained with FX17 are more representative.
Overall, the results indicate that the FX17 hyperspectral imaging camera is a highly promising technology for the classification and categorization of both sturgeon caviar and trout roe.

# EFFECTS OF OCEAN ACIDIFICATION ON GROWTH AND MINERALIZATION OF SKELETAL STRUCTURES IN GILTHEAD SEA BREAM (*Sparus aurata*)

Inmaculada Rodríguez[1], Isabel García-Pérez[1], Nazanin Sadeghi[2], Manel Montblanch[1], Joaquim Gutiérrez[1], Isabel Navarro[1], Encarnación Capilla[1] and Daniel Garcia de la serrana[1]

## Introduction

The increase in anthropogenic carbon dioxide ($CO_2$) emissions results in a decrease in oceanic pH, a phenomenon known as ocean acidification (OA), which represents a considerable risk to the future of aquaculture. In marine invertebrates, OA reduces survival, growth, and calcification. In fish, elevated $CO_2$ levels in water have also been associated with reduced survival, specific growth rate (SGR) and protein biosynthesis, as well as alterations in behavior and reproduction (Heuer and Grosell, 2014). Contrarily, OA has been reported to enhance otoliths growth and calcification, as well as to modify their shape and composition, possibly due to efficient plasma pH compensation mechanisms. In fish with cellular bone, changes in bone mineralization under hypercapnic conditions have also been reported (Drábiková et al., 2023; Gil Martens et al., 2006). Furthermore, *in vitro* studies in mammals have demonstrated that osteoblasts activity is significantly affected by low pH conditions. However, the impact of $CO_2$ on fish with acellular bone mineralization remains less understood. The aim of this study is to assess the potential effects of OA on the skeleton in gilthead sea bream juveniles, using both *in vivo/in vitro* approaches.

## Material and methods

Gilthead sea bream juveniles provided by the commercial hatchery Piscimar (Burriana, Spain) were maintained in the animal facilities at the Faculty of Biology at the University of Barcelona (Spain). After an acclimation period, animals were weighed and randomly distributed in two experimental groups exposed to different pH conditions: a control group maintained at pH 7.9, and a low pH group maintained at pH 7.3 by $CO_2$ injection through a glass diffusor connected to a $CO_2$ bottle. After 68 days of exposure, fish were measured and weighed, and 15 fish per condition were sampled. Blood was collected to determine hematocrit levels and plasma composition. Otoliths, gills and vertebral bone were carefully extracted and immediately frozen in liquid nitrogen. Bone mineral composition and mineralization by X-ray, remodeling and mineralization-related genes expression, as well as ion transport gene transcription in gills, were analyzed. Furthermore, primary cultures of gilthead sea bream bone-derived cells were performed. Then, cell viability and mineralization were assessed on cells cultivated under three different conditions, 2.5%, 1.5%, or 0% $CO_2$, corresponding to a pH value of 7.79 ± 0.04, 7.49 ± 0.01, and 7.38 ± 0.02, respectively.

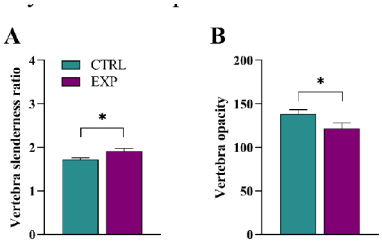

**Figure 1. (A)** Slenderness ratio and **(B)** opacity of the vertebrae of gilthead sea bream juveniles exposed to control (CTRL) pH (7.9) and experimental (EXP) pH (7.3) for 68 days. Data are shown as Mean + SEM ($n$ = 15). Statistical differences were determined by student-unpaired t-test ($p$<0.05).

*(Continued on next page)*

**Results and discussion**

No significant differences were observed in body weight or body length at the end of the experimental period. However, the SGR values were significantly lower in the experimental group compared to the control group, consistent with findings in European sea bass (*Dicentrarchus labrax*) (Alves et al., 2020). Plasma analysis revealed significantly higher pH and potassium levels in the experimental group, while ionic calcium, magnesium, and phosphorous levels remained unaltered, in agreement with previous studies (Alves et al., 2020; Costa et al., 2022). Bone mineral composition did not show significant differences between groups for any of the ions evaluated. However, X-ray analysis indicated an increase in vertebra slenderness ratio and a reduction in opacity in the experimental group (Figure 1). This suggests that, despite being less mineralized than in the control group at this time, the vertebrae of animals exposed to low pH appear to have undergone more longitudinal growth and could potentially reach higher mineralization levels if given a longer growth period. Otoliths from fish exposed to low pH exhibited a generalized increase in size, with a significant increase in most of the parameters determined compared to the control pH group. No significant differences were identified in the transcription levels of gills ion transporters between groups. Nevertheless, the low pH condition significantly upregulated the expression of the osteoblast marker, *alkaline phosphatase* (*alp*), and the osteoclast-related gene, *matrix metalloproteinase-9* (*mmp9*), suggesting increased bone turnover in the experimental fish. In the *in vitro* experiments, the percentage of $CO_2$ had a significant effect on both cell viability and mineralization, with the highest values for those parameters observed under the 0% $CO_2$ condition after 30 days. Overall, the results of the present study provide new evidence of how climate change, particularly OA, can impact the skeletal structures of gilthead sea bream, an important species for both Mediterranean ecosystems and aquaculture industries.

## Introduction

Biochar, a carbonaceous material derived from the thermochemical conversion of biomass under oxygen-limited conditions, has emerged as a versatile material with applications in environmental remediation, including the sequestration of heavy metals, organic pollutants and other hazardous substances. In recent years, the supplementation of aquatic feeds with biochar has shown potential to stimulate growth and development in various aquatic organisms (Rai et al., 2025). In this study, two experimental diets supplemented with biochar GM-530-P, produced industrially from cork oak and holm oak stumps at 530 ºC, were evaluated after 5 months of administration in *Solea senegalensis* juveniles.

## Material and methods

Experimental diets were formulated according to the nutritional requirements of the species *Solea senegalensis*. A control diet (CT) and two experimental diets supplemented with 0.5% (B0.5) and 2% (B2) of biochar GM-530-P were assayed. A total of 135 fish (average length of 14.46±0.5 cm and weight of 40.93±4.01 g) were randomly distributed across 9 tanks. Fish were reared for 5 months at the Marine Aquaculture Facility "El Bocal" of the Spanish Institute of Oceanography (Santander), and sampled monthly to monitor growth. At the end of the trial, intestines were aseptically dissected. Mucosal samples from the anterior and posterior intestinal sections were collected in sterile microtube, and stored at –80 °C until further analysis. DNA metabarcoding library preparation and sequencing were carried out by AllGenetics & Biology SL (www.allgenetics.eu).

## Results and discussion

The microbial community structures were successfully described at various taxonomic levels, including phylum, class, order, and family. Analysis of the alpha diversity in the anterior intestine revealed that B05 diet generally led to significantly greater microbial richness compared to both the B2 and CT diets. Also, the fish fed B05 diet demonstrated significantly higher overall diversity, as indicate by a higher Shannon index and a lower Simpson index. In contrast, the posterior intestine samples exhibited less pronounced differences, with no statistically significant variations in alpha diversity indices among the B0.5, B2, and CT dietary groups.

Graphical representations of microbial relative abundance models, highlighting differentially abundant taxa at the family level, are shown in Figure 1.In the anterior gut (Figure 1A), both biochar-supplemented diets (B05 and B2) consistently induced significant shifts in the microbial landscape relative to the control (CT). A notably increased relative abundance was observed for families such as *Alteromonadaceae, Vibrionaceae, Thiohalorhabdaceae, Halieaceae, Nitrosomonadaceae, Rhodobacteraceae*, and members of the *SAR116 clade,* all showing positive associations with biochar inclusion ($p < 0.05$). These groups often include opportunistic colonizers or taxa involved in various metabolic processes, including sulfur and carbon cycling. In contrast, the posterior gut (Figure 1B) displayed a more nuanced and compartment-specific response to biochar supplementation. While some families, like *Vibrionaceae, Thiohalorhabdaceae,* and *Nitrosomonadaceae*, showed consistent increases in abundance across both gut sections, other prominent changes were unique to the posterior segment. Notably, significant reductions in relative abundance were observed for *Desulfocapsaceae,* certain *Actinobacteriota*, and *Flavobacteriaceae*.

*(Continued on next page)*

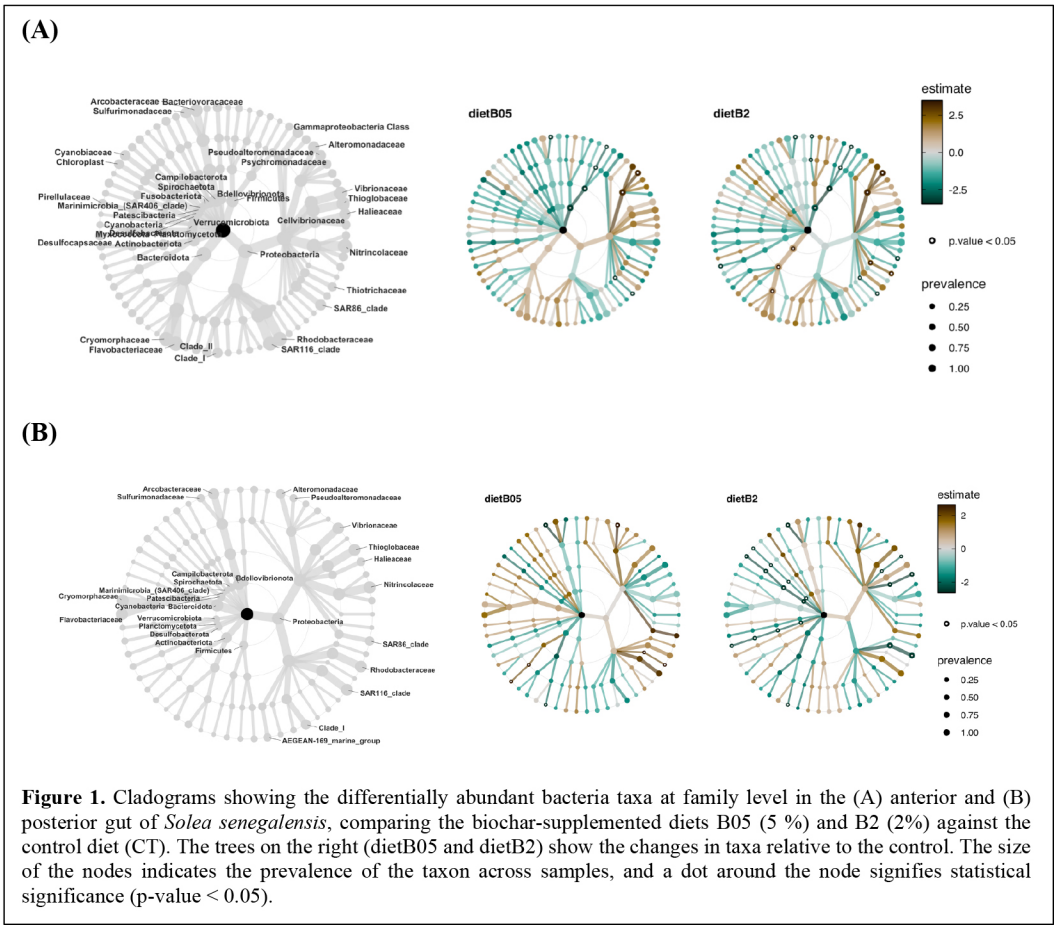

**Figure 1.** Cladograms showing the differentially abundant bacteria taxa at family level in the (A) anterior and (B) posterior gut of *Solea senegalensis*, comparing the biochar-supplemented diets B05 (5 %) and B2 (2%) against the control diet (CT). The trees on the right (dietB05 and dietB2) show the changes in taxa relative to the control. The size of the nodes indicates the prevalence of the taxon across samples, and a dot around the node signifies statistical significance (p-value < 0.05).

The observed microbial shifts have potential implications for Senegalese sole aquaculture. An increased diversity in the anterior gut, particularly in fish fed B0.5 group, could enhance digestive efficiency and nutrient absorption. Alterations in specific metabolic groups (e.g., sulfur and nitrogen cycling bacteria) may influence gut functionality and the production of beneficial or detrimental metabolites. Further research is warranted to elucidate the functional consequences of these taxonomic shifts on host physiology, nutrient utilization efficiency, disease resistance, and growth performance.

## Introduction

The increasing demand for protein by the human population has driven the growth of the aquaculture industry, with fish being the most widely farmed organisms. Nevertheless, captive conditions are often inadequate due to spatial uniformity, homogeneity, and the immutability of the environment. These conditions can impair the welfare and cognitive abilities of the fish 1,2. In this context, providing environmental enrichment (EE) is a well-established strategy to promote animal welfare by offering novel stimuli that support behavioral, physiological, and psychological needs 1,3. In aquatic species, structural EE, understood as the addition of physical complexity through objects or structural modifications 1, has been shown to reduce stress, enhance cognitive abilities, and mitigate abnormal behaviors 4–8. The effects of EE vary depending on the species and its life stage1,8. Despite the growing interest in the effects of this strategy in captive fish, there remains a significant lack of knowledge regarding some of the most relevant species for the industry, such as the European seabass (Dicentrarchus labrax, L.)3. Consequently, our aim was to analyze the effects of environmental stimulation through physical structures, considering behavioral, physiological, and cognitive aspects in European seabass, to assess their potential applications for improving welfare.

## Material and Methods

The study was carried out in experimental facilities located in the coastal waters of Port of Andratx (Balearic Islands, Spain), belonging to the Laboratory of Marine Research and Aquaculture (LIMIA-IRFAP). A total of 4000 juvenile seabass of about 30 g in weight, were randomly distributed into 8 experimental marine sea-cages. Four of these sea-cages were structurally enriched, while the remaining four were kept bare, serving as the control (EE and NE cages, respectively). The applied structural EE consisted of a floating rectangular cork from which six knotted ropes with a weight at the end were suspended, occupying more than half of the vertical space within the sea-cage (1.5 m). The juvenile individuals were maintained under the influence of the treatments for approximately 3.5 months (03/11/2024 - 07/05/2024; 116 days).

After 2.5 months from the beginning of the enrichment period, the emotional reactivity test (ERT) was conducted over four consecutive days to evaluate the effects of structural EE on the behavioral response of seabass, testing ten individuals per marine sea-cage. For this behavioral test the fish was placed into a circular experimental tank (Ø 55 cm, 38 cm high) that it had never explored before (Open-field test). The researcher then leaved the vicinity, marking the start of the ERT, during which behavioral responses of each fish were recorded individually for 10 minutes with a top-view camera (GoProHero10®). At the end of the testing period all individuals were euthanized with an overdose of anesthetic and subsequently sampled. Muscle and telencephalon tissues were dissected and immediately frozen at –80 °C for subsequent analysis of oxidative status in the laboratory. The activity of three antioxidant enzymes [catalase (CAT), superoxide dismutase (SOD), and glutathione reductase (GRd)] was quantified, along with the concentration of malondialdehyde (MDA), a compound commonly used as a marker of membrane phospholipid oxidation.

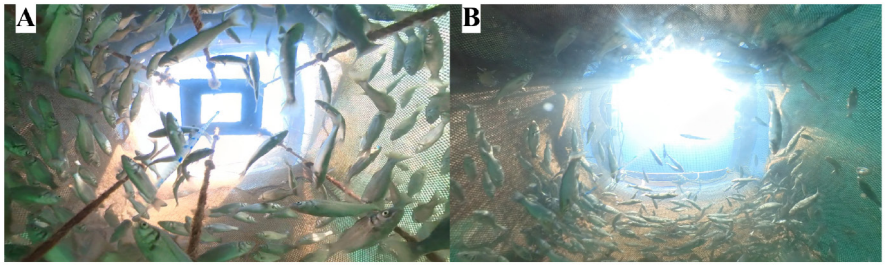

**Figure 1.** Underwater view with 360º cameras of the EE cages (A) and the NE cages (B)

*(Continued on next page)*

**Results and Discussion**

Results showed that fish reared under environmental enrichment displayed enhanced exploratory behavior, covering greater distances, and utilizing a larger area more uniformly across the available space. Furthermore, the day-to-day variations observed in the different parameters of the ERT in enriched fish were consistent with a normal habituation process to a novel environment, indicative of positive welfare. In contrast, control fish exhibited higher anxiety levels and lacked such habituation patterns. Overall, enriched fish demonstrated more active behavior and greater adaptability to unfamiliar situations, whereas non-enriched fish showed limited exploration and a more constrained response. Additionally, this behavioral pattern was associated with the activation of muscle enzymatic mechanisms that prevented oxidative damage, reflecting greater physiological resilience under challenging conditions. These findings highlight the role of EE in fostering positive welfare states in fish by promoting natural behaviors and reducing stress responses. The implementation of structural EE represents a promising, non-invasive approach to improving fish welfare in captivity or controlled environments, warranting further investigation and potential applications.

**Acknowledgements**

We would like to thank the staff, technicians, and researchers of LIMIA for their help and assistance during the process of the study, and for their facilities and resources in Port d'Andratx. We would also like to thank the staff of Aqüicultura Balear (ABSA, Culmarex Group) for their fish, help and assistance during the experiment.

## Introduction

Rainbow trout (*Oncorhynchus mykiss*) is one of the most extensively cultivated freshwater fish species, with a global production reaching 900 thousand tonnes per year (FAO, 2024). However, this species is vulnerable to a range of diseases that present major challenges to animal health and welfare, which negatively impacts on aquaculture production and results in significant economic losses for aquaculture farms (Kania & Buchmann, 2025). To mitigate these adverse effects, genetic improvement can be accelerated through quantitative trait loci (QTL) mapping. This approach has enabled the identification of genomic regions associated with disease resistance in rainbow trout (Buchmann, 2022). Although numerous QTLs associated with pathogen resistance have been reported in rainbow trout, differences among studies, such as experimental design, fish populations, trait selection, statistical methods and the quality and density of the genetic map, make it challenging to identify QTLs for all relevant traits within a single analysis. To address these challenges, meta-analysis supported by mathematical models has emerged as an effective strategy to improve the accuracy and reliability of QTL localization, as it allows for the integration of data from multiple studies (Kaur et al., 2023). To the best of our knowledge, this study represents the first meta-analysis of pathogen resistance QTLs in rainbow trout, highlighting a major research gap that could improve disease-resistant breeding programmes in aquaculture.

## Material and Methods

A comprehensive literature review was conducted to collect QTLs associated with pathogen resistance in rainbow trout, covering studies from the last two decades. Key data including population mapping type, population size, chromosome number, QTL and flanking markers positions, LOD score, and explained variance were extracted. The consensus map for meta-QTL analysis was constructed using the R package "LPmerge" and six genetic maps. QTL positions were projected onto this consensus map, and 95% confidence intervals were calculated with population-specific formulas: For $F_2$ generation and Backcross populations: CI (95%) = $530/(R^2 \times N)$; for doubled haploid populations: CI (95%) = $287/(R^2 \times N)$, where $R^2$ is the phenotypic variance explained by the individual QTL and $N$ is the population size. Meta-analysis of QTLs was performed for each chromosome using Biomercator v4.2.3, applying the Goffinet & Gerber's method for chromosomes with ≤10 QTLs and the Veyrieras et al.'s method for those with >10 QTLs.

## Results

A total of 138 QTLs associated with pathogen resistance traits were available for meta-QTL analysis. The number of initial QTLs per chromosomes ranged from a minimum of 1 QTLs on chromosome 9, 14,15,16 and 17 to a maximum of 21 QTLs on 8 (Fig 1). Most QTLs (88.40% of total) had LOD score between 2 and 3. The phenotypic variation explained by individual QTL varied from <5 to 30> with an average of 15.16%, suggesting the involvement of both major and minor QTLs in governing pathogen resistance.

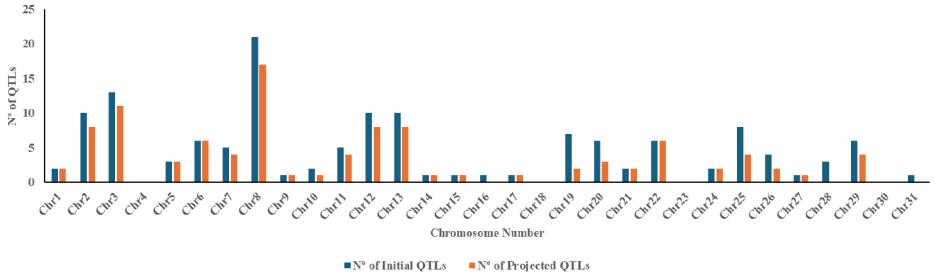

**Fig 1.** Distribution of initial and projected QTLs for Meta-QTL analysis.

*(Continued on next page)*

The high-density rainbow trout consensus map generated in present study, using six different genetic maps, exhibited an average marker density of 2.84 markers/cM across the genome. Moreover, there were approximately 513 markers mapped on average per chromosome. Out of 138 QTLs, a total of 101(73.19%) could be projected of the total onto the newly constructed consensus map (Fig. 1). The method proposed by Gerber and Goffinet was employed for meta-analysis of QTLs on all chromosomes except for chromosome 3 and 8, for which the Veyrieras approach was used. A total of 26 meta-QTLs (MQTLs) were predicted for resistance to pathogens. Across the whole genome, the maximum number of MQTLs was predicted on chromosome 8.

**Discussion**

The quantitative genetics of pathogen resistance has been explored in numerous studies, mainly because of the molecular markers availability, lower genotyping expenses, and advances in QTL mapping techniques (Huang et al., 2025). In this study, we analyzed QTLs in rainbow trout, focusing on diseases such as BCWD, IHN or IPN, among others. The stability of QTLs could be influenced by different genetic backgrounds, environmental or population type. To address this variability, meta-QTL could identify consistent stable and robust QTLs by integrating data from multiple studies (Kaur et al., 2023). To the best of our knowledge, this is the first meta-analysis of QTLs related to pathogen resistance in *O. mykiss*, revealing chromosome 8 as a key genomic hotspot for pathogen resistance QTLs and consolidating finding across diverse studies. Further validation of candidate genes through GWAS is essential to facilitate practical applications in aquaculture.

**Conclusions**

This meta-analysis underscores the value of integrating data from multiple studies to identify genomic regions associated with pathogen resistance in rainbow trout. The consolidation of 26 MQTLs provides a robust foundation for developing more precise and efficient selective breeding strategies in aquaculture. The identification of chromosome 8 as a genomic hotspot for disease resistance opens new avenues for functional genomics research and supports the development of disease-resistant rainbow trout, contributing to a more sustainable aquaculture industry.

## Introduction

Aquaculture is crucial to address the growing global demand for marine products, particularly in Europe, where species such as *Scophthalmus maximus* (turbot)*, Sparus aurata* (gilthead seabream) and *Dicentrarchus labrax* (seabass) are valued for their production efficiency (FAO, 2024). However, the rapid expansion of the industry has led to increased viral diseases (Lafferty *et al.,* 2015). Understanding the immune mechanisms underlying resistance to these pathogens is essential for improving aquaculture sustainability (Sood *et al.,* 2021). High-throughput transcriptomic analyses, such as RNA-seq, have emerged as powerful tools to unravel the molecular basis of immune responses in fish (Song *et al.,* 2022). *In vitro* stimulations with viral mimics like Poly I:C enables direct comparison of antiviral responses across species (Rao *et al.,* 2023). Despite these advances, comparative studies evaluating *in vitro* immune responses to viral challenges across species remain scarce, limiting our knowledge of conserved and divergent immune pathways. The aim of this study is to comparatively analyze the *in vitro* immune responses of turbot, seabream and seabass leukocytes to Poly I:C in order to identify conserved and species-specific immune mechanisms that could inform future strategies for disease resistance in aquaculture.

## Material and Methods

Leukocytes were isolated from head kidney of turbot, seabream and sea bass, pooled, and treated with Poly I:C or PBS. After 24 h incubation, RNA was extracted, quality-checked, and sequenced (Illumina NovaSeq S4, 150 bp paired-end). Reads were quality-assessed (FastQC), trimmed (FastP) and pseudo-aligned to species-specific reference transcriptomes (Kallisto). Differential expression analysis was performed with DESeq2 (FDR <0.05) and PCA for quality control. Functional enrichment (G:Profiler), GO visualization (ReViGO), and immune orthologue mapping (Ensembl Biomart) enabled comparative analysis across species, summarized by Venn diagrams and heatmaps.

## Results

A total of 36 RNA-seq datasets were generated in this study. Differential expression analysis identified a total of 1,383 DEGs in turbot, 4,335 DEGs in seabream and 504 DEGs in seabass (Fig 1). GO analysis of DEGs in the three teleost species revealed that *D. labrax* exhibited the highest number of clusters and GO terms associated with the immune response. Notably, all three species exhibit a number of common GO terms related to the immune response, response to external stimuli/pathogens and biological interactions.

Homology analysis of immune-related DEGs identified 502 homologous genes following *in vitro* Poly I:C stimulation, with 31 shared among all three species. Turbot showed higher expression of interferon-related and immune regulatory genes, while seabream and seabass exhibited increased expression of proteasome, antigen processing, and other immune system components-related genes.

## Discussion

In the current work, we examined the impact of Poly I:C, as a mimic for RNA viral infections, on transcript levels in diverse fish species using *in vitro* approaches, as a first step towards elucidating their role in the conserved defence mechanisms in teleosts. The RNA-seq results revealed a proportional overall expression response, with a constant percentage of up- and downregulated DEGs across species, although seabass exhibited fewer DEGs compared to the other species.

Fig. 1 Number (A) and Proportion (B) of Up- and Down-regulated DEGs in response to Poly I:C stimulation in *S. maximus, S. aurata* and *D. labrax*.

To identify genes potentially subject to evolutionary conservation, homologous DEGs across the three species were compared. The general observations suggested a total of 6.17% shared for the three species when a potent stimulant such as Poly I:C was employed. This results are in accordance with previous findings in salmonid fishes, where the overlap of orthologous DEGs between species is also low, likely due to virus-induced evolutionary pressures driving rapid adaptation of immune regulatory sequences (Clark *et al.,* 2023).

Noteworthy, a conserved pattern was observed across all three species, where a subset of DEGs displaying a more similar expression profile between seabass and seabream than with turbot. This is expected given the closer evolutionary relationship between seabass and seabream (Hughes *et al.,* 2018). Moreover, the shared genes were found to be mainly related to key pattern recognition receptors.

**Conclusion**

This study presents a transcriptomic analysis of the immune response to Poly I:C, a mimic for RNA virus infection, in turbot, seabream and seabass, revealing robust and conserved regulation of immune-related genes across these species. Several orthologous immune-defense genes were identified as part of shared antiviral response. These findings provide valuable molecular resources for future research on fish immunity.

*Email: deirod@ull.edu.es

## Introduction

The culture of the greater amberjack (*Seriola dumerili*) is limited by parasitic diseases, with the monogenean *Neobenedenia* spp. and *Zeuxapta seriolae* being two of the main challenges (Rigos et al., 2020). Understanding the host's molecular defense mechanisms is key to developing effective control strategies. Plasma proteomic analysis could help identify resistance biomarkers and improve management and control strategies. This study aimed to analyze and differentiate the plasma proteomic profile of *S. dumerili* in response to parasitism by both pathogens. To this end, label-free quantification (LFQ) proteomics was applied to plasma samples from fish with different parasitic loads.

## Material and methods

Label-free quantification (LFQ) proteomics was applied to plasma samples from fish with different parasite loads. Specimens of *Seriola dumerili* with varying levels of *Neobenedenia* spp. (N) and *Zeuxapta seriolae* (Z) infestation were obtained from the Canary Islands Oceanographic Centre (IEO, Tenerife). Eleven fish of similar size and weight (85 ± 9.42 cm; 11.91 ± 3.07 kg) were assigned to high (H) or low (L) infestation groups based on thresholds arbitrarily established from COC-IEO experience on the physiological and pathological effects of each parasite (>2000 *Neobenedenia*, >50 *Zeuxapta*). Four experimental categories were defined according to the H/L status for N and Z, respectively: HH (high infestation with both parasites), HL (high *Neobenedenia*; low *Zeuxapta*), LH (low *Neobenedenia*; high *Zeuxapta*), and LL (low infestation with both ≡ control), with 2–3 biological replicates each. Blood was collected via caudal venipuncture after anaesthesia with butanol chloride (30 ml/100 L) using heparinized syringes, centrifuged (2500 g, 15 min, 4 °C) to obtain plasma, stored at −80 °C, and transported to PROMEC (NTNU, Norway) for proteomic analysis. Samples were treated with lysis buffer (SDC, Tris-HCl, TCEP, CAA), heated (95 °C, 20 min), digested with trypsin (overnight, 37 °C), purified on C18 columns, dried, and resuspended in 0.1% formic acid for LC-MS/MS on a timsTOF Pro coupled to a nanoElute HPLC, using a 75 min gradient (0–40% acetonitrile). Data processing in R (v4.4.2) involved contaminant/decoy removal, variance-stabilizing normalization, and MNAR value imputation. Multivariate analyses included PCA (top 500 variable proteins), ANOVA with Tukey's post hoc for the PC, and differential expression analysis (DEP). Functionally relevant proteins were examined for GO term and pathway enrichment using g-Profiler.

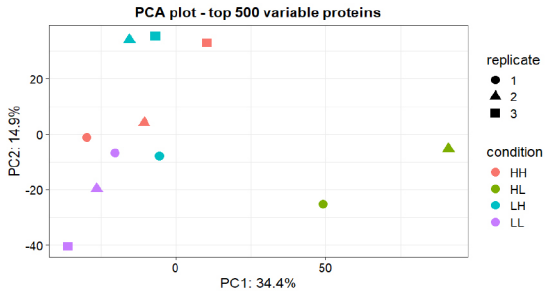

**Figure 1.** PCA of *S. dumerili* plasma samples based on the 500 most variable proteins, showing the clustering of replicates (shape) according to experimental conditions (color). The first two principal components explain 34.4% (PC1) and 14.9% (PC2) of the total variance, respectively.

*(Continued on next page)*

**Results and Discussion**

PCA revealed clear separation among infection conditions. HL (high *Neobenedenia*, low *Zeuxapta*) separated strongly on PC1, indicating a distinct host proteomic response. HH and LH (involving *Zeuxapta*) clustered closer to LL (low infection), suggesting a milder proteomic effect. PC2 partially separated HH and LH from LL, reflecting shared features linked to *Zeuxapta*. ANOVA on PC1 confirmed significant differences between conditions ($F_{(3,7)} = 15.82$, $p = 0.00168$), with HL showing significantly higher PC1 scores than all others. PC2 differences were not statistically significant ($F_{(3, 7)} = 3.217$, $p = 0.0919$) but suggested a marginal trend consistent with visual separation.

Proteins contributing most to PC1 and PC2 were grouped into three subsets: HNP (high PC1 loadings, linked to *Neobenedenia*), HZP (high PC2 loadings, linked to *Zeuxapta*), and LZP (low PC2 loadings). HNP proteins were enriched in proton transport and phagosome-related processes. HZP proteins related to adaptive immunity, branched-chain fatty acid metabolism, and extracellular matrix remodelling, while LZP proteins were associated with primary metabolism and protein translation.

Differential expression analysis showed no significant differences between parasitized groups and LL but revealed 11 significant proteins between HL and LH (padj < 0.05). LH displayed higher levels of proteins linked to muscle contraction, oxidative metabolism, and epigenetic regulation, whereas HL showed increased proteins related to vesicular trafficking and intracellular signalling. The lack of univariate differences with LL likely reflects its low but non-zero parasite load, while multivariate analyses (PCA) captured coordinated proteomic shifts.

The results revealed unique and specific molecular responses for each parasite. The integration of multivariate (PCA) and univariate analyses proved crucial. While few individual proteins showed significant differential expression, PCA revealed clear, distinct host response patterns for each parasite. This indicates the host's reaction is based on coordinated, systemic changes rather than the overexpression of a few key proteins.

The response to the ectoparasite *Neobenedenia* was characterized by a localized innate immune activation centered on phagocytosis, suggesting a controlled strategy to minimize systemic inflammation. In contrast, *Zeuxapta* triggered a more complex and systemic response, involving the activation of adaptive immunity (immunoglobulins, complement), indicators of tissue damage, oxidative stress, metabolic reprogramming, and epigenetic regulation. Based on our results, evasion strategies to survive within the host cannot be ruled out.

Due to the pilot nature of this study, we cannot yet define reliable biomarkers to separate infected fish from healthy ones. However, a key finding of this study, it is of a specific group of proteins can effectively tell us which of the two parasites is responsible for an infection.

**Introduction**

Extracellular vesicles (EVs) are membrane-bound structures that carry proteins, lipids, and nucleic acids, including mRNAs, miRNAs, and lncRNAs, enabling intercellular communication and gene regulation (Li et al., 2019). They are classified as exosomes, ectosomes, or apoptotic bodies, differing in size and origin. EVs may also mediate the transfer of epigenetic information between somatic and germline cells, potentially influencing inheritance (Spadafora, 2020).

RNA from EVs can be isolated via ultracentrifugation, size-exclusion chromatography, immunoaffinity, or commercial kits. The exoRNeasy™ kit allows simultaneous EV isolation and RNA purification with high purity, reproducibility, minimal degradation, and compatibility with small sample volumes, making it suitable for studies with limited material ((Lobb et al., 2015). While EV research is established in humans and model organisms, studies in teleost fish are emerging, showing EVs in plasma, mucus, and cell cultures with roles in immunity, stress response, and development (Lange et al., 2019; Sun et al., 2017). Standardized protocols are lacking, and preanalytical variables can affect RNA yield and integrity. Optimizing EV-RNA isolation and purification in non-model species is therefore essential for reproducible and reliable studies, which is the main goal of this work. Here we aim to optimize the protocol for RNA extraction from EVs in *Sparus aurata* using the exoRNeasy® kit, evaluating the impact of sample volume and freezing on RNA quality, and validating the presence of lncRNAs for epigenetic studies in aquaculture.

**Material and methods**

Blood from 13 fish of similar size and weight (35,42 ± 1,48 cm; 1,08 ± 0,13 kg) was collected via caudal venipuncture after anaesthesia with butanol chloride (30 ml/100 L) using EDTA-prepared syringe syringes, centrifuged (2500 g, 15 min, 4 °C) to obtain plasma. Plasma was then filtered through 0.8 μm Sartorius Minisart™ NML syringe filters to remove cellular debris and large particles and was either processed immediately after extraction (fresh) or processed after being frozen (-20°C) for two weeks. EVs were isolated from plasma and their RNA purified using the commercial exoRNeasy Kit (QIAGEN, 2019) following the manufacturer's instructions with minor adaptations. Both exoRNeasy Midi and Maxi kits were used, with the Midi kit applied for treatment comparisons (fresh vs -20°C) and the Maxi kit only for sample volume comparisons. the quality of the EVs was assessed by dynamic light scattering (DLS) (Zetasizer Nano ZS, Malvern) and transmission electron microscopy (TEM). RNA concentration and integrity were quantified with Qubit® using RNA HS Assay and TapeStation®, respectively. Nanopore sequencing (MinION) was performed to characterize the lncRNAs. cDNA libraries were prepared with the PCR-cDNA Barcoding Kit 24 (SQK-PCB114-24, ONT). Sequencing reads were aligned to the gilthead sea bream reference genome (fSpaAur1.1, RefSeq 2019) via EPI2ME, normalized by rarefaction, and quantified using GenomicAlignments in R with strict intersection and multimapping assigned to all overlapping genes to enhance sensitivity for low-abundance lncRNAs. Transcript size distributions, RNA biotype proportions, and the lncRNA/mRNA ratio were evaluated.

Statistical analyses were performed in R, using parametric (t-test) or nonparametric tests (Mann–Whitney, permutation, bootstrap) depending on data distribution, and transcript size distributions were compared with Kolmogorov–Smirnov and $\chi^2$ tests.

**Results and Discussion**

Validation of the exoRNeasy kit in gilthead sea bream: The exoRNeasy kit efficiently isolated EVs and purified total RNA, including lncRNAs, from *Sparus aurata* plasma, establishing a reproducible protocol for non-model aquaculture species and representing the first validation of this kit in this species.

Sample volume and yield: No significant differences in RNA yield were observed between the Midi (100–1000 μL) and Maxi (1–4 mL) kit formats, allowing flexibility in sample volume without compromising efficiency.

*(Continued on next page)*

Impact of preprocessing: Although no statistically significant differences were detected, freezing tended to reduce RNA concentration (p=0.01). Further studies with larger sample sizes are needed to confirm these trends. Freezing, significantly affected transcript size distribution transcripts. $\chi^2$ tests using 100 bp and 250 bp intervals revealed highly significant differences across all three subsamples ($p < 0.001$). reducing long transcripts (>800 bp). Results were consistent regardless of interval size, indicating robust transcript size distribution differences.

These findings support the impact of preprocessing on long transcript representation in EV RNA.

EV characterization: Isolated EVs showed variable sizes and typical morphology, with RNA profiles consistent with those commonly observed in EVs.

Detection of lncRNAs in EVs: The presence of lncRNAs was confirmed, identifying 302 distinct transcripts, demonstrating the suitability of the selected protocol for lncRNA detection.

Introduction

Scuticociliatosis is a severe protozoan disease caused by ciliates, posing a significant economic burden on the global aquaculture sector. In Spain, it was first reported in turbot *(Scophthalmus maximus)* by Iglesias et al. (2001), with *Philasterides dicentrarchi* identified as the causative agent. Although *P. dicentrarchi* is considered a facultative parasite, its adaptability, rapid reproduction, and environmental resilience enable efficient spread and colonization, leading to high mortality rates of turbot production in Galicia. It is closely related to *Miamiensis avidus*, a scuticociliate affecting.

Outbreaks are typically associated with elevated seawater temperatures, and climate change is expected to increase both prevalence and geographic range, making *P. dicentrarchi* an emerging pathogen. As developing chemotherapeutic treatments is challenging due to strict regulations and environmental concerns, preventive measures, particularly vaccination, become the most viable approach. An autologous vaccine against scuticociliatosis, developed by CETGA, provides effective protection against the specific strain involved in a given outbreak. However, there is no crossprotection between geographically distinct isolates, such as those from northern and southern Galicia. Identifying conserved antigens across *P. dicentrarchi* strains and understanding their gene regulation could pave the way for broader, more effective disease control strategies. In this study, the transcriptomes of 2 *P. dicentrarchi* isolates from CETGA´s collection, were compared.

Materials and methods

**RNA Isolation and Sequencing**: Samples obtained from *P. dicentrarchi* cultures were mechanically homogenized in a TissueLyser II (Qiagen), and RNA was extracted. RNA quality and quantity were assessed using an Agilent 2100 Bioanalyzer with the RNA 6000 Nano Kit.

**Library Preparation and Sequencing, *de novo* assembly, RNAseq, and bioinformatic analyses** were carried out by AllGenetics & Biology SL (www.allgenetics.eu)".

**Differential expression analysis:** a differential expression analysis was conducted using the Bioconductor packages NOISeq and NOISeqBIO (Tarazona et al., 2013), which allow for the use of data obtained from biological replicates. The probability threshold was set to q = 0. For the differential analysis, only proteins with <1.5 fold change, were considered. Functional analysis with STRING was performed. *Tetrahymena thermophila* database was used as a model to annotate transcripts from *P. dicentrarchi* in STRING: functional protein association networks (https://string- db.org/) (Szklarczyk et al., 2023). STRING was used for searching protein interaction evidence.

STRING settings were based on evidence, with the high confidence (0.700) for interaction score. A minimum number of nodes was added when needed to reach a significant PPI enrichment p-value. Proteins were then grouped into clusters in STRING using the k-means clustering method. Functional analysis was performed including biological process, molecular function and cellular component. Functional analysis was performed separately for upregulated and downregulated genes.

Results

The differential expression analysis of the comparison "Control P6 vs P9" identified a total of 5532 differentially expressed features. Of these, 2827 features were up-regulated and 2705 features were down-regulated in the control P6 group.

*(Continued on next page)*

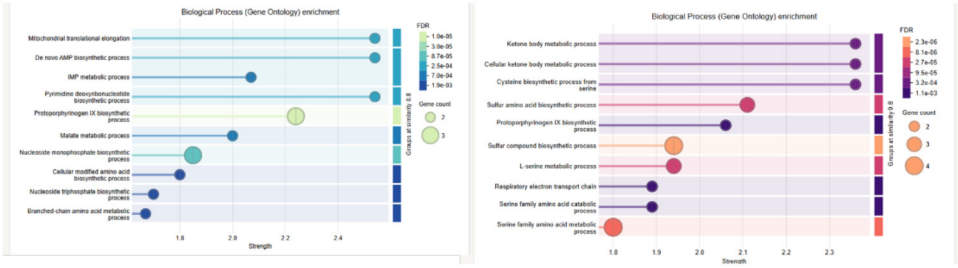

Figure 1: Most representative Biological processes represented in the networks formed by differentially expressed genes (DEGs), for significativelly upregulated (left) and downregulated (right).

Regarding functional analysis with STRING, for the upregulated genes, k-means clustering identified six main functional groups. The most enriched biological processes, with a strength greater than 2.0, included mitochondrial translational elongation, de novo AMP biosynthesis, pyrimidine deoxyribonucleotide biosynthetic process, protoporphyrinogen IX biosynthetic process, IMP metabolic process, and malate metabolic process. Concerning the downregulated genes, the main biological processes involved ketone body metabolism, cysteine biosynthesis, and sulfur amino acid metabolism. In terms of molecular functions, the most notable enrichments included oxidoreductase and oxoacid activities, ribonuclear protein complexes, and mitochondrial-associated processes.

## Conclusion

The functional clustering of upregulated genes suggests that *P. dicentrarchi* responds to infection or environmental stimuli with a marked activation of metabolic and biosynthetic pathways, particularly those involved in nucleotide synthesis, amino acid metabolism, and mitochondrial activity. The enrichment of mitochondrial translational elongation, AMP and pyrimidine biosynthesis, and TCA cycle-related components indicates an increased demand for energy production and macromolecular synthesis, consistent with a proliferative or metabolically active state in the P9 isolate, the more virulent one.

Conversely, the downregulated gene clusters point to a suppression of certain catabolic and structural processes, including branched-chain amino acid degradation, ribosomal structural protein expression, and specific molecular motor functions such as dynein activity. The reduced activity of ribonucleoprotein complexes and translational GTP-binding proteins may reflect a reallocation of cellular resources away from housekeeping functions toward processes critical for survival and adaptation.

Overall, the data reveal a metabolic reprogramming in *P. dicentrarchi*, characterized by the upregulation of biosynthetic and energy-related pathways and the downregulation of components associated with protein degradation, structural maintenance, and motility. This shift likely supports rapid growth, pathogenicity, and adaptation during infection, and highlights potential targets for therapeutic intervention.

## Introduction

The use of bioactive compounds derived from macro- and microalgae in aquafeeds has shown a positive effect on the overall welfare of cultured fish, improving growth performance, digestive function, metabolism, immune status, and stress resilience. Moreover, the inclusion of these bioactive compounds has been associated with enhanced intestinal health and integrity, as evidenced by increased transepithelial electrical resistance and improved apparent epithelial permeability, measured using electrophysiological methods (Caderno *et al*., 2025). Halophyte plants, which grow in highly saline environments, have also emerged as promising sources of bioactive compounds. These species are increasingly recognized as valuable tools in sustainable aquaculture due to their potential to enhance immune response and disease resistance in European seabass (*D. labrax*) (Machado *et al*., 2024). The aim of the present study is to evaluate the effects of various halophyte-derived bioactive extracts on the growth and intestinal health of European seabass by using a preliminary *ex vivo* assessment of the organism's physiological response to each extract to select the most promising for subsequent *in vivo* experiments.

## Materials and methods

This work was structured into three trials involving different electrophysiological techniques, using voltage clamp in Ussing chambers and permeability assays.

Trial 1. An *ex vivo* assay was conducted using juvenile seabass fed a standard commercial diet. Intestinal tissue sections (Anterior Intestine - AI; Mid Intestine - MI; Posterior Intestine - PI) were isolated and mounted on tissue holders to determine the most efficient intestinal region for electrogenic amino acid transport.

Trial 2. MI sections were used for *ex vivo* electrophysiological trials, where seven different halophyte-derived bioactive extracts (FERM, FRAC3, XAD1, XAD2, XAD3, EXT2 and EXT3) were tested at a concentration of 1 mg/mL. The extract showing the most favorable response was selected for further *in vivo* testing.

Trial 3. An *in vivo* feeding trial (30 days) was carried out with juvenile seabass with four different diets: i) Control Diet, without aquafeed supplementation, or supplemented with ii) 0.25% (Diet 1), iii) 0.5% (Diet 2), and iv) 1% (Diet 3) of EXT3, in triplicate. After the feeding period, MI sections were collected from 12 individuals per treatment and electrophysiological techniques were used to evaluate intestinal health and integrity by means of tissue resistance, amino acid transport, and apparent permeability.

## Results and discussion

Preliminary *ex vivo* assays using different intestinal sections revealed that the MI exhibited significantly higher electrogenic amino acid transport compared to both AI and PI sections. As a result, the MI was selected for all subsequent analyses. This finding suggests that the MI is the primary region for nutrient absorption, consistent with previous work by Fuentes *et al*. (2025). Based on this, different halophyte-derived bioactive extracts were tested on MI sections to identify the most effective compound, where EXT3 was ultimately selected as the most promising extract for the *in vivo* feeding trial.

*(Continued on next page)*

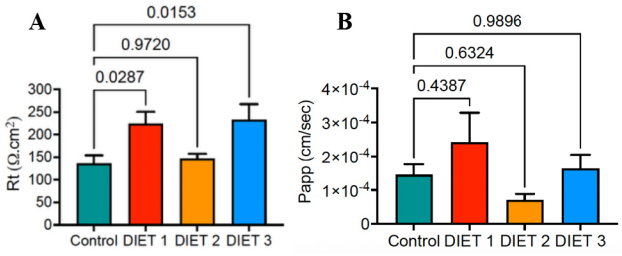

**Figure 1**. Effect of different diets: A) on intestinal tissue resistance (Rt, Ω $cm^{-2}$), B) on intestinal apparent permeability (Papp, cm/sec). Control: Commercial diet; Diet 1, 2 and 3: Experimental diets with 0.25%, 0.5% and 1% EXT3 inclusion respectively. Each column represents the average ± SEM (n = 12). Statistics among dietary treatments were based on one-way ANOVA followed by Tukey's post-hoc test, indicating significant differences between experimental groups.

After one month of feeding seabass with either a control or three experimental diets, no significant differences in growth performance were observed. However, all experimental diets enhanced amino acid transport in intestinal tissues, with the highest increase observed in DIET3 (1% EXT3). Regarding intestinal integrity, epithelial resistance (Rt) was significantly higher in DIET1 and DIET3 (Fig. 1A), which was consistent with the same (although no significantly different) pattern observed for apparent permeability (Papp, Fig. 1B). These results are indicative of a putative improvement of intestinal functioning after a short-feeding period of this tested compound.

**Conclusions**

The seabass mid intestine (MI) exhibited the highest electrogenic amino acid transport activity, confirming it as the primary site for nutrient absorption and the most suitable region for *ex vivo* electrophysiological assessments. In addition to that, among the halophyte-derived bioactive extracts tested, EXT3 demonstrated the most favorable effects on intestinal function to be used for *in vivo* validation. Even so, although no significant differences in growth performance were observed after 30 days of feeding, all diets containing EXT3 improved amino acid transport across the intestinal epithelium, with the highest and most positive effect seen in the diet containing 1% EXT3 (DIET3).

## Introduction

In the context of a more sustainable and environmentally friendly aquaculture, there is a growing interest in incorporating non-conventional feed ingredients that provide essential nutrients and bioactive compounds beneficial to fish health and welfare. Among these compounds, grape marc polyphenols stand out for their antioxidant, immunostimulant and anti-stress properties. These attributes contribute to enhancing the overall health status of fish, improving their resistance to pathogens, and reducing the reliance on antibiotics and chemical additives. Consequently, grape marc polyphenols represent a promising natural alternative for improving both the quality and sustainability of aquaculture production (Martínez-Antequera, 2023).

## Materials and methods

In order to evaluate the effect of Albariño grape marc (*Vitis vinifera*) extract inclusion in the diet of juvenile greater amberjack (*Seriola dumerili*), three experimental diets were formulated: a control diet, corresponding to a standard commercial formulation for this species, and two additional diets supplemented with 750 and 1500 ppm of Albariño grape marc extract (i-Grape grape extract® 500 mL, i-Grape Laboratories, Santiago de Compostela, Spain), respectively. The experiment was conducted in triplicate. During the experimental feeding period (77 days), fish were fed *ad libitum* 6 days per week, with four daily meals (9:00 am, 12:00 pm, 15:00 and 18:00 pm). In addition to the initial and final samplings, two intermediate biometric samplings were carried out during the trial. At the end of the feeding trial, four animals per tank were anaesthetised with a lethal dose of 2-phenoxyethanol and blood, liver and muscle samples were taken for further analysis. In addition, intestinal tissue samples were also taken for *ex vivo* testing using electrophysiological techniques to observe the effect of different diets on intestinal health and integrity through resistance (Rt), active net transport capacity ($I_{sc}$) and apparent tissue permeability (Papp).

## Results and discussion

Although no significant differences in growth or feed conversion ratio (FCR) were observed, fish fed the diet supplemented with 1500 ppm of grape marc extract showed a clear trend toward greater growth and reduced feed intake. It is likely that, with a longer trial period, the diet with the highest polyphenol concentration (1500 ppm) would have resulted in a significantly improved growth and feed efficiency, thus enhancing sustainability and cost-effectiveness. Moreover, the protein efficiency ratio (PER) showed a dose-dependent increase, being highest with the 1500 ppm diet, suggesting better protein utilization. In addition to that, polyphenols can influence lipid metabolism (Lizárraga & Hernández, 2018). In our study, fish fed the 750 ppm diet showed greater fat mobilization, with higher plasma triglyceride (TAG) levels (Fig. 1A). This diet also appears to reduce stress, as indicated by lower cortisol levels (Fig. 1B), likely due to its antioxidant and anti-inflammatory properties. Furthermore, hepatic cholesterol levels (Fig. 1C) decreased with increasing dietary polyphenol content, potentially aiding in the prevention of fatty liver and improve the use of fats as an energy source. These effects are attributed to the capacity of polyphenols to mitigate oxidative damage and inflammation, thereby preventing hepatic lipid accumulation and supporting a more balanced metabolism (Lizárraga-Velázquez *et al.,* 2018).

*(Continued on next page)*

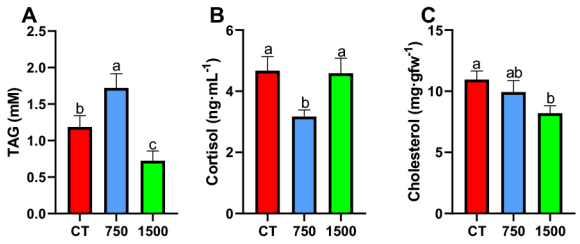

**Figure 1**. Results of plasmatic and hepatic metabolites. A) Plasma triglycerides (TAG), B) Plasma cortisol and C) Hepatic cholesterol in *S. dumerili* with different experimental diets (mean ± SEM, n=12). Different letters indicate significant differences among dietary treatments based on one-way ANOVA followed by Tukey's post hoc test ($p < 0.05$).

Regarding the results obtained through electrophysiological measurements in intestinal tissue, we observed that none of the diets altered the epithelial barrier function or resistance. On the other hand, both diets supplemented with polyphenols induced a modification in the active net transport capacity of the intestine. Finally, the apparent permeability values were significantly lower in the diet with 750 ppm compared to both the control diet and 1500 ppm groups, suggesting a modification in intestine configuration.

## Conclusions

Although growth performance and feed conversion were not significantly affected within the trial duration, fish fed the highest marc grape polyphenol dose (1500 ppm) showed trends toward improved growth, reduced feed intake, and significantly enhanced protein efficiency ratio and condition factor, indicating better nutrient utilization and welfare. 750 ppm diet appears to preserve a greater integrity and functionality of the intestinal epithelium, as it does not show altered resistance values but does exhibit lower apparent permeability compared to the other diets. Moreover, the 750 ppm diet led to more efficient lipid metabolism, as evidenced by higher plasma TAG, lower cortisol, and reduced hepatic cholesterol levels. These results suggest that dietary polyphenols can promote metabolic balance, reduce oxidative stress, and improve feed utilization, thus offering a promising functional strategy to enhance sustainability in aquaculture systems.

# HARNESSING THE POWER OF PROBIOTICS: PREVENTING AND CONTROLLING INFECTIOUS DISEASES IN ATLANTIC SALMON AQUACULTURE

Valentina Romboli[1], Fotini Kokou[2], Detmer Sipkema[1]

[1]Laboratory of Microbiology, Wageningen University and Research, 6708WE Wageningen, The Netherlands
[2]Aquaculture and Fisheries Group, Department of Animal Sciences, Wageningen University and Research, 6700AH Wageningen, The Netherlands
Email: valentina.romboli@wur.nl

Infectious diseases remain a persistent and costly challenge in Atlantic salmon (*Salmo salar*) aquaculture, contributing to mortality rates, compromised animal welfare, and economic losses. Central to the first line of defense of the host are mucosal surfaces which are the gills, skin, and gut, serving as a critical immunological interface with the external environment. These barriers are not only sites of pathogen entry but also hubs of complex host-microbiota-pathogen interactions that can determine infection outcomes. Consequently, strategies that modulate mucosal microbiota, such as probiotic administration, have gained growing attention. This study critically examined the current body of evidence on the microbiota composition in healthy salmon and modulation via the application of probiotics to reinforce mucosal barrier function and microbiome resilience in salmon. Probiotic strains, including *Pediococcus acidilactici*, *Carnobacterium* spp., and *Lactococcus lactis*, have demonstrated protective effects through competitive exclusion, enhancement of innate immunity, and reduction of pathogen load in challenge experiments. However, findings across studies often diverge due to strain-dependent effects and lack of consistency in experimental designs, highlighting a need for more harmonised methodologies. A significant bottleneck in the field is the limited and inconsistent use of microbial profiling tools such as 16S rRNA gene amplicon sequencing, making cross-study comparisons difficult and potentially hindering progress toward evidence-based probiotic application. Despite promising results, significant knowledge gaps remain regarding the mechanisms of action, host-microbe interactions, long-term impacts, and the lack of standardised protocols for probiotic research in salmon. Addressing these gaps will be essential for developing robust, evidence-based probiotic interventions for disease management in Atlantic salmon farming.

# ROLE OF THE INTESTINAL MICROBIOTA IN WEIGHT AND PRODUCTIVE PERFORMANCE OF RAINBOW TROUT (*Oncorhynchus mykiss)*

## Introduction

The intestinal microbiota constitutes a central regulator of host metabolism, influencing nutrient digestion, energy balance, and lipid deposition. Several studies in poultry, pigs, and fish have demonstrated that changes in microbial composition or activity impact growth performance, with short-chain fatty acids (SCFAs) such as acetate, propionate, and butyrate acting as additional energy sources and modulators of lipid metabolism (Yao et al., 2024; Shi et al., 2025). These microbial functions enhance nutrient utilization and contribute directly to weight gain, a parameter of high commercial importance in animal production systems.

Despite these advances, most research has focused on indirect modulation of the microbiota through diet, probiotics, or environmental conditions, rather than by direct disruption. To address this gap, we applied a strategy based on the administration of non-absorbable antibiotics (neomycin and bacitracin) to selectively disturb the intestinal microbiota of rainbow trout (*Oncorhynchus mykiss*). This approach enabled us to evaluate more specifically the role of the microbiota in host growth and productive performance, providing insights into the metabolic contribution of intestinal bacteria in aquaculture species.

## Materials and Methods

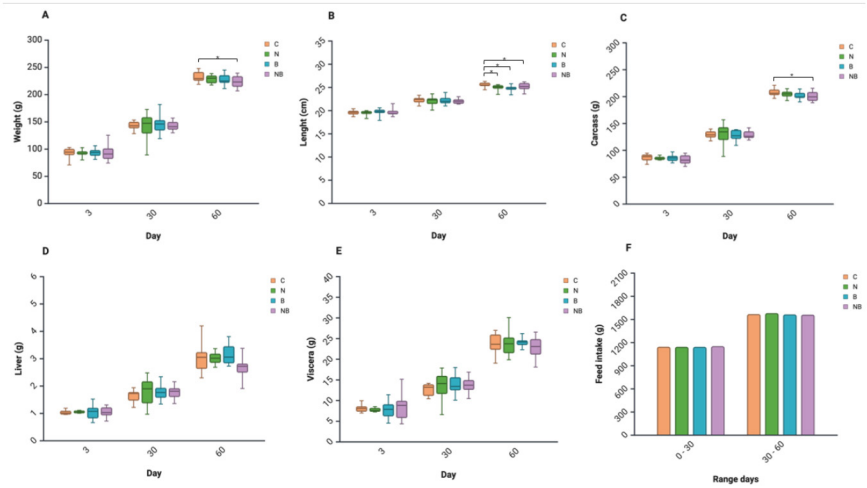
The trial was conducted at the Aquaculture Center, Faculty of Agronomy, University of Chile, using rainbow trout (*Oncorhynchus mykiss*) with an initial mean weight of ~70 g. After two weeks of acclimation in 400 L tanks within a recirculating aquaculture system (RAS, 15°C), 340 fish were distributed into four experimental conditions (Neomycin, Bacitracin, Neomycin+Bacitracin, Control) with two replicates per group (40 fish/tank). Fish were fed a commercial diet at 1.5% BW throughout the trial. Antibiotics were administered via force feeding at 100 mg/kg BW, a dose previously validated to reduce cultivable microbiota without affecting biofilter performance. Sampling was carried out at days 3, 30, and 60 post-treatment, with 14 fish per condition anesthetized, weighed, measured, and blood-sampled prior to euthanasia. Tissues collected included viscera, liver, muscle, and intestinal content/mucosa, which were stored at –20°C or –80°C depending on downstream analysis.

Biometric indices (VSI, HSI, CF) and productive parameters (WG, SGR, FCR) were calculated using standard formulas from individual and tank-level data. Statistical analyses were performed in RStudio; normality and homogeneity were tested (Shapiro–Wilk, Levene), and pairwise comparisons with the control were evaluated using t-test, Welch, or Wilcoxon tests as appropriate. Figures were generated with the ggplot2 package.

## Results

At 60 days post-treatment, fish in the NB group showed significantly lower body weight and carcass weight compared to the control, while groups N and B did not differ from C. Body length was also greater in the control group than in all antibiotic-treated groups at this time point. No significant differences were detected in liver or viscera weight across treatments. Regarding productive indices, feed conversion ratio (FCR) did not differ among groups, whereas the specific growth rate (SGR) was significantly reduced in NB compared to the control. Importantly, feed intake remained similar across treatments, suggesting that the lower growth observed in NB fish was not related to reduced consumption but rather to alterations in nutrient utilization efficiency.

*(Continued on next page)*



**Discussion**

The combined treatment with neomycin and bacitracin (NB) significantly reduced body weight, carcass weight, and specific growth rate (SGR) compared to the control, while individual antibiotic treatments (N, B) did not show these effects. This suggests that the simultaneous targeting of Gram-negative and Gram-positive bacteria caused a broader disruption of the intestinal microbiota, impairing microbial functions linked to nutrient utilization and energy metabolism. In mammals, Nemoto et al. (2023) reported that germ-free mice showed lower body weight than conventional counterparts despite equal food intake, largely due to reduced lipid deposition. A similar mechanism may explain our findings, as disruption of the microbiota in trout could compromise lipid metabolism, limiting energy storage and consequently growth performance.

The decrease in carcass weight indicates that the negative impact of NB was expressed mainly as reduced somatic growth rather than changes in visceral or hepatic mass, since liver and viscera weights did not differ among treatments. Thus, the observed reduction in growth and SGR may reflect not only diminished nutrient absorption efficiency but also an altered balance of lipid metabolism, resulting in lower deposition of energy reserves in muscle tissue. Together, these results reinforce the role of the intestinal microbiota in supporting both energy harvest and lipid storage, processes that are critical for productive performance in aquaculture species.

# NUCLEAR ESTROGEN RECEPTORS OF EUROPEAN SEA BASS (DICENTRARCHUS LABRAX) AS TARGETS OF ENDOCRINE DISRUPTING COMPOUNDS: EFFECTS ON REPRODUCTION AND RISK ASSESSMENT POTENTIAL

J. Romero[1]*, G. Molés[2], P.I.S. Pinto[3], D.M. Power[3], A. Gómez[1] and C. Zapater[1]

[1]Instituto Acuicultura de Torre de la Sal, CSIC, Spain
[2]Centro Interdisciplinar de Investigação Marinha e Ambiental, Portugal
[3]Centro de Ciências do Mar, Universidade do Algarve, Portugal
E-mail: julen.romero@csic.es

**Introduction**

Estrogens are involved in the regulation of a wide range of processes in teleost reproduction (Lubzens et al, 2010; Schulz et al, 2010) and exert their functions mainly through ligand-activation of their specific cognate receptors. Two main classes of estrogen receptors have been reported in vertebrates: membrane-associated estrogen receptors (GPER), which are G-protein coupled receptors that mediate rapid nongenomic actions through intracellular signaling pathways (Filardo et al, 2012), and nuclear estrogen receptors (ESR), transcription factors that bind to estrogen response elements (EREs) on gene promoters to regulate their expression. (Tsai et al, 1994). Three Esr subtypes have been identified in most teleost species, Esr1, Esr2a (also named Esr***β***1 or Esr***β***a), and Esr2b (also named Esr***β***2 or Esr***β***b), of which Esr2a and Esr2b coding genes arose from the whole genome duplication event specific of the teleost lineage. Differences in binding affinity and seasonal expression patterns in reproductive tissues among estrogen receptor subtypes suggest different roles during gametogenesis along the brain-pituitary-gonad axis. Endocrine-disrupting compounds (EDCs) are known to act as agonists or antagonists of steroid receptor functions and interfere in the production of the receptors themselves. Thus, many different points in the endocrine control of fish reproduction can be potential targets for the actions of EDCs. In aquaculture, the presence of estrogenic compounds is a concern, both in water and in newly formulated commercial fish diets (Arpin-Pont et al, 2016; Nacher-Mestre et al, 2013;). This study aimed to investigate the role of the three nuclear estrogen receptor subtypes in European sea bass, assess the impact of endocrine-disrupting compounds on nuclear estrogen receptors using transactivation assays, generate *in vitro* stable clones, and evaluate their potential as bioassays tools for risk assessment.

**Material and Methods**

To investigate the role of the three nuclear estrogen receptors subtypes in European sea bass, analysis of the expression of their coding genes during a whole reproductive cycle was investigated by qPCR in testis, ovary and pituitary. Localization of the nuclear estrogen receptors along the brain-pituitary-gonad axis was performed by immunohistochemistry using specific antibodies for each subtype.

Using transactivation of an ERE-luciferase reporter gene assay, transient transfection was conducted in human embryonic kidney cell line (HEK293), to functionally characterize the three sea bass nuclear estrogen receptors. The effect of two possible EDCs, genistein – a phytoestrogen also present in fish meals – and fluoxetine – an antidepressant, mainly constituent of Prozac- were assessed across all Esr subtypes.

Based on results from transient transactivation assays, stable HEK293 clones expressing each Esr subtype were generated using antibiotic selection with G418 and Hygromycin. Clones were screened by treatments with $10^{-8}$ M 17β-estradiol ($E_2$), using ethanol as vehicle control. The most responsive clones were expanded and cryopreserved. Subsequent transactivation assays using $E_2$ concentrations ranging from $10^{-5}$ M to $10^{-10}$ M were performed to determine the $EC_{50}$ (half-maximal effective concentration) and $E_{max}$ (the maximum response) values for each sea bass Esr subtype. Finally, to evaluate the potential of these stable clones as *in vitro* bioassay tools for EDCs risk assessment, environmental and biologically relevant samples (water, fish feed) were tested.

**Results**

The coding genes of the three nuclear estrogen receptor subtypes of sea bass are highly expressed in reproductive-related tissues such as pituitary and gonad. Quantitative analysis of *esr1*, *esr2a* and *esr2b* expression in the gonad and pituitary across the reproductive cycle revealed subtype and stage-specific expression patterns. Immunohistochemical localization along the pituitary-gonad axis confirmed differences among receptor subtypes depending on the gonadal stage.

*(Continued on next page)*

Functional characterization using an ERE-luciferase reporter assay demonstrated distinct ligand affinities among the Esr subtypes, which translated into differential transactivation responses to the EDCs genistein and fluoxetine.

Furthermore, stable HEK293 clones expressing each sea bass Esr subtype were successfully generated and validated using dose-responses assays with $E_2$ as natural ligand. Values for EC50 and Emax align with previous activations in transient transfections. Finally, the effect of different environmental and biological relevant samples on Esr subtypes confirm the reliability of these stable cell lines as *in vitro* bioassay tools for detecting and evaluating the activity of potential EDCs.

**Conclusion**

These findings indicate that the three nuclear estrogen receptors in European sea bass have non-redundant, subtype-specific roles in the regulation of gametogenesis. Consequently, exposure to EDCs—whether present in water or newly commercial fish feeds—may disrupt reproductive processes. Moreover, the development of stable Esr-expressing HEK293 clones offers a potential *in vitro* bioassay platform for the detection and risk assessment of EDCs in environmental and biological samples, with particular relevance to marine aquaculture.

The integration of offshore aquaculture with marine renewable energy platforms requires structural materials that minimize biofouling to ensure water exchange, reduce maintenance costs, and safeguard fish welfare. This study evaluated the colonization dynamics of marine biota on copper-alloy netting and conventional nylon netting, deployed simultaneously under identical environmental conditions at the Port of Taliarte (Gran Canaria, Spain).

Net panels (50×50 cm; n=3 per material and sampling) were mounted alternately on a submerged frame at 1.5–3 m depth, south-facing, and monitored over 89 days. Sampling at days 0, 28, 57, and 89 included wet and dry biofouling biomass, taxonomic identification, and percentage cover analysis using ImageJ-Fiji. Environmental parameters (temperature, dissolved oxygen) were recorded throughout.

Copper nets showed no detectable biofouling at day 28, while nylon nets reached 4.5 g dry weight (0.0018 g/cm²). At day 89, mean biofouling biomass was 12.38 g (0.0050 g/cm²) on copper and 15.57 g (0.0062 g/cm²) on nylon. Maximum surface coverage reached 1.20% at day 89 on copper versus 4.74% on nylon. *Cladophoropsis membranacea* was the dominant alga on both materials, but *Ellisolandia elongata* and *Neogoniolithon orotavicum* showed a clear preference for nylon. Amphipods, particularly *Ericthonius punctatus*, dominated the faunal assemblage, with sporadic decapods (*Natantia*) detected on nylon.

Temperature increases coincided with higher biomass growth, while oxygen effects were non-linear, peaking at ~7.8 mL/L. Copper nets maintained lower colonization rates and mesh permeability for longer periods, suggesting reduced cleaning frequency, lower operational costs, and decreased pathogen risk.

The results confirm that copper-alloy netting effectively delays early biofouling settlement compared to nylon under the same offshore conditions, supporting its potential application in integrated aquaculture–renewable energy platforms. Multi-season trials are recommended to assess long-term durability, seasonal variability, and economic feasibility at commercial scale.

Offshore aquaculture is expanding through technologies that enable large-scale, sustainable fish farming. Within the *AquaWind* project, we compared a prototype cage, designed for integration with offshore renewable energy platforms, with a conventional commercial cage. The prototype featured a copper alloy net and remote monitoring systems, and was tested with gilthead seabream (*Sparus aurata*) in two consecutive trials.
In the first 42-day trial, fish were juveniles with an initial mean weight of 33.60 ± 12.51 g. Survival was 83.7% in the prototype versus 94.0% in the control, with lower specific growth rate (SGR 1.42% day$^{-1}$ vs. 2.04% day$^{-1}$) and reduced lipid reserves. These results were linked to operational noise, suboptimal manual feed supply, and a *lymphocystis* disease (LCD) outbreak confirmed histologically, which impaired condition and increased plasma stress markers.

The second 64-day trial (7 March to 9 May) involved adults in the final grow-out phase (initial mean weight 557.10 ± 110.50 g). Survival exceeded 96% in both cages, with no significant differences in growth (SGR ≈ 0.30% day$^{-1}$) or biochemical parameters. The lower SGR reflects the limited growth potential at this production stage. Achieving equivalent production performance in both cages demonstrates that the optimized feeding and husbandry —enabled by an remoted controlled and automated feeding system in the prototype cage to replicate commercial practices— can overcome earlier performance gaps. The copper alloy net effectively reduced biofouling, lowering maintenance needs.

These findings confirm the feasibility of automated, remotely operated offshore aquaculture to be integrated with renewable energy prototype, and highlight the importance of cage design and feeding strategies to ensure fish welfare and production efficiency across different life stages.

# ACUTE PHYSIOLOGICAL RESPONSES OF RAINBOW TROUT TO THREE ELECTROFISHING DEVICES: A LABORATORY STUDY

Jonathan Roques*, Mahibul Islam, Lise Brault, Magnus Lovén Wallerius, Johan Höjesjö

Department of Biological and Environmental Sciences
University of Gothenburg
Gothenburg 413 90, Sweden
Jonathan.roques@bioenv.gu.se

Electrofishing has been used widely as a standardized sampling technique for assessing density of fish. Although primarily used in fisheries and ecological studies, it could also play important roles in aquaculture practices such as for wild broodstock capture or the monitoring of stocked fish populations. However, the complex and dynamic impact of electricity on fish health and welfare still remain poorly understood.

In this laboratory-study, we investigated the effect of three electrofishing devices: LR-20 (Smith-Root), L-600 (Lug AB) and FA-50 (Terik Technology) on the acute stress response of rainbow trout (*Onchorynchus mykiss*). Forty to forty-six fish with an initial weight of 220 g were distributed into four circular 400 L tanks. Three tanks were exposed to the same protocol, 10 sec electrical pulse, followed by 5 sec of rest and then a second 10 sec period of electrical pulse. Ten fish from each treatment were sampled for blood and plasma at 0, 1, 6 and 24 h post exposure. A fourth tank served as undisturbed control, sampled at the same time points. After 6 h, fish showing difficulties swimming and balance issues were euthanized.

Our results show that the different electrofishing devices impacted the primary and secondary stress response differently. Overall, the LR-20 seemed to induce the lowest acute stress response. Two fish died and one fish was euthanized after 6 h in this group while six fish were euthanized with the L-600. No fish survived past 6 h with the FA-50, with 11 dead and four fish euthanized. The cortisol peaked between 1 and 6 h in all the experimental groups, with the LR-20 displaying the lowest levels (ca. 45 ng/mL) at both time points, while the FA-50 peaked at over 100 ng/mL. Both LR-20 and L-600 cortisol levels were back to basal levels after 24 h (Fig 1a). Glucose levels showed a similar pattern (Fig 1b), with an initial increase already after 1h for the L-600 and the FA-50, while the RT-20 was only significantly higher than the control after 6 h. There was no difference between the RT-20 and the L-600 for this parameter. Plasma osmolality, blood hemoglobin, hematocrit, and MCHC also indicated a mild transient stress effect, most pronounced in fish exposed to the FA-50. These more severe effects may be related to the type of electrical current used by the FA-50 (AC) known to cause more extensive neuromuscular disruption compared to pulsed DC used by the LR-20 and L-600.

Further studies are needed to assess potential long-term and indirect effects, including impacts on growth, skin integrity, and pigmentation. Additional field-based comparisons are also warranted in order to validate the results generated from different electrofishing gears.

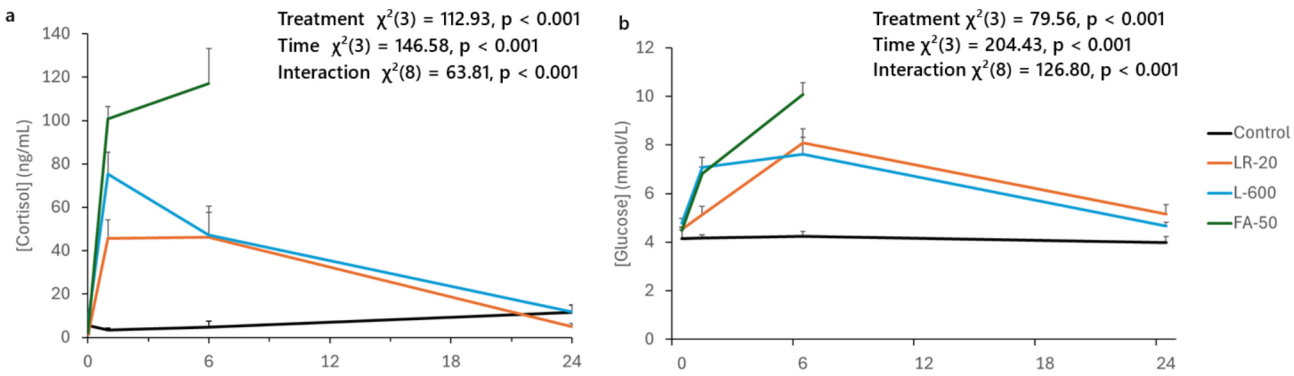

**Figure 1.** Means (± SEM) of the plasma cortisol (a) and glucose (b) of rainbow trout 0, 1, 6 and 24 h after electrofishing. Different letters indicate statistically significant differences between treatments (GLM, Wald Chi-square tests).

# ADVANCING CELLULAR AQUACULTURE BY ESTABLISHING MEAGRE *Argyrosomus regius* CELL LINES AND DEVELOPING A CIRCULAR BIOPROCESS USING MICROALGAE

## Introduction

The global collapse of some fisheries and ongoing challenges in aquaculture highlight the urgent need for alternative sources of marine animal proteins. Cellular aquaculture - the production of these proteins from cells rather than whole animals - offers a sustainable and ethical solution to mitigate seafood shortages by reducing natural resource use and environmental impact. However, key challenges remain, particularly the development of robust marine animal cell lines, the formulation of animal-free culture media, and the reduction/upcycling of waste effluents through circular cultivation systems.

## Results

To address the scarcity of marine animal cell lines, we established and characterized lines from the meagre *Argyrosomus regius*, a commercially valuable species with limited aquaculture production. Cells were obtained from explant cultures of vertebra (VAR3), branchial arch (BAAR1) and jaw (JAR5) tissues using established protocols and propagated in Leibovitz's L-15 medium supplemented with 10% fetal bovine serum (FBS). Cultures were maintained for over 100 passages. Growth of spontaneously immortalized lines (>60 passages) was optimized by reducing serum concentrations and adjusting incubation temperatures. Growth curves, population doubling times (PDT), biomass yield, and differentiation potential into myogenic and adipogenic lineages were evaluated, and preliminary results indicate reduced FBS requirements without compromising growth, enhanced proliferation at 33°C, with observed PDTs of 11.1 ± 0.5 h for VAR3, 25.2 ± 0.5 h for BAAR1, and 19.9 ± 0.7 h for JAR5, and successful lipid accumulation throughout adipogenic differentiation (Figure 1).

To enhance the sustainability of cellular aquaculture, we developed a circular bioprocess that integrates microalgae into the cell culture system. This approach addresses two major limitations: the dependence on animal-derived components and the generation of nutrient-rich waste. First, we evaluated the use of a microalgae-derived serum (MS) as a functional substitute for fetal bovine serum (FBS) in culture media. Results demonstrated that fish (MS4 and MS5; Figure 2A) and mammalian (MS3; Figure 2B) cell lines maintained comparable proliferation rates with up to 75% and 99.6% replacement of FBS by MS, respectively. These findings highlight the potential of microalgal-derived nutrients to effectively supply essential growth-supporting factors

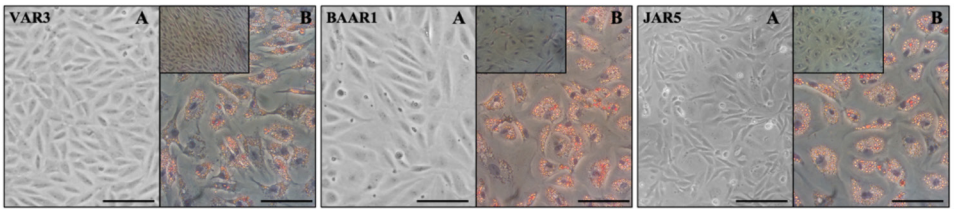

**Figure 1. Characterization of meagre cell lines derived from vertebra (VAR3), branchial arches (BAAR1) and jaw (JAR5).** (A) Phase-contrast images of proliferating cells in culture. (B) Adipogenic differentiation assessed by Oil Red O staining; lipid droplets appear in red. Insets show undifferentiated control cells. Scale bars: 100 µm.

*(Continued on next page)*

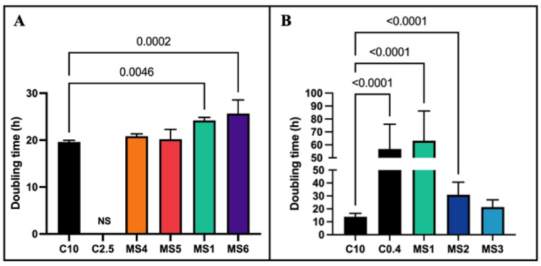

**Figure 2. Effect of microalgae serum (MS) on the proliferation of fish (A) and mammalian (B) cell lines.** Graphs show the population doubling times of cells cultured in medium supplemented with either FBS or MS. C10: medium with 10% FBS; C2.5 / C0.4: media with 2.5% or 0.4% FBS. MS1–MS6: media with different MS formulations. P-values (unpaired t-test) indicate significant differences between C10 and experimental conditions. NS: no cell survival.

**Table 1. Bioremediation of cell culture effluents using microalgae.** Ammonia, nitrate/nitrite and phosphates concentrations in the spent cell media before and after microalgal cultivation. Superscript letters denote statistically significant differences between pre- and post-bioremediation values (a = $p < 0.05$; b = $p < 0.001$).

| | Before bioremediation | After bioremediation | % of reduction |
|---|---|---|---|
| **Ammonia (mmol/L)** | 1.948 ± 0.012 | 0.356 ± 0.411[a] | 81.72% |
| **Nitrates/nitrites (mmol/L)** | 0.024 ± 0.002 | 0.007 ± 0.001[a] | 70.83% |
| **Phosphates (mmol/L)** | 0.902 ± 0.004 | 0.353 ± 0.125[b] | 60.86% |

Then, we explored the potential of spent cell culture medium as a substrate for microalgae cultivation. Microalgae cultured in spent medium exhibited significantly enhanced growth, achieving a final dry weight of 2.468 ± 0.413 mg/mL by day 7, compared to 0.915 ± 0.436 mg/mL in control medium. Moreover, microalgae grown in spent medium displayed a significantly higher nitrogen content (6.03 ± 2.73%) than those in control medium (1.82 ± 0.25%). Cultivation in spent medium also resulted in substantial reductions in residual nutrients - including ammonia, nitrites/nitrates, and phosphates -indicating efficient nutrient uptake and bioremediation (Table 1). These findings underscore the capacity of microalgae to valorize nutrient-rich effluents and contribute to the sustainable recycling of cell culture medium waste.

## Conclusion

Our results demonstrate the feasibility of combining marine animal cell culture with microalgal systems to foster a circular, zero-waste model for cellular aquaculture. Together, the establishment of robust meagre cell lines and the integration of microalgae-based bioprocessing lay the foundation for a scalable, ethical, and resource-efficient platform for the production of cultivated seafood.

## Introduction

Biochar is a carbon-rich material synthetized by the pyrolysis of biomass under oxygen-poor atmosphere. Among its many potential applications, its inclusion as a feed additive in aquaculture has gained attention due to promising results. Its porous structure and strong adsorption capacity have been associated with improved nutrient uptake, which may enhance feed utilization and promote better overall fish health (Amjad et al., 2024). The retention capacity could help trap nitrogenous compounds, thereby reducing their concentration in the water (Khalid et al., 2024). In addition to its functional advantages, using biochar derived from wood waste supports circular economy strategies, encouraging more sustainable production practices and potentially lowering the reliance on conventional ingredients like fish meal and fish oil. Within this framework, the aim of the present study was to assess the metabolic impact of dietary biochar supplementation in Senegalese sole (*Solea senegalensis*), focusing on an inclusion level that maintains growth and health.

## Material and methods

The biochar was produced on an industrial scale through the carbonization of plum (*Prunus domestica*) residues at around 450 °C.

A total of 270 Senegalese sole (*Solea senegalensis*) (initial mean body weight ~65 g) were randomly distributed into 9 tanks (30 fish per tank, in triplicate), ensuring similar initial biomass. Fish were fed three times daily with a ration equivalent to 1% of the estimated tank biomass (adjusted weekly), using three experimental diets: i) control, ii) supplemented with 0.25 % biochar, and iii) supplemented with 0.50 % biochar. The sole were reared for 84 days at the facilities of the Central Marine Culture Research Service of the University of Cádiz.

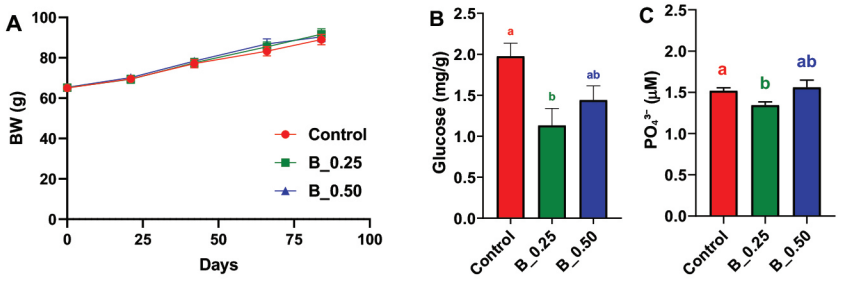

**Fig.1: A)** body weight (BW); **B)** muscle glucose and **C)** water $PO_4^{3-}$ levels at the end of the trial.

*(Continued on next page)*

During the initial sampling, all fish were chipped to allow individual growth monitoring, adding robustness to the dataset. Intermediate biometric samplings were conducted every 21 days to track growth evolution. Water samples were collected over 5 consecutive days at 2 time points: one prior to feeding (low nitrogen compounds levels) and another 9 h after the first intake (high nitrogen compounds levels). At the end of the feeding trial, biometric data were recorded, and plasma, liver, and muscle samples were collected. Somatic indexes were calculated, and cortisol and metabolite levels from each tissue were analysed, along with the determination of phosphate, silicate and nitrogenous compounds in water samples.

**Results and discussion**

The inclusion of biochar at 0.25–0.50% did not impair overall growth performance of Senegalense sole (Figure 1A). However, a significant improvement in SGR was observed during the third period at 0.25%, along with positive trends in final BW, and overall SGR and FCR. ILI and HSI also tended to decrease, particularly with 0.25%. The shortening of the intestine may result from improved absorptive efficiency, induced by biochar, while the reduction in liver size could reflect greater metabolic optimization.

Although plasma and liver metabolites showed no significant changes, some trends were observed. Hepatic glycogen and glucose levels appeared to decrease, possibly due to their use in *de novo lipogenesis* for TAG synthesis, which tended to increase in both liver and plasma. Alternatively, these reductions, along with the slight decrease in plasma protein levels, may reflect increased metabolic demands in muscle, where significant decreases in energy-related metabolites (e.g. glucose Figure 1B) were found, potentially supporting enhanced growth. This effect was most evident with the 0.25% diet, which recorded the highest final BW, yet not statistically significant. Cholesterol levels remained unchanged in plasma and liver but increased significantly in muscle with 0.50% biochar, possibly reflecting membrane remodelling or shifts in lipid composition. Plasma lactate slightly increased with 0.25% biochar, likely due to greater muscle activity. Cortisol levels also showed a modest increase, possibly related to physiological adaptations such as intestinal shortening. However, both parameters remained below stress-indicative thresholds, suggesting only mild physiological adjustments.

Finally, the significant reduction in $PO_4^{3-}$ (Figure 1C) and downward trends in $NH_4^+$ and $SiO_2$ levels in water of specimens fed the experimental diets points to potential environmental advantages of incorporating biochar.

Short-term inclusion of biochar appears to induce promising functional effects, particularly at 0.25% supplementation. Longer trials are required to explore the implications not only in microbiota and enzymatic activity, but also its interaction with other additives such as microalgae.

# HARNESSING POSTBIOTICS FOR SUSTAINABLE HEALTH MANAGEMENT IN SHRIMP AQUACULTURE

Roy Rosen[1]*, Ester Santigosa[2], and Philippe Tacon[3]

[1] dsm-firmenich, Animal Nutrition and Health R&D Center, Tulln an der Donau, Austria
[2] dsm-firmenich Nutritional Products, Kaiseraugst, Switzerland

Email: Roy.rosen@dsm-firmenich.com

Shrimp aquaculture, a rapidly expanding sector of global seafood production, faces critical challenges related to disease outbreaks, antibiotic overuse, and environmental sustainability. Postbiotics—non-viable microbial cells, metabolites, and cell components conferring health benefits—have emerged as a promising alternative to traditional antimicrobials and probiotics. Unlike probiotics, postbiotics offer enhanced stability during feed processing and storage and pose no risk of horizontal gene transfer or uncontrolled microbial proliferation in the aquatic environment.

Two recent studies were conducted to evaluate the efficacy of dietary postbiotics in improving shrimp (*Litopenaeus vannamei*) resilience under Early Mortality Syndrome (EMS) and White Spot Syndrome Virus (WSSV) challenges, including exposure to salinity stress. In both trials, shrimp were fed a basal diet supplemented with postbiotics and assessed following pathogen exposure under controlled experimental conditions.

Postbiotic-fed groups showed significantly higher survival rates and improved outcomes under both EMS and WSSV challenge models. In the EMS trial, reduced mortality and better intestinal and hepatopancreatic condition were observed. Under WSSV and salinity challenge, shrimp exhibited enhanced resistance and lower stress-induced susceptibility. Histological analysis also indicated improved gut integrity, supporting overall robustness under environmental and infectious stressors.

These findings support the integration of postbiotics as a viable functional feed additive in shrimp aquaculture, contributing to disease prevention and production efficiency. As regulatory frameworks evolve and consumer demand for antibiotic-free aquaculture intensifies, postbiotics offer a sustainable solution aligned with industry trends. Future work should focus on optimizing postbiotic formulations and elucidating molecular mechanisms underlying their beneficial effects in shrimp and other aquaculture species.

# TOWARDS *Salmo carpio* AQUACULTURE: PRELIMINARY ASSESSMENT OF THE USE OF FUNCTIONAL INGREDIENTS IN DIET

Lorenzo Rossi*, Elia Ciani, Filippo Faccenda

Aquaculture and Hydrobiology Unit
Technology Transfer Centre
Fondazione Edmund Mach.
Via Mach 1, 38098, San Michele all'Adige (TN)
Italy
E-mail: lorenzo.rossi@fmach.it

## Introduction

Carpione del Garda (*Salmo carpio*, hereafter carpio) represents a unique element of European ichthyofauna. This salmonid fish is strictly endemic to Lake Garda, the largest lake in Italy, meaning it naturally occurs nowhere else. Moreover, carpio is listed as endangered species by International Union for Conservation of Nature due to the rapid decline of wild population. Therefore, several conservation actions, including the exploration and development of aquaculture techniques, have been attempted so far. There are several aspects that must be properly addressed in carpio farming, including optimal diet formulation, welfare assessment, fillet quality, health management, definition of proper larval-stage and weaning protocols.

The project "Filiera ASTRO: Competitiveness and Sustainability of Mountain Aquaculture" (CUP J38H23001450007), funded by "Piano Nazionale Complementare – PNC" of the Ministry of Agriculture, Food Sovereignty and Forests (MASAF), aim to improve the local aquaculture industry through the reuse of fish farming by-products, and applying new technologies to reduce feed waste and environmental impacts. The project framework consists of four work packages (WP). The present activity has been conducted within the WP1 which is focus on developing farming protocol for carpio, improving animal survival through larval weaning techniques, studying factors for successful sexual maturation and reproduction to enhance fecundity and hatching rates. WP1 will also include a genetic characterization of the breeding stock to ensure genetic purity and establish a suitable management plan.

In this context, the use of functional ingredients might help in supporting growth and health status of fish in farming condition. The aim of this work is to assess the use of functional ingredients in carpio's diet evaluating the effect on growth performances and other common indicators in aquaculture. The same diet was tested simultaneously on rainbow trout (*Oncorhynchus mykiss*). In the present work, only data referring to carpio will be reported.

## Material and Methods

The trial was conducted at the fish experimental facility of Fondazione Edmund Mach (San Michele all'Adige, TN, Italy). The trial was conducted in 700 l flow-through tanks (24 water renewal per day). Water parameters were maintained at a temperature of 12.5 °C, pH 7.85, and oxygen saturation between 80% and 95%. The fish were exposed to natural photoperiod (46°11'37"68 N; 11°8'4"56 E).

A total of 180 carpio (mix sex; 1+ year old. The average initial body weight was (mean ± SD) 120.5 ± 21.7 g for carpio. Fish were randomly distributed into three tanks per group, with 30 fish per tank. Two dietary groups were compared: a control diet (Vita 3, Veronesi, Verona, Italy) and a treatment diet (Vita 3, Veronesi, Verona, Italy) supplemented with 5 g $kg^{-1}$ of functional ingredient (GillFish Professional, Greenvet, Italy). Diet was supplemented according to feed manufacturer specifications from 1.8 % to 1 % of fish biomass in each tank. Fish were fed four times per day, five days per week, until apparent satiation. Any feed leftover was collected and quantified.

Growth performance and feed efficiency were evaluated through the following parameters: mortality rate (MR), mean final body weight (FBW), Condition factor (K) specific growth rate (SGR), feed conversion ratio (FCR) and feed intake (FI).

Data was compared between groups within species using the most appropriate statistical test. The detail of statistical test used is reported in Table 1. The software used for statistical analysis was R.

*(Continued on next page)*

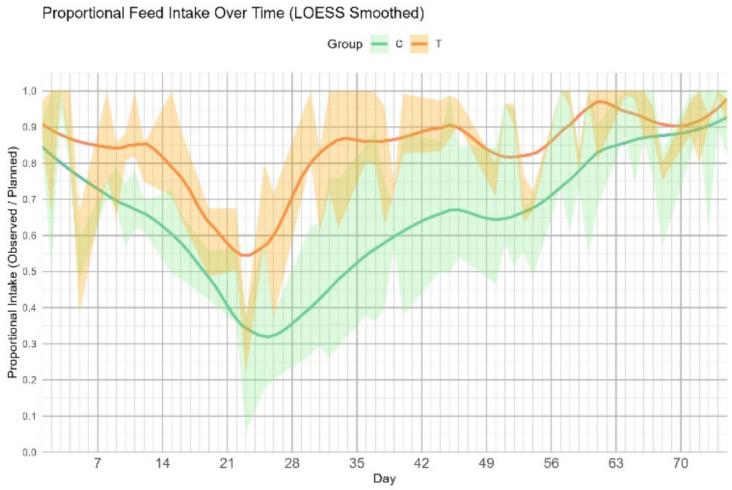

Figure 1. Comparison of relative daily feed intake (apparent/planned) in carpio fed either a control (C, green line) or treatment (T, red line) diet. Data are presented as smoothed mean (solid lines) with shaded areas indicating the minimum and maximum feed intake across replicate tanks.

**Results and Discussion**

The results showed that the use of functional ingredients in carpio diet improved final body weight (Two samples T-test, $P < 0.001$, $157.9 \pm 39.0$ and $178.1 \pm 34.9$ in control and treatment group, respectively), and K (Two samples T-test, $P < 0.001$, $1.19 \pm 0.11$ and $1.28 \pm 0.12$ in control and treatment group, respectively). The mortality rate observed in carpio fed treatment diet (5.6 %) was lower compared to those fed on control diet (13.3 %). One of the main bacterial diseases affecting carpio is the cutaneous flavobacteriosis. During the trial, both fish in the control and treatment group were affected, but the severity of the infection resulted lower in those fish fed on treatment diet. Regarding feed consumption no statistical differences have been observed between both group despite the highest FCR observed in control group ($2.57 \pm 0.85$) than in treatment group ($1.43 \pm 0.10$). As showed in Figure 1, the treatment group showed a significantly higher (Generalised linear mixed-effect model GLMM, adjusted for repeated measures of the same tank; $p = 0{,}004$) relative feed intake (apparent/planned) compared to control group over time. Towards the end of the experiment, feed intake in the control group increased, eventually overlapping with that observed in the treatment group. This suggests that the use of functional ingredient in carpio could be useful during specific stages of farming (e.g., manipulation, sorting, etc.) while in case of long-term exposure, benefits could not be so evident.

**Conclusion and future perspectives**

The present study offers preliminary insight on the use of functional ingredients in carpio. The growth performances and survival rate resulted increased when functional ingredients are used. Despite beneficial in terms of growth rate and feed intake, the addition of functional ingredients represents and additional cost to fish farmers. Therefore, the trade-off between growth, survival, and costs should be properly evaluated in case of long-term exposure to functional ingredients. Considering the observed positive effects, additional data (e.g., gene expression and histological analysis) are needed to further support the present findings.

# GROWTH PERFORMANCE AND ROBUSTNESS OF ATLANTIC SALMON (*Salmon salar*) FED DIETS CONTAINING VARYING COMBINATIONS AND INCLUSION LEVELS OF TWO DIFFERENT MICROBIAL INGREDIENTS (*Paecilomyces variotii* and *Schizochytrium sp.*)

M. Røsvik [1]*, B. Morales-Lange[1], S. Rocha[1], M. Øverland[1], D. D. Mensah[1], H. Sørum[2], L. T. Mydland[1], V. Blihovde[1]

**Introduction**

The aquaculture industry is faced with several challenges, including access to high quality feed ingredients, and exposure to multi-stressor conditions such as changing environmental conditions and diseases leading to mortalities and economic losses. Therefore, there is an urgent need for novel, sustainable feed ingredients that can also improve the health and robustness of the fish. Microbial ingredients are viable alternatives to address the shortage of both protein and long-chain omega-3 fatty acids. Furthermore, many microbial ingredients contain bioactive components such as β-glucans, mannans and nucleic acids which can improve robustness and health of fish.

*Paecilomyces variotii* (PEKILO®) is a filamentous fungus that can be fermented on forestry side-streams and has promising nutritional properties for use in aquafeeds. *P. variotii* has a high protein content of 60-70% (dry matter basis) with a favorable amino acid composition and has shown to be rich in β-glucans and nucleotides (Hooft et al., 2024), which promote immune modulation and growth. Mensah et al. (2024) observed that spleen leukocytes exposed to *P. variotii* and *Moritella viscosa* showed up-regulation of proximal pro-inflammatory cytokines *Il1β* and *tfnα*, suggesting that *P. variotii* induces pro-inflammatory responses. Additionally, spleen leukocytes co-stimulated with *P. variotii* and *M. viscosa* showed immune homeostasis, with higher gene expression of *il6* and *tgfβ* after 48 hours. These observations indicate that *P.variotii* can potentially boost immune responses and produce a more robust fish.

Another microbial ingredient is *Schizochytrium sp.,* which is a microalgae specie that is high in the essential omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Santigosa et al., 2020) and has been shown to improve mucosal barrier of skin, gills and intestine of Atlantic salmon and can replace up to 50% of fish oil (Islam et al., 2024). EPA and DHA have essential roles in many biological processes and properties like the cell membrane and cellular synthesis, and both the level and ratio of EPA and DHA have effects on the health of Atlantic salmon (Berge et al., 2019; Lutfi et al., 2023; Santigosa et al., 2023).

**Methods and materials**

In this experiment, vaccinated pre-smolt Atlantic salmon has been fed five different diets containing varying inclusions of *P. variotii* and *Schizochytrium sp.* in freshwater tanks for four weeks. Currently, the fish is being transferred to saltwater tanks where they will be exposed to the winter ulcer causing pathogen *M. viscosa*. The experiment will be concluded early June this year, and a wide range of samples will be collected.

We will present the main effects of feeding diets containing varying inclusions of *P.variotii* and *Schizochytrium sp.* for four weeks in fresh water and the effects on growth performance, robustness and health of salmon after being transferred to salt water then exposed to pathogens.

*(Continued on next page)*

*Table 1. Diets and inclusion level based on crude protein and crude fat*

| Diet | Inclusion |
|---|---|
| Diet 1 | 0% *P.variotii* + 0% *Schizochytrium sp.* |
| Diet 2 | 10% *P.variotii* + 5% *Schizochytrium sp.* |
| Diet 3 | 20% *P.variotii* + 10% *Schizochytrium sp.* |
| Diet 4 | 0% *P.variotii* + 10% *Schizochytrium sp.* |
| Diet 5 | 20% *P.variotii* + 0% *Schizochytrium sp.* |

E-mail:*guio@icm.csic.es.

**Introduction**

The European Commission (EC) Regulation 1099/2009 states that animas shall be spared any avoidable pain, distress, or suffering during killing and related operations. This is likely since slaughter is one of the most critical moments in the life of animals caught or reared for food, during which their welfare can be severely compromised. In crustaceans, sufficient evidence of pain perception is still under debate. Nonetheless, several studies have shown that crustaceans possess a well-developed nervous system, nociceptors, and exhibit responses to noxious stimuli that go beyond simple reflexes (Crump et al., 2022). According to EFSA (2004), signs of pain and distress in animals should, whenever possible, be confirmed using animal-based indicators (ABIs), such as physiological biomarkers. Based on these indicators, strategies such as an adequate electrical stunning could be developed to mitigate pain in the American lobster (*Homarus americanus*) prior to slaughter. The aim of this study was to evaluate changes in a panel of substances, some measured for the first time in this species, following an electrical stunning process. This could contribute to the identification of potential biomarkers that may improve both animal welfare and meat quality.

**Materials and methods**

Male lobsters were acclimated for four weeks in six fibre tanks (2,000 × 1,000 mm) with individual compartments in a cold chamber with running seawater at 12°C and 12:12 photoperiod of dark and blue light. They were fed mussels throughout the rearing period. Lobsters were divided into two groups: a control group (C, $n = 19$) and a stunning group (TL, $n = 18$). To induce immediate unconsciousness prior to slaughter, lobsters in the TL group were subjected to electrical stunning using the commercial Crustastun™ device (Mitchell & Cooper Ltd, UK). The standard long cycle (10 seconds at 8 A, 220 V) was applied, following manufacturer's operational procedures. Lobsters in the control group (C) were placed in the Crustastun™ with no electrical current. After stunning, lobsters were kept on ice for 30 min prior to dissection, to sedate the animals. Haemolymph was extracted and immediately freezed in $N_2$ (l) and later preserved at -80ºC using standardized protocols (Lorenzo et al., 2024). Biochemical parameters measured in haemolymph included glucose, lactate, L-lactate dehydrogenase (LDH), urea, triglycerides, cholesterol, total proteins, alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), and D-dimer. Analyses were conducted at the Interdisciplinary Clinical Analysis Laboratory of the University of Murcia (Interlab-UMU) using an Olympus AU600 automated biochemical analyser (Olympus Diagnostica GmbH AU600) with commercial kits from Beckman Coulter Inc. and Diazyme Laboratories (CA, USA). Differences in biomarker levels between groups were assessed using the non-parametric Mann–Whitney U test for unpaired samples, performed with GraphPad Prism 9 (La Jolla, CA, USA). A $P < 0.05$ was considered statistically significant.

**Results and discussion**

The biomarkers that showed the greatest changes between groups are shown in Figure 1; the rest of the biomarkers did not show significant differences.

There is little data on this species in relation to the assessment of pain and stress after electrical stunning, increase in metabolites such as glucose and lactate have previously been described in stunned lobsters also showing that lactate was a better indicator than glucose (Lorenzo et al. 2024). Increases in triglycerides have also been reported in other crustacean species (Coneely and Coates, 2023) in response to stress. However, there are no data on D-dimer, and this is the first time it has been determined in this specie. D-dimer is a peptide found is derived from the degradation of blood clots and significant increases has been found in species as pig after stress (López-Martínez et al., 2020).

*(Continued on next page)*

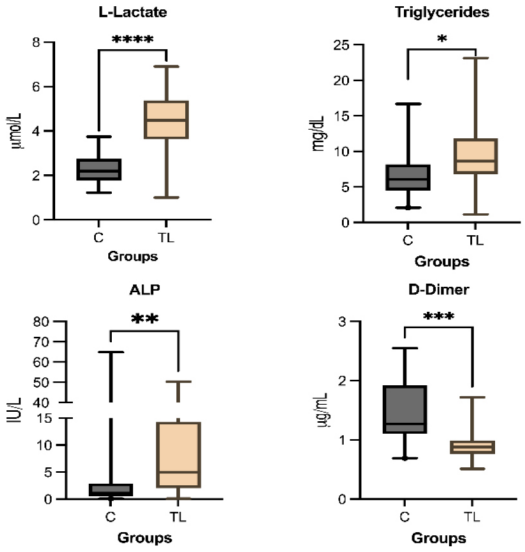

Figure 1. L-Lactate, triglycerides, alkaline phosphates (ALP) and D-dimer values in haemolymph obtained from control (C; n = 19 lobsters) and stunning group (TL; n = 18 lobsters). Graphs show medians (line within box), 25th and 75th. percentiles (boxes), min and max values (whiskers) and individual values (points). Asterisks indicate statistically significant differences (*$P < 0.05$; **$P < 0.01$; ***$P < 0.001$ and **** $P < 0.0001$).

**Conclusion**

Significant differences were observed in lactate, triglycerides, ALP, and D-dimer, biomarkers linked to different aspects of physiological response. While further research is necessary, these parameters show potential as indicators for evaluating the effects of electrical stunning on animal welfare and possibly the future quality of lobster meat.

**Introduction**

Animal protein production faces challenges such as intensifying farming practices, boosting feedstuff yields, and reducing environmental impacts to meet UN sustainability goals. Ethical concerns about animal welfare, recognizing animals as sentient beings, have pressured producers, legislators and consumers to adopt humane farming practices. This study examines Latin American aquaculture stakeholders' perceptions in order to address issues ensuring the four domains of animal welfare: nutrition, environment, behavioural interactions and health freedom from hunger, discomfort, pain, and the ability to express normal behaviour.

**Methods**

Aquaculture stakeholders from Latin American Countries (scientist, national administrations and private sector), participated in a 3-days Aquatic Animal Welfare (AAW) workshop within the framework of the CEREBAL project, with a total of 150 respondents. Focus group interviews encouraged participants to respond to the question: *what problems can be found in aquatic-animal welfare?* across four dimensions (good nutrition GN, appropriated housing AH, appropriate behaviour AB and good health GH), aquaculture processes (developmental stages, culture methods transport and slaughter) and eight species (tagging responses to research, legislation, or operational practices). A Latent Dirichlet Allocation (topic modelling analysis), was performed for Spanish words, revealing main topics and the most frequent terms used for describing each dimension and category problems.

**Results**

Participant's answers in the developmental stages category highlighted three latent topics: 1) animal-based welfare indicators, 2) feeding strategies, and 3) sanitary conditions. Frequent terms across dimensions included "food", "stress" and "mortality", while "cannibalism" was related to early life stages. Reproductive stage emphasized "spawning", "stress" and "females", while grow-out stage featured "feeding" and "sanitation". When comparing different culture systems, the main topics of GN were: 1) the availability of appropriate quality food, 2) food distribution, and 3) feeding strategies, using "distribution", "food" and "bottom" as more frequent words. The main topics identified in AH dimension were: 1) water quality and density, 2) environmental variables and 3) predator entry to the facility. The words "density" and "environmental" and "predator" were prevalent in all categories. The GH dimension featured: 1) availability of veterinary healthcare, 2) water control, 3) disease control and appropriate diagnose, as main topics. The most frequent words used within these topics included: "difficulty", "diagnose", "control", "pathogen" and "presence". Recirculating Aquaculture Systems included "correct", "veterinary" and "treatment", whereas the floating cages systems related more to "presence", "environmental" and "disease". The AB dimension answers, according to culture systems, showed: 1) behaviour assessment, 2) appropriate facilities and 3) natural behaviour in production; as the most relevant topics. Words choice indicated general and ambiguous responses, suggesting limited participant knowledge. Main topics in the slaughter methods category featured: 1) capacity building, 2) avoid stress, suffering and pain during procedures, 3) procedures in tanks may cause suffering and stress. "Training" (as in capacity building) was the

*(Continued on next page)*

Figure 1: Most frequent words showcase “behaviour”, “diagnose” and “disease” for Research needs; “pharmacological”, “legislation” and “traceability” for Rules and regulations whereas “management”, “handling” and “food” for Operational practices.

leading word across responses and dimensions. The GN included words such as “fastening” and “stress”. The words “tank” and “overcrowding” appeared recurrently in AH. AB included “method” and “protocol”, whereas GH included “stress”, “suffering” and “pain”. Slaughter methods featured words as: “type”, “adequate” “concentration” (for anaesthesia); “need”, “effectiveness” and “training” (electric shock); “suffering”, “procedure” and “protocol” (for ice). The responses to species-specific problems showed the need to develop welfare indicators based on the animal. It showcased topics such as 1) nutritional needs, 2) species- specific behaviour, 3) feeding strategies and 4) disease diagnose. The needs for research include: nutrition and feeding, behaviour, stress, water management and environment. Rules and regulations should address key aspects on: food, production facilities, animal health, capacity building and environmental impact. Operational practices showed: management and animal handling, standardized protocols, personnel training and comprehensive guidance documents. The most frequent words used are displayed in Fig.1.

**Discussion and Conclusion**

In general, Latin- American stakeholders show concern of topics mainly related to increase sustainability in their process, and a deep need to develop theoretical and technical abilities to address issues related to welfare concerns such as stress, pain and suffering. As each species has unique needs and challenges, it is necessary to establish interventions that result in effectively distinguish the best conditions for improving welfare (1). We hope that these data can raise awareness of Aquatic Animal Welfare issues and promote innovation and development to address local issues and be translated into laws and guidelines that guarantee the welfare of farmed aquatic organisms.

## Introduction

The white leg shrimp, *Penaeus vannamei* is the worldwide leader of aquaculture production for crustaceans, with over 7 million tonnes farmed in 2022 alone (FAO, 2024). Production at these volumes can lead to poor welfare standards, especially if done in remote or inaccessible places. Welfare standards include the best practices for manipulation and before euthanasia, especially in farms with large volumes of production.

However, for shrimps, the effect/response to anaesthetics is vaguely known (Rotllant et al., 2023). A newly developed definition should tackle EFSA's triangulation principle, correlating the organisms' responses at different levels of organisation. Farm standard practices involve using slurry ice as an anaesthetic before dispatch, although its effect remains unknown. In this work, we conducted a three-part experiment to characterize behavioural, metabolic, and neurophysiological responses to 'cold' seawater (~10°C) as an anaesthetic to determine if this practice reduces this shrimp species' neural and physiological activities.

## Materials and methods

Juveniles of *P. vannamei* of 21.1±1.3 mm carapace length (CL) and 6.3±0.5 g wet weight (ww) were delivered to the aquaria facilities of the Autonomous University of México (UNAM), Sisal, and left for two weeks at 24°C and 34UPS. Animals were fed commercial pellet food daily and maintained under a 12L:12D period. The working temperature was 10°C, defined as the thermal condition in which animals were rendered unresponsive in less than 10 min and recovered their normal position in under 20 min.

The first set of experiments on the effects of temperature focused on the behavioural responses of shrimp, particularly aiming to find the time when animals remain at the bottom of the tank lying on their side, and after were unresponsive when stimulated by touching the legs. This last marked the desired response and after which water was changed to let the animals recover (at 24°C). Animals were sampled at the end of the anaesthesia stage (n=7), or the end of the recovery (n=7) to measure metabolic and immunologic stress markers in haemolymph, muscle and midgut gland.

The second set of experiments focused on the effects of temperature on the metabolic rate (MR) of *P. vannamei*. The oxygen consumption ($VO_2$) was measured using a continuous flow respirometer of a closed chamber connected to a recirculating seawater system. Animals were placed in the respirometry chamber 12h before the experimental measurements, with a shrimp-less chamber used as a baseline. Once 120 min of baseline was recorded, the cooled seawater was added to the system, allowing the temperature inside the respiratory chambers to drop to ~10°C after 17 min. After 10 min of exposure, the system was refilled with seawater at 24°C. Metabolic rate was measured after, during, and before the seawater temperature change.

Lastly, neurophysiological activity and heart rate were recorded. Electrodes were implanted flanking the supraesophageal ganglion to measure electroencephalogram (EEG), visual evoked responses (VERs), and flanking the pericardial zone to measure heart rate (HR). Once a baseline was measured, water was changed to add the anaesthetic (cold water, ~10.5°C) and measures continued for 5 min, before water was changed again, to measure the parameters of recovery.

*(Continued on next page)*

Analysis of variance (ANOVA) was used to evaluate if there were differences in each experimental process; analyses were carried out using R version 4.4.2.

**Results**

Exposing animals to cold water induced an almost immediate equilibrium loss, after several body spasms, and, unresponsiveness after 1.3±0.3 min. The recovery happened after 11.0±5.9 min in renewed seawater. The haemolymph lactate levels remained unaltered after anaesthesia (initial, 0.060±0.053 mg/mL vs unresponsive, 0.141±0.062 mg/mL). Interestingly, the lactate levels were significantly increased after recovery (0.422±0.025 mg/mL, $p < 0.0008$) when compared to the original levels. The opposite is seen for cholesterol in the midgut gland, where it decreased after the recovery (initial, 0.815±0.023 mg/mL vs. recovery, 0.668±0.016 mg/mL, $p<0.05$). The MR of animals exposed to cold seawater, was 20% lower than the MR before the cold exposure. After recovery, the MR remained 3% higher than before exposure to cold water.

During the first minute of exposure to cold sweater (~10.5°C) VERs were lost, and remained undetected for the 5 min. Once the water was changed, animals recovered VERs within the first minute. Similarly, the HR had a sharp drop (ca.50%) in the first minute of exposure, dropping to 35% of the basal response (168±17 bpm vs 59±11 bpm, baseline vs cold seawater). Interestingly, the recovery of the HR took about 2 min, but it remained 16% lower than during the baseline (168±17 bpm vs 141±31 bpm).

**Discussion and conclusions**

During experimental trials, the loss of equilibrium was expected (called 'stage II') and the following stage (III), both characteristics previously described as inactivity of the cephalothoracic appendages and lack of response when stimulated (De Souza Valente C., 2022). Exposure to 'cold' (~10.5°C) seawater had animals losing their balance almost instantly, although they performed some vigorous escape response before it. During the respirometry analysis some animals lost their balance, displaying vigorous movements since the drop in temperature happened progressively (17 min). In such a condition, the physiological stress was revealed, showing mobilization of reserves and increased lactate.
On a neurophysiological level, the loss of the VERs could indicate the desired anaesthetic stage. The sharp drop in the HR reinforces the idea that cold water could be and effective anaesthetic. It is necessary to point out that the temperature chosen is around this species' minimum critical temperature ($CT_{min}$). This could explain the increase in lactate (and metabolic rate) during recovery. Acute exposure to near CTmin temperature could instantly achieve the desired anaesthesia stage, since some sensorial pathways are shut down. Yet, other organizational levels could be irreversibly damaged and only be seen after a late recovery of *P. vannamei*. The effect of cold water studied on the different levels of organization evaluated show that shrimps were quickly anesthetized, however their recovery was as well quick. Hence, we suggest that the use of slurry ice in farms is followed by a quick slaughter process.

## Introduction

The white leg shrimp, *Penaeus vannamei* is the worldwide leader of aquaculture production for crustaceans, with over 7 million tonnes farmed in 2022 alone (FAO, 2024). Production at these volumes can lead to poor welfare standards, especially if done in remote or inaccessible places. Welfare standards include the best practices for manipulation and before euthanasia, for which the use of sedatives or anaesthetics is recommended. An ideal anaesthetic should be affordable and readily available in most places, with known working concentrations (Rotllant et al., 2023). Yet, for this group of animals, the effect/response to anaesthetic is vaguely known (De Souza Valente, 2022). A newly developed definition should tackle EFSA's the triangulation principle, correlating the organisms' responses in different levels of organisation. In this work, we conducted a three-part experiment in order to characterize behavioural, metabolic and neurophysiologic responses to oregano oil as an anaesthetic.

## Materials and methods

Juveniles of *P. vannamei* of 21.1±1.3 mm carapace length (CL) and 6.3±0.5 g wet weight (ww) were delivered to the aquaria facilities of the Autonomous University of México (UNAM) in Sisal, and left for two weeks at 24°C and 34UPS. Animals were fed commercial pellet food daily and maintained under a 12L:12D period. The working concentration of oregano oil was established once animals were rendered unresponsive in less than 10 min, and were able to recover their normal position under 20 min. The first set of experiments focused on evaluating the effects of oregano oil (150 $\mu$L/L) on shrimp's behavioural responses. It aimed to find out when animals remained on the bottom of the tank, lying on their sides, and were unresponsive when stimulated by touching the legs. This last marked the desired response, and after which water was changed to let the animals recover. Animals were also sampled at the end of the anaesthesia (n=8) and recovery (n=9) to measure metabolic and immunological stress markers in haemolymph, muscle and digestive gland. The second set of experiments focused on the effects of oregano oil (150 $\mu$L/L) on the metabolic rate (RMR) of *P. vannamei*. The oxygen consumption ($VO_2$) was measured using a continuous flow respirometer of a closed chamber connected to a recirculating seawater system. Animals were placed in the respirometry chamber 12h before the experimental measurements, with a shrimp-less chamber used as a baseline. Once 120 min of baseline was recorded, the oregano oil was introduced into the chambers via de flow-through seawater system, allowing for a complete water change after 17 min. After 10 min of exposure, the system was refilled with aerated seawater, with constant change, and measures continued for 4 h. Metabolic rate was measured after, during, and before the seawater temperature change. Lastly, we recorded neurophysiological and heart rate parameters. Electrodes were implanted flanking the supraesophageal ganglion to measure electroencephalogram (EEG), visual evoked responses (VERs), and flanking the pericardial zone to measure heart rate (HR). Once a baseline was measured, water was changed to add oregano oil (150 $\mu$L/L) and measures continued for 6 min, before water was changed again, to measure during recovery phase.

Analysis of variance (ANOVA) was used to evaluate if there were differences in each experimental process; analyses were carried out using R version 4.4.2.

## Results

The oregano oil induced an equilibrium loss after 6.1±0.7 min, a complete unresponsiveness after 10.0±1.1 min, and recovered after 15.3±5.7 min. Before losing balance, animals experience multiple spasms, after which they lost equilibrium. After the

animals were unresponsive the lactate levels were increased by 10-fold (0.8±0.2 mg/mL), and after the recovery period they were still increased by 20-fold (1.7±0.3 mg/mL), when compared with basal levels (0.1±0.1 mg/mL). The RMR was 10% higher than observed in shrimp exposed to control seawater or ethanol (oregano's solvent). Yet, the recovery of the metabolic rate at the end of the experiment showed no difference. The exposure with oregano oil did not affect the VERs, since the beta waves amplitude during light stimulation was always distinguishable from dark or control periods (>10 ratio of magnitude), during and after the anaesthesia. For the HR, a slight decrease was observed from control levels during the exposure to oregano oil (a 17% drop). The HR returned to control levels after water change (~180 BPM).

**Discussion and conclusions**

As a starting point when doing trials with anaesthetics, the loss of equilibrium was expected, and noted as stage II, yet no other considerations (as what it took to be achieved) were taken into account. The following stage (III) of the anaesthetic involved the total inactivity of cephalothoracic appendices and lack of response when they were stimulated, while pleopod movement continued; cessation of pleopod movements resulted in no recovery (shrimp died). The exposure with oregano oil had animals lose their balance, but not before they performed an escape attempt from the aquaria. Similarly, during the respirometry analysis, after some time of avoidant response (or escape), animals lost their balance. The escape response could explain the higher metabolic rate found after the oregano oil was applied, and the loss of equilibrium could be a result of fatigue. This fatigue hypothesis could be reinforced by the unaffected VERs, since the loss of balance or inactivity does not involve any frontal ganglion dysfunction or failure on the primary sensory pathway. Interestingly, the mild drop in the HR is not consistent with a rise on the metabolic rate, but it is worth mentioning that the movement of these shrimps was restricted for electrodes placement and that could impact the oregano oil uptake. Overall, our results considering behavioural, physiological and neurological approach might indicate that oregano oil has not an anaesthetic effect on juvenile shrimps, although the animals have lost equilibrium after exposure. Therefore, without further results to ensure replicability and robustness, we will not suggest the use of oregano oil for shrimp aquaculture.

## Introduction

Due to the high cost of fishmeal and concerns about its limited availability and sustainability as the global aquaculture sector develops, research into suitable substitutes has been a longstanding priority. One of the most commonly used plant-based alternatives is soybean meal, which is generally regarded as the most nutritious protein feed for aquatic animals. Soybean meal has a relatively high protein content and a complementary blend of amino acids, making it suitable for inclusion in commercial fish feeds at levels of approximately 10-12%. The nutritional value of soybean meal (SBM) is often limited for cultured species due to deficiencies in methionine and the presence of antinutritional factors (ANFs).Various methods have been explored to reduce the adverse effects caused by these ANFs and specific oligosaccharides, with fermentation being a prominent approach of interest (Kumar et al., 2020). This study aimed to evaluate the potential of fermented soybean meal (FSBM) as an alternative protein source to fishmeal for the diets of European seabass (*Dicentrarchus labrax*) and to examine its effects on feed efficiency, growth performance, and immune response in a field trial under intensive aquaculture conditions.

## Materials and Methods

A 12-week trial was conducted to examine the effects of varying levels of fermented soybean meal (FSBM) (PERMEX VET Kft., Hungary) as a replacement for fishmeal (FM). Six diets were formulated to be isonitrogenous (46% crude protein) and isolipidic (16% crude lipid). These included a control diet containing 30% FM and three experimental diets that replaced FM with 30%, 50%, and 70% FSBM. All diets were produced as 3.5 mm pellets through a cooking extrusion process by SPAROS Lda (Olhão, Portugal). At the end of the feeding trial, the fish were collectively anesthetized, and 16 fish per cage were randomly sampled. Ten of these fish were used to assess proximate composition and fillet quality. From three additional fish, tissues from the anterior and mid intestines, along with the liver, were collected and immediately fixed in 10% buffered formalin for histological analysis. Finally, blood samples were collected from the caudal vein of three other fish per cage, and the serum was used for immunological assessments. All animal handling and sampling procedures adhered to the EU directive 2010/63.

## Results and Discussion

Overall, there were no statistically significant differences in growth performance and feed utilization indices ($P > 0.05$) among the experimental feeds. However, it is notable that the fish fed the 50% fishmeal (FSBM) diet exhibited the highest numerical growth parameters, including fish weight gain, specific growth rate (SGR), daily growth index (DGI), protein efficiency ratio (PER), and daily feed intake. In terms of feed conversion ratio (FCR), the lowest values were observed in cages fed diets containing 30% and 50% FSBM ($1.32 \pm 0.06$ and $1.33 \pm 0.03$, respectively). Similar to a previous lab trial (Roussos et al., 2023), the diet with 70% fishmeal substitution performed worse than the control, indicating limitations associated with higher inclusion rates of FSBM in the diets of European seabass. Furthermore, no significant differences were observed in the fish somatometric indices. However, the fish fed a diet containing 30% fermented soybean meal (FSBM) exhibited the lowest perivisceral fat index ($2.87 \pm 0.64$) compared to the control group ($3.42 \pm 0.59$). The overall body composition and fillet composition of the fish were not significantly affected by the substitution of FM with FSBM at any level of its inclusion. Nevertheless, a decrease in crude protein level ($18.24 \pm 1.57$, $18.93 \pm 1.32$, and $18.29 \pm 1.02$) was noted in the fillets of fish fed diets containing 30%, 50%, and

*(Continued on next page)*

70% FSBM, respectively, compared to the control group (19.42 ± 1.63). Additionally, the inclusion of FSBM did not impact the retention of n-3 long-chain polyunsaturated fatty acids (LC-PUFAs), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in the fish muscle, as no significant differences were found. Moreover, no significant differences were found in serum total proteins, myeloperoxidase, and anti-proteases (% trypsin inhibition) among the different dietary treatments. However, protease activity was significantly lower in the diet containing 70% FSBM compared to both the control and the diet with 50% inclusion of FSBM. Also, a non-significant decreasing trend was observed in the serum lysozyme levels of fish that were fed diets containing increasing levels of FSBM. Lysozyme activity has been linked to bile acids (BA) concentrations, which play a role in regulating immune functions (Zhao et al., 2025). Additionally, BA have been associated with the presence of dietary taurine in feed. However, the substitution of fishmeal (FM) with plant proteins can lead to a decrease in taurine levels. It will be very interesting to further investigate the supplementation of fishmeal substitute-based feeds with taurine. Previous studies conducted by Kotzamanis et al. (2020a, 2020b) demonstrated that European seabass showed improved growth and fillet quality when fed a diet that included a mixture of soybean products and other plant meals, supplemented with 1% or 2% taurine as a replacement for fishmeal. These findings suggest that taurine is an essential nutrient that is often lacking in diets with high levels of soybean meal and other plant meal inclusions.

The results clearly demonstrated the high nutritional value of Fermented Soybean Meal (FSBM) for European seabass. In line with our previous trial, FSBM enabled the successful replacement of up to 50% of fishmeal without negatively affecting growth performance and feed utilization. However, it is important to emphasize that further research is needed to fully understand the effects of high inclusion rates of FSBM on the immune status of cultured fish.

**Introduction**

The use of insect meals in feed for farmed fish was recently approved by the European Commission (EU 2017/893). Over the past years, insect meals have gained significant interest, performing in a similar way to fishmeal-based diets (Piccolo et al., 2017; Ido et al., 2019). Insect larvae meals offer significant environmental and economic advantages. Insects reproduce and cultivate rapidly, requiring minimal water and land resources compared to other feed ingredients. They also facilitate waste biodegradation by transforming low-quality organic material into high-value nutrients, thereby contributing to enhanced soil fertility. Additionally, insects contain substantial amounts of high-quality protein and a balanced amino acid profile, which is superior to plant alternatives. Nevertheless, the potential of an ingredient should not be solely assessed based on its effects on growth performance. As with any novel feed ingredient, certain limitations merit further investigation. Previous research has indicated that the dietary inclusion of insect meals may impact intermediary metabolism across different species. Understanding the potential effects of dietary inclusion of insect meals on fish metabolism is also mandatory to improve fish nutrition as it may compromise fish growth performance and nutrient utilization, affecting fish health in the long term.

**Materials and Methods**

Black soldier fly (*Hermetia illucens*, BSF) larvae reared on plant-based residual substrates were experimentally produced and incorporated into aquafeed formulations, replacing fishmeal (30% incorporation in the control group - CTRL) at inclusion levels of up to 60%. A three-month feeding trial was carried out at the experimental facilities of the Hellenic Centre for Marine Research (HCMR), using European seabass (*Dicentrarchus labrax*, initial mean weight ~30 g). Fish were fed six experimental diets in which fishmeal was progressively replaced by black soldier fly larvae meal at 0 (CTRL), 20, 30, 40, 50, and 60% substitution levels. At the end of the trial, 108 tissue samples (liver and anterior intestine) were collected for molecular analyses. Gene expression profiling was performed using customized qPCR arrays targeting seabass markers that had been previously optimized at the IATS-ANA infrastructure. Several reference genes, including actb and ef1, were employed to normalize mRNA expression levels. A total of 58 target genes were examined, with 29 genes analyzed from each tissue type. More precisely, in the INT the expression profiling of genes related to antibacterial peptides (e.g., defb, leap2), mucus proteins (e.g., muc2), immunoglobulins and transcription factors (e.g., igms, nfkb2, il1b), T-cell markers (e.g., cd247, cd8b, ccr3), phagocyte activity (e.g., csf1r, mif, mmd), were evaluated. In the LIV, several lipid metabolism-related genes (e.g. elovl1, lpl, atgl) were investigated. The impact on fish growth was also assessed through the expression of hepatic genes related to growth hormone and insulin-like growth factor system regulation (e.g., ghr-i, igf-ii, igfbp1a).

The data normality and homogeneity of variances were checked through the Shapiro-Wilk and Levene's tests, respectively. In a normality and equal variance scenario, One-way ANOVA followed by a Tukey post hoc test was used to assess statistical differences ($p < 0.05$). Whenever data normality or homogeneity was not achieved, data transformation (i.e., logarithmic) or nonparametric statistical analysis (i.e., Kruskal-Wallis for gene expression, Spearman for correlation; $p < 0.05$) were employed. All statistical analyses were performed using SigmaPlot (version 15). To further explore tissue-specific gene expression patterns, partial least-squares discriminant analysis (PLS-DA) was performed using EZinfo v3.0 (Umetrics, Sweden), which enabled the visualization of multivariate clustering and discrimination among dietary groups.

*(Continued on next page)*

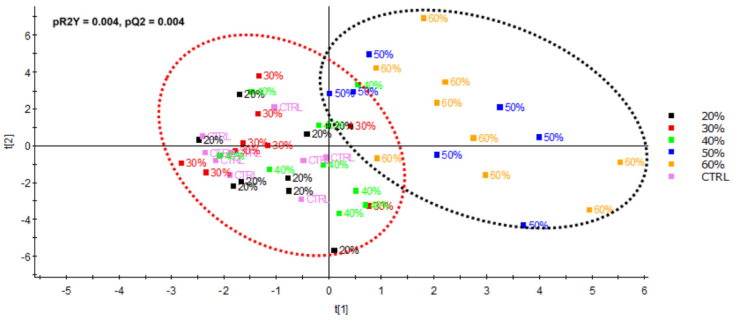

**Fig. 1** Multi-tissue PLS-DA

## Results and Discussion

No statistically significant differences in the expression of individual genes were initially detected among dietary groups in either tissue ($p > 0.05$). To further investigate potential dose-dependent effects across tissues, a partial least-squares discriminant analysis (PLS-DA) was performed by grouping the samples into CTRL–20–30–40 and 50–60. The PLS-DA model effectively discriminated between the two groups and identified 15 genes with a variable importance in projection (VIP) score > 1 as the primary contributors to class separation. In the anterior intestine, several immune-related genes were notably affected. Leap2 (Liver-expressed antimicrobial peptide 2), IL-8 (Interleukin 8), IL-22 (Interleukin 22), CSF1R (Macrophage colony-stimulating factor 1 receptor), and CD8b (T-cell surface glycoprotein CD8 beta) were upregulated in the higher inclusion group, suggesting enhanced immune activation and a shift towards a pro-inflammatory state. Conversely, the downregulation of CD4 (a T-cell surface glycoprotein) and IL-10 (Interleukin-10) indicated a reduction in regulatory and anti-inflammatory signaling.

These transcriptional changes underscore a potential compromise between immune activation and immune regulation in response to increased dietary incorporation of BSF larvae meal. Such responses could influence nutrient absorption, intestinal homeostasis, and overall health, thereby suggesting that inclusion levels approaching 60% may exceed the physiological tolerance of European seabass. Further investigation is necessary to identify strategies that may mitigate these effects, including biotechnological processing of insect meals to enhance digestibility or the addition of functional additives with immunomodulatory properties. These approaches could facilitate the optimization of insect-derived proteins, consequently reducing the aquafeed industry's dependence on fishmeal and advancing sustainability.

## Acknowledgments

The feeding trial was funded through the Greek national project "Insects4Aqua" (Grant Agreement 5029335, Ministry of Rural Development and Food). The access of Efstratios Roussos to the IATS-CSIC facilities for gene expression analyses was supported by the TNA program (PID36931) within the H2020 AQUAEXCEL3.0 project (871108). **Introduction**

Every year, the Central Eastern European region fishponds (0.25 million hectares, 0.12 million tons fish) consume ≥0.3 million tons of grains such as wheat, corn, triticale, rye, and barley, that could be otherwise fed directly to human food chain. Pond-fed grains may occupy approximately 46000 hectares of arable land that could be directly used for cultivating human food. Although European fishponds have low footprints, this grain-feeding still poses feed-food conflict in the current food system and require alternatives. In the present experiment (vegetative season 2024), our aim was to understand the limits of European fishponds by reducing 55% of wheat input and replacing it with a low-cost, non-refined and plant-based LOCB (low-opportunity-cost-biomass, *i.e.* local agri-food by-products or co-products) feed that was fed in harmony with the pond's natural food web following the 'balanced pond feeding concept'. Specific objectives were to evaluate: (1) production performance, (2) environmental impact assessment (both LCA and *in-situ*), and (3) human food systems impact of reducing feed-food conflict associated with European fishponds.

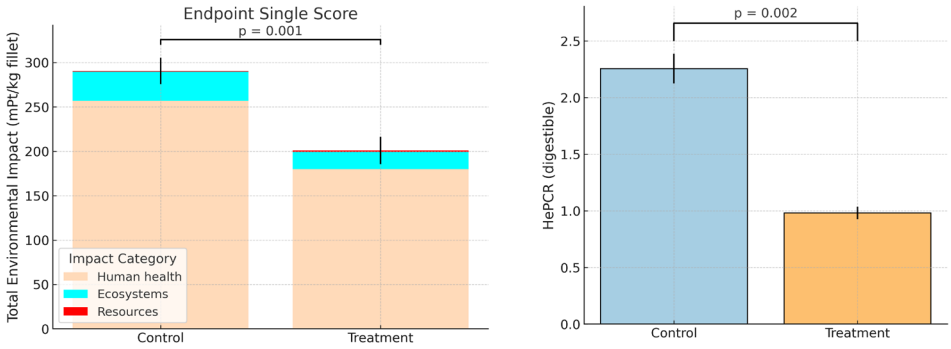
**Materials and Methods**

The LOCB pond feed that was fed to common carp (*Cyprinus carpio*) resembled more of a ruminant/ monogastric feed (than a fish feed) having low crude protein (22.7%, lysine 0.9%, methionine 0.47%) possibly with high anti-nutritional factors (ANF), low crude fat (3.78%), and high fiber (neutral detergent fiber, NDF= 21%; acid detergent fiber, ADF= 14%; starch 27.7%) contents with poor feed conversion ratio (FCR ~4), measured in laboratory. It was composed of 71% human-inedible, locally-sourced LOCBs (breakfast-cereals factory discards, rapeseed, sunflower expellers, and corn DDGS) and 29% human edible biomass (28% wheat + 1% rapeseed oil) with formula cost of ~0.32 EUR $kg^{-1}$ near the cost of wheat (~0.20 EUR $kg^{-1}$). The LOCB pellet was twin-screw extruded floating-type. Wheat (fed as grains; sinking) was more refined, low protein (9.5%, lysine 0.27%, methionine 0.16%) without a high ANF, high in starch (59.1%), and low in fibers (NDF 9.9%, ADF 4.4%) with lab FCR also ~4. A set of 9 experimental fishponds (each 0.16 ha area, 0.8 m depth each, stocking density 471 kg scaly common carp $ha^{-1}$, initial body weight: 384 ± 81 g, 2+ years old) was assigned into two groups: "control" (triplicates) and "treatment" (six replicates). Treatment was nested (3+3) for optimizing LOCB feed utilization by fixed-time hand-feeding or all-day demand feeders. The isogenous stocked ponds received isogenous amounts of supplementary feed (3500 kg $ha^{-1}$) with control ponds fed traditionally with wheat. Total dosage was sub-divided into fixed monthly feeding plan: April (3%), May (7%), June (11%), July (32%), August (25%), September (15%), and October (7%). The treatment ponds received wheat during beginning-of-season (April to June, 22% of total input) and LOCB-feed during end-of-season (July to October, 78%). Ponds were fed daily. Monthly sampling for fish growth, water quality, plankton, and sediment (bi-monthly) were done. Ponds were harvested in beginning of November, filleting yield and fillet nutrient composition was assessed. Life cycle impact assessment and nutrient (material) flow analysis for food system was carried out.

**Results**

All ponds had statistically similar ($p>0.05$) survivability, fish yield, final fish size, FCR, filleting yield, EPA+DHA or total amino acids irrespective of control or treatment. Results suggest commercial production is not hampered by replacing 55% of wheat input with LOCB. Treatment carp was significantly ($p<0.05$) less fatty than control carp, which is a positive takeaway for regional fish gastronomy sector.

*(Continued on next page)*



All ponds had statistically similar (*p>0.05*) chlorophyll-a, zooplankton trends, and nutrient (C, N, P) concentrations in water or sediment. The organic C reserves in pond soil before harvest were maximum in treatment ponds. Results suggest LOCB feeding cannot be associated with causing nutrient pollution or eutrophication.

In terms of food web, from a lab-measured FCR of ~4 (bad), both wheat and LOCB-feed showed pond-measured FCR of ~2.7 (good). The contribution from pond's natural food web to support carp yield was not altered (*p>0.05*) by replacing 55% of wheat input with LOCB. This is a win-win for fish farmers and water protection.

Total environmental impact was significantly lower (*p<0.01)* in treatment (200 mPt $kg^{-1}$ fillet) than control (290 mPt $kg^{-1}$ fillet). Impacts on human health and ecosystems are significantly lowered (*p<0.01*), except for resources consumption being significantly increased (*p<0.05*) due to capturing, mobilizing, and re-manufacturing LOCBs itself.

For the food system, the treatment became 'net producers of protein' with human edible protein conversion ratio (digestible), $HePCR_d$ of ≤1, significantly different (*p<0.01*) from control which was identified as net consumer of protein (HePCRd 2.2) due to input of human-edible wheat. Ponds are solely net-producers of n-3 LC-PUFA, as there is zero-input via wheat or LOCB-feed. The net n-3 LC-PUFA production is more sustainable (*p<0.01*) in treatment (500 mg $kg^{-1}$ human-edible ingredient) than control (250 mg $kg^{-1}$ human-edible ingredient). Results suggest a need for a reduction of feed-food conflict associated with grain-fed European fishponds, at least 55% as a starting point, by replacement with plant-based LOCBs.

**Discussions**

Integrating LOCB feeds would position European pond carp farming as the "cow of aquaculture and food systems" efficiently converting low-value biomass into nutritious food. Government subsidies should support such LOCB pond feed adoption, offsetting higher costs than grain-feeding to fulfill EU food system (*i.e.,* low feed-food conflict, net producers of farmed nutrients) and nature restoration targets (*i.e.,* higher recycling, regenerative farming). European fish-feed companies should seize the untapped market niche (≥0.3-million-ton $year^{-1}$) for LOCB-based pond feeds, uniquely suited for regenerative pond systems. Although gaseous emissions were not measured, sediment organic C reserves improved with LOCB feeds. Overall, at semi-intensive carp production levels (≤0.5-ton $ha^{-1}$ stocking, 1.2–1.4 tons $ha^{-1}$ yield in 7 months), LOCB feeds strongly outperform grain-based alternatives in reducing feed-food competition.

# NEUROENDOCRINE STRESS RESPONSE TO STRESSORS OF DIFFERENT SEVERITY IN THE MUCOUSAL TISSUES OF S*parus aurata*

Nuria Ruiz*, Manuel Blonç, Lluis Tort

Department of Cell Biology, Physiology and Immunology
Universitat Autònoma de Barcelona, Spain
*Presenting author: Nuria.Ruiz.Iglesias@uab.cat

## Introduction

It is known that fish are subjected to different stressors in the aquaculture industry such as anoxia or density. These stressors can activate a stress response, but the level of this response will depend on the severity of the stressor. Such severity may be due to different factors such as the species studied, the age, or duration, intensity and type of stressors among other factors. In this case it was selected a stressor of high severity such as anoxia where the fish must be out of the water, and a crowding stress which is less severe than anoxia. Moreover, crowding stress has an additional emotional component that anoxia does not have. Also, the stress response can modulate other responses such as the immune or the endocrine and energetic response that can also have further effects on fish health. This is why the aim of this study was to investigate the neuroendocrine stress response of a juveniles of *S.aurata* subjected to two different severe stressors such as anoxia and crowding to understand how the severity can modulate the activation level of the response. Also, another objective was to observe if the recovery time was affected by the severity of the stressor.

## Materials and methods

A total of 48 gilthead seabream juveniles were acclimated to AQUAB fish facilities (Universitat Autònoma de Barcelona, UAB), After the acclimation period, fish were randomly divided in 3 different treatment groups; control, anoxia, and crowding group that were sampled at 1 and 24 h after the stressor. The fish subjected to anoxia were exposed to air for 3 min and then were placed back in thanks for 1 hour or 24 hours until the sampling. The crowding stress was performed by decreasing the water level from 20 L to 10 L, remaining like this for 30 min and then restoring the water volume, and wait until sampling at 1 or 24 hours. From each fish, plasma was sampled for haematological and biochemical analysis, and the mucosal tissues (gills, skin, and gut) were sampled for qPCR gene expression analysis.

## Results

No differences were found in cortisol levels in plasma, but the parameters related with the oxidative stress changed in the groups subjected to stress compared with controls. Regarding the gene expression results, it was observed a tissue-specific response, being the gills the most affected one. What was relevant is that glucocorticoids receptors did not show any difference compared with the control, but in the case of *cfos* gene there was an upregulation that can be clearly associated to the stress response. Moreover, the genes related with the immune and the oxidative stress were also affected. Another interesting discovery was that crowding stress showed more effects than anoxia, and the effects from the density lasted for longer time in the fish.

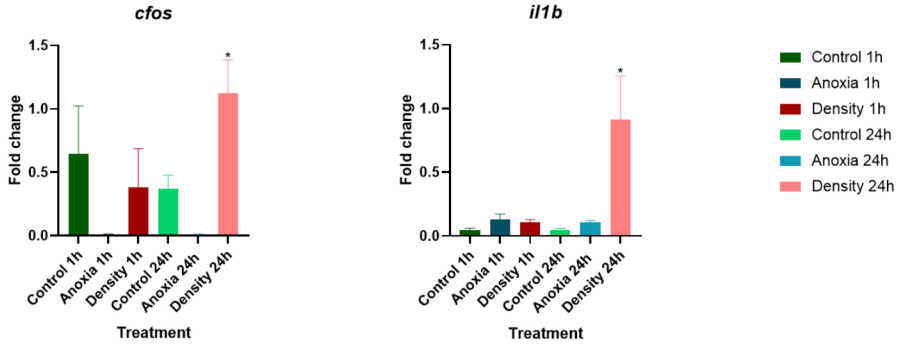

Figure 1. Fold change of a) cfos and b) il1b of the gill after the stressors tratments. The * symbol indicates the group significantly different from the others.

*(Continued on next page)*

**Discussion**

As it was expected different severities had different effects on the fish (Figure 1), since anoxia did not cause the upregulation of *cfos*, but the crowding stress caused an upregulation but after 24 hours. Despite glucocorticoids receptors were not significantly regulated, *il1β* in the case of the crowding group at 24h suffered an upregulation and an interesting fact is that the anoxia exposure did not affect the immune genes in gills. Also it is relevant to remark the tissue specific response, as this could be due to the exposure of each tissue to the stressors and the main function of the tissue. In the case of gills and the skin both tissues are in direct contact with the environment but the main specific function of each tissue is completely different which may explain the different sensitivity of the response

## Introduction

In recent decades, the search for functional ingredients to overcome the effects of reducing the use of animal marine protein in aquafeeds has been one of the great challenges in the aquaculture sector. In response to this problem, terrestrial plant feedstuffs have emerged as possible alternative proteins to fishmeal (Quagliardi *et al.,* 2024). In spite they have a high protein content, they may contain anti-nutritional compounds that can induce digestive problems in animals and hinder the nutrient digestibility (Seibel *et al.,* 2022). In this sense, the concept of dietary fortification arises as a feeds supplemented in very low proportions with functional ingredient that can promote fish growth, health and improve the resistance of animals to diseases and stress, even improving the digestibility of plant-based aquafeeds. From a nutritional point of view, algae are a natural source of proteins, lipids, vitamins and carotenoids, whose use is associated with beneficial effects on fish status. Similarly, white grape marc extract contains polyphenols which could help to mitigate the potential negative effects they might cause in fish (Quagliardi *et al.,* 2024). Thus, the main objective of this study was to evaluate the effect of dietary fortification with a functional ingredient based on white grape marc extract and microalgae, in liquid and solid format, in feeds with a high proportion of plant protein ingredient on growth performance, proximal muscle composition and digestive functionality in juvenile rainbow trout (*Oncorhynchus mykiss*).

## Material and Methods

The feeding trial was carried out at the Aguas Blancas Fish Farm (Quéntar, Granada). For this purpose, three experimental diets were formulated: a control diet that did not contain the functional ingredient (CT) mimicking the formulation used in commercial aquafeeds, and two diets similar to the previous one, but 2% fortified with the functional ingredient in liquid (NL) and solid (NS) format. Fish were fed for 100 days until triplication of their initial body weight (12.5 g). At the end of the feeding trial, growth performance and zootechnical parameters were evaluated, and samples of muscle tissue were obtained for analysis of proximal composition, and intestine for evaluation of pancreatic and intestinal digestive enzyme activities.

## Results and Discussion

The final weight of fish fed the diet fortified with NL (57.9 ± 12.2 g) was higher than that of fish fed CT (54.7 ± 12.3 g) or NS (54.0 ± 12.8 g) diets. However, body length did not differ among experimental groups. Regarding the composition of muscle, lipid content decreased in specimens of NL and NS groups compared to CT group, which might indicate a better utilization of lipid as source of energy in these groups (Perera *et al.,* 2020).

Figure 1 shows digestive enzymatic activities measured in fish fed the different dietary treatments. Overall, higher trypsin and chymotrypsin activities were observed in the NS group, which could be associated with better digestion processes at intestinal level. However, leucine aminopeptidase and alkaline phosphatase activities were higher in fish of NL group compared to specimens from the NS batch. The observed changes in the digestive enzymatic activities seems to reflects that dietary fortification with this functional ingredient can be useful for modulating the digestive functionality in juvenile rainbow trout. Further analysis are in progress for ascertaining the effect of these fortified diets on the intestinal microbiota and the antioxidant capacity in these fish.

E-mail: ykyou0111@kiost.ac.kr

**Introduction**
Ocean warming due to climate change has significantly altered the distribution and physiology of marine species. Jeju Island, located in rapidly warming waters, has seen a decline in kelp beds and a rise in coralline algae, affecting local biodiversity and food webs. *Turbo sazae*, a subtropical gastropod, is influenced by these habitat changes and food availability. Understanding its physiological response to dietary shifts is critical. This study investigates how different macroalgal diets affect *T. sazae* under controlled conditions.

**Materials and Methods**
Ninety *T. sazae* specimens were collected and acclimated before being divided into groups fed with either *Ecklonia cava* or *Corallina officinalis*. The experiment lasted 18 weeks in controlled tanks at 20°C with weekly feeding. Wet weight, immune function, gonad development, and biochemical composition were analyzed. Hemocyte parameters were measured using flow cytometry, and tissues were used for proximate and amino acid profiling. Statistical analyses were conducted using ANOVA and t-tests.

**Results**
throughout the 18-week experiment, *T. sazae* showed no significant differences in wet weight between groups fed with *E. cava* or *C. officinalis*, indicating both diets were nutritionally adequate. Hemocyte parameters including viability, phagocytosis, and ROS production remained stable and showed no significant variation between feeding groups or over time. Gonad development progressed similarly in both groups, with most individuals remaining in the ripe stage and limited spawning observed, likely due to the constant 20 °C water temperature. Proximate composition analysis revealed decreases in carbohydrate content and increases in lipid content over time, while protein levels remained consistently high. Amino acid profiling showed significant temporal and feed-related changes: glutamic acid, taurine, and aspartic acid declined initially, but later increased in the *C. officinalis*-fed group, suggesting enhanced metabolic activity; in contrast, *E. cava*-fed individuals showed decreased glycine and proline levels. These results indicate diet-specific influences on amino acid composition and energy metabolism, despite overall physiological stability.

**Discussion**
*T. sazae* exhibited dietary adaptability, with both macroalgae supporting immune function, gonad development, and biochemical stability. Lipid accumulation and AA fluctuations reflect metabolic adjustments to environmental stress. Although total protein was unaffected, feed type influenced AA composition, which may impact tissue function. Future studies should assess long-term effects under natural environmental variability.

**Conclusion**
*T. sazae* maintained physiological stability under both feeding conditions, demonstrating adaptability to dietary changes. While no major differences in growth or immunity were observed, AA composition varied with diet, suggesting subtle metabolic effects. Further field research is needed to evaluate the ecological implications under climate change.

# IMPACT OF TRANSPORT ON *Laminaria ochroleuca* SEEDLINGS FOR SEAWEED FARMING

Maria Francisca Sá[1], Isabel Sousa-Pinto[1,2] and Gonçalo Silva Marinho[1]*

[1]CIIMAR/CIMAR LA, Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Terminal de Cruzeiros do Porto de Leixões, 4450-208 Matosinhos, Portugal

## Introduction

The transportation of seaweeds from the hatcheries to the cultivation sites represents a critical step in aquaculture, with direct implications on the physiological integrity and subsequent survival of the seedlings. Transport usually occurs without immersion in seawater, using cool, humid conditions maintained by isothermal containers to reduce desiccation and thermal stress. Controlled temperature and humidity are essential, as even short-term exposures to suboptimal conditions can cause physiological deterioration and reduced viability. These risks are particularly relevant when hatcheries are located far from offshore cultivation sites, making transport logistics a key factor for successful farming.

*Laminaria ochroleuca*, has attracted growing interest in Portugal due to its ecological adaptability and commercial value in the food, cosmetics, and biotechnology sectors. As a native species with promising biochemical traits, it is considered a strong candidate for large-scale aquaculture. Successful cultivation depends on maintaining seedling quality throughout the production cycle, including during transportation. Stress during this stage can impair photosynthesis, alter pigmentation, and reduce post-deployment performance.

This study aimed to assess the impact of transportation on the physiological condition and survival rate of *L. ochroleuca* seedlings before deployment at sea, to support the development of evidence-based protocols that ensure viability and optimize offshore yields.

## Material and Methods

To simulate the transport conditions of *L. ochroleuca* seedlings, isothermal containers with an ice pack were used. Seeded spools were placed inside the containers without seawater, under high relative humidity, reproducing the environmental conditions experienced during transport from the hatchery to the deployment site. Temperature and relative humidity were continuously monitored using appropriate sensors during experiment period.

Physiological condition of seedlings was assessed at 0, 6, 12, and 24 hours after the beginning of the simulation trial. At each time point, the maximum quantum yield of photosystem II (Fv/Fm) was measured using a Junior-PAM fluorometer, as a proxy for photosynthetic efficiency and overall physiological status. Photographic documentation of the seedlings was also performed at each time point to detect any visible colour changes that could indicate stress-related responses.

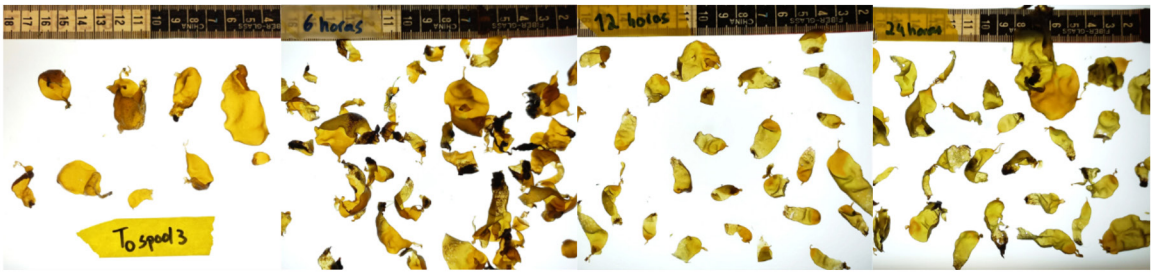

Figure 1. Images of *L. ochroleuca* seedlings after being transported in isothermal containers for 0, 6, 12, and 24 hours

*(Continued on next page)*

Following the respective transport period, seedlings were transferred back to a controlled culture system for a period of one week. The culture tanks were maintained under standard cultivation conditions (14ºC and 12h:12h). At the end of this period, Fv/Fm measurements and photographic assessments were repeated to evaluate the potential of recovery of physiological condition and viability of the seedlings.

**Results and Discussion**

During the first 6 h the Fv/Fm remained stable and similar to that observed in the beginning of the trial ($0.77 \pm 0.04 – 0.75 \pm 0.06$, $p \leq 0.05$). However, these values significantly decreased after 12h ($0.56 \pm 0.3$) and 24h ($0.35 \pm 0.3$). Indeed, the proportion of individuals in good physiological condition (Fv/Fm > 0.65) at the beginning of the trial (97%), was significantly reduced to 63% and 43% after 12h and 24 h, respectively. On the other hand, the proportion of individual considered non-viable (Fv/Fm < 0.2) raised to 23% and 43% during the same period.

The negative effect of transportation was also reflected in the coloration of *L. ochroleuca*. Seedlings exhibited a typical bright brown coloration at the beginning of the trial, which gradually shifted to a greenish coloration after 6h–24h.

After one week of "recovery" in standard culture conditions, Fv/Fm results showed that the proportion of individuals in good physiological condition further declined to 33% and 13% in the 12h and 24h transportation treatments, respectively.

The results revealed that *L. ochroleuca* seedlings maintain stable physiological performance during the first 6 hours of simulated transport, as evidenced by consistent Fv/Fm values and minimal visual changes. However, extended exposure (12–24 hours) led to a significant decline in photosynthetic efficiency and an increase in the proportion of non-viable individuals. The shift in coloration from bright brown to greenish tones further supports the onset of physiological stress during prolonged periods under transport-like conditions.

Recovery after one week in standard culture conditions was limited, particularly for seedlings exposed to 12 and 24 hours of simulation, where the proportion of physiologically healthy individuals remained low. These results suggest that the effects of extended transport are not easily reversible and may compromise seedling quality. Therefore, under the investigated conditions, transport duration should ideally not exceed 6 hours to preserve physiological integrity and maximize the success of subsequent deployment. Nonetheless, even after 12 hours, 33% of the individuals remained in good physiological condition, which may still be acceptable for achieving effective coverage in high-density deployments.

# UNDERSTANDING FISH BEHAVIOR FOR IMPROVED AQUACULTURE FEEDING MANAGEMENT

Aya Saad*[,1], Dana Margareta King[1], Muriel Dunn[1], Sébastien Kerhervé[2], Oscar Nissen[1], Berit Heltne[2]

1)SINTEF Ocean, P.O.Box 4762 Torgarden, 7465 Trondheim, Norway
2)WAIVE AS, Bergen, Norway
*E-mail: aya.saad@sintef.no

Feed inefficiency remains a critical challenge in global aquaculture, with Norway alone wasting up to 10\% of annual feed inputs [1].

Our study developed a comprehensive monitoring framework integrating 3D multibeam sonar technology [10] with environmental sensing to decode fish behavior patterns in sea cages near Bergen, Norway (Figure 1). The system captured continuous volumetric data while monitoring key environmental parameters including temperature, oxygen levels, and current velocity [8].

Our methodology employed Maximum Biomass Depth (MBD) calculations and Boundary Biomass (BB) detection [3] to track fish aggregations, enhanced through k-means clustering [7]. This revealed consistent diurnal patterns (Figure 2), with fish aggregating deeper (10-20 m) at night [12] and moving toward surface waters (3-10 m) during daylight. These patterns showed strong alignment with feeding times [6], suggesting anticipatory behavior.

*Fig. 1: Bergadalen aquaculture site (60.121 ◦N, 5.908 ◦N) on the west coast of Norway. The thick red arrow shows the position of the SeapiX sonar on the side of the test cage. Thin arrows indicate the x- and y-axes. The thick light blue arrow marks the location of environmental instruments at 5 m and 15 m depths*

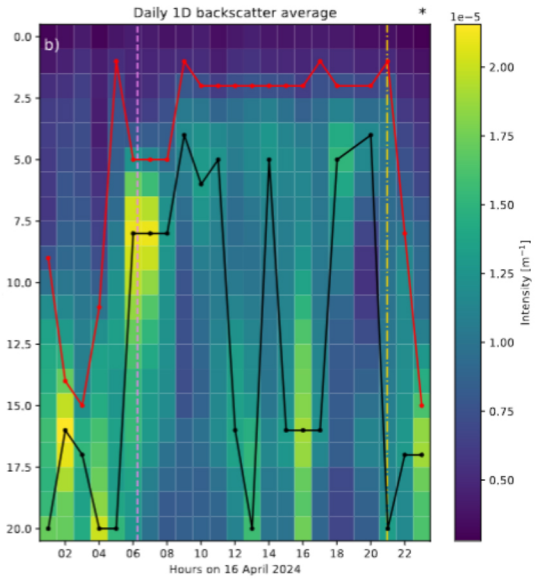

*Fig. 2: Hourly averaged intensities in the yz-direction from 16 April 2024 over the whole day. The red line represents a boundary biomass detector where underneath fish accumulate. The black line represents maximum biomass depth values, where fish accumulate each hour. The star (*) marks 23:00 on 16 April 2024.*

*(Continued on next page)*

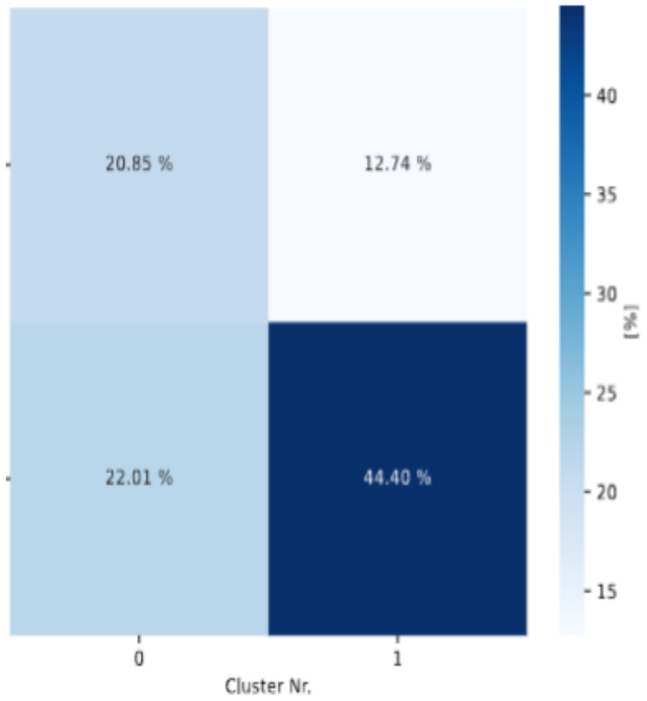

*Fig. 3: Based on cluster results, the distribution of maximum, biomass depth values is split between 3 - 10 m and 10 - 20 m.*

Vertical distribution analysis quantified behavioral states, showing fish spend 66.4% of low-activity periods at 10-20 m depths [11] while distributing more evenly during high-activity feeding periods. These findings enable data-driven feeding optimization [5] while improving fish welfare [4].

The study demonstrates how advanced monitoring can transform aquaculture practices [2]. Future work will focus on real-time implementation [9] to enhance feeding efficiency and sustainability.

# BETTER STUNNING, BETTER QUALITY: IMPACTS OF STUNNING METHOD ON BRAIN FUNCTION AND PRODUCT QUALITY IN TILAPIA (*Oreochromis niloticus*) AND CATFISH (*Clarias gariepinus*)

Ulla Saarinen[1]*, Jeroen Brjis[2], Erika Sundell[1], Anders H. Karlsson[1] and Albin Gräns[1]

[2] Institute of Zoology, University of Innsbruck, Innsbruck, Austria

*Email: ulla.saarinen@slu.se

**Background**
With increasing societal and regulatory focus on ethical practices in aquaculture, the identification of humane stunning and killing methods has become imperative. Electrical and percussive stunning techniques have been proposed as viable means to minimize suffering by ensuring rapid and sustained loss of sensibility. However, for species extensively farmed for human consumption, such as Nile tilapia (*Oreochromis niloticus*) and African sharptooth catfish (*Clarias gariepinus*), it is critical to evaluate stunning methods not only in terms of welfare but also regarding their effects on product quality. A multidisciplinary approach, combining assessments of brain function with product quality, provides critical insights into the broader implications of stunning practices.

**Material and methods**
Electrical stunning was performed using an in-air electrical stunner prototype (Optimar AS, Norway) delivering a 20 s stun at maximum current of ~3.9 A for tilapia and ~5.7 A for catfish. Percussive stunning was carried out with an automated percussive stunner (Baader, Germany), set to deliver ~60 J (velocity of ~28 $ms^{-1}$) and ~71 J (velocity of ~31 $ms^{-1}$), for tilapia, while catfish were exposed only to the higher settings.

Immediately post-stunning, electroencephalogram (EEG) electrodes were attached to record brain function continuously for 10 min. Stunning effectiveness was determined by the presence or absence of visually evoked responses (VERs) in the EEG recordings. All groups assessed for VERs are presented in Figure 1. Product quality assessments were conducted only on groups subjected to maximum stunning intensities, evaluating water holding capacity and rigor mortis progression. The water-holding capacity of flesh was measured as drip loss (%) which was determined as percentage weight loss relative to initial fillet weight at 4, 24, 48, 72, and 96 hours post-stunning (n = 8 per group). Rigor mortis was monitored hourly over 7 h post-stunning, quantified via a rigor index (%) based on vertical displacement of the caudal fin (n = 6 per group).

**Results**
At the lower electrical stunning intensities, 25-100% of tilapia and 100% of catfish recovered during monitoring, whereas at maximum intensity, recovery decreased to 20% in tilapia and 67% in catfish (Fig. 1). For tilapia, percussive stunning at ~60 J was insufficient to ensure insensibility in all individuals; however, ~71 J achieved a 100% success rate. In catfish, one recovery occurred after percussive stunning (~71 J), attributed to a misaligned strike targeting the nose rather than the brain. Preliminary analyses indicated that drip loss increased more rapidly over time in electrically stunned tilapia compared to percussively stunned individuals (Time x Treatment: $F_{2.0,28.5} = 13.7$, $p < 0.001$). Also in catfish, drip loss was significantly higher in electrically stunned individuals compared to those stunned percussively (Treatment: $F_{1.0,14.0} = 5.1$, $p = 0.04$). However, the difference in drip loss between groups remained consistent over time (Time x Treatment: $F_{1.1,15.6} = 2.6$, $p = 0.124$). The onset of rigor mortis typically occurred between 1 and 4 h post-stunning across methods. However, after 7 h, electrically stunned tilapia showed a significantly higher rigor index (87.0 ± 8.3%) than percussively stunned fish (22.4 ± 5.8%, $t_9 = -6.7$, $p < 0.001$), while no differences were observed in catfish (7.9 ± 4.2% *vs*. 12.1 ± 2.5%, $t_{10.0} = 0.9$, $p = 0.205$).

*(Continued on next page)*

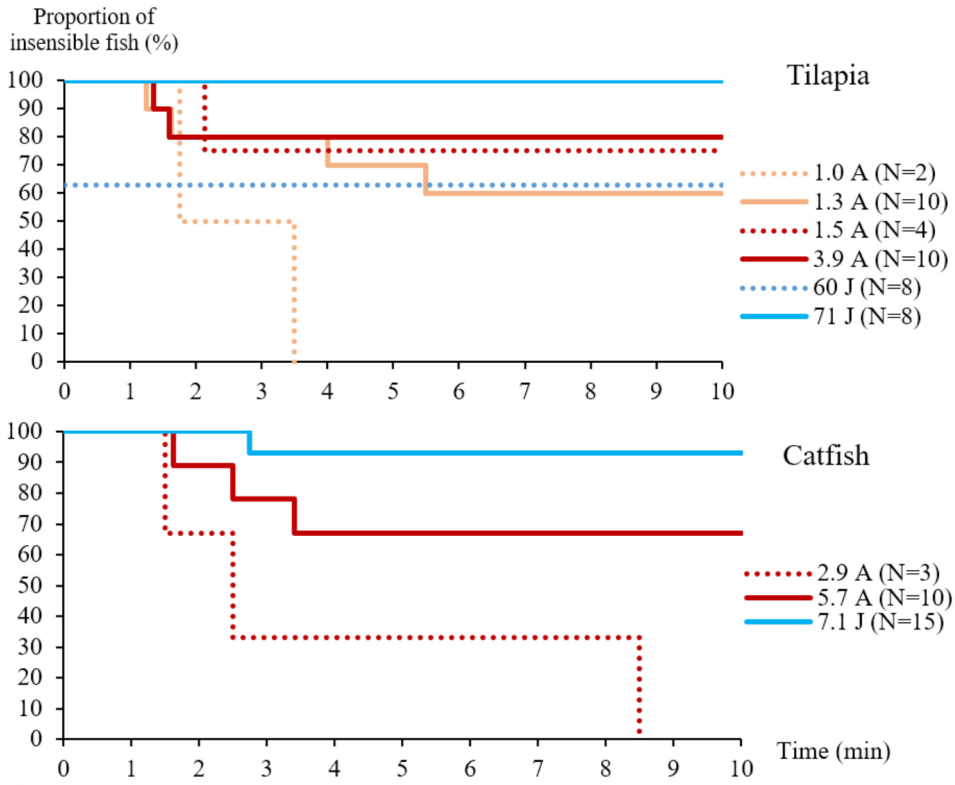

**Figure 1. The proportion of insensible tilapia and catfish during the monitoring period following electrical and percussive stunning.** Kaplan-Meier distributions of electrically (orange and red dashed and solid lines) and percussively (blue dashed and solid lines) stunned tilapia (upper panel) and catfish (lower panel).

## Conclusions

In both tilapia and catfish, a proportion of individuals regained brain function following electrical stunning. Although increasing stun intensity improved stunning efficacy, this was associated with compromised product quality, increasing drip loss and accelerating the development of rigor mortis, thus having a negative impact on water holding capacity, processing, and texture of the flesh. Automatic percussive stunning achieved higher welfare outcomes when appropriate force and accuracy were applied and better preserved product quality. Our findings demonstrate that percussive stunning may be a commercially viable solution for tilapia and catfish, aligning both welfare and quality objectives. Further research should explore the consistency of force and accuracy under large-scale commercial production conditions.

# HATCHERY PRODUCTION OF THE STRIPED VENUS CLAM *Chamelea gallina* FOR FISHERY RESTORATION, AND GENETIC VARIABILITY IN THE SEED

C. Saavedra*, D. Cordero, E. A. Omole, M. Babucci, P. Soms, S. Falcó, C. Papetti, and M. Rodilla

Instituto de Acuicultura Torre de la Sal, CSIC
12595 Ribera de Cabanes
Castellón, Spain
E-mail: saavedra@iats.csic.es

## Introduction

The striped Venus clam is an infaunal, subtidal species living in the Mediterranean Sea and its neighbour Atlantic coasts, and in the Black Sea. The species is exploited as a fishery but is facing a reduction in catches. In the Gulf of Valencia (Spain) and neighbouring areas, the fishery has collapsed and has been closed, but in spite of the ban, it has not recovered (Baeta, 2021). Supplementation of wild populations with clam seed obtained in captivity by using bivalve aquaculture methodology might help the recovery of populations and favour an aquaculture industry. A problem with this strategy is that the high fecundity and large variance of family size in bivalves may lead to large numbers of spat that have less genetic variability and higher relatedness than the supplemented population. Therefore, a strict control of the parental contributions and the genetic variability in the offspring is recommended. Here, the successful production of striped Venus clam spat in hatchery under controlled conditions, and the characterization of its genetic variability, are reported.

## Materials and Methods

Clams (N = 350) were collected near Gandía (Valencia, Spain) in May 2023, before the peak of the reproductive season (summer), in order to have as much control as possible of the gonad maturation process. They were placed in 150L PVC tanks with running seawater, and were subjected to two conditioning treatments, with two replicates each: food only (FO) and food plus temperature (FT, average 2°C above ambient). Food ration was 3% of average clam dry meat weight, with 50% *Isochrysis glabana*, 30% *Chaetoceros calcitrans*, and 20% *Tetraselmis suecica*. Gonad maturation was studied by histology and condition indices (CI). The gametogenic stages were classified as in Delgado et al. (2013). A CI = dry meat weigh / dry shell weight was used. After 4-5 weeks of conditioning, the broodstock was subjected to thermal shocks (17-27°C ) to induce spawning. Larvae were cultured in 200 L conical tanks. Water was changed three times a week. When most larvae had reached the pediveliger stage, they were moved to 200 µm mesh-bottom containers for settlement. Larvae and postlarvae were fed *Isochrysis galbana* ($10^5$ cells/ml).

The 11 parents and 72 spat were genotyped for 11 microsatellites with the primers designed by Papetti et al. (2016). Allele frequencies and gene diversity were calculated with the program Arlequin (Excoffier et al., 2025).

## Results

Histology and condition indices of the broodstock showed that most clams were sexually mature after conditioning with the FO treatment, while before conditioning most animals were immature. The 17-27°C thermal shocks induced spawning only in clams from the FO treatment. Six females and five males spawned, and three million eggs were recovered. *Ca*. two million larvae were alive at 48 hours after fertilization. The size of the larvae increased up to an average of 220 µm and reached a plateau 21 days after fertilization. Survival at this point was 25%. Larvae were then moved to the settlement tanks. A few days later water temperature raised suddenly to 29°C, coinciding with a summer heat wave, and mass mortality of the larvae occurred. Surviving spat were collected for further study.

All scored microsatellites were polymorphic. Out of the 57 alleles observed in the parents, 49 were present in the offspring, and nine new alleles appeared by mutation. Gene diversity in the parents was 0.624±0.040 and 0.554±0.007 in the progeny.

*(Continued on next page)*

## Discussion

Rearing larvae obtained from spontaneous spawning in captivity of clams collected at the peak of the reproductive season was achieved by Joaquim et al. (2016). However, this approach provided no control over the parental contribution to the offspring. These authors also tried inducing spawning in controlled conditions by thermal shock without success. Here, it has been shown that conditioning of clams collected before the natural reproduction peak during four weeks at ambient temperature results in large numbers of larvae, and potentially large numbers of spat. However, too high a seawater temperature can be a problem, inducing spontaneous spawning before the gonad is completely mature, and mortality during the larval to juvenile metamorphosis stage.

The genetic characterization of the parents and the progeny showed that 14% of the parental alleles and 11% of gene diversity were lost due to due to the variable contribution to offspring among parents. Clearly much larger numbers of parents are needed to produce clam seed that meets the recommended standards for supplementation of wild populations. Prolonging the conditioning period, increasing the food ration and changing the diet composition are three factors that should be explored to achieve this goal.

## Introduction

Biofloc technology (BFT) offers new opportunities for intensive freshwater aquaculture by improving water quality through microbial flocculation and nutrient recycling[1]. It also allows for reduced water consumption, better feed conversion, and the potential reuse of microbial biomass as a nutritional resource. While widely used for tropical species like tilapia (*O. niloticus*) and shrimp, its application to temperate freshwater fish is limited and relatively unknow. The POLYRAS project (Interreg GR) aims to diversify and develop polyculture, which is widely used in pond systems, in three sustainable aquaculture systems: Recirculating Aquaculture Systems (RAS), aquaponics systems, and BFT. Within this cooperative project, our study focuses specifically on the Biofloc technology.

This work explores the possibility to rear new temperate freshwater species in polyculture in BFT mainly focusing on survival rate and growth performances. The six selected species, black bass (*Micropterus salmoides*), Russian sturgeon (*Acipenser gueldenstaedtii*), pikeperch (*Sander lucioperca*), perch (*Perca fluviatilis*), catfish (*Silurus glanis*), and tench (*Tinca tinca*), were chosen based on their economic potential in the Greater Region and adaptation to different polyculture scenarios, as identified in the TOFF database[2]. As most of these species have not been previously reared in BFT systems, this preliminary study was designed to screen and identify new candidate species for BFT aquaculture, evaluating their growth and investigating how each species may influence microbial dynamics in the system.

## Material and Methods

The experiment was performed in three individual 250 L tanks maintained in BFT and one 250 L control tank in clear water (RAS). Fish were stocked at an initial density of 6 kg/m³, with the number of individuals adjusted according to species size. Each species was successively reared for a period of three weeks and fed to satiation throughout the experimental period.

Growth performances were assessed through morphometric measurements (body weight and total or fork length) and food conversion ratio (FCR) assessment. Water quality was monitored daily (t°, $O_2$, floc volume) or twice a week (pH, conductivity, TAN, and alkalinity) to ensure stable environmental conditions.

At the end of the experiment, water samples from BFT tanks were analyzed to characterize microbial communities. Zooplankton and phytoplankton were counted in 1 mL subsamples, and floc particle size and bacterial density were measured.

## Results and discussion

The performance of black bass in BFT is promising, with 100% survival, as in the RAS control, and a positive growth (3 g), slightly lower than in RAS (5.9 g). In contrast, sturgeon showed variable survival (50–100%) and marked weight loss in BFT (−16.5 to −61.4 g), while 100% survival and significant weight gain (44.3 g) were recorded in RAS. With stable water quality parameters, no specific issue could explain these results, suggesting sturgeon may not be suitable for BFT systems. Preliminary trials with perch and catfish were stopped after one week due to signs of stress, such as reduced feeding and abnormal behavior. These findings highlight both the potential and the limitations of BFT for temperate freshwater species (Table 1).

Pikeperch demonstrated good growth performance across all BFT tanks (9.3 g). Survival was affected by elevated ammonia concentrations linked to a temporary instability of the biofloc. Under more stable conditions, pikeperch could be successfully reared in BFT. Tench demonstrated excellent adaptability to BFT system, with 100% survival (Table 1). Individual weight gain ranged from 34.7 to 51.1 g in the BFT tanks, slightly surpassing the 34.5 g average in the RAS control. The stability of physicochemical parameters throughout the trial supported these good performances (Table 1).

*(Continued on next page)*

*Table 1 : Summary of survival, growth, and feed efficiency data reared for three weeks in BFT (mean of 3 tanks) and RAS.*

| | Black-bass | | Sturgeon | | Pikeperch | | Tench | |
|---|---|---|---|---|---|---|---|---|
| | BFT | RAS | BFT | RAS | BFT | RAS | BFT | RAS |
| Survival (%) | 100 | 100 | 72 | 100 | 77 | 100 | 100 | 100 |
| N initial | 36 | 37 | 6 | 5 | 19 | 19 | 6 | 6 |
| Initial mean weight (g) | 42.0 | 41.5 | 274.4 | 317.6 | 77.7 | 79.4 | 245.1 | 252.7 |
| Individual weight gain (g) | 3.0* | 5.9 | -39.7 | 44.3 | 9.3 | 21.5 | 42.5 | 34.5 |
| FCR | 2.9* | 1.8 | / | 1.2 | 1.2* | 0.7 | 1.9 | 2.3 |

(*: Data based on two tanks for Black-bass and one tank for Pikeperch)

*Table 2 : Mean (±sd) abundance of rotifers, ciliates and phytoplankton (ind./mL) in BFT water at the end of the rearing period for each species.*

| | Black-bass | Sturgeon | Sander | Tench |
|---|---|---|---|---|
| N rotifers/ml | 4 ± 4 | 12 ± 16 | 6.7 ± 11 | 10 ± 5 |
| N ciliates/ml | 73 ± 43 | 214 ± 137 | 1577 ± 1714 | 1799 ± 1978 |
| N phytoplankton/ml | 44 ± 28 | 36 ± 45 | 5 ± 6 | 13 ± 10 |

The analysis of planktonic communities suggests that species reared in BFT systems may influence the abundance and composition of phytoplankton and zooplankton, with noticeable differences in ciliate, and phytoplankton counts (Table 2). Measurements of floc particle size and bacterial abundance are still in progress and should further clarify the interactions between fish species and microbial dynamics in BFT systems.

These preliminary results highlight black bass, pikeperch and tench as promising candidates for BFT culture.

Global climate change is driving a continuous rise in water temperature, posing significant challenges to aquaculture productivity, animal welfare, and product quality. As ectothermic organisms, fish rely on ambient temperature to regulate metabolic and physiological processes, rendering them particularly vulnerable to thermal stress (Ahmad et al., 2011). This review synthesizes current knowledge on neuroendocrine and molecular mechanisms underlying the responses of skeletal muscle and liver—two critical tissues for growth and energy homeostasis—under elevated temperature conditions.

Thermal stress triggers activation of the hypothalamic–pituitary–interrenal (HPI) axis and the brain–sympathetic–chromaffin cell pathway, leading to cortisol and catecholamine release. These endocrine mediators mobilize energy reserves, modulate carbohydrate and lipid metabolism, and regulate immune and oxidative stress responses (Alfonso et al., 2021). In skeletal muscle, increased temperature induces the expression of heat shock proteins (Hsp70, Hsp90), which safeguard protein folding and stability, while also affecting growth-regulating pathways such as growth hormone (GH) and insulin-like growth factors (IGF). Transcriptional regulation of myogenic factors (MyoD, Myf5, myogenin) and transforming growth factor-beta family members (myostatin, follistatin) influences myofiber hypertrophy and hyperplasia, ultimately shaping muscle growth potential (Akbarzadeh et al., 2018).

The liver exhibits profound transcriptomic and proteomic changes under heat stress, including modulation of antioxidant defenses (Sod, Cat, Gpx), metabolic pathways, immune signaling cascades (NF-κB, IL-17), and apoptosis regulators (Aidos et al., 2020). Proteomic analyses further highlight alterations in proteins involved in cellular homeostasis, energy production, and cytoskeletal integrity. Additionally, specific microRNAs (e.g., miR-122, miR-194-3p) emerge as important regulators of glycolysis and lipid biosynthesis under high-temperature regimes, providing potential molecular biomarkers for stress adaptation (Mohanty et al., 2018).

While some of these responses are adaptive in the short term, chronic exposure to elevated temperatures can lead to growth suppression, reduced feed conversion efficiency, impaired immunity, and increased susceptibility to disease. In the context of aquaculture, these effects translate into lower yields, higher production costs, and compromised sustainability. Mitigation strategies include selective breeding for thermal tolerance, nutritional interventions targeting oxidative stress and growth pathways, and technological improvements in farming systems to optimize environmental control.

*(Continued on next page)*

This comprehensive understanding of neuroendocrine and molecular responses to heat stress is essential for developing climate-resilient aquaculture practices. By identifying key biomarkers and regulatory mechanisms, the industry can improve the capacity of farmed fish to cope with thermal challenges, ensuring long-term productivity and food security.

# PUBLIC ATTITUDES TOWARDS AQUATIC ANIMAL WELFARE

Robyn Sahota*
Aquatic Animals Project Officer, Eurogroup for Animals
r.sahota@eurogroupforanimals.org

Compassion in World Farming, River Court, Mill Lane, Godalming, Surrey GU7 1EZ, United Kingdom
Eurogroup for Animals, 29 Rue Ducale, 1000 Brussels, Belgium

## Introduction

Each year, up to one billion fish are farmed in the European Union [1]. Despite this scale, there is currently no species-specific legislation that addresses their distinct welfare needs. Consequently, poor farming conditions, including overcrowding, disease, and inhumane slaughter methods, remain common. A growing body of scientific evidence affirms fish sentience, yet welfare protections lag behind those for terrestrial farmed animals.

## Objectives

This study aimed to assess public attitudes toward aquatic animal welfare across the EU, evaluate awareness of fish farming practices, and understand how these perceptions influence consumer behaviour.

## Methods

The survey [2], commissioned by Compassion in World Farming and Eurogroup for Animals, was conducted by Sapience between 20 March and 5 April 2024. A total of 9,225 participants from nine EU countries—Czechia, France, Germany, Greece, Italy, Poland, Spain, Sweden, and The Netherlands—completed an online questionnaire. Questions addressed attitudes toward fish sentience, awareness of farming methods, support for legislative change, and consumer preferences for welfare-friendly products.

## Results

The findings reveal strong public concern for fish welfare, with most supporting stronger legislative protections and demonstrating a preference for purchase higher welfare products:

- **91%** of respondents believe that fish welfare should be protected to the same or a greater extent as other farmed animals.
- **4 in 5** support legislation requiring best practices based on scientific evidence to meet fish welfare needs.
- **71%** agreed that fish can feel pain, with the highest agreement in Czechia (**77%**).
- **A significant majority of people in Spain (65%) consume fish at least once a week**. However, awareness of current fish farming methods was low: in Spain, **63%** reported low awareness, the lowest of all countries surveyed despite their high fish consumption—a significant majority of people in Spain (65%) consume fish at least once a week, which is notably higher than the overall EU average of 40%.
- Only **39%** knew that most farmed fish are not stunned before slaughter, but **70%** supported making stunning a legal requirement.
- **90%** expressed a preference for purchasing fish raised in higher welfare conditions. In Germany, **74%** supported clear welfare labelling for fish products.

## Conclusion

The survey results highlight significant public support across the EU for improving the welfare of farmed aquatic animals. Awareness of farming practices remains limited, yet consumer demand for higher welfare products is strong. These findings underscore the urgent need for legislative action to close the welfare gap between aquatic and terrestrial farmed animals.

## Introduction

The development of sustainable aquaculture relies on diversifying production with low-trophic-level species whose nutritional needs do not depend on fishmeal (FM) and fish oil (FO). Given that feed costs represent approximately 60% of aquaculture production expenses (APROMAR, 2022), farming species with reduced FM and FO diets offers both environmental and economic advantages. Flathead grey mullet (*Mugil cephalus)* is a promising candidate due to its natural lack of dependency on FM and FO (Gisbert et al., 2016; Wassef et al., 2002)optimizing weaning diets is of special importance for this species at this particular stage of development. Thus, authors have tested a weaning protocol for wild flathead grey mullet fry (202mg initial body weight. However, despite extensive knowledge of its natural feeding habits (Brusle, 1981), data on its nutritional requirements and response to formulated feeds remain limited. Moreover, the effects of these low FM and FO diets on the polyunsaturated fatty acids (PUFA) content of the fish must be taken into account, as this is an important factor in the quality of the final product (Sprague et al., 2016)as an oily fish, contain a rich source of the health promoting long-chain omega-3 fatty acids, eicosapentaenoic (EPA. Scientific research is therefore essential to know the appropriate composition of the specific diet for this species and the identification of the best culture methods.

## Material and Methods

Two feeding trials were conducted using juvenile flathead grey mullet hatched and reared at IRTA. In Trial 1, 495 fish (11.77 ± 2.17 g) were randomly distributed into nine 500 L tanks (IRTAmar® water recirculation system) to test three diets (triplicate groups): Control (20% FM), FM-0 (0% FM), and FM-5 (5% FM). After 72 days of *ad-libitum*-feeding trial, a final biometric sampling was performed, and samples of plasma, liver, and muscle were collected. Somatic and zootechnical indices were calculated, and samples from each tissue were analysed (biochemical profile in plasma and circulating cortisol levels; proximate composition and fatty acid profile in liver and muscle; and gene expression in liver). Trial 2 required 720 fish (16.39 ± 4.07 g) distributed across 18 tanks (200 L) in two salinity conditions (36 and 8 ppt) at 20 °C with natural photoperiod. Three diets (Control: 10% FO; FO-0: 0% FO; FO-5: 5% FO) were tested in triplicate per salinity. After 83 days, samples of plasma, liver, anterior intestine, gill, and muscle were taken for the same analyses, with gene expression additionally assessed in the intestine and gill. Statistical analyses were performed using one-way ANOVA followed by Tukey's post hoc test or Welch's ANOVA when variance homogeneity assumptions were not met (Trial 1) and two-way ANOVA followed by Tukey's post hoc test (Trial 2).

## Results and Discussion

In Trial 1, final body weight ($BW_f$) was lower in the FM-5 group (17.15 ± 4.66 g) compared to the Control (18.42 ± 4.71 g) and FM-0 (18.56 ± 4.16 g) groups, with a significant difference between the FM-0 and FM-5 groups ($p < 0.05$; Welch's ANOVA). Feed conversion ratio (FCR) and specific growth rate (SGR) were similar between the Control (FCR: 8.39 ± 1.46; SGR: 0.62 ± 0.08) and FM-0 (FCR: 7.66 ± 1.64; SGR: 0.61 ± 0.12) groups, while FM-5 exhibited a higher FCR (13.11 ± 6.93) and a lower SGR (0.55 ± 0.29). Viscerosomatic index (VSI) and hepatosomatic index (HSI) values showed no significant differences among treatments. No differences were found in plasma glucose and cortisol levels; however, lactate levels were significantly lower in the FM-0 group compared to the Control group ($p < 0.05$; one-way ANOVA). This study indicated that the total replacement of FM with plant protein sources (FM-0 diet) did not significantly affect growth performance, feed efficiency, or somatic indices in juvenile flathead grey mullet compared to the Control diet. These findings align with the natural feeding behavior of mullet, a species well adapted to herbivorous and detritivorous diets (Brusle, 1981; Wassef et al., 2002).

*(Continued on next page)*

In contrast, partial replacement (FM-5 diet) led to a significant reduction in $BW_f$ compared to the FM-0 group, suggesting that intermediate FM levels combined with plant-based ingredients may have negatively impacted diet palatability (Gisbert et al., 2016)optimizing weaning diets is of special importance for this species at this particular stage of development. Thus, authors have tested a weaning protocol for wild flathead grey mullet fry (202mg initial body weight. Regarding plasma biochemical parameters, such as lower plasma lactate concentrations were recorded in fish fed the FM-0 diet compared to the control group, potentially reflecting a better metabolic adaptation to the plant-based formulation.

In Trial 2, $BW_f$ did not differ significantly among dietary treatments at either salinity level. Mean values were: Control, 28.96 ± 7.332 g (8 ppt) and 30.79 ± 8.964 g (36 ppt); FO-0, 27.45 ± 10.11 g (8 ppt) and 28.84 ± 11.53 g (36 ppt); FO-5, 28.80 ± 8.847 g (8 ppt) and 28.98 ± 9.920 g (36 ppt). Similarly, no significant differences were observed in FCR or SGR. At 36 ppt, VSI was significantly higher in fish fed the Control diet (9.22 ± 0.91%) compared to those fed FO-0 (7.76 ± 0.55%) and FO-5 (7.55 ± 0.54%) diets ($p < 0.05$). HIS was significantly higher in FO-5 fed fish at 8 ppt (0.80 ± 0.15%) than at 36 ppt (0.64 ± 0.13%) ($p < 0.05$). Plasma glucose levels were significantly higher in FM-5 fed fish at 36 ppt compared to the Control group ($p < 0.05$). A salinity effect was also evident in FO-5 fed fish, with significantly higher glucose concentrations at 36 ppt than at 8 ppt ($p < 0.05$). Plasma lactate levels showed a similar trend. Finally, circulating cortisol was significantly higher in control-fed fish reared at 8 ppt compared to those at 36 ppt ($p < 0.05$). This trial indicated that the total replacement of FO with vegetable lipids did not affect growth performance and feed efficiency in mullet, consistent with their omnivorous feeding habits (Wassef et al., 2002). This is highly positive from a sustainability perspective, supporting the reduction of marine resource dependency. However, metabolic responses varied with diet and salinity, highlighting the need to consider environmental factors in feed formulation.

# INTEGRATIVE OMICS APPROACHES FOR UNDERSTANDING THE FISH LOCAL AND SYSTEMIC IMMUNE RESPONSES TO SINGLE AND CO-INFECTIONS

Mona Saleh ; Naveed Akram; El-Matbouli M.; Holzer A.S.

Division of Fish Health
University of Veterinary Medicine
1210 Vienna, Austria
E-mail: mona.saleh@vetmeduni.ac.at

## Introduction

Currently, fish production through aquaculture and wild capture is growing as a result of the increased fish protein demand for human consumption. The adverse effects caused by pathogens both in hatchery and grow-out ponds, have decreased aquaculture production and causing high economic losses for the aquaculturalists. Therefore, it is becoming increasingly important to improve fish products in size and value through adequate disease management procedures. A systematic study using omics approaches can help us to understand the complex and sophisticated interactions in the host-pathogen network, leading to identifying new targets and biomarkers for diseases caused by bacteria, viruses, and parasites. The use of different omics approaches is a powerful that can provide new knowledge on host-pathogen interactions and can help us develop novel approaches for disease management and sustainable aquaculture production.

## Materials and methods

We used the two prominent omics approaches proteomics and transcriptomics to study host immune responses and host-parasite interactions in a well-established co-infection disease model. We have investigated how the myxozoans *Myxobolus cerebralis, and Tetracapsuloides bryosalmonae* modulate the host fish immune response after single and co-infections by quantitative proteomics and transcriptomics. For the infection experiment, one group of fish was infected with *M. cerebralis* (Mc group) and another group with *T. bryosalmonae* (Tb group). After 30 day, half of the fish in each group were then co-infected with the other parasite (Mc+ group and Tb+ group). At day 31, the proteomic changes and the transcriptomic modulation in the caudal fins, gills, head cartilage and kidney of rainbow trout were investigated at different time points. The parasite load was determined post exposure in single and co-infection groups.

## Results

In the caudal fins and the gills, multiple transcripts and proteins mostly involved in parasite recognition, tissue repair and the regulation of host immune responses were differentially modulated between the groups in the caudal fin. In the head cartilage and kidney, numerous transcripts and proteins were differentially regulated between the groups. The identified proteins in the head cartilage were primarily involved in host protection against oxidative stress, DNA and RNA synthesis and metabolism. The differentially regulated proteins in the kidney were mainly involved in proteasomal degradation, metabolism and host immunity. Several myxozoans transcripts and proteins involved in parasite development and virulence were identified. The biological processes, molecular pathways and molecular functions of the differentially regulated transcripts and proteins were also analysed. It appears that *M. cerebralis* modulates the rainbow trout immune response in a path that likely synergistically facilitates a subsequent co-infection with *T. bryosalmonae*. Conversely, *T. bryosalmonae* triggers the host immunity apparently by induction of the several B-cell markers including MHC II, B-cell receptor CD22 and Ig-like domain containing protein, which may antagonistically amend the outcome of a subsequent co-infection with *M. cerebralis*.

## Conclusion

The results of the undertaken quantitative proteomic and transcriptomic analysis indicate the successful integration of multiple omics approaches for systemic investigation of biological systems in single and co-infection disease models. The investigations provide novel insights of how myxozoan parasites modulate host immune responses influencing the outcome of co-infections in rainbow trout. The analysis revealed key parasite virulence transcripts and proteins and highlighted potential invasion/evasion strategies during myxozoan infections. The results reveal novel traits of host-parasite interactions and paves the way for the development of novel tools for myxozoan disease management in aquaculture.

# IMMUNOMODULATORY EFFECT OF A DIETARY SUPPLEMENT IN WHITELEG SHRIMP *Litopenaeus vannamei* CHALLENGED WITH *Vibrio parahaemolyticus*

H. Salehi[1*], E. M. Ko[2], N. Dang[2], K. Nguyen[2], B. Fronte[3], R. Licitra[3], R. Heavyside[4]

## Introduction

Whiteleg shrimp (*Litopenaeus vannamei*) have experienced rising production over the past decade, but intensified farming has led to increased susceptibility to diseases such as acute hepatopancreatic necrosis disease (AHPND). This, caused by *Vibrio parahaemolyticus* (VP), severely impacts the hepatopancreas (HP), a key organ for metabolism and immunity. This infection can be detected through the dissection of shrimp HP, where typical signs include a pale appearance and organ atrophy. Due to the economic losses caused by AHPND for shrimp farmers, the use of antibiotics to prevent and treat this infection is common in developing countries. However, the misuse of antibiotics has caused microbial resistance, which poses a significant global threat by reducing the effectiveness of disease treatments. To combat this, alternatives to antibiotics have been explored in shrimp such as essential oils, mannanoligosaccharides and β-glucan, which strengthen shrimp immunity. Additionally, glycerol fatty acid esters have shown antimicrobial properties against Vibrio pathogens. The aim of this study was to evaluate whether a combination of dietary immunomodulators (Marfeed Gut12) can improve the immune resistance of whiteleg shrimp against VP and at which dosage.

Figure 1. Survival rate after challenge

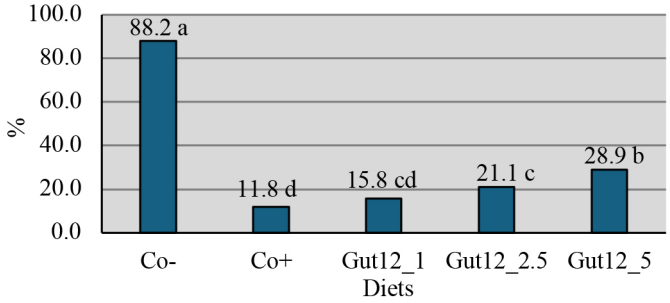

Figure 2. *Vibrio parahaemolyticus* load in hepatopancreas at the end of challenge period

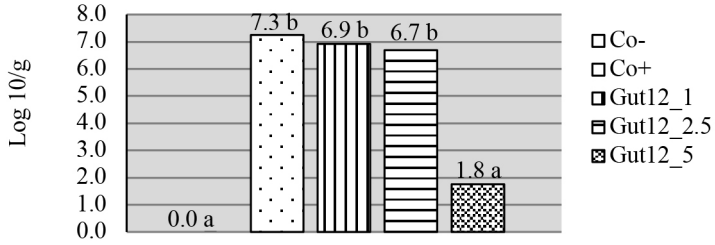

A significant difference between experimental groups is indicated by different letters above the bars ($p < 0.05$).

*(Continued on next page)*

Materials and Methods

In a four-replicate setup, five treatments were investigated, including two control groups and three test groups with 30 shrimp (average initial weight of 1.53 ± 0.07 g) per replicate. The controls included an unchallenged negative control (Co-) and a positive control (Co+) challenged with AHPND. The test groups were also challenged and fed a diet supplemented with test product at dosages of 1.0 (Gut12_1), 2.5 (Gut12_2.5), and 5.0 (Gut12_5) g/kg Marfeed Gut12. The 27-day trial comprised a 2-day acclimation period, 14 days of pre-challenge feeding, a 1-day VP challenge, and a 10-day post-challenge observation phase. The challenge was conducted via immersion in water by an $LD_{50\text{-}60/96\text{-}120\ h}$ dose of $VP_{AHPND}$ for all diets, excluding the negative control group. Shrimp survival rates were assessed post-challenge eight times per day. At the end of the challenge, qPCR was used to measure VP quantities in the HP, with samples taken from three shrimp per tank. Data analysis through one-way ANOVA revealed statistically significant differences between mean values at $p < 0.05$.

Results

The findings suggest that dietary supplementation of Marfeed Gut12 significantly enhanced shrimp survival rates in groups challenged with AHPND (Fig. 1). The survival rate, nearly doubled ($p < 0.05$) in the group receiving 5 g/kg of the supplement (28.95 ± 6.8%) compared to the positive control group (11.84 ± 2.63%). Furthermore, the 5 g/kg dosage notably reduced the quantity of VP in the HP compared to other infected groups (Fig. 2).

Conclusions

Incorporating Marfeed Gut12 at 5 g/kg in shrimp diets significantly enhances their resistance and survival against *Vibrio parahaemolyticus*.

# A NOVEL, ACCESSIBLE SENSOR FOR THE PROMPT DETECTION OF *Vibrio vulnificus* IN AQUATIC ENVIRONMENTS

Rubén Salvador-Clavell[a*], Pedro Quintero-Campos[b], Blanca Martín[b], Belén Fouz[a], Luís A. Tortajada-Genaro[b,c], Ángel Maquieira[b,c], Carmen Amaro[a]

E-mail: ruben.salvador@uv.es

## Introduction

Global warming is driving rapid ecological shifts, including changes in the geographical range and virulence of pathogenic bacteria. *Vibrio vulnificus* (Vv), a species linked to warmer waters, has emerged as a key biomarker for climate change, with recent detections in aquatic ecosystems that are traditionally colder. Effective assessment of these changes and the implementation of mitigation strategies require localized environmental surveillance. However, current monitoring methods often rely on complex instrumentation, which limits their widespread applicability. Consequently, there is a pressing need for novel detection strategies that are portable, affordable, and effective.

## Materials and Methods

This study describes the monitoring of a Mediterranean coastal wetland using a rapid and straightforward technology for detecting Vv in water samples (Figure 1). The method integrates an enrichment step with isothermal amplification of the *vvhA* gene via recombinase polymerase amplification (RPA). The final detection is performed visually on a lateral flow strip, which is incorporated into a microfluidic chip.

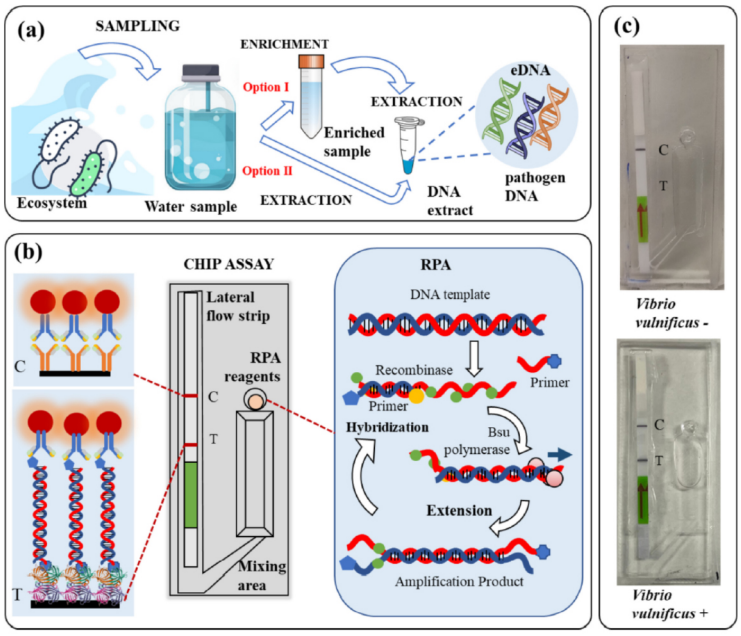

***Figure 1. Overview of Vv detection in environmental samples****. (a) Schematic workflow for samples collected from aquatic ecosystems. An enrichment step (Option I) is required for low Vibrio concentrations, while high concentrations can bypass this step (Option II). (b) Assay principle for on-chip amplification and detection, which uses recombinase polymerase amplification (RPA). (c) Chip images showing the visual detection of the target bacterium in lake water samples, where a T (test) line indicates the presence of Vv and a C (control) line confirms a successful assay. Figure taken from Quintero-Campos et al. (2025); DOI: 10.1016/j.scitotenv.2025.179791.*

*(Continued on next page)*

**Results**

The sampling campaign identified areas within the wetland where Vv concentrations surged by up to 300 times, notably in brackish zones and at points of water inflow or outflow. The new system's results were a perfect match with those from traditional PCR and electrophoresis, confirming its reliability. This innovative tool has the potential to pinpoint microenvironments that support or inhibit bacterial growth and could be a vital component of global surveillance strategies for climate change-related diseases.

**Conclusion**

The implemented sensor demonstrated high sensitivity, effectively identifying Vv blooms in environmental waters that could pose a risk to public health.

# MULTIGENERATIONAL TEMPERATURE EFFECTS ON PATERNAL-TO-OFFSPRING EPIGENETIC INHERITANCE IN SEA BASS

## Introduction

Environmental changes can trigger epigenetic modifications that influence gene expression and, consequently, the phenotype. However, key questions remain about the mechanisms underlying epigenetic inheritance and the extent to which environmentally induced epigenetic marks are transmitted across generations. In particular, the potential role of epigenetic mechanisms —especially DNA methylation—in facilitating short-term adaptation is still under investigation. To address these questions, we examined how temperature influences genome-wide DNA methylation patterns, with a specific focus on the sex phenotype and genes involved in sex determination and differentiation, and assessed the potential transmission of these modifications to the offspring.

## Materials and Methods

We used the European sea bass (*Dicentrarchus labrax*), a fish species with a polygenic and temperature-sensitive sex determination system, to investigate the effects of temperature on DNA methylation. Genome-wide profiles were obtained at single-nucleotide resolution using reduced representation bisulfite sequencing in 66 individuals from five families across two generations ($F_0$ and $F_1$). Individuals were exposed to control (16 °C, C) or elevated (21 °C, T) temperatures between 12 and 60 days post-fertilization in a multigenerational experimental design. Four temperature exposure regimes were applied to the $F_1$ generation: control (CC), ancestral exposure via sires (TC), developmental exposure in offspring (CT), and dual exposure (TT).

To assess the effects of temperature and sex on DNA methylation, we performed the following analyses: First, for each region covered, we applied a generalized linear model with a binomial distribution to methylation count data, using $F_0$ and $F_1$temperature treatments as fixed effects and correction for multiple testing. Analyses were performed separately for testes and ovaries. This approach allowed us to classify regions into five categories: no effect, $F_0$-only effect, $F_1$-only effect, additive effect (same direction of change in $F_0$ and $F_1$ without interaction), and interactive effect (significant interaction between $F_0$ and $F_1$, regardless of direction of change). These regions were further filtered based on differential methylation, using sex and sire as covariates. Second, we investigated temperature effects, specifically focusing on a panel of sex-related genes. And, third, we assessed the proportion of stable (constitutive) versus environmentally-induced epigenetic marks between generations to evaluate the potential for inheritance of methylation changes.

## Results and Discussion

In terms of phenotypic sex, we observed a significant increase in the proportion of males in temperature-treated groups, as expected. However, when comparing the dual-exposure group (TT) with the control group (CC), differences in sex ratios approached but did not reach statistical significance ($P = 0.051$). Regarding other traits, males exhibited significantly higher body weight and length in response to temperature treatment when compared to CC males, with the TT group showing the highest values. In contrast, temperature-resistant females also displayed an increase in body size under temperature treatment, but this effect was not significant when comparing CC and TT groups.

Analysis of DNA methylation data revealed marked sex-specific differences in the distribution of regions across model-defined categories. Notably, only 5.1% of regions in males and 3.7% in females exhibited an additive temperature effect. In contrast, a substantial proportion of regions —37.0% in males and 31.1% in females— showed qualitative interactions, where the direction of the temperature effect differed between generations ($F_0$ and $F_1$). This pattern suggests the presence of compensatory epigenetic mechanisms in response to repeated temperature exposure.

*(Continued on next page)*

We are currently working on analyses on neomales (genetic females that developed as phenotypic males); results from these individuals will provide further insight into temperature- and sex-specific methylation dynamics.

Additionally, we identified several key sex-related genes whose methylation patterns were significantly affected by temperature in a regime-dependent manner. Furthermore, we found that while a substantial portion of epigenetic marks were stably transmitted from sires to offspring, a small but noteworthy fraction (~5%) of inherited marks were temperature-induced and transmitted to the following generation. These findings offer new insights into the extent of environmentally-driven epigenetic inheritance.

**Conclusions**

Overall, our study underscores the influence of temperature on the epigenetic landscape, with important implications for understanding plasticity, adaptation, and epigenetic effects transmitted across generations in the context of global climate change.

**Introduction**
Microbial communities inhabiting fish-associated niches and surrounding water play a crucial role in host health, environmental resilience, and pathogens persistence. However, little is known about how these communities mediate the coexistence of antibiotic resistance genes (ARGs) and metal resistance genes (MRGs), particularly across wild and captive environments. As part of the *BlueRemediomics* project, we investigated the microbiota resistome of Atlantic salmon (*Salmo salar*) from freshwater and marine environments by sampling the skin, gut, feces and surrounding water. Fish were collected from sea cage farms (captive) and from rivers or fjords (wild), all corresponding to the smolt stage and of comparable size.

**Materials and methods**
DNA was extracted using the Zymo Research Miniprep kit following the manufacturer's recommendations. Total genomic DNA from 40 samples was then processed for metagenomic sequencing on the NovaSeq 6000 PE150 platform, targeting ~10 million reads per library. Raw reads were quality-checked using *fastp*, and host DNA contamination was removed with *Bowtie2* using the reference genome GCF_905237065.1. ARGs and MRGs were annotated using the PanRes database (v1.0.1) and the KMA tool. The same DNA samples were used for metabarcoding sequencing targeting the V3–V4 regions (341F/R805) of the 16S rRNA gene, using the Illumina NextSeq PE250 platform. Genetic and taxonomic diversity was analyzed using ecological indices (alpha and beta diversity) and compared across sample types, environments, and rearing systems.

**Results**
Results showed that the abundance and diversity of ARG classes was significantly influenced by sampling origin and type. Mucosal niches (skin and gut) harbored the highest diversity of ARG–MRG combinations in both captive and wild fish. Water samples exhibited distinct resistance profiles, while fecal samples contained only a marginal presence of resistance genes. This highlights the importance of sample type selection when profiling ARG–MRG communities, with more tightly fish-associated microbiota carrying more diverse resistance families.

Among clinically relevant families, aminoglycoside, fluoroquinolone, and beta-lactamase resistance genes were the most dominant. Notably, aminoglycoside profiles mirrored the abundance of copper resistance genes, particularly in skin microbiota. Furthermore, genera such as *Stenotrophomonas* and the NS5 marine group were positively associated with several specific resistance genes, suggesting potential co-selection. Future work should include the isolation and comprehensive characterization of these Atlantic salmon–associated strains to better understand their clinical relevance in both captive and wild populations.

**Conclusion**
The present findings highlight the influence of the ecosystem niche on the resistome development, including the environmental pathways that may facilitate ARG–MRG co-selection. Our results aim to contribute towards the improvement of targeted monitoring and mitigation strategies to reduce the dissemination of resistance genes while supporting sustainable aquaculture practices.

## Introduction

One of the objectives of the project PHYTOWELFISH aims to determine if a phytogenic antioxidant, AquaNeox (TECNOVIT-FARMFaes Ltd.), can improve the physiological status in European seabass (*Dicentrarchus labrax*) raised at high stocking density. Phytogenics, which are plant-derived compounds like carotenoids or phenolic compounds, are used in aquaculture to protect tissues and improve animal welfare (Hu et al., 2025). This study will focus on how AquaNeox and stocking density affect skeletal muscle development, specifically the formation of new muscle fibers (hyperplasia) and the growth of existing ones (hypertrophy) (Alami-Durante et al., 2010; Zho et al., 2018). While various factors influence muscle growth, the combined effects of diet and stocking conditions in muscle physical parameters and cellularity are not yet well understood.

## Materials and methods

European seabass (*D. labrax*) fish (n = 480; $w_i$ = 105 ± 30 g) were divided into four groups, each with three replicates. The groups were based on two factors: diet (control or AquaNeox at 0.05%) and stocking density (low-LD: 5 kg/m$^3$ or high-HD: 37 kg/m$^3$). After two months, muscle samples from 12 fish per experimental group were taken to analyze the combined effects of stocking density and dietary supplementation on physical parameters such pH, torrymeter, color, and moisture. Additionally, muscle samples from 9 fish per group were taken below the dorsal fin, sectioned and fixed in 10%-formalin. These sections were stained with hematoxylin/eosin to photograph whole muscle cross-sections in a light microscope (Nikon Eclipse Ci-L) with a Jenoptik ProgRes CT5 camera. Then, histomorphometric parameters such muscle fiber perimeter, area, and Feret's diameter were measured using FIJI software in IMAGEJ (50 measurements per fish). Fiber diameters were then grouped into five classes to determine hyperplasia, hypertrophy rates, and fiber density.

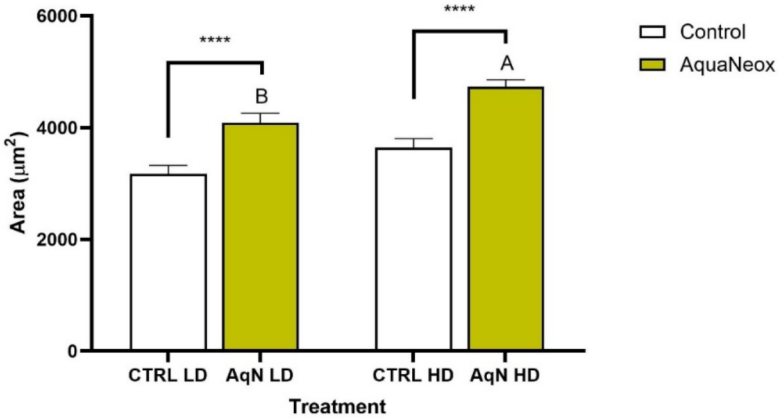

**Figure 1.** White muscle transverse area (µm$^2$) in European seabass (*Dicentrarchus labrax*) ($n$ = 9 animals per group). Different capital letters represent significant differences between stocking densities within the AquaNeox diet ($p < 0.05$). Asterisks indicate significant differences between diets within the same stocking density ($p < 0.0001$).

*(Continued on next page)*

## Results and discussion

The study focused on key physical parameters of muscle quality and cellularity. At the end of the study, no significant differences were found across any experimental group for muscle moisture (65 ± 4%), pH (7.3 ± 0.1), or Torrymeter values (13.5 ± 0.4). Low-density groups (CTRL-LD and AquaNeox-LD) tended to have higher L* (lightness) values, regardless of AquaNeox, suggesting lighter muscle compared to high-density groups (CTRL-HD and AquaNeox-HD). There were no significant differences in a* (green/blue shift) or b* (redness) values across any of the groups, regardless of the AquaNeox treatment or density. Regarding muscular cellularity, the study found no evidence of hyperplasia (new muscle fiber formation), based on fiber density and distribution. Instead, a clear trend toward hypertrophic growth was observed, characterized by an increase in fibers with diameters exceeding 45 $\mu$m and reduced recruitment of new fibers. While stocking density did not significantly affect muscle cellularity, AquaNeox treatment significantly increased muscle fiber area (Figure 1), perimeter, and Feret's diameter across both low and high stocking densities. This strong hypertrophic effect of AquaNeox aligns with previous studies with antioxidants, in which also increased fiber diameter and related gene expression (Thomazini Zanella et al., 2021).

## Conclusions

Adding AquaNeox to the diet of European seabass effectively promoted muscle growth through hypertrophy (increase in fiber size) by increasing fiber area, perimeter, and diameter. It did not, however, lead to hyperplasia (formation of new muscle fibers). This effect of AquaNeox is independent of stocking density, which had no significant impact on muscle cellularity or physical parameters such as moisture, pH, or color. Therefore, AquaNeox is a promising dietary supplement for improving muscle quality in European seabass.

## Introduction

Global demand for high-quality aquatic products necessitates effective freshness and shelf-life strategies (Yeşilsu et al., 2025). Consumers favor natural, plant-derived phytochemicals over synthetic additives due to the latter's antioxidant and antimicrobial properties, which can prevent degradation and inhibit microbial growth, thereby improving food quality (Biswas et al., 2023). For example, AquaNeox (TECNOVIT-FARMFaes Ltd.), a phytogenic nutraceutical, provides substantial antioxidant benefits and can be incorporated into the diet of fish to reduce oxidation. In the PHYTOWELFISH project it was evaluated the potential of this additive to increase the quality of European seabass (*Dicentrarchus labrax*) meat, based on the hypothesis that dietary natural antioxidants would counteract oxidative spoilage and improve the freshness and shelf life of processed fish fillets.

## Materials and Methods

European seabass adults (*D. labrax*) (initial mean weight 300 g) were divided into three experimental groups, in duplicate, according to their diet: i) control group, ii) diet supplemented with AquaNeox at low concentration (0.05%), iii) and supplemented with AquaNeox at high concentration (0.1%). After 64 days, fish were euthanized using ice slurry, to mimic commercial practices, and kept on ice for 24-48 hours to simulate commercial conditions, then eviscerated, processed into fillets (with bone), packaged, and stored under refrigeration at 4 °C. Freshness and shelf-life were monitored through periodic sampling at day 0, 5, 8, 12, 15, and 20. Analyzed parameters included pH, water activity, color, texture, TVB-N and TMA as physicochemical indicators of freshness; LPO and ORAC as indicators of oxidative stability and the effectiveness of antioxidant strategies; and microbiological analysis as detection of pathogens/indicator microorganisms of spoilage.

## Results

The results showed that pH values generally increased over storage time across all groups, with AquaNeox having a slightly favourable effect. It helped maintain water activity and preserve the product's initial colour better, specifically reducing yellowness (b). Adding 0.1% AquaNeox resulted in the lowest total colour difference (ΔE) over time (Figure 1a). AquaNeox also mitigated the increase in spoilage indicators such as total volatile basic nitrogen (TVB-N) and trimethylamine (TMA), with the 0.1% concentration performing best (Figure 1b). The additive demonstrated good antioxidant capacity, resulting in low lipid peroxidation (LPO) and improved preservation, particularly with 0.1% AquaNeox on days 8 and 15 (Figure 1c–d). Although microbiological quality remained stable below spoilage levels for the first eight days, mesophilic bacteria increased at a similar rate across all groups from day 15 onwards, though all samples met international standards (Regulation EC No. 2073/2005). Texture parameters remained stable and were not significantly affected by the treatment.

## Conclusions

This study demonstrates that supplementing with AquaNeox, particularly at concentration of 0.1%, could extend the shelf life of sea bass fillets by reducing spoilage markers (TVB-N and TMA), oxidative damage (ORAC) and color loss. This supports the use of AquaNeox as a nutraceutical in aquaculture.

# FIRST REPRODUCTIVE EVENT OF HATCHERY-PRODUCED *Ostrea edulis* FROM THE MAR MENOR LAGOON

Silvia Sanchez-Segarra*[1], Sebastian Hernandis[1], Fiz Da Costa[2], Rosa Alcaraz[1], Marina Albentosa[1]

[1]IEO-CSIC, Centro Oceanográfico de Murcia, Varadero 1, 30740 San Pedro del Pinatar, Murcia, Spain
[2]IEO-CSIC, Centro Oceanográfico de Vigo, Subida Radio Faro 50-52, 36390 Vigo, Pontevedra, Spain
silvia.sanchez.segarra@ieo.csic.es

## Introduction

The flat oyster *Ostrea edulis* is a native European species known for its significant role in ecosystem services such as habitat creation and biofiltration. Historically abundant across the northeastern Atlantic and the Mediterranean basin, its populations have drastically declined due to overexploitation, habitat loss, and environmental degradation (Thurstan et al., 2024).

*O. edulis* is increasingly being used in restorative aquaculture, which, when properly implemented, offers a promising and sustainable approach to ecosystem restoration. In the Mediterranean Sea, specifically in the southeast of Spain, the Mar Menor Oyster Initiative (MMOI, https://noraeurope.eu/spain-the-mar-menor-oyster-initiative/) is being carrying out. This initiative aims to study the nutrient extraction capacity of *O. edulis* in the hypersaline Mar Menor lagoon and to develop tools necessary for future restoration and bioextraction actions (Albentosa et al., 2023).

The main objective of this study is to increase the *O. edulis* stock to support ecosystem restoration efforts in the Mar Menor and to validate the reproduction of hatchery-produced oysters in 2022 (Hernandis et al., 2023), confirming their viability for successful breeding.

## Material and methods

The reproduction of the oysters was carried out from March to May 2024 according to its natural reproductive season in the Mar Menor lagoon (SE Spain). It took place at the IEO-CSIC experimental hatchery using 69 broodstock individuals: 29 wild oysters from the lagoon (WB) and 40 hatchery-produced in 2022 (HB) in the same experimental hatchery.

## Results and discussion

Spawning followed natural thermal cycles, producing a total of 36 spawns and 59.8 million larvae, 48% of which originated from HB (Figure 1). These findings confirm for the first time that individuals bred in hatchery in 2022 (Hernandis et al., 2023) are reproductively viable. Larvae from WB were significantly larger (mean = 168.5 $\mu$m) than those from HB (mean = 153.3 $\mu$m), and their survival to settlement was also higher (54% vs. 21%, respectively). However, the survival rate to postlarvae stage was higher (24%) for those larvae from HB than those from WB (16%). The observed differences in fecundity and larval performance are consistent with age-related reproductive maturity: WB individuals were older and fully mature

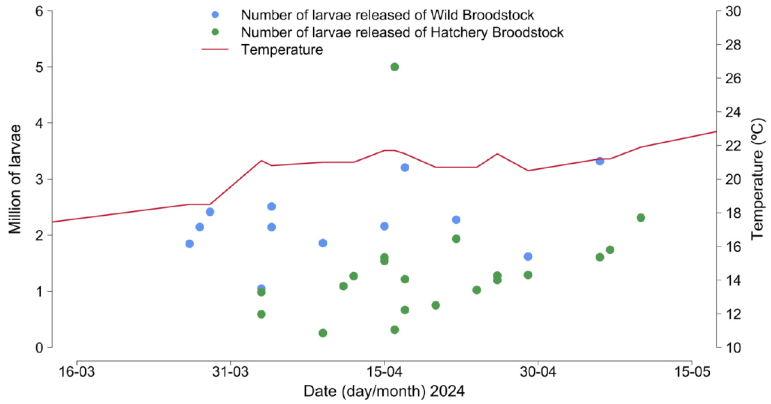

Figure 1. Monthly spawns per broodstock origin related with the temperature.

*(Continued on next page)*

possessing greater energy reserves and more developed gonads, whereas HB were in their first reproductive cycle after reaching sexual maturity. This may influence reproductive outcomes, with older individuals typically having larger energy reserves and more developed reproductive organs (Bayne, 2017).

This study demonstrates the reproductive potential of both wild and hatchery *O. edulis* from the Mar Menor, highlighting the viability of establishing a reliable stock of locally adapted native oysters. This integrates aquaculture into restoration frameworks allowing large-scale actions in the lagoon, aligned with global efforts to recover native oyster habitats and the ecosystem services they provide.

# TRANSCRIPTOMIC PROFILING OF SPERMATOGENESIS IN THE EUROPEAN SEA BASS (*Dicentrarchus labrax*) ACROSS THE REPRODUCTIVE CYCLE

Nerea Sanchis*, Noelia Díaz, and Mercedes Blázquez

Institute of Marine Sciences (ICM-CSIC)
Passeig Marítim de la Barceloneta 37-49

*nsanchis@icm.csic.es

**Introduction**

The European sea bass (*Dicentrarchus labrax* L.) is a key aquaculture species in Mediterranean countries. In farming conditions, males often undergo precocious puberty, which negatively affects their growth (Felip et al., 2006). Understanding the molecular mechanisms that regulate testicular maturation is essential for improving reproductive management and minimising growth retardation. This study aims to characterise the transcriptomic landscape of spermatogenesis across the annual reproductive cycle in this economically important fish species.

**Materials and methods**

Testes were collected during the second year of life covering the six stages of spermatogenesis that comprise the entire annual reproductive cycle (Begtashi et al., 2004): Stage I (immature), Stage II-SIV (early, mid and late recrudescence), Stage V (fully spermiating), and Stage VI (post-spawning). Samples were processed for histological analysis and directional RNA sequencing (RNA-seq). The histological study enabled precise staging and quantification of germ cell types in the testes. Moreover, it allowed for the selection of eighteen samples (three per stage) that were further used for transcriptomic profiling by RNA-seq (Love et al., 2014).

**Results**

Transcriptomic analysis enabled the *de novo* assembly of the sea bass testis transcriptome and the identification of differentially expressed genes (DEGs) across all stages compared to the basal stage (SI). Early spermatogenesis (SII vs SI) was characterised by the activation of gonadotropin and steroid hormone signalling pathways, promoting the proliferation of spermatogonia A. In mid-spermatogenesis (SIII vs SI), genes involved in mitosis, DNA replication, and chromatin remodelling were upregulated, reflecting the intense proliferation of spermatogonia B and spermatocytes I. Spermiogenesis (SIV vs SI) was characterised by a DEG enrichment in pathways associated with flagellar assembly, chromatin packaging, and transcriptional regulation. During spermiation (SV vs SI), DEGs included genes involved in sperm maturation and release, such as those related to calcium signalling and proteolytic activity. Finally, testicular regression (SVI vs SI) was characterised by the upregulation of genes involved in vascular remodelling and immune response.

**Discussion**

Bulk RNA sequencing data revealed the presence of DEGs and functional pathways associated with steroidogenic activity, and mitotic and meiotic proliferation of spermatogonial stem cells at the onset of spermatogenesis (SI-SIII). This pattern is consistent with Gene Ontology enrichment analyses, which are strongly associated with DNA replication and recombination processes. Notably, this stage also featured a downregulation of *amh* and *cyp26a*, highlighting their importance in initiating and driving the progression of spermatogenesis (Skaar et al., 2011; Blázquez et al., 2017). During late spermatogenesis (SIV-SV), the expression of sperm-specific DEGs was increased, suggesting a mechanism for sperm-chromatin packaging that relies on a diverse group of histones (Barrachina et al., 2018). In line with previous studies, the regression stage (SVI) that marks the end of the spermatogenic cycle was characterised by testicular remodelling, accompanied by increased expression of immune-related genes and enhanced vasculogenesis (Valero et al., 2015). Furthermore, developmental function analysis led to the identification of other novel spermatogenesis-related genes across the different stages.

*(Continued on next page)*

**Conclusions**

This study provides the first comprehensive transcriptomic atlas of spermatogenesis in the European sea bass, identifying key molecular markers and regulatory pathways across the annual reproductive cycle. These findings shed light on the genetic and molecular mechanisms underlying spermatogenesis, an essential process for ensuring reproductive efficiency and optimising growth in cultured fish species.

**Introduction**

Bivalve mollusk aquaculture is very appealing due to its benefits for human nutrition, the economy, and the environment. However, production is currently constrained by issues like feed deficiencies, diseases, and quality concerns (FAO, 2024). Recent advancements in microencapsulation technology offer promising opportunities to enhance bivalve farming. Microparticles (MPs) can effectively deliver important molecules in aquaculture, such as peptides or antibiotics, by protecting these substances from degradation in acidic environments (Shah, et al., 2020).

In this study, MPs serve as delivery vehicles for both small molecules and nucleic acids. Main component of MPs were small unit vesicles or SUV liposomes (Walde et al., 2001) combined with graphene oxide and/or polyethylenimine polyplexes, each component played different structural and functional roles. Graphene oxide (GO), a biocompatible two-dimensional nanomaterial, acted as a flat assembly platform, aiding the integration of liposomes and other elements. Branched polyethylenimine 25KDa (PEI), a cationic polymer recognized for its gene delivery properties, was used to compact a plasmid encoding green fluorescent protein (GFP) forming polyplexes (Deng et al., 2009; Kim et al., 2011; Sercombe et al., 2015). The main objective of this project was to assess the ability of three different MPs to serve as delivery vehicles for small molecules and nucleic acids to bivalve mollusks.

**Materials and Methods**

Different formulations of MPs were prepared using SUV liposomes, GO and polyplexes (PP) composed of PEI and a plasmid DNA encoding GFP as the nucleic acid cargo. Three types of MPs were tested: (1) GO/liposomes, (2) PP/liposomes, and (3) PP/GO/liposomes. For experimental validation, all liposomes were loaded with carboxyfluorescein (CF), except the control group, whose liposomes were not charged with CF. The size distribution of each kind of microparticles was analyzed using a Corning Videodrop (Corning Incorporated, USA). The delivery properties of CF or the GFP plasmid were tested *in-vivo* in the Mediterranean scallop (*Pecten jacobaeus*).

The *in-vivo* experiment included three treatment groups and one control group, with a total of twelve animals—three individuals per treatment and three in the control group. Each animal was kept individually in a 1L tank, where the different microparticle formulations were added. Fecal samples were collected over a 48 to 72-hour period. After this, the animals were sacrificed, and tissue samples were collected and preserved in 1 mL tubes containing RNAlater, then stored at 4 °C until further analysis. The collected tissues included gills, mantle, crystalline style, adductor muscle, digestive gland, and gonad.

All tissue samples were examined using an InCellis fluorescent microscope (Bertin Technologies, Montigny-le-Bretonneux, France). Total RNA was extracted from all tissues using the RNeasy Kit (QIAGEN, Hilden, Germany) following the manufacturer's standard protocol. RNA concentration was determined with a BioPhotometer D30 (Eppendorf, Hamburg, Germany). To eliminate genomic DNA contamination, total RNA was treated with DNase I (New England Biolabs, MA, USA). Complementary DNA (cDNA) was synthesized from total RNA using the LunaScript RT SuperMix Kit (New England Biolabs). Quantitative PCR (qPCR) was performed on a CFX96 Touch Real-Time PCR System (Bio-Rad, CA, USA) using *Pecten jacobaeus* 18S rRNA as the reference gene (forward: TCGATGGTACGTGCTATGCC; reverse: CCTTGGATGTGGTAGCCGTT) and EGFP as the target gene (forward: GACGTAAACGGCCACAAGTT; reverse: AAGTCGTGCTGCTTCATGTG).

**Results and Discussion**

Three different formulations of MPs were successfully synthesized. The median diameters were 153 nm for GO/liposomes, 163 nm for PP/liposomes, and 180 nm for PP/GO/liposomes. The major size means of the PP/GO/liposomes complexes likely reflects the increasing supramolecular structure complexity.

*(Continued on next page)*

Fluorescence was detected in all samples when observed under a fluorescent microscope, except for the crystalline style samples from the control group and one crystalline style sample from the LPG treatment. This may be because the crystalline style mainly consists of extracellular enzymes with few active cells, limiting the expression of fluorescence. Nonetheless, the detected fluorescence confirms successful ingestion of the MPs and release of their encapsulated content beyond the digestive tract, with visible signals in the gills, mantle, adductor muscle, digestive gland, and gonad, suggesting possible diffusion of the released compounds. Since the MPs used in the control group lack CF, the fluorescence observed is probably due to the internalization of the MP into cells and the expression of the green fluorescent protein GFP (Deng et al., 2009; Kim et al., 2011).

**Conclusion**

In conclusion, the study successfully engineered and synthesized different microparticle formulations with varying sizes in the nanometer range and different structural complexity. Fluorescence microscopy confirmed the effective ingestion and distribution of these microparticles and their contents across multiple bivalve tissues. Notably, the fluorescence observed in the control group, which lacked carboxyfluorescein, constitutes evidence of cellular internalization of the microparticles and expression of the GFP encoded by the plasmid. Preliminary qPCR results support this finding, showing positive amplification in two samples. Further qPCR analysis will offer a clearer understanding of the gene delivery and expression efficiency of the different microparticle formulations.

**Introduction**
Studies testing the applicability of insect oils as alternatives to fish oil in aquaculture have demonstrated positive effects related to lipid metabolism and fish immunity. However, the impact of insect oil on the gut microbiota of fish remains largely unexplored. In this study, we examined the gut microbiota of European catfish (*Silurus glanis*) and hybrid African catfish (*Clarias gariepinus* × *Heterobranchus longifilis*) fed extruded experimental diets containing black soldier fly larvae oil, comparing them to fish fed a traditional fish oil-plant oil-based diet. The aim was to assess how dietary insect oil influences the composition of gastrointestinal microbiota.

**Materials and methods**
Fish were fed with three isonitrogenous (430 g/kg) and isolipidic (110 g/kg) diets (a control and two insect oil (IO) based diets). The main differences between the diets were the oil source and physical properties of the pellets (sinking feed for European catfish, floating feed for African catfish). The control (CTR) diet contained a mixture of fish oil and rapeseed oil (1:1 ratio), IO50 diet contained 50% black soldier fly larvae oil (BSFLO) replacing fish oil and rapeseed oil mixture, and IO100 diet contained only BSFLO (100%). The first feeding trial (T1) involved a total of 630 European catfish juveniles (average body weight of 28.1 ± 0.17 g), randomly distributed into three dietary groups (CTR, IO50, and IO100), each replicated three times (70 fish per tank), and reared in a recirculation aquaculture system at 24.5 °C for eight weeks. A second trial (T2) involved 900 juvenile hybrid African catfish (average weight: 29.1 ± 1.69 g), similarly treated as the first trial. At the end of the feeding period, intestinal fecal samples were aseptically obtained from individual fish specimens and subjected to DNA extraction, amplification of the V3-V4 region of 16S rRNA, sequencing using an Illumina MiSeq sequencer, and analysis of raw sequence reads. The raw 16S rRNA gene sequence files and metadata were deposited at the NCBI SRA database under the BioProject PRJNA1222409.

**Results**
The alpha diversity (Shannon, Simpson, Pielou and Chao1) of intestinal microbiota in groups of European catfish fed the CTR, IO50, and IO100 were similar. Similar results were also obtained between dietary groups (CTR, IO50, and IO100) of hybrid African catfish. However, the Shannon and Pielou indices were significantly higher in hybrid African catfish than observed in European catfish. Regardless of the diet, the intestinal bacterial community of European catfish was dominated by either Fusobacteriota or Spirochaetota which together accounted for over 99% of the total bacterial abundance while that of hybrid African catfish was dominated by Fusobacteriota in all samples (>75% of total abundance). Other bacterial phyla including Proteobacteria, Firmicutes, Actinobacteriota, Bacteroidota, and Verrucomicrobiota, occurred with relative abundances <1% in European catfish and <1% to 24.2% in hybrid African catfish. The abundances of these phyla were not significantly influenced by the inclusion of insect oil in the fish diets. The Firmicutes to Bacteroidota ratio, known to be associated with enhanced oxidative response and more resistance to pathogens was higher in groups fed insect oil-based diets (IO50 and IO100) than those fed the control diet (CTR), with significant results obtained for hybrid African catfish. Fusobacteriota was dominated by the genus *Cetobacterium* in both fish species. The genus *Brevinema* was the most dominant in the phylum Spirochaetota and was only identified in faecal samples of European catfish in varying abundances. The numerically dominant Firmicutes in European catfish was *Exiguobacterium* while *Romboutsia* was the dominant Firmicute in hybrid African catfish. There were no major differences in the abundance of these genera between fish fed the CTR, IO50, and IO100.

*(Continued on next page)*

The highest number of amplicon sequence variants (ASVs) was shared between the dietary groups for each fish species and between the fish species fed a particular diet. Replacement of the CTR diet with insect oil-based diets led to an increase in the number of unique ASVs from 28.2% to 38.3% in the IO50 and 35.4% in IO100 groups of European catfish and a decrease from 29.8% in the CTR to 17.2% in IO50 and 22.8 in IO100 groups of hybrid African catfish. Most of the ASVs shared between the two species before and after replacement of the CTR with insect oil-based diets, could be core members of these species. These were mainly affiliated to the genus *Cetobacterium* (over 87% of the shared ASVs), the rest being affiliated to *Corynebacterium*, *Cutibacterium*, *Escherichia-shigella*, *Exiguobacterium*, *Bifidobacterium*, *Staphylococcus*, and other members of the family Comamonadaceae. ASVs unique to hybrid African catfish before and after replacement of the CTR diet with insect oil-based diets were mainly affiliated to the genera *Romboutsia, Plesiomonas, Turicibacter, Clostridium sensu stricto 1, Aurantimicrobium, Terrisporobacter,* and *Epulopiscium*. In European catfish, most of the unique ASVs identified before and after replacement of the CTR diet belonged to the genera *Brevinema,* and *Leifsonia*. The differences in bacterial functional composition between the dietary fish groups were similar for each species. The relatively abundant bacterial functions were associated with metabolism, environmental information processing, cellular processes, and genetic information processing.

**Conclusion**

Overall, these results indicated that complete substitution of fish oil or vegetable oils with black soldier fly larvae oil (BSFLO) is possible in the practical diets of siluriform fish, without causing deleterious effects on gastrointestinal microbiota. The observed trends in the Firmicutes/Bacteroidota ratio across the dietary groups, indicated that BSFLO exhibits antioxidant and anti-inflammatory effects closely associated with the increased Firmicutes/Bacteroidota ratio. Although it is unlikely that the *Brevinema* recorded in this study could be an opportunistic pathogen in European catfish, further studies are required to fully understand the effects of such variations in *Brevinema* abundance on the health of European catfish in aquaculture.

# GROWTH PERFORMANCE OF JUVENILE TILAPIA *(Oreochromis niloticus)* AT DIFFERENT DENSITIES USING BLUEBERRY *(Vaccinium corymbosum L., 1753)* UNDER EXPERIMENTAL DIET CONDITIONS

[1]Apolinar Santamaría Miranda* [1]Guillermo Arturo Espinoza Serrano, [1]Juan Pablo Apún Molina.
[1]Diego Oliver Apún Santamaria, [1]Maximo Garcia Marciano, [2]Alytza Madai Arzate Mendoza,
[2]Diana Jazmín De la Cruz Torres, [2]Jorge Enrique Salgado Ortíz

[1]Instituto Politécnico Nacional.
[2]Universidad Autónoma de Guerrero.

The Tilapia *(Oreochromis niloticus)* aquaculture production is the second most produced aquatic species worldwide and is also extremely important in the production of animal protein. There is interest in using plant-based products in diets, to increase productive performance, fish health, to decrease stress in culture and to support food safety. The importance of blueberry flour (BF) lies in its antioxidant and nutraceutical properties. The objective of this research is to evaluate the effect of including blueberry flour as a feed additive, in tilapia's O. niloticus health farmed in different densities at an experimental level.

A bioassay was performed for 3 weeks in tubs with 32, 40 and 56 organisms per treatment, commercial feed plus 3% BF additive was supplied, they were stocked with an approximate weight of 2.0 grams, with a control density of 25 organisms where BF was not supplied, only commercial feed. Physicochemical parameters, water quality, and hematological analysis were monitored.

The biochemical analysis results show there were differences.

The physicochemical parameters were within optimal range, the temperature was held at 28.0°C ± 2.0, dissolved oxygen at 6 ± 0.8 mg/L and pH at 8.3 UPpH. There were no significant differences ($P<0.05$) between treatments, with the greater organism density consisting of 32 and 24 organisms per square meter.

# ASSESSING THE POTENTIAL BENEFITS OF INTEGRATED MULTI-TROPHIC AQUACULTURE OF *Ulva* spp. AND *Mytilus edulis*

M. Santi*, I. MacMillan, A. Kennerley, E. Capuzzo

Centre for Environment, Fisheries and Aquaculture Science
Weymouth, United Kingdom
Email: morena.santi@cefas.gov.uk

## Introduction

Bivalves and seaweed extract organic and inorganic compounds from their surrounding environment, including carbon in its particulate or dissolved form, through biocalcification and photosynthesis processes, respectively. Seaweed also absorbs dissolved nutrients such as nitrogen and phosphate (Hurd et al., 2022, Jia *et al*., 2023). In the UK, both seaweed and bivalve monocultures are practiced, with bivalve aquaculture being more widespread and developed. However, instances of co-location of bivalves and seaweed aquaculture in an Integrated Multi-Trophic Aquaculture (IMTA) setting are limited. Initial studies on the co-cultivation of bivalves and seaweed have shown that CO2 and nutrients produced by bivalves (from pseudo-faeces) enhance seaweed growth, while seaweed's CO2 uptake reduces water acidification, thereby improving the growth rates of bivalves' shells and tissues (Young *et al*., 2022). This copilot study aimed to provide further evidence of the benefits of co-locating green seaweed (*Ulva* spp.) with blue mussels (*Mytilus edulis*) in a Recirculating Aquaculture System (RAS), focusing on both species' growth and water quality parameters.

## Materials and Methods

A total of 9 medium tanks (350L) each associated with its own RAS system were set up. Three distinct conditions were established in triplicate: the cultivation of mussels alone, the co-cultivation of mussels and *Ulva* spp., and the cultivation of *Ulva* spp. alone. Tanks with mussels housed a total of 20 individuals each and tanks with *Ulva* spp. approximately 100 grams of algae. The experiment was conducted over a period of six months, during which mussels were measured monthly, and water samples were collected for nutrient analysis, including ammonium, nitrite, Total Oxidise Nitrogen (Nitrate+Nitrite) TOxN, phosphate and silicate.

## Results

During the six-month experiment, mussels exhibited growth with high variability however, no statistically significant differences were observed between mussels-only treatments and mussels co-cultivated with *Ulva*. Most nutrient concentrations showed no significant differences between tanks, except for TOxN. levels which were statistically lower in the *Ulva*-only tanks as opposed to the mussel-only tanks (Figure 1). Differences in the TOxN level were noted between the cohabitation and monoculture conditions, but these differences were not statistically significant. These are preliminary non-parametric test and further investigation will be made as this test does not count for a nested structure, nor changes over time.

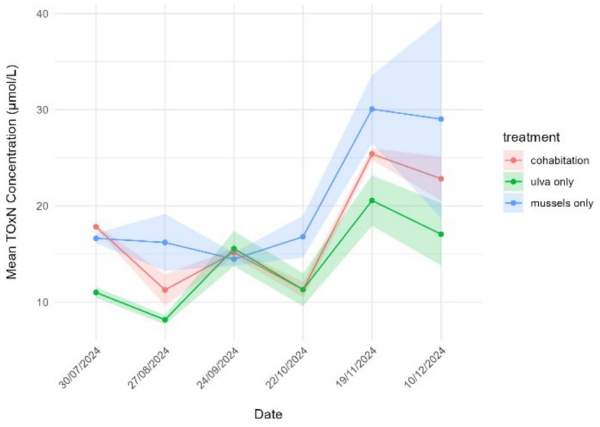

Figure 1: Mean concentration of TOxN overtime per treatment with standard error

*(Continued on next page)*

## Discussion

Although this study did not provide evidence of improved growth of mussel and *Ulva* when co-cultured, it highlighted the ability of *Ulva* to effectively uptake TOxN in the RAS setting. The lack of a significant enhancement in growth in the co-cultured tanks, in both species, may be the result of different factors including the practical challenges of managing both species within shared tanks. Maintaining optimal conditions for both organisms highlighted the logistical complexities of co-cultivation in a confined system. Therefore, a sequential tank setup, where mussels and *Ulva* are cultivated separately but interconnected (with water moving from mussels to *Ulva*), appears more feasible, and would likely maximise the nutrient uptake from *Ulva*. Stocking density of both species and water circulation within the RAS setups may also have influenced the interactions between mussels and *Ulva* in the co-cultured tanks.

Future research should involve scaling up experiments to open waters to evaluate potential growth differences under natural conditions, where hydrodynamic (current, wave action) can affect pseudo-faeces dispersal and nutrient uptake by seaweed. Key factors such as the stocking density of seaweed and mussels, size of the farm, proximity between seaweed and mussels, local hydrodynamic and environmental conditions (such as dissolved inorganic nutrient concentrations), should be investigated to determine the ecological interactions and operational feasibility of these integrated setups.

# A NUTRITIONAL SOLUTION DECREASES SEA LICE ATTACHMENT IN ATLANTIC SALMON BY 70% IN CONTROLLED CONDITIONS IN VIVO

Ester Santigosa[1*], Jutta Kesselring [2], Michaela Mohnl [2], Vladimira Ocelova[2]

[1] dsm-firmenich, Animal Nutrition and Health, Switzerland
[2] dsm-firmenich Animal Nutrition and Health, Austria
Email: ester.santigosa@dsm-firmenich.com

## Introduction

Sea lice is one of the major problems for salmon farming operations, resulting in 2024 in over 3000 mechanical treatments that have the potential to negatively impact fish performance, fish welfare and farm benefits (Moldal et al., 2025). Industry efforts to decrease parasite pressure combine technical, medical and genetic solutions (Santigosa, 2025). Moreover, the use of nutritional approaches to optimize sea lice management is often considered as part of the toolbox. To demonstrate the benefits of a feed additive on sea lice attachment, in this trial we tested a control feed versus three experimental feeds containing a matrix-encapsulated phytogenic that is based on essential oils of oregano, thyme, and citrus (Digestarom®) at three inclusion levels (400, 800 and 1200 g/ton). The aim of the trial was to validate the following hypothesis: this feed additive can reduce the attachment of sea lice at adult stage whilst maintaining zootechnical performance.

## Methods

Atlantic salmon post smolt (186g) were acclimated for 7 days in seawater tanks and then fed one of the dietary trial treatments for 45 days, using triplicate tanks per treatment. After this pre-challenge period, animals were challenged with sea lice (*Lepeophtheirus salmonis*) using a flush. The trial continued for a further 53 days. At the end of the trial (day 105), sea lice counts were performed, in addition to zootechnical performance and welfare scoring. Samples were taken for the determination of blood biochemistry.

## Results

Results show a significant decrease (70%) in the total number of sea lice with the two highest inclusion doses (800 and 1200 g/t). In addition, in these two treatments there was a concomitant increase in the percentage of fish without any lice in those specific treatments. Feed intake was not negatively impacted by the inclusion of the feed additive. Final body weight, FCR and SGR welfare scores were similar across the four treatments.

## Conclusions

The role of feed additives in sea lice management has long been considered as part of the toolbox to reduce sea lice infestation in salmon farming operations. The results obtained in this trial show that the in-feed inclusion of Digesterom® at 800 and 1200g/ton had a significant effect on sea lice attachment, reducing the count by 70%. The findings from the present R&D work support the need for large-scale commercial testing of this feed additive as the next step toward full validation.

## Introduction

Nursery systems using biofloc technology have proven effective in boosting productivity, improving survival, and minimizing environmental impacts in shrimp farming. However, in subtropical regions, cold fronts during autumn and winter pose a growing challenge by lowering temperatures, which negatively affect shrimp health and growth. Recently, macroalgae have gained attention as feed additives due to their nutritional value and their immunostimulant, antiviral, antibacterial, and growth-enhancing properties, offering a sustainable alternative to antibiotics in shrimp aquaculture. This study aimed to assess the effects of including dry biomass of the green macroalga *Ulva ohnoi* in the diet of *Penaeus vannamei* post-larvae reared in a biofloc system, focusing on growth performance, post-larvae microbiology, and thermal shock resistance.

## Material and methods

The study was conducted at the Marine Shrimp Laboratory, Department of Aquaculture, Federal University of Santa Catarina, Brazil *U. ohnoi* was sourced from an integrated multitrophic aquaculture system using biofloc technology, included in diets at three levels (0, 0.5, and 2% inclusion) and added to diets to replace kaolin. Post-larvae, with an initial mean weight of $0.068 \pm 0.01$ g, were reared for 46 days in 60-L tanks at a density of 2,000 shrimp $m^{-3}$ and fed six times a day. The nutritional requirements of *P. monodon* were used as a reference for formulating diets for *P. vannamei*.

## Results

Temperature was kept at 28 °C and dissolved oxygen above 5 mg $L^{-1}$ in all treatments. No significant differences were observed among treatments for total ammonia nitrogen, nitrite, nitrate, alkalinity, pH, total suspended solids, or salinity. Shrimp fed with 0.5% of *U. ohnoi* in diet showed significantly higher final mean weight (an 18.7% increase), weight gain, and growth rate than those in the control group, without affecting survival or feed conversion ratio. Increasing the levels of *U. ohnoi* in the diets led to a rise in the abundance of heterotrophic bacteria in shrimp, with the 2% inclusion treatment showing a significantly higher bacterial count compared to control group. Although a numerical reduction in *Vibrio* spp. was observed in shrimp fed with algae-supplemented diets, this decrease was not statistically significant when compared to control. Additionally, the inclusion of *U. ohnoi* had no effect on the thermal resistance of shrimp reared in the biofloc system over the 46-day period.

## Conclusions

Considering shrimp performance was similar across diets containing *U. ohnoi*, the inclusion level of 0.5% is recommended, as it resulted in higher growth rates compared to control group.

## Introduction

The production of formulated feed for fish larvae is crucial in aquaculture, as it directly affects larval survival, growth, and health. During early development, larvae have specific nutritional needs and limited feeding and digestive capacity, making the production of high-quality microdiets challenging. These diets must have precise physical and nutritional characteristics—such as suitable particle size, buoyancy, water stability, and digestibility—to ensure effective ingestion and nutrient absorption. Achieving these features is particularly difficult with conventional processing methods when particles below 0.5 mm are required (Pinto et al 2019).

Fluidized bed agglomeration (FB agglomeration) offers a promising solution. This technology transforms fine powders into granules with controlled size and improved physical properties, while preserving thermolabile compounds. In this process, particles are suspended in hot air and bound using a sprayed binder solution, producing agglomerates with defined size and density. Benefits include improved flowability, water stability, particle uniformity, and incorporation of sensitive ingredients (Dhanalakshmi et al., 2011). This enables the production of high-performance microdiets suited to the demanding needs of fish larvae.

This study evaluated the effects of different types and levels of binders and technical additives on the physical and functional properties of larval feeds. Three binder types—proteins, gums, and carbohydrates—and two technical additives were tested. Feed pellets were analyzed for water stability, nutrient retention, sinking rate, flowability, water dispersion, and larval acceptability.

## Materials and methods

All diets were produced at NIRO GEA MP1 (Denmark) under standardized conditions. The powders were placed in the expansion chamber and heated up to 40ºC. Subsequently, the oils were added by spraying, followed by the binder. After the binder was added, the product temperature was allowed to return to 40ºC before ending the process. The diets were then sieved into the following fractions: 0.1–0.2 mm, 0.2–0.4 mm, and 0.4–0.6 mm. To determine the physical properties of the diets, methodologies developed internally at SPAROS were used.

## Results

The protein leaching was around 10% for all binders tested, except for one non-protein binder, which showed a lower leaching value of approximately 6% and higher water stability. No significant differences were observed among prototypes in terms of bulk density, flowability, sinking behavior, or dispersion. The bulk density ranged between 320–380 g/L. All prototypes initially exhibited low flowability and a high sinking velocity. However, following the addition of the technical additives, an improvement in dispersion was observed, which indirectly led to a reduction in the sinking velocity of the pellets and an improvement in flowability behavior. The larvae acceptance tests are still ongoing.

## Discussion

The protein leaching values around 10% for most binders indicate a relatively moderate level of nutrient loss to the surrounding water, which is a critical parameter in larval feeding due to the sensitivity of larvae to nutrient availability. Notably, one of the non-protein binder showed a significantly lower leaching rate (~6%) and improved water stability, highlighting its potential to enhance pellet integrity and reduce nutrient wastage. This suggests that some binders may play a key role in improving microdiet performance, possibly by forming stronger or more cohesive matrices during agglomeration.

*(Continued on next page)*

During the first set of trials, the lack of significant variation in bulk density, flowability, and sinking behavior among the prototypes suggests that the agglomeration process was consistent and that the binder type alone may not drastically influence these parameters under the tested conditions. However, all diets showed low flowability and high sinking velocity, which could hinder feeding efficiency, particularly for surface or mid-water feeding larvae.

In a second set of trials, we observed improvement in dispersion and flowability after the addition of technical additives. These additives appear to have enhanced the physical behavior of the pellets, likely by modifying surface characteristics or water interaction dynamics. This is relevant as improved dispersion can increase the availability of feed in the water column, thereby enhancing feeding opportunities and potentially improving larval growth and survival.

Ongoing larvae acceptance tests will provide critical complementary data, as physical quality must ultimately align with biological performance. The integration of physical and biological results will be essential to identify the most effective formulation strategy for high-performance microdiets.

## Introduction

The use of functional ingredients is considered a valuable tool to promote fish robustness and welfare during intensive farming. Among them, marine algae arise as promising candidates for inclusion in aquafeeds due to their antibacterial, immunestimulant and anti-oxidant properties. However, information regarding the potential of combining different algae biomasses and extracts as well as optimal supplementation periods is still lacking. Therefore, the present study aims to evaluate innate immune defenses and disease resistance of European seabass, *Dicentrarchus labrax*, juveniles fed diets containing different combinations of biorefined algae-derived compounds.

## Materials and methods

After acclimation, 1080 fish (12.12 ± 1.01 g) were randomly distributed in 15 tanks to which the experimental diets were assigned in triplicates. Dietary treatments consisted of a commercial diet (CTRL), a commercial diet with an immunestimulant (CTRL+) and three CTRL-based diets in which a mix of *Ulva* extract and different algae broken cells were included (Diet1 - *Ulva* spp., Diet2 - *Gracilaria gracilis*, Diet3 - *Euglena gracilis*). The boosting strategy consisted of feeding the animals for two different periods (5 and 14 days) before a stressfull stimulus. The chosen stressful condition was a bacterial challenge (intraperitoneal injection, 2.75 x $10^5$ CFU/mL of *Photobacterium damselae piscicida* strain MT1415). Samplings were performed immediately before and 6 hours after the bacterial challenge. At each sampling point, fish were euthanized (n=9 per tank) and sampled for blood (haematology), plasma (humoral immune defences), liver (oxidative stress), anterior intentine and head-kidney (gene expression).

## Results

The statistical analysis allowed a clear distinction between non infected and infected animals among groups within the same boosting strategy. For a better comprehension of diet-induced effect on fish immune status and response to infection, a discriminant analysis (DA) was performed for each sampling time. After 5 days of feeding, a clear separation between non-infected fish fed Diet3 and their counterparts fed Diet1, Diet2 and CTRL+ was observed, mainly driven by the positive load on expression of genes related with epithelial cells integrity and detoxifying enzymes in the anterior intestine. However, in infected groups, both Diet3 and Diet2 were significantly separated from those fed CTRL. This discrimination was positively loaded by the intestinal gene expression related with the antioxidant response and cell stability, in opposition to a negative loading of pro-inflammatory cytokines transcripts. The longer-term stimulation with algae derived compounds have produced no significant differences both before and after infection.

*(Continued on next page)*

## Discussion and conclusion

The experimental diets showed no significant immune modulation on both boosting strategies tested. However, Diet3 seems to have a beneficial effect on intestinal integrity after 5 days of feeding both before and after bacterial stimulus, once there was an increased gene expression levels related with cell adhesion.

Gathering all the information, it can be hypothesized that a short-term feeding period using a combination of *Ulva* spp. aqueous extract and *Euglena gracilis* broken cells (Diet3) may contribute to the stability and integrity of intestine, enabling an enhanced resistance to pathogenic threats. Future work will focus on microbiome and proteome analyses for a deeper comprehension of these diets' modulatory mechanisms.

## Introduction

The green macroalgae *Ulva spp*., has attracted growing interest due to its content of bioactive molecules with potential applications in biotechnology and health. Notably, ulvans—sulfated polysaccharides present in its cell walls—have been associated with antioxidant, immunomodulatory, and antimicrobial activities.

Among the available extraction methods, autohydrolysis stands out as a sustainable alternative, relying solely on water and elevated temperature to release functional components from the biomass. This solvent-free approach yields complex extracts containing a mixture of compounds such as polysaccharides, proteins, phenolics, and minerals.

In the present study, we examined the effects of *Ulva* extracts obtained by autohydrolysis and ethanol purification on the growth kinetics of three clinically relevant bacterial strains: *Staphylococcus aureus*, *Escherichia coli*, and *Klebsiella pneumoniae*. These microorganisms are frequently implicated in opportunistic and nosocomial infections, making them relevant models for evaluating the antimicrobial activity of algal-derived compounds.

## Materials and Methods

Fresh Ulva biomass, sustainably cultivated and manually harvested along the Galician coast under certified organic practices, was subjected to autohydrolysis at 160 °C. The resulting crude extract (AF) was then purified by ethanol precipitation, yielding a second extract (AFp) enriched in water-soluble compounds, including ulvan-type polysaccharides.

Both extracts were characterized to determine their physicochemical properties, including molecular weight distribution, ash content, protein levels, total phenolic content, antioxidant capacity, carbohydrate composition, and mineral profile.

The antimicrobial activity of the crude and purified extracts was evaluated against three clinically relevant bacterial strains: *Staphylococcus aureus*, *Escherichia coli*, and *Klebsiella pneumoniae*. Growth kinetics were assessed in the presence of the extracts, using standard microplate assays to monitor optical density and calculate inhibition effects.

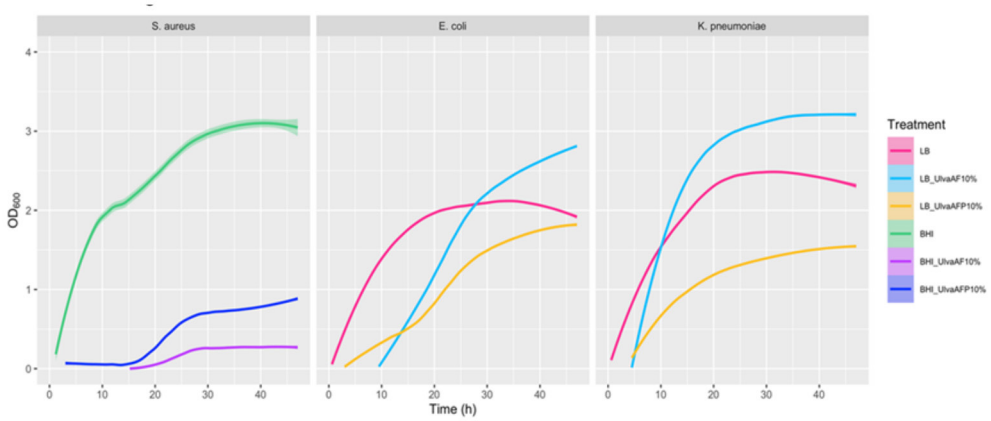

Figure 1. Growth kinetics of *Staphylococcus aureus*, *Escherichia coli*, and *Klebsiella pneumoniae* in the presence of crude (AF) and ulvan-enriched (AFp) Ulva extracts.

*(Continued on next page)*

**Results**

The growth inhibition assays demonstrated that both crude and purified Ulva extracts had a noticeable antimicrobial effect on *S. aureus*, with growth curves significantly below those of the control. Notably, the purified extract (AFp), which was enriched in ulvans, exhibited a prolonged lag phase and reduced final population density compared to the crude extract (AF), suggesting enhanced antimicrobial potency.

For *E. coli* and *K. pneumoniae*, similar trends were observed, although to a lesser extent, indicating a possible strain-dependent response to ulvan-rich extracts.

**Conclusion**

Our results demonstrate that Ulva extracts obtained through environmentally friendly autohydrolysis and ethanol purification possess the ability to modulate bacterial growth. These findings suggest that compounds present in the extracts may interfere with bacterial colonization mechanisms.

This study reinforces the value of macroalgae as a renewable source of multifunctional bioactives and supports the exploration of Ulva-derived products in the development of alternative microbial control strategies. The sustainable nature of the extraction process adds further relevance, aligning with current efforts to identify eco-conscious solutions with potential applications in aquaculture, food safety, and biomedical fields.

# MATURATION OF A RAS BIOFILTER IN A FISH LARVAL REARING FACILITY AT THE MARIEL MARICULTURE STATION, ARTEMISA PROVINCE, CUBA

## Introduction

Recirculating Aquaculture Systems (RAS) reuse the maximum volume of water for the cultivation of aquatic organisms, maintaining water quality through various filtration methods. A RAS comprise production units equipped with automated feeding systems and sensors to control water chemical parameters such as pH and oxygen. It may also include mechanical and biological filtration systems, as well as UV-treatment for pathogen removal. Biological filtration includes the removal of nitrogen compounds as measured by *e.g.* Total Ammonia Nitrogen (TAN) from the water through nitrification performed by nitrifying bacteria as a biofilm on a carrier substrate with a large surface. The maturation of biofilters is the period when the nitrifying bacteria colonize the substrate. This process is a crucial step in the startup of a RAS system (Timmons *et al*., 2018; Pulkkinen, 2020; Balami, 2021; Burut-Archanai *et al*., 2021). A biofilter is considered mature when the concentration of TAN stabilizes below 0.7 mg/l (Rojas & Pedersen, 2016). As an outcome of the Cuban/Norwegian project "Production of marine fingerlings in Cuba", a RAS have been installed at the Mariel Mariculture Station of the Centro de Investigaciones Pesqueras (CIP). This study describes the maturation process that is observed in the biofilter of the larval rearing area of the Mariel Station, Artemisa Province, Cuba.

## Materials and methods

The maturation process of the RAS biofilter for tilapia production, were initiated the medio February 2025. Sediments from culture tanks of tilapia within the culture units of the area, were applied as fertilisers. During maturation, temperature and salinity were measured daily. The pH and TAN were measured once a week applying the commercial kit Colombo Aquatest (Colombo, The Netherlands), with a lover level of quantification for $NH_3$ of 0.5 mg/L. Nitrite, nitrate and phosphate were also measured on a weekly basis by the same kit, and with quantification limits of 0.5, 10.0 and 0.5 mg/L, respectively. In addition, water samples were collected from the culture units and biofilter carriers twice a month, for the subsequent identification of the bacterial community and its succession.

Furthermore, a laboratory experiment was conducted simulating RAS conditions with the aim of identifying the salinity range in which the biofilter maturation process occurs most efficiently. This experiment aimed to optimize the biofilter maturation process that will be carried out in the breeding and weaning areas of the RAS system in Mariel Mariculture Station.

In the laboratory experiment, three ranges of salinity were evaluated, each in hree replicates: Treatment 1 (T1): 30-40 ppm; Treatment 2 (T2): 20-30 ppm; Treatment 3 (T3): 10-20 ppm. Each replicate consisted of 10 L aquarium where biofilter particles were added and that were daily fertilized with water from siphoning two 60 L tanks with 20 tilapia (weighing 2-4 g each). The experiment began on the 6th of February and ended on the 12th of March 2025. During the first week, 100 mL of combined siphoning water from both fish tanks was added to all replicates. The volume was increased to 200 mL in week 2, and since week 3, 300 mL were added. Temperature and salinity were measured daily. Nitrite, nitrate, phosphate, ammonium and pH were measured once a week. In the last week of the experiment, water samples were taken from all the replicates and from the fish tanks, and biofilter carriers were sampled from all replicates to determine significant differences between the bacterial communities. The analysis of bacterial communities will be conducted in two parts, one through classical taxonomy at the lab of CIP in Cuba and the other through DNA sequencing at the Institute of Marine Research (IMR), Bergen, Norway.

*(Continued on next page)*

**Results**

The TAN values were less than 0.5 mg/L during the entire period the values were measured. This happened in the Mariel Station and during the experiment conducted in the lab. Nitrite values went from 0.5 mg/L during four weeks at the Station to a spike in week 5, presenting 2 mg/L during three consecutive weeks. Something similar occurred with nitrate, going from 20 mg/L to 50 mg/L in the same period. With the aim of keeping the welfare of the fish, the density of the culture was decreased, and the nitrite and nitrate values were restored in week 8.

**Conclusions**

A TAN value lower than 0.7 mg/L, are the main indicator of a mature biofilter. Given that the values of these compounds were less than 0.5 mg/L from the beginning in both experiments, at the Station and the lab, the nitrite and nitrate were taken as the main indicators. The increase in the values of both compounds during week 5 until week 7 in the Station may be due to the development of the nitrifying bacteria that carry out the first step of the nitrification process (ammonium oxidation). Nonetheless, the results of the bacterial community identification from the samples that were taken during the entire experiment, will allow a better understanding of the functioning of the biofilter and to give definitive conclusions about the experiment. The above is also the case in the experiment conducted in the lab, where the bacterial community analysis to be conducted is necessary to determine if there were significant differences between the salinities examined.

# ADVANCES IN THE QUANTIFICATION OF NATURAL ANTIOXIDANTS (NAOX) IN FISH FEED INGREDIENTS BY LC-MS AND CORRELATION WITH ANTIOXIDANT ACTIVITY

V. Sarmiento[1,2,3], K. Hamre[1], A. Arnø[1,4], O. Elvebø[2], R. Heavyside[2], P. Araujo[1]

## Introduction[1]

Oxidative stress is a widespread condition generated by various environmental and farming practices. leading to poor fish health and quality issues. Insufficient dietary antioxidants to alleviate oxidative stress have generated the need for more natural alternatives, and several promising natural antioxidants (NAOX) have been identified. For their successful application in aquaculture, one critical factor is the use of reliable and accurate methods for NAOX quantification in the production chain, that allow a better study of their effects, more controlled processes, and higher reproducibility in the production conditions. Liquid chromatography mass spectrometry (LCMS) is commonly used for analysing from few to over hundreds NAOX in diverse types of samples. However, aspects such as the stability of the compounds and matrix effects are often ignored although they can have an important impact on the accuracy of the results. Thus, in this work, we implemented a LC/MS method for accurate and reliable quantification of NAOX in a commercial antioxidant ingredient containing natural sources commonly used.

## Materials and Methods

Three commercial samples of antioxidant ingredients for fish feed, containing a mixture of NAOX, were supplied by Arctic Feed Ingredients (AFI, Steinskjer, Norway). An accurate and reliable method by LC-MS illustrated in Figure 1. was implemented for quantification of the main NAOX. The comprehensive study included; 1) the evaluation of different solvents for extraction of the NAOX from the samples, 2) optimization of the instrumental parameters for the collision cell in mass spectrometry, and 3) stability studies of the NAOX in the selected solvent individually and in groups. For the latter, the stability was measured as the change of the LC-MS signals of the polyphenols in terms of their storage time (0, 1, 6, and 9 days), temperature (4, – 20, and – 80 °C), vial colour (transparent, amber), and concentration (0.1 and 30 $\mu$g/mL). The analytical method was validated for selectivity, linearity, detection, and quantification limits (LOD and LOQ) and additionally, a comprehensive study of matrix effects was included. As evaluation of the antioxidant capacity, CUPRAC and DPPH methods were used.

## Results and discussion

Methanol showed the global best performance for extraction for all the selected compounds in the evaluated solvent. Regarding stability of the LC-MS signal of the NAOX, no consistent effect was observed for the storage of the solutions at different temperatures, or the different vials, but in contrast, time of storage was found to affect the signal obtained. In general, a reduction of the signals was observed for 3 out of 6 NAOX. The worst stability was found for 2 NAOX, for which even 1 day post preparation, changes were more noticeable than for the other compounds. Stability improved with higher concentrations of the NAOX.

For the validation parameters, evaluation of the extracted ion chromatograms demonstrated that LC-MS/MS can determine the selected NAOX without interference from other components in the sample. The matrix effect, evaluated not in a single point but by comparison of the slopes of external standard and standard addition calibrations for each compound, was negligible for 3 out of 6 compounds. However, significant matrix effects were observed in the other 3. For instance, the ratio of the standard addition to external standard slope for 2 NAOX showed enhanced sensitivity of 3.84 and 1.93, respectively. In contrast, the same relationship for a 3$^{rd}$ one was 0.47, indicating a significant signal suppression of the sample matrix on the analytical signal. Considering the important matrix effects found, the linearity was assessed by using standard addition calibrations by coefficient of regression ($r^2$) and a lack of fit test using the experimental Fisher test for the 6 compounds. The six models were

*(Continued on next page)*

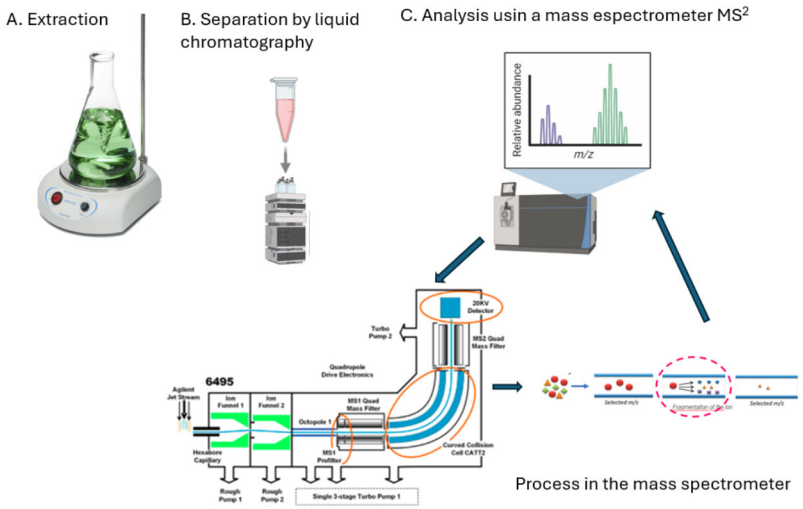

**Figure 1.** LC-MS analysis applied to the quantification of NAOX in commercial antioxidant ingredient samples

used to evaluate LOD, LOQ, and method accuracy by introducing the experimental signals back into the calibration model to determine the estimated concentration in relation to the nominal value. The accuracy for the six polyphenols was within the ± 15 % interval of variation suggested by the ICH and regarded as acceptable for the determination of polyphenols in fish feed ingredients.

The antioxidant activity was evaluated by 2 different methods, CUPRAC and DPPH. The total content of polyphenols quantified in the samples did not show a direct correlation with the antioxidant capacity. Possible explanations are the different potency of individual compounds and/or the presence of NAOX not quantified.

Conclusion

To the authors knowledge, this is the first report on the validation of a LC-MS/MS method for quantifying selected polyphenols in commercial fish feed ingredients, supplemented with polyphenols from plant extracts using the standard addition method. The study highlighted the importance of performing a prior evaluation of the stability and matrix effects to decide the correct calibration strategy. The method showed adequate performance and demonstrated to be adequate for the accurate quantification of NAOX in industrial samples in aquaculture. The complementary study of antioxidant capacity showed that both approaches are complementary and important to product applications and standardizations.

## Introduction

The use of natural antioxidants (NAOX) for preventing fish feed oxidation and reducing oxidative stress in fish is gaining popularity. NAOX present a more sustainable and consumer acceptable alternative to the more traditional, synthetic antioxidants. Further, NAOX contribute to the substitution, or partial replacement of synthetic antioxidants, which is especially relevant following the restriction of ethoxyquin and the anticipated reduction of BHT and BHA.

In order to implement NAOX effectively, it is imperative to study the behaviour of those compounds with natural antioxidant activity throughout the whole production cycle, from raw materials, through the stages of feed production, to the fish tissues. This project studied the effects of a commercial NAOX ingredient that was added to a commercial fish feed at two levels (0.01 and 0.05%). The objective was to analyze quantitatively selected antioxidant compounds (polyphenols) in various stages of a fish farming process for salmon. Extraction methods for the selected polyphenols were developed for different matrices: antioxidant ingredient, fish feed, and fish tissue and each matrices was analysed by LC-MS/MS. Additionally, for studying the antioxidant effect of the NAOX throughout the production process, several oxidation and oxidative stress indicators were measured; in feed ingredients, in feed at different stages of production, in feed after 3 months storage, and in the tissues of fish fed the two diets.

## Materials and Methods

The experimental diets were formulated to meet the nutritional requirements of Atlantic salmon and were produced at the BioMar AS pilot plant. A commercial antioxidant was added at different inclusion levels (0.0, 0.01 and 0.05%). The fish trials were conducted at Matre Aquaculture Station, Institute of Marine Research, Norway. Nine tanks (1×1×0.4 m3) were stocked with 35 post-smolts with an average weight of 473±11 g. Fish in triplicate tanks were randomly assigned to each of the three diets.

The antioxidant ingredient used in the production of the NAOX diet was sampled for analysis. Samples of the three fish feed meals used in the fish trial were also taken before and after extrusion, and after drying (final feed). Several parameters related to feed quality were measured: dry matter, protein, vitamins C and E, astaxanthin, TBARS, total (tGSH) and oxidized (GSSG) glutathione, peroxide value (PV) and anisidine value (AV). Additionally, a LC-MS method established previously was used for the quantitative analysis of the main NAOX compounds in the antioxidant ingredient, in different stages of the production of the 3 diets with different inclusion levels of NAOX (0.0, 0.01 and 0.05%) and in tissue (liver and muscle) of the fish fed the 3 diets.

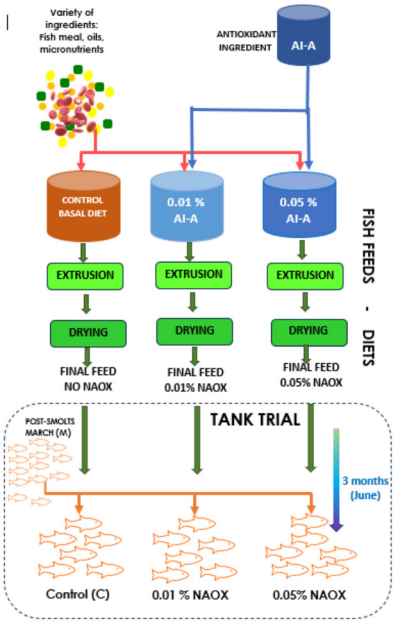

**Figure 1.** General scheme of the study

*(Continued on next page)*

For the quantitative analysis of the selected NAOX compounds (polyphenols), extraction of the antioxidant ingredient and the fish feed samples containing different levels of the commercial NAOX ingredient (0, 0.01, 0.05 %) were carried out, as well as at different stages of production (before extrusion, before drying and final feed).

In sampled fish, growth, condition factor, body indices, and cataracts were recorded. Liver and muscle samples were collected and pooled from three fish per tank and analysed for vitamin C, vitamin E, MDA, and astaxanthin. Individual liver and muscle samples from an additional three fish were analysed for GSH/GSSG and antioxidant enzyme analyses. Plasma was taken from all 9 fish and pooled before analysis of vitamin C and vitamin E.

**Conclusions**

The main NAOX polyphenols were quantified in fish feed ingredients, fish diets at different stages of production, and fish tissues, allowing the complete traceability throughout the production process. The NAOX content was not stable, an important loss of polyphenols was evidenced, especially during the extrusion process. However, positive results were observed in feed, lower TBARS and a protection for tocopherol were observed, as well as a possible protection of astaxanthin.

The analysis of liver and muscle samples, dissected from salmon fed the final feed of the production process, revealed that two polyphenols were transferred into these tissues. Interestingly, and despite of the loss of NAOX during the production of the feed, results from oxidative parameters suggest that dietary NAOX affected MDA and glutathione metabolism in both the muscle and liver of Atlantic salmon: MDA was lowered at 0.01% NAOX in the muscle, while 0.05% was necessary to significantly lower liver MDA. This could indicate that dietary NAOX prevented *in vivo* lipid oxidation in the fish tissues. GSH and GSSG were lowered in the liver while Eh was constant. In the muscle, GSH increased while GSSG was constant, leading to a more reduced Eh. This shows that redox metabolism was affected by dietary NAOX. No effects of the dietary NAOX were observed on growth, condition factor, body indices or cataracts. The results obtained were promising and further studies are needed for advancing in the understanding of NAOX in redox biology of fish.

**NOTE:** This work is in parallel/relates to the methods developed and described in the first abstract submitted: 1_Sarmiento et al_ V3: ADVANCES IN THE QUANTIFICATION OF NATURAL ANTIOXIDANTS (NAOX) IN FISH FEED INGREDIENTS BY LC-MS AND CORRELATION WITH ANTIOXIDANT ACTIVITY

# IMPACT OF ALTERNATIVE FEED INGREDIENTS AND FEEDING STRATEGIES ON MUSCLE MORPHOLOGY, AND FILLET QUALITY OF GENETICALLY SELECTED GILTHEAD SEABREAM (*Sparus aurata*) IN A LONG-TERM FEEDING TRIAL

**Introduction**

To address the limited availability of fishmeal (FM) and fish oil (FO), it is necessary to find new sustainable ingredients, such as animal by-products, insect meal, and microalgae oil, with proven benefits in aquafeeds (Carvalho *et al.,* 2024). Additionally, restricted feeding strategies reduce costs and improve sustainability by minimizing feed waste and enhancing water quality (Assis *et al*., 2020), while selective breeding boosts growth and diet adaptation (Carvalho *et al*., 2024). However, these strategies can affect fillet texture and shelf life, influencing consumer acceptance. Understanding post-harvest proteolytic degradation and muscle changes is essential for preserving fillet quality (Castro *et al*., 2022). This study evaluates the combined effect of sustainable alternative diets, genetic selection, and feed restriction strategies on muscle histomorphology and fillet texture of gilthead seabream (*Sparus aurata*; GSB) over a long-term feeding trial up to commercial size, with additional attention to fillet quality during shelf life.

**Materials & Methods**

GSBs selected for high growth (HG) or non-selected (REF) were reared for 300 days until apparent satiety (AS) or with food restrictions (85% or 65% AS) using a control diet (CON) with low FM and FO balanced with vegetable meals (VM), and an alternative diet (ALT) where FM was half-replaced with insect and animal by-product meals, while FO was completely replaced by microalgae and animal by-product oils.

Texture profile analysis was performed at 1 and 4 days post-harvest (dph) using a TA.XT2 Texture Analyzer. Muscle samples from 1 and 4 dph were paraffin embedded, sectioned, and analyzed by immunohistochemistry for calpastatin, calpains, and actin, and evaluated blindy. Immunostained sections were scanned and semi-quantitatively analyzed. Muscle ultrastructure was processed for Transmission Electron Microscopy (TEM; SIMACE ULPGC) to assess mitochondrial, sarcomere, and connective tissue integrity.

**Results**

Fillets from fish fed the ALT diet showed significantly higher hardness and adhesiveness than those fed the CON diet, while REF fish exhibited greater fillet cohesion, gumminess and resilience than HG fish. The 85%AS feeding strategy led to the best overall texture. Ice storage reduced all texture parameters after 4 dph.

No major histological differences were observed at 1 dph. At 4dph, actin and m-calpain reactivity increased and a slight decrease in fiber-to-fiber adhesion and detachment to the myocommata was noted. TEM analysis revealed that 65%AS feed restriction caused mitochondrial elongation and fusion. Ice storage led to ultrastructural degradation, including mitochondrial damage, loss of sarcomere integrity (decrease Z-disc integrity and increase I-band width), and interfibrillar disjunction.

**Discussion**

The ALT diet improved hardness via higher hydroxyproline from animal by-products compared to VM, strengthening connective tissue (Donadelli *et al*., 2006). HG fish, with greater hypertrophy, had softer texture due to lower fiber density (Palstra *et al*., 2011). Feeding strategy had the greatest impact on fillet texture. Compared to AS, moderate feed restriction (85%AS) increased firmness by reducing fat content, as high fat softens flesh (Lefevre *et al*., 2015). Ultrastructurally, 65%AS feeding showed mitochondrial elongation, suggesting mitophagy and fusion under nutritional stress. This result, first described in fish, alings with studies in other species under starvation (Rambold *et al*., 2011).

*(Continued on next page)*

During ice storage, texture parameters declined alongside increased actin and m-calpain immunoreactivity, suggesting early calpain-mediated degradation (Ahmed *et al*., 2015). Calpain activity degrades actin filaments, disrupting Z-discs and increasing actin detection by antibodies, which reduces fillet firmness, affecting consumer acceptance (Singh and Benjakul, 2018). Ultrastructural changes, more evident at 4 dph, included mitochondrial dense granule formation and membrane rupture, linked to calcium accumulation, mitochondrial permeability, and activation of calpains proteases, which degrade structural proteins and soften flesh (Ahmed *et al*., 2015). Slight connective tissue detachment and interfibrillar separation appeared at 1 dph, progressing to marked Z-disc loss and increased I-band width by 4 dph, consistent with previous studies in GSB (Ayala *et al*., 2010).

**Conclusion**

Combining moderate dietary restriction and innovative diets can improve GSB aquaculture sustainability and product quality during long-term feeding. The ALT diet improved fillet texture. The 85%AS feeding strategy optimized fillet quality by preventing lipid accumulation and muscle adaptations, as observed with the other feeding strategies. Histological analyses were key to understanding postmortem muscle changes, offering new insight into supporting nutritional strategies to maintain GSB fillet quality.

## Introduction

Fishmeal and fish oil (FMFO), obtained from intensive fishing, remain key aquafeed ingredients, but their replacement with plant-based alternatives (VMVO) has shown negative effects on gut health in several carnivorous fish species (Montero *et al*., 2023). Sustainable alternatives such as insects, microalgae, and animal by-products are being explored for their high nutritional value. Additionally, restricted feeding strategies reduce costs and enhance sustainability by minimizing feed waste and improving water quality, while selective breeding promotes growth and dietary adaptation. However, knowledge of their combined effects is limited, and responses appear species- and context-specific (Montero *et al*., 2023). Alternative protein sources can affect intestinal morphology, including villus length, goblet cell number, and inflammatory cell infiltration (Gai *et al*., 2023). This study assesses the long-term combined effects of novel feed formulations replacing FMFO and VMVO, genetic selection, and feeding strategies on gut morphology and health in gilthead seabream (*Sparus aurata*; GSB).

## Material & Methods

GSBs selected for high growth (HG) or non-selected (REF) were reared for 300 days until apparent satiety (AS) or with food restrictions (85% or 65% AS) using a control diet (CON) with low FMFO balanced with VMVO; and an alternative diet (ALT) where FM was half-replaced with insect (IM) and animal by-product meals, while FO was completely replaced by microalgae and animal by-product oils. At the end of the trial, samples from the foregut and hindgut were collected, processed, sectioned, and stained with Alcian Blue–PAS. Sections were scanned and morphometric analysis performed using Image-Pro Plus software to measure lamina propria (LP) width and villus width and length. Goblet cell (GC) area was quantified automatically using the eyedropper tool within each fold. GC density was expressed as the number of cells per 1,000 μm² of villus area to account for villus size variability. Additionally, foregut villus tip detachment and fusion were assessed using a continuous intensity scale from 0 to 100.

## Results

Regarding foregut morphometry, villus width and length were not significantly affected by the different experimental factors. However, feeding the CON diet was associated with greater LP width. GSB fed the ALT diet showed a higher degree of fusion. Furthermore, HG fishes had less villus tip detachment than REF. Regarding GC, fish fed the CON diet had a higher intestinal GC density than those fed the ALT diet.

In the hindgut, HG fishes had a significantly greater LP width than REF. The highest food restriction (65%AS) decreased LP thickening. Furthermore, GSB fed the ALT diet showed significantly greater villi length than those fed the CON diet, while no significant differences were found in GC density per fold.

## Discussion

Regarding foregut morphometry, the CON diet was associated with greater LP width, irrespective of genotype, consistent with Randazzo *et al*. (2021), who reported increased LP in GSB fed VM compared with diets containing IM and poultry by-product meals. Foregut GC density per fold was also higher in the CON diet, aligning with studies in salmonids linking VM, particularly soybean meal, to elevated GC numbers, LP widening, and other enteritis-related changes (Seibel *et al*., 2022). Plant-based ingredients may promote inflammatory cell infiltration, thereby widening LP (Torrecillas *et al*., 2019). GSB fed the ALT diet showed a higher degree of fold fusion, consistent with previous findings where FM was partially replaced by IM (Gai et al., 2023). The greater fold tip detachment and stronger response of REF fish to dietary and feeding strategy changes suggest that HG fish exhibit greater intestinal plasticity, as previously reported (Montero *et al.,* 2023).

*(Continued on next page)*

In the hindgut, villus height was greater in fish fed the ALT diet, potentially enhancing digestive capacity, whereas higher VM levels have been associated with villus shortening (Seibel *et al.,* 2022). The 65%AS restricted feeding reduced LP thickening, likely due to the absence of feeding stimulation, as observed in fasted fishes (Nogueira Farias *et al.,* 2025). GC density per fold showed no significant differences, consistent with Di Rosa et al. (2023), who reported limited diet-induced changes in the hindgut compared with the foregut, likely due to nutrient absorption occurring primarily in the foregut.

**Conclusion**

Replacing FMFO and VMVO with a combination of novel alternative ingredients, modulated intestinal morphology in GSB, with responses differing by intestinal segment, genotype, and feeding regime. In the foregut, the CON diet (plant-based) increased LP width and goblet cell density and HG fish exhibited reduced villus tip detachment, suggesting higher intestinal plasticity. In the hindgut, the ALT diet increased villus length, while 65% feed restriction reduced LP thickening. These findings confirm region-specific intestinal responses, with the foregut being more sensitive to dietary modifications.

## Introduction

The aquafeed sector is progressively shifting towards reducing dependence on finite and costly marine-derived fish meal by diversifying formulations using plant-based ingredients (Naylor et al., 2021; Aragão et al., 2022). However, plant-based ingredients, particularly soybean meal (SBM), present several limitations, including reduced diet palatability, impaired fish growth performance and health, and escalating costs driven by their high demand across various animal and food production sectors, thereby casting doubt on their long-term sustainability (Zlaugotne et al., 2022). To overcome these challenges, continued efforts are required to identify novel, nutrient-rich, economically viable, and eco-friendly protein sources for the sustainable development of the sector (Naylor et al., 2021). One promising alternative protein source is mushroom by-products, often classified as waste, representing *ca.* 5% to 50% of the total mushroom biomass produced (Navarro-Simarro et al., 2024; Infochampi, 2025). These by-products have a rich nutrient profile, low cost, and excellent digestibility (Liu et al., 2025). Their valorization as aquafeed ingredients addresses both waste management challenges in the mushroom sector and the nutritional needs of aquaculture, aligning with a circular economy framework. Therefore, the present study aimed to evaluate mushroom industry by-products derived from *Agaricus bisporus* (AB) and *Pleurotus ostreatus* (PO) as a potential alternative to plant-based ingredients for rainbow trout (*Oncorhynchus mykiss*) diets.

## Materials and methods

Five isonitrogenous (47.21 ± 0.93%), isolipidic (24.34 ± 1.50%), and isoenergetic (5611.83 ± 39.11 cal/g) diets were formulated by replacing SBM at 0%, 41.67% and 83.33% with AB or PO meals (dried and ground biomass, CTICH, Autol, Spain), corresponding to nominal dietary inclusion levels of 5% and 10%. The diets were named according to the dietary inclusion levels and/or the type of mushroom as follows: D1 (control diet), D2 (AB5), D3 (AB10), D4 (PO5) and D5 (PO10). Diets were fed to rainbow trout (initial body weight: 22.07 ± 0.05g) *ad libitum* in quadruplicate tanks for 60 days. During the trial, feces were collected using a settling column to evaluate the apparent digestibility coefficients (ADCs) of the experimental diets. After 60 days, all fish were individually measured, and fish key performance indicators associated with growth performance, survival and feed efficiency were analyzed. Following fish biometry, four fish/tank (n=16/diet) were anesthetized (100 mg MS-222/L) for blood sample collection and biochemical and hematological analyses, while the rest were transferred to IRTA's biosafety level 2 challenge room for an *in vivo* bacterial challenge against *Aeromonas salmonicida* subsp. *salmonicida*. After determining the lethal dose 60 (LD60), fish (n = 10 fish/tank, 5 tanks/diet) were injected intraperitoneally with 0.1 ml of 2.43 x $10^6$ CFU/ml of *A. salmonicida* subsp. *salmonicida* and mortality patterns were monitored for 21 days.

## Results

At the end of the trial, no significant differences ($p > 0.05$) in survival were found among dietary groups. The ADCs of the experimental diets were high (crude protein and lipid ADCs > 91%), although the AB diets showed significantly lower crude protein ADC ($p < 0.05$) than the control diet. Fish fed the AB5 diet presented similar growth ($p > 0.05$) to fish fed the control diet, while fish fed the AB10, PO5 and PO10 diets presented lower performance ($p < 0.05$) (Figure 1). Fish fed the AB diets presented similar feed intake (FI), feed conversion ratio (FCR) and somatic indices (hepatosomatic, HSI; visceral, VSI; and perivisceral fat, PVFI indices) ($p > 0.05$) in relation to those fed the CTRL diet. However, fish fed the PO diets presented significantly reduced FI, FCR and HIS ($p < 0.05$), while VSI and PVFI remained unaffected ($p > 0.05$), compared to the group fed the control diet Significantly higher protein and lipid efficiency ratios ($p < 0.05$) were recorded in the AB5-fed group

*(Continued on next page)*

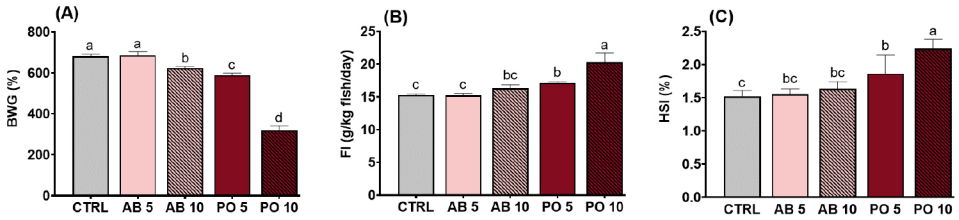

Figure 1. (A) Growth (% body weight gain, BWG), (B) feed intake (FI), (C) hepatosomatic index (HSI) in rainbow trout fed with the experimental diets containing different sources of mushroom meals for 60 days. Feed conversion ratio (FCR) followed the same pattern with FI (data not shown). Data are shown as mean ± SD (n = 4). Different letters indicate significant differences (ANOVA, $p < 0.05$). AB 5 (5% *Agaricus bisporus)*, AB 10 (10% *Agaricus bisporus)*, PO 5 (5 % *Pleurotus ostreatus),* PO 10 (10 % *Pleurotus ostreatus).*

compared to the rest of the dietary treatments. Blood counts and levels of ions and electrolytes, enzymes and metabolic and nutritional markers were similar for all experimental groups ($p > 0.05$), except for a significantly lower mean corpuscular hemoglobin, alkaline phosphatase, and sodium levels ($p < 0.05$) in fish fed the PO diets, particularly those fed the PO10 diet. The *in vivo* bacterial challenge results showed no significant differences in survival among dietary groups ($p > 0.05$).

## Conclusions

In conclusion, AB meal may replace plant-based diets, such as soybean meal, without compromising growth, feed efficiency, blood biochemical and hematological parameters, and the host's disease resistance, whereas the use of PO reduced fish performance.

## Introduction

Mushrooms are emerging as an eco-friendly alternative protein source due to their ability to convert organic waste, low production costs, and excellent digestibility (Liu et al., 2025). They are naturally rich in nutrients, particularly carbohydrates (*ca.* 35–70% dry weight), including complex cell wall polysaccharides such as chitin, β-glucans, and mannans. These compounds are recognized as "biological response modifiers," also referred to as prebiotics, due to their ability to modulate gut microbiota (Zhao et al., 2023). The gut microbiota plays a crucial role in numerous host biological processes, including digestion, absorption, metabolism of nutrients, and immune response, which together may contribute to promoting fish growth performance and health status (Vargas-Albores et al., 2021). For this reason, mushroom meal may be a promising aquafeed ingredient, not only as an alternative protein source but also for its potential functional effects, which may promote fish health status. Therefore, the present study formulated mushroom meal-rich diets derived from *Agaricus bisporus*, *Lentinula edodes* and *Pleurotus ostreatus* by-products and investigated their effects on the growth and gut microbiota of rainbow trout (*Oncorhynchus mykiss*).

## Materials and methods

Three experimental mushroom-based diets derived from *A. bisporus* (AB), *P. ostreatus* (PO), and *L. edodes* (LE) were formulated based on a control diet (CTRL) containing 49% crude protein and 22% crude fat. Mushroom meals (30%) were prepared by mixing with the CTRL diet (70%) and fed to rainbow trout juveniles (initial body weight: 120.1 ± 0.4 g) for 42 days. After 42 days, fish biometry was performed to evaluate growth, and representative fish samples (n = 4 fish/tank, 12 fish/diet) were euthanized, eviscerated, and their gastrointestinal tracts dissected for microbiota analysis. Gut samples were divided into three segments (pyloric caeca, PC; anterior intestine, AI; and posterior intestine, PI), and microbiota analysis was performed in each region. After DNA extraction, quality was checked, and the bacterial V3-V4 region of the 16s rRNA gene was amplified and sequenced on an Illumina MiSeq platform (2 × 300 bp paired-end; FISABIO, Valencia, Spain). Bioinformatic analysis was performed using QIIME2 and DADA2 for cleaning and denoising, and taxonomic assignment with the SILVA database. Diversity and relative abundance were calculated based on the *microeco* package.

## Results

Results showed no significant differences in final fish body weight, body weight gain, and specific growth rate between fish fed the CTRL and mushroom-based diets ($p > 0.05$). Similarly, somatic indices (condition factor, hepatosomatic index, viscerosomatic index, and perivisceral fat index) and feed efficiency parameters (feed intake and feed conversion ratio) were not affected by the dietary inclusion of mushroom meals compared to fish fed the CTRL diet ($p > 0.05$).

In terms of microbial diversity across gut regions, alpha and beta diversity showed a stronger similarity between PC and AI than the PI. In addition, phylogenetic diversity, which considers the number of species and the phylogenetic distance, indicates that each region is different. In terms of composition, the three gut regions analyzed in this study were dominated by Firmicutes and Proteobacteria. Regarding the effect of diets, the AB-fed group showed reduced alpha diversity in the PC region compared to the group fed the CTRL diet ($p < 0.05$), whereas the alpha diversity of fish fed the LE and PO diets remained unchanged ($p > 0.05$). In terms of beta diversity, fish fed AB and LE diets presented significantly different bacterial community structures

*(Continued on next page)*

compared to the CTRL diet-fed group ($p < 0.05$). In the AI region, a similar pattern was observed, with fish fed the AB diet showing reduced alpha diversity compared to the CTRL-fed group ($p < 0.05$), whereas PO and LE fed groups were similar to those fed the CTRL diet ($p > 0.05$). Beta diversity showed significantly different structure among the CTRL, LE, and PO groups ($p < 0.05$). In the PI region, the alpha diversity of AB and LE was similar to the CTRL fed group, whereas this was reduced in the LE fed group ($p < 0.05$). Beta diversity showed that all dietary groups had significantly different bacterial community structure ($p < 0.05$).

In terms of microbial composition, the PC region showed that the CTRL-fed group has a higher relative abundance of Desulfovibrionaceae and *Ligilactobacillus* than the mushroom-fed groups ($p < 0.05$). Fish fed with AB showed a higher abundance of *Mycoplasma*, whereas the LE and PO groups showed dominance of Bacilli (class) and Bacillaceae *and Paenobacillus*, respectively. In the AI region, microbial composition for the CTRL fed group was dominated by Desulfovibrionaceae*,* Lactobacillaceae and *Weissella*. The AB-fed group showed a higher abundance of *Mycoplasma,* Bacilli (class) and *Legionella.* The LE-fed group did not reveal any significant change in bacterial abundance, whereas the PO-fed group showed an increase in *Ligilactobacillus* and Alphaproteobacteria. In the PI region, the CTRL-fed group maintained a higher abundance of Desulfovibrionaceae. The AB-fed group showed a higher abundance of Lactobacillaceae, whereas the PO-fed group did not show any significant change in bacterial abundance.

## Conclusions

Overall, the results showed that fish fed with mushroom-based diets presented similar performance to fish fed the control diet, suggesting that mushrooms may be a suitable alternative protein source in aquafeed. Furthermore, dietary inclusion of mushroom meals differentially modulated gut microbiota in terms of diversity and composition depending on the type of mushroom and region of the intestine considered. In particular, mushroom-based diets reduced the abundance of Desulfovibrionaceae across gut regions and shifted to an increase in different bacterial genera, particularly those that are classified as probiotics, such as *Lactobacillus,* indicating the potential of mushrooms not just as a protein source but also as a prebiotic ingredient.

## Introduction

The common octopus (*Octopus vulgaris*) is an ecologically and economically valuable cephalopod distributed across the eastern Atlantic and Mediterranean Sea. Due to its high commercial demand, fisheries targeting this species are intense, raising concerns about the erosion of genetic diversity and the long-term viability of populations. A clear understanding of genetic structure, variability, and effective population size is essential for designing conservation measures and sustainable management strategies capable of preserving adaptive potential under growing anthropogenic pressures.

## Materials and Methods

Samples of 117 individuals were collected from seven Atlantic sites and one Mediterranean location. Restriction-site associated DNA sequencing (RAD-seq) produced genome-wide single nucleotide polymorphisms (SNPs), with 15,548 high-quality markers retained after filtering. Population structure was inferred using discriminant analysis of principal components (DAPC) and ADMIXTURE modelling. Genetic differentiation was quantified with pairwise fixation indices ($F_{ST}$), and isolation-by-distance was tested using a Mantel test. Inbreeding coefficients were estimated, and contemporary effective population sizes ($N_e$) were calculated based on genome-wide linkage disequilibrium.

## Results

Population structure analyses revealed a pronounced latitudinal genetic gradient across the Atlantic distribution of common octopus. ADMIXTURE modelling identified two ancestral clusters (K = 2), corresponding to European and African populations (Figure 1), with the Mediterranean sample exhibiting a partially distinct genetic signature at higher resolution. PCA and DAPC supported this structure, showing a clear north-south separation and highlighting limited differentiation among northern European populations. Pairwise fixation indices ($F_{ST}$) ranged from 0.000 to 0.270, with a mean of 0.116, indicating moderate genetic differentiation overall. The Mantel test confirmed a significant isolation-by-distance pattern ($r = 0.857$, $p < 0.001$), suggesting restricted gene flow driven by geographic separation. Inbreeding coefficients were elevated in several populations, particularly Mauritania, where levels of homozygosity were highest. Estimates of contemporary $N_e$ were critically low, ranging from 8 individuals in Mauritania to less than 200 across all other sites (Figure 2).

## Discussion

The pronounced latitudinal cline and moderate differentiation suggest that neutral processes, such as genetic drift and limited dispersal, shape the population structure of common octopus. The partial differentiation of the Mediterranean sample likely reflects a historical phylogeographic barrier imposed by the Strait of Gibraltar. Critically low $N_e$ values across all populations raise concerns about the long-term adaptive potential of this species. According to the widely cited 50/500 conservation rule, populations with $N_e < 50$ are at risk of short-term inbreeding depression, while $N_e < 500$ limits adaptive capacity over evolutionary timescales. In Mauritania and Morocco, where $N_e$ estimates were below 15, intensive fishing pressure combined with reduced gene flow may exacerbate the risk of genetic erosion and fitness loss. These findings highlight the urgent need for region-specific fishery management plans that integrate genomic indicators, alongside traditional demographic and ecological data. Continuous genetic monitoring will be essential to mitigate overexploitation under changing environmental pressures. Furthermore, the implementation of controlled aquaculture programs for *O. vulgaris* could help alleviate fishing pressure on natural populations, safeguard wild stocks, and promote a sustainable and economically viable production system.

## Introduction

Rainbow trout (*Oncorhynchus mykiss*) is one of the most preferred species in aquaculture due to its high commercial value and widespread use as a food source for human consumption. Owing to its economic and biological significance in aquaculture, various studies have been conducted to ensure the sustainability of this species. Among these efforts, the use of probiotic-additive (PBa) feeds has gained considerable attention. For this purpose, Lactic acid bacteria have been identified as the most frequently used probiotics in this field (Torres-Maravilla et al., 2024). Most studies on PBa diets have focused on maintaining the physiological health of fish and enhancing their immune systems (Mondal et al., 2022). In addition, probiotics in aquaculture have been reported to improve growth (Carnevali et al., 2017) and reproductive performance (Akbari Nargesi and Falahatkat, 2023), increase the expression levels of genes involved in gametogenesis and gamete quality (Safari et al., 2022;). In these studies, rainbow trout, other species such as ornamental fish, Nile tilapia (*Oreochromis niloticus*), zebrafish (*Danio rerio*), and African catfish (*Clarias gariepinus*) were used. In the present study, rainbow trout were fed with diets supplemented with the probiotic strains *Carnobacterium maltaromaticum* and *Lactococcus lactis*. At the beginning and end of the feeding period, tissue samples (liver, testis, ovary, brain, and pituitary) will be collected to analyze the expression profiles of steroidogenic genes associated with the gametogenesis process, aiming to evaluate the effects of the probiotic- additive diets.

## Material and Methods

The aim of this study was to determine the effects of Probiotic Additive (PBa) diets on the expression levels of steroidogenic genes involved in the gametogenesis process in rainbow trout (*Oncorhynchus mykiss*). The experimental procedures were conducted at the Sapanca Inland Fisheries Research and Application Unit of the Faculty of Aquatic Sciences, Istanbul University. During the experimental period, a total of 90 broodstock fish were used, with each of the six tanks containing 7 female (♀) and 8 male (♂) individuals. Probiotic Bacteria in freeze-dried form produced within the scope of the TÜBİTAK-UPAG supported project were added to commercial rainbow trout feed. The probiotic bacteria used in the study were *Carnobacterium maltaromaticum* and *Lactococcus lactis*. A total of six experimental groups were established; two control groups (negative and positive controls) and four treatment groups receiving either *C. maltaromaticum* and *L. lactis* at two different final concentrations in the feed ($10^7$ and $10^9$ CFU $g^{-1}$). Sunflower oil was used as a carrier in the preparation of the feeds for both the positive control and probiotic treatment groups. In order to investigate the effect of PBa diet on gametogenesis in rainbow trout, PBa diet was applied to individuals two months before the reproduction time.Gene expression analyses were performed at two time points; at the beginning (Day 0) and at the end of the experiment. During the feeding trial, tissue samples were collected from a total of 36 broodstock fish, consisting of 5 females (♀) and 5 males (♂) from each experimental group. Brain, liver, pituitary, testes, and ovary tissues were dissected from rainbow trout and kept in RNAlater® solution and stored at -86°C and after that RNA isolation was carried out. Following RNA isolation, complementary DNA (cDNA) synthesis will be performed. The isolated RNA will be expression levels of steroidogenic genes using real-time polymerase chain reaction (qRT-PCR) methodology. The steroidogenic genes analyzed in the present study included; *lh* (pituitary) (Hou et al., 2016), *cyp19b1* (female, brain) (Chen et al., 2021), *star* (ovary) (Bhat et al., 2024), *star* (testis) (Kusakabe et al., 2006), *erβ1* (female, liver) (Chen et al., 2021), *vtg* (ovary and liver) (Chen et al., 2021), *hsd3b1* (gonad) (Vizziano et al., 2007), *dmrt1* (testis) (Vizziano et al., 2007), *amh* (testis) (Vizziano et al., 2007), *β-actin* (all tissues).

## Introduction

Ensuring the sustainability of cultured species depends on gamete quality, and the most important factor affecting it is the composition of the feed. Probiotics have been characterized as live microorganisms that colonize the host's gut and provide health benefits when added to feeds. The benefits of probiotics are bactericidal activities and immune activating properties. Although there is a relationship between the microorganism population in the fish gut and fertilization (Gioacchini et al. 2014), the information on probiotic applications is limited. Based on the limited information, it has been determined that probiotics added to the diet improve reproductive performance, as well as gamete quality in zebrafish (Gioacchini et al. 2014; Safari et al. 2022), rainbow trout (Akbari-Nargesi et al., 2019), killifish (Lombardo et al., 2011) and Nile tilapia (Abdelal et al. 2021).

## Materials and methods

Experimental trials were conducted at the Sapanca Inland Fisheries Research and Application Unit of the Faculty of Aquatic Sciences, Istanbul University. In the study, *Hafnia alvei* + *Carnobacterium maltaromaticum* (P4) and *Lactococcus lactis* (P9), which were isolated within the scope of the TÜBİTAK project number 222N019, produced and lyophilized by MCS Aquatic R&D Aquaculture Inc. Company, were used as probiotic bacteria. Experimental groups were established, including a control group and four treatment groups supplemented with either P4 or P9 at two different final concentrations in the feed ($10^7$ and $10^9$ CFU $kg^{-1}$). Sunflower oil was added to the feed of experimental groups. Gamete quality parameters measured for both male and female trout included total fecundity and egg diameter for females, and total motility, motility duration, sperm volume, VCL (curvilinear velocity), osmolality, and pH for males. Additionally, fertilization and hatching rates were calculated for both sexes. Statistical analyses were calculated using Statistica software.

## Results

Fecundity and egg diameter, as indicators of gamete quality in females, did not show any significant differences between treatments ($P > 0.01$). Similarly, for males, parameters including total motility, motility duration, sperm volume, curvilinear velocity (VCL), osmolality, and pH did not show significant differences across the treatment groups ($P > 0.01$). However, the groups treated with P4 at $10^7$ and $10^9$ CFU $kg^{-1}$ showed a better performance in fertilization rates using female individuals from the treated groups and males from the control group ($P < 0.01$), while hatching rate from the same fertilization groups did not show significant differences ($P > 0.01$). Contrary, male individuals used from the treated groups and fertilized with females from the control groups were not significantly different across treatments ($P > 0.01$).

**Discussion and conclusions**

The aim of this study was to determine the effects of probiotic additive diets on gamete quality in rainbow trout (*Oncorhynchus mykiss*). Studies such as those by Akbari et. al., (2019) in rainbow trout and Gioacchini et al. (2014) in zebrafish reported an increase in total fecundity, as well as in the number and diameter of eggs produced by females treated with probiotics, compared to the control group. This contrasts with the results obtained in the present study, where no significant differences were observed between the groups. In the group where females were treated with probiotics and fertilized with males from the control group, a higher fertilization rate was observed; however, the hatching rate was not affected. These results are consistent with those reported by Lombardo et al. (2011) in killifish, but not with those of Gioacchini et al. (2014), in which hatching rates were affected by probiotic treatment. On the other hand, an increase in fertilization and hatching rates in rainbow trout following probiotic supplementation has also been reported by Akbari et. al., (2019).

## Introduction

The global market demand for collagen is increasing (CAGR 6.52% until 2027). Due to its special properties such as high biocompatibility, good bioactivity, and weak antigenicity, collagen is a protein with a wide range of applications. It is used in pharmaceuticals, biomedical products, as well as in the nutritional supplements, cosmetics, and food sectors. Although terrestrial sources of collagen are numerous, outbreaks of various diseases in terrestrial animals complicate its use in humans. Marine collagen represents a promising alternative. Marine sponges are a highly valuable source of marine collagen. Among them, *Chondrosia reniformis* is of particular interest due to the high concentration (> 30%) of type I collagen in the sponge biomass (Pozzolini et al. 2012; Swatschek et al., 2002) and the absence of any inorganic components (spicules).

A major constraint regarding the industrial application of sponge collagen is the sufficient supply of sponge biomass. Promising efforts have been made in the mariculture of *C reniformis* targeting sustainable production of sponge biomass needed for collagen production (Gökalp et al, 2020; Orel et al, 2021), but the success of sponge farming is influenced by naturally fluctuating conditions such as light, current, and turbidity (Gökalp et al., 2020; Wilkinson and Vacelet, 1979). Predation, disease, and fouling can also harm this species in mariculture. Reports of sponge diseases have increased in recent decades, leading to depletion of sponge populations throughout the Mediterranean (Webster, 2007). In closed, recirculating aquaculture systems, optimal species-specific cultivation conditions can be established, enabling sustainable, reliable, and location-independent production of sponge biomass and, as a result, maximized collagen production.

The concept of integrated multitrophic aquaculture (IMTA) represents an even more sustainable approach. IMTA is based on the ecological concept of efficient reuse of organic and inorganic sidestreams through the application of different trophic levels of the food web within the culture system. Pronzato et al. (1998) were the first to include sponges in IMTA. Sponges can remove large amounts of organic matter from large volumes of water through very rapid and efficient filtration of a wide variety of suspended particles (Weisz et al. 2008; Riisgård et al. 1993; Reiswig 1974).

The efficient filtration of organic particles by sponges, coupled with their ability to produce commercially interesting natural compounds (Gökalp et al. 2019; Müller et al. 2009), is driving the interest in integrating these animals into IMTA approaches. However, examples of commercial applications of sponge farming are still rare (Duckworth 2009), and the inclusion of sponges as an element in IMTA is still in its infancy.

The focus of this study is the joint cultivation of the sponge species *C. reniformis* together with commercially relevant macroalgae and fish in an IMTA approach.

## Materials and methods

The experimental phase will start in July 2025.

***Chondrosia reniformis:*** The sponge specimen are obtained by diving from the Adriatic Sea, transported to the recirculation aquaculture system at the Alfred Wegener Institute, Bremerhaven, Germany and kept for an acclimatization period of two weeks in culturing tanks with artificial seawater. They are fragmented for growth experiments, placed on clay dishes in two divers systems: a shelf system (6 x 0.05 $m^3$) and a circular tank (1 $m^3$). They are fed once daily with a self-designed powder feed (2 ml/50, project AkPhaKol), which is dissolved shortly before feeding.

*(Continued on next page)*

Three experiments are conducted during the project: one experiment on the growth behavior of the sponge fragments during the IMTA assembly and two additional experiments on the targeted increase of the collagen content in the IMTA assembly. 1) Increase in vitamin C intake as feed additive or as direct application. 2) Application of silicate in the form of a) sand and b) diatom fragments. During the experiments, the survival of the sponge fragments is documented at regular intervals, and growth is calculated in g and $cm^2$ at the beginning and end of each experiment. The collagen content of the sponge fragments is determined as a percentage of dry weight at the beginning and end of each experiment.

***Ulva lactuca:*** Free-floating algae are obtained from macroalgae project (Novafoodies) conducting at the AWI. Those are distributed in four cascaded tanks (each 0.06 $m^3$). After determining the ammonium, nitrate, and phosphate levels, the cascade system is connected to the sponge cycle. The nutrient concentrations (ammonium, nitrite, nitrate, phosphate) in the sponge and algae tanks are regularly monitored. If the algae are undersupplied with nutrients, the connection to the sponge tank can be removed if necessary to ensure additional food supply. The growth and photosynthetic efficiency parameters of the algae in the cascade-system are measured every three weeks.

***Dicentrarchus labrax*:** Juveniles of European sea bass are obtained (approximately 5g body weight) from a commercial European fish farm. After an acclimation period of one week and removal of group 0 for measurement of length, weight, and health status, the fish tank is connected to the sponge-algae system. To ensure consistent conditions for the IMTA system, the following conditions are continuously evaluated: Stocking size and density, feed quantity and size, documentation of health status and feed availability for the sponge tank: The amount of feed available in the form of feces and fish food residues is documented. Additionally, water quality (ammonia, nitrate, nitrite, and phosphate levels) is monitored.

**Expected Outcome**

The location-independent, constant, and controllable conditions in a closed aquaculture system represent an optimal starting point for the development of refined sponge biomass and collagen. In former projects, an ex-situ aquaculture system for the sponge species *C. reniformis* has already been designed, constructed and adapted, in addition a feed specially tailored to the needs of the sponge *C. reniformis* has been developed. The collagen content in the obtained sponge fragments increased depending on the amount of this feed, resulting in a higher percentage of collagen to be extracted per sponge fragment.

The aim of the joint cultivation of macroalgae and fish in IMTA is to improve the maintenance and growth conditions for the sponge species *C. reniformis*. The macroalgae improve water quality by filtering nutrients such as ammonium and nitrate from the culture water and using them as food. Furthermore, the feces and food residues in the fish tanks increase the proportion of dissolved and particulate carbon in the process water, which serves as additional and constantly available food for the sponges in addition to the daily feed. Further, collagens with special properties can be produced and *C. reniformis* can be used as a sustainable collagen source on an economically relevant scale.

The concept of integrated multi-trophic aquaculture closes nutrient cycles by providing fish culture with food particles for the sponges, and using algae culture to absorb the increased nitrogen compounds in the culturing water. In an integrated multi-trophic aquaculture system, in which sponges are cultivated together with other economically relevant species, species-specific water quality and high fitness and growth of the sponge fragments are expected. In addition to the use of residual streams from fish culture, the integration of co-cultivated organisms leads to more diverse products with commercial value than monoculture

# EFFECTS OF DIETARY VITAMIN C ON THE GROWTH AND COLLAGEN LEVEL OF THE MARINE SPONGE *Chondrosia reniformis*

M. Schiffer-Harms*, K. Schiefenhövel, T. Schatton, C. Cerrano and J. Henjes

Alfred Wegener Institute
Sustainable Marine Bioeconomy, Aquaculture Research
Am Handelshafen 12
27570 Bremerhaven, Germany
Email: Melanie.schiffer@awi.de

**Background**
Collagen plays an important role in healthcare and overall well-being, with numerous potential applications in areas such as drug delivery, cosmetics and the food industry. As a result, the global collagen market is expanding rapidly. Marine sponges are considered a valuable source of marine collagen, with *Chondrosia reniformis* being of special interest. This species contains a high concentration (over 30% of DW) of type I collagen in its biomass (Ghosh et al., 2019) and lacks inorganic structural components like spicules. In *C. reniformis*, ascorbic acid plays an important role as a reducing agent in the biosynthesis of collagen (Cerrano et al., 1999). During collagen synthesis, ascorbic acid is essential for the hydroxylation of proline and lysine residues, stabilizing the structure of collagen.

A major constraint regarding the industrial application of sponge collagen is the sufficient supply of sponge biomass. Land-based aquaculture represents an interesting economic approach to grow marine sponges under species-specific conditions and, as a result, maximized collagen production.

**Materials and methods**
*Chondrosia reniformis* were obtained from the sampling area in the Mediterranean Sea near Ancona/Italy and subsequently reared in a recirculation aquaculture system at the Centre for Aquaculture Research, Bremerhaven/Germany. Sponge specimens were cut and sponge fragments were allowed to attach to different substrates (oyster shells and clay plates). Sponge fragments were fed twice a day with a self-designed liquid feed with two different vitamin C concentrations (2.5 mg/ml and 22.5 mg/ml). Attachment, fragments growth and survival rate were measured at the end of the experiment. Sponge collagen was isolated (Swatschek et al, 2002) and collagen content was determined before and at the end of the experiment.

**Results**
Attachment and survival rate during the experiment were high with 86% and 100%, respectively. Collagen content of *C. reniformis* was not significantly affected by either the dietary vitamin C concentration or the substrate they grew on. *Chondrosia* attached to clay plates had a mean collagen content of 30% when fed with a vitamin C concentration of 22.5mg/ml. Cultivation on oyster shells resulted in mean collagen contents of 27%. *Chondrosia* growing on oyster shells and a vitamin C concentration of 2.5 mg/ml showed a collagen content of 26% and 27% when attached to clay plates. However, there was a slight increase in the collagen content from the beginning of the experiment to the end.

The dietary vitamin C concentration and substrate had no significant effect on the growth of *Chondrosia*. Overall, a negative growth was detected under all experimental conditions.

**Conclusion**
Land-based aquaculture of *C. reniformis* is a promising approach to grow marine sponges and increase their collagen content. Our study revealed that attachment and survival rates of *C. reniformis* during the experiment were high, at 86% and 100% respectively, indicating good viability. The collagen content was not significantly influenced by dietary vitamin C concentration. A slight increase in collagen content was observed from the start to the end of the experiment, but overall, there was no significant effect on growth, as all conditions showed negative growth. These findings suggest that while *C. reniformis* maintains collagen production independent of vitamin C supplementation, its growth may be limited under the experimental settings. This work highlights the need for further research on optimizing growth conditions for aquaculture or biomedical applications.

# TRANSFORMING AFRICAN CITY REGION FOOD SYSTEMS THROUGH CIRCULAR AGRI-FOOD TECHNOLOGIES: THE INCITIS-FOOD PROJECT

Zala Schmautz* & Ranka Junge

Institute of Natural Resource Sciences
Zurich University of Applied Sciences
Grüentalstrasse 14
8820 Wädenswil, Switzerland

Email: zala.schmautz@zhaw.ch

The EU-funded project INtegrated and Circular Technologies for Sustainable city region FOOD systems in Africa (INCiTiS-FOOD) addresses the urgent need to improve food and nutrition security (FNS) in African urban areas while reducing environmental impacts and fostering circularity. Operating across six countries, Kenya, Ghana, Nigeria, Sierra Leone, Cameroon, and Gabon, eight Living Labs serve as innovation hubs where local actors co-design, test, and adapt agri-food technologies to context-specific needs.

Core technologies include soilless cultivation systems (hydroponics, aquaponics, bioponics), recirculating aquaculture systems, and insect and snail farming. These solutions are designed to require minimal land, water, and financial inputs, making them particularly suitable for urban and peri-urban settings. The Living Labs follow an iterative design process, developing and optimizing prototypes into minimum viable products (MVPs) that meet local technical, societal, and business requirements.

In the first half of the four-year project, all Living Labs became operational, established prototype systems, and initiated multi-actor co-creation processes. Cross-Lab networking and knowledge sharing have fostered capacity building, while early results demonstrate resilience to challenges such as political instability, climate extremes, and resource constraints. The next phases will focus on scale-up, entrepreneurship incubation, and generating evidence to guide urban food policy in African cities.

By integrating technological innovation with inclusive stakeholder engagement, INCiTiS-FOOD aims to deliver scalable circular agri-food solutions, strengthen local food value chains, and contribute to sustainable, resilient city-region food systems.

# JOURNEY OF A CORAL: SCALING REEF RESTORATION THROUGH AI-DRIVEN DIGITAL TWINS

Mark Miller[1], Naeem Atta[1]

[1]DigyCorp Ltd.
United Kingdom

The Shushah Island Reef restoration project, located in the Northern Red Sea off the coast of NEOM, is the world's largest active coral restoration initiative—aiming to restore 100 hectares of reef by outplanting 2 million corals across 300 native species. This presentation outlines the full lifecycle of coral propagation—from wild colony sourcing and nursery production to outplanting and long-term reef monitoring—within a digitally managed, AI-enhanced framework.

Central to this approach is the *eCoral™ Digital Twin*, an orchestration platform integrating real-time sensor data, image analytics, environmental logs, and predictive models to optimize nursery management, coral health tracking, and restoration success. AI models assist in identifying ideal genotypes for site-specific deployment, simulate environmental stressors, and forecast spawning and survivability rates—enabling adaptive reef management at industrial scale. Data from ex-situ (land-based) and in-situ (reef-based) nurseries feed into coral growth simulations and digital reef mapping to enhance restoration planning.

The integration of AI, digital twins, and ecological science offers a replicable blueprint for scaling coral reef restoration globally, while supporting biodiversity recovery, blue carbon valuation, and resilience against climate change. This talk will share lessons from operationalizing coral production at scale and the transformative role of technology in nature-based solutions.

# ACIDIFICATION CHALLENGE AFFECT THE GILTHEAD SEA BREAM SKIN MUCOSA

C. Scirè Scappuzzo[1]*, M. Tejero[1], A. Vallejo-Castaño[1], I. Sanahuja[1], E. Gisbert[2], A. Ibarz[1], L. Fernández-Alacid[1]

## Introduction

Global climate change and anthropogenic pressures are exerting profound effects on marine fish populations and aquaculture systems. Among current environmental threats, ocean acidification represents a major concern. Driven by ongoing atmospheric $CO_2$ emissions, this phenomenon can negatively impact all marine life by limiting both growth and survival. Temperate fish species are highly sensitive to environmental fluctuations, including elevated temperatures, water acidification, and heavy metal contamination, all of which can induce physiological stress. These stressors primarily affect external tissues, such as the gills and the skin, which serve as the primary barrier between the internal and external environment, often triggering structural changes like epithelial cell damage, mucous cell hypertrophy and hyperplasia, chloride cell proliferation, and pigment cell migration within the skin (Kalogianni *et al.,* 2011). It is known that the mucosal barriers of fish undergo significant structural and molecular changes in response to altered pH, including epithelial hypertrophy, tight junctions modification, and antioxidant gene regulation (Mohammadi et al., 2019). Goblet cells, the principal mucus-secreting cells of the epidermis, are integral to this protective function. Little is known about how chronic exposure to lowered pH influences epidermal architecture and mucosal response in gilthead sea bream. This study aims to evaluate the effect of a controlled acidification challenge (pH 7.9 *vs.* pH 7.3) on sea bream alevins, integrating histological and non-invasive analyses of key skin mucus bioindicators (Sanahuja *et al.,* 2023). This approach may also contribute to the development of robust, non-invasive tools for health monitoring in aquaculture under changing environmental conditions.

## Material and methods

Gilthead sea bream alevins were exposed to two different pH conditions (7.3 and 7.9) for a period of 10 weeks under controlled laboratory conditions. Each pH treatment was maintained in triplicate tanks, and a total of 12 fish per condition were sampled at the end of the experimental period. The skin mucus was obtained and analised as described in Fernandez-Alacid *et al.,* (2018). The histological analysis was performed by fixing the skin in Bouin's solution for 24 h at room temperature, dehydrated in graded ethanol, cleared in xylene, embedded in paraffin, and sectioned at 3 μm. After dewaxing and rehydration, sections were mounted on glass slides and stained with periodic acid-Schiff (PAS) and Alcian blue (AB). Slides were digitized at 600 dpi and analyzed using ImageJ program. Epidermal thickness and mucous cell parameters were measured from randomly selected fields per sample. The skin barrier status was assessed as described in Dang *et al.* (2020) using 3 different indices:

a) Mean mucous cell (MC) area (μm2)
b) Mean MC volumetric density (%) = (MC area MC number)/(Epithelial area) x 100
c) Barrier status = 1/(MC area MC density) x 100

## Results and discussion

Exposure to pH 7.3 led to notable changes in mucus secretion and composition. Under acidified conditions, a reduction in exuded mucus volume and soluble fraction was observed, suggesting an increase in structural components. Stress-related metabolites (lactate and cortisol) were elevated in fish exposed to pH 7.3, while antioxidant power showed an upward trend, but not significant, potentially enhancing mucosal defensive sensitivity. Although mean goblet cell area was not significantly different between groups (pH 7.3: 83.8 ± 33.6 μm²; pH 7.9: 77.6 ± 17.2 μm²), histological assessment revealed a higher proportion of small-sized goblet cells (0–50 μm²) in the acidified group. This indicates increased mucus cell turnover, supporting the observed boost in secretion. No significant differences were found in goblet cell volumetric density (pH 7.3: 3.66 ± 2.52%; pH 7.9: 4.06 ± 2.28%) or in the calculated barrier index, suggesting that barrier integrity remained intact despite cellular changes. These results will be subjected to further analysis within the multidisciplinary framework of the ACUISOST project, which aims to determine how new feed formulations can interact in productive terms with the acidification of seawater.

*(Continued on next page)*

**Conclusions**

The preliminary results indicate that ocean acidification results in a reduction in skin mucus exudation, with a lower soluble fraction and a less optimal composition, accompanied by increased levels of stress-related metabolites. These findings suggest that long-term exposure to moderate acidification (pH 7.3) alters the skin mucosa of gilthead seabream mainly by modulating mucus cell dynamics, while preserving epidermal structural integrity. Despite the reduction in mucus exudation, no significant changes were observed in goblet cell area, volumetric density, or barrier index. Notably, the acidified group showed a higher frequency of small-sized goblet cells (0–50 μm²), indicating an increased mucus cell turnover as a compensatory mechanism to maintain mucosal defense.

## Introduction

Mariculture is the main source of bivalves globally, but this supply is often limited to a few species. In the Mediterranean Sea, the primary bivalves being farmed are mussels and oysters, which highlights the need to introduce new species. The Mediterranean scallop (*Pecten jacobaeus* Linnaeus 1758) is a commercially sought-after species mostly targeted by beam trawlers in the northern Adriatic Sea. However, constant fishing pressure has led to decreased landings in recent years. *Pecten jacobaeus* has a high market value and, according to previous research, can reach market size in just 18 months, with high survival rates, making it a potential candidate for aquaculture. The biggest challenge in farming this species, however, is the lack of a reliable and inexpensive source of seed.

The aim of this study was to investigate the potential for collecting juvenile *P. jacobaeus* from nature - referred to as wild spat collection - and to monitor their growth in farming installations, specifically lantern nets, for future aquaculture purposes.

## Materials and methods

Collectors, which were mesh bags filled with netron filament nets, were deployed each month from a raft at a bivalve farm located in the Krka River estuary, between the fall of 2024 and the summer of 2025. Two types of collectors, differing in mesh size (10 mm and 1 mm) were placed at various depths, ranging from 8 to 20 meters in 2-meter increments. After two months of submersion, the collectors were retrieved and examined for collected juveniles, which were then counted based on collector type and depth. Collected juveniles were measured and then placed in lantern nets at two depths, 8 and 15 m. Each subsequent month juveniles were measured again to estimate their growth. During the experiment environmental parameters, such as temperature, salinity and chlorophyll a, were monitored.

## Results

Our results indicate that the collection of *P. jacobaeus* juveniles from the Krka River estuary was highest during the spring and fall seasons. We observed that collectors with larger mesh sizes captured more juveniles than those with smaller mesh sizes. Additionally, collectors that were positioned at greater depths yielded the highest numbers of collected juveniles, with a decline in numbers closer to the surface.

The growth rate of juveniles was fastest during the spring and fall seasons. We found that juveniles placed in lantern nets at lower depth exhibited better growth compared to those placed in lanterns at greater depth, although growth varied among individual juveniles. The survival rate was low overall, with the highest mortality recorded among the smallest juveniles, which decreased as the juveniles grew larger.

## Discussion

The collection of juvenile *P. jacobaeus* from the Krka River estuary coincide with the scallop's reproductive cycle, as larvae attach to collectors 3-4 weeks after spawning. The highest numbers of juveniles were recorded following the spring and fall spawning periods. Collectors with larger mesh size yielded better results, likely because larvae could more easily enter these collectors, while smaller mesh sized collectors became clogged with fouling. The increased collection of juveniles at greater depths is attributed to the fact that *P. jacobaeus* is a benthic species; therefore, the highest numbers of larvae are found closer to the bottom.

*(Continued on next page)*

The faster growth of juveniles during spring and fall can be linked to the optimal temperature conditions and the abundance of available food, which peak during these seasons. Greater mortality rates were observed among the smallest juveniles, as they are most vulnerable to changes in conditions and handling. In contrast, the mortality rate decreased as juveniles grew larger and became more resilient.

**Conclusions**

Collecting *P. jacobaeus* spat from the wild is most effective during the spring and fall seasons after spawning occur. Using collectors with larger mesh sizes (approximately 10 mm) and placing them at greater depths results in better juvenile collection. Juvenile growth is rapid but depends on ambient temperature and food availability, and there are high mortality rates during the early stages of development. The number of juveniles typically collected is insufficient for starting commercial aquaculture production, so alternative methods for acquiring juveniles are necessary.

# SUPPLEMENTATION WITH NUCLEOTIDES COMBINED WITH SEAWEED MEAL IMPROVES SURVIVAL UPON AHPND CHALLENGE IN PACIFIC WHITE SHRIMP

Sergi Segarra*, Juan Diego Calvo-Perez, Jose Antonio Talledo, Thanh Chau, Phuc Hoang, and Loc Tran

*R&D Bioiberica S.A.U.
Esplugues de Llobregat
Spain
ssegarra@bioiberica.com

Acute hepatopancreatic necrosis disease (AHPND) is a bacterial disease mainly caused by *Vibrio parahaemolyticus* which causes high mortality rates in Pacific white shrimp (PWS), *Litopenaeus vannamei*, and consequently leads to substantial economic losses. Dietary nucleotides modulate the immune response and have been shown to improve health of PWS, and seaweed products contain bioactive compounds with reported benefits in several animal species. The study was aimed at evaluating the effects of combining nucleotides (NU; Nucleoforce®, Bioiberica S.A.U., Spain) and a *Macrocystis integrifolia* seaweed meal (SM; Algaemix®, Algaex, Peru) on PWS survival upon challenge with an AHPND-causing *V. parahaemolyticus* strain.

After acclimatation for 2 days, 720 PWS (0.57±0.11 g) were classified into six groups (4 replicates/group; 30 PWS/90L-tank) and received different diet supplementation for 28 days: one group with no challenge (NC, Negative Control) and five groups challenged by immersion with *V. parahaemolyticus* and supplemented with either 500ppm NU (NU500), 500ppm SM (SM500), 500ppm NU with 500ppm SM (NU500SM500), 334ppm NU with 666ppm SM (NU334SM666) or no supplementation (PC, Positive Control). PWS were followed for 10 days post-challenge.

After 10 days, the PC group showed a significantly lower survival rate (30.63±4.70%) vs NC (88.29±2.73%; $p<0.05$). A non-significantly increased survival rate was seen with NU500 (33.95±9.62%), SM500 (41.02 ± 3.17%) and NU500SM500 (45.00±13.54%), while NU334SM666 achieved a significantly higher survival rate (59.61 ± 9.55%; $p<0.05$) (Figure 1).

In conclusion, the 1:2 combination of nucleotides with SM has a synergistic effect, reducing mortality in AHPND-challenged PWS. This innovative and sustainable nutritional intervention could therefore be used to improve PWS health, especially as an alternative to conventional management approaches to AHPND which often have limited success and negative consequences, such as antibiotics and disinfectants.

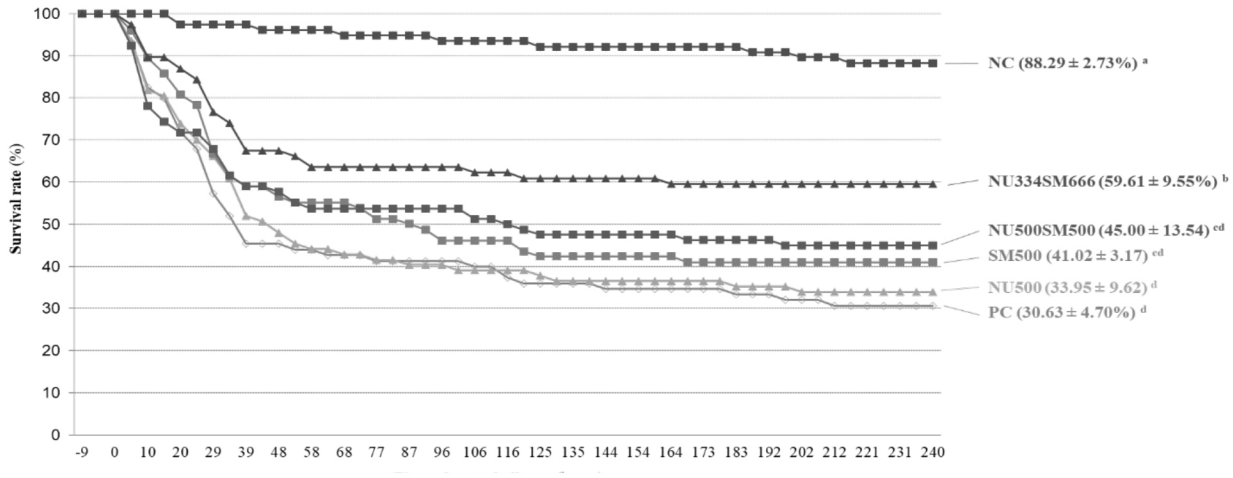

Figure 1. Survival rate of PWS after AHPND challenge. Different superindex letters indicate statistically significant differences ($p<0.05$).

# UNLOCKING EU-APPROVED HEALTH AND NUTRITIONAL CLAIMS FOR CONSUMERS OF *Sparus aurata* FED BY ALTERNATIVE FEED

Esther Sendra-Nadal[1,*], Francisca Hernández-García[1], Marina Cano-Lamadrid[1]

[1]Instituto de Investigación e Innovación Agroalimentaria y Agroambiental (CIAGRO-UMH), Universidad Miguel Hernández, Carretera de Beniel, km 3.2, 03312 Orihuela, Alicante, Spain
esther.sendra@umh.es

## Introduction

As aquaculture intensifies, optimizing fish nutrition remains a critical aspect of improving growth performance, health status and product quality, all of which are closely related to diet composition and nutrient availability (Glencross et al., 2020). Fundamental to the success of this sector is the formulation of nutritionally balanced feeds, in which fatty acids play a key role in supporting fish growth, health and overall product quality. Carnivorous fish species such as gilthead seabream have dietary requirements for the essential fatty acids (EFA), especially the LC-PUFA (n–3 and n–6 series with 20 or more carbons), eicosapentaenoic acid (EPA; 20:5n–3), docosahexaenoic acid (DHA, 22:6n–3) and arachidonic acid (ARA, 20:4n–6). These fatty acids not only contribute to fish health and growth but also improve the nutritional profile of aquaculture products for human consumption, supporting cardiovascular and cognitive benefits (Calder, 2020). EPA and DHA fatty acids are essential for proper brain development, including foetus, infants and toddlers (Innis, 2007; Lauritzen et al., 2016). The European Commission authorized 9 of the 54 health claims requested for the health benefits of DHA, including visual development in children, proper brain development and proper functioning of the circulatory system (R (UE) 1924/2006). In the case of EPA, there were 82 claims requested, but only 3 were authorized, related to the proper functioning of the circulatory system. Unauthorized claims denial was based on the fact that the available scientific evidence on the claimed effects was not sufficiently substantiated (R (UE) 1924/2006).

Traditionally, fishmeal (FM) and fish oil (FO) have been the main sources of essential fatty acids in aquafeeds, considering both the biological quality of the protein, and its digestibility. However, their continued use poses significant challenges, including sustainability concerns linked to overfishing, fluctuating costs and environmental impact (Moutinho et al., 2022; Naylor et al., 2021). These problems have prompted extensive research into alternative ingredients capable of replacing FM and FO without compromising feed efficiency or the quality of the fish produced.

This study investigates the potential of alternative feed (PAP and ALT)—as substitutes for traditional fishmeal (CTRL) in the diet of *Sparus aurata* (gilthead seabream), with a focus on the nutritional and health claims authorized in the European Union. The trial assessed the fatty acid profile across two key growth stages (300 g and 800 g). Results were interpreted in the context of EU Regulation (EC) No 1924/2006 on nutrition and health claims made on foods. The findings contribute to the development of sustainable feed capable of delivering fish products with added value for human health.

## Materials and methods

Three types of feed formulations (n=3, CTRL: fish meal-based diet, PAP: processed animal protein-based diet, and ALT: alternative protein-based diet). Fish sampling took place at two growing stages: when fish reached 300 g and 800 g. The nomenclature for fish was as follows: i) individuals reached 300 g: CTRL300, PAP300 and ALT300; and, ii) individuals reached 800 g: CTRL800, PAP800 and ALT800. A Gas chromatograph coupled to a Flame Ionization Detector (GC-FID) was used for detection and semi quantification of fatty acids. Sample (50 mg) was methylated following a direct extraction-methylation method with a first basic step with sodium methoxide followed by an acid step with boron trifluoride 14% in methanol as described by Trigueros & Sendra (2015).

## Results and discussion

European Union rules on nutrition and health claims were established by Regulation (EC) No 1924/2006. This regulation is the legal framework used by food business operators to inform consumers through labelling or advertising on the beneficial effects of their products, concerning health and nutrition.

*(Continued on next page)*

The specification of the three authorized Health Claims (HC) other than risk reduction and children's claims are detailed as follows: i) HC 1: DHA helps maintain normal triglyceride levels in the blood. *This claim can only be used for foods that provide a daily intake of 2 g of DHA and contain DHA in combination with eicosapentaenoic acid (EPA). For a product to carry this claim, consumers must be informed that the beneficial effect is obtained with a daily intake of 2 g of DHA; ii)* HC 2: DHA and EPA contribute to maintaining normal blood pressure. *This claim can only be used for foods that provide a daily intake of 3 g of EPA and DHA. For a product to carry this claim, consumers must be informed that the beneficial effect is obtained with a daily intake of 3 g of EPA and DHA; and, iii)* HC 3: DHA and EPA contribute to maintaining normal triglyceride levels in the blood. *This claim can only be used for foods that provide a daily intake of 2 g of EPA and DHA. For a product to carry this claim, consumers must be informed that the beneficial effect is obtained with a daily intake of 2 g of EPA and DHA.* It is essential to mention that following the recommended serving size for an average consumer, a portion of fish ranges between 125-150 g. Considering the percentage of DHA and EPA in the total analysed fat for each diet in 300 g and 800 g fish, we can only apply Claim 1 to ALT800 (2.07). However, claims 2 and 3 can be used for all diets (EPA: 1.79-2.08 g per serving; DHA: 1.75-2.32 g per serving; EPA+DHA: 3.45-4.39 g per serving). If we consider a 150 g serving, all three claims can be applied to all diets for both 300 g and 800 g fish (EPA: 2.15-2.5 g per serving; DHA: 2.22-2.79 g per serving; EPA+DHA: 4.37-5.27 g per serving).

On the other hand, as to authorizing nutritional claims (NC) under European Union regulation, the established criteria are included in the following lines: i) NC1: Source of omega-3 fatty acids: *if the product contains at least 0.3 g of alpha-linolenic acid per 100 g and per 100 kcal, or at least 40 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal; ii)* NC2: High content of omega-3 fatty acids: *if the product contains at least 0.6 g of alpha-linolenic acid per 100 g and per 100 kcal, or at least 80 mg of the sum of eicosapentaenoic acid and docosahexaenoic acid per 100 g and per 100 kcal; iii)* NC3: High content of monounsaturated fats: *if at least 45% of the fatty acids present in the product come from monounsaturated fats and these monounsaturated fats provide more than 20% of the product's total energy value; iv)* NC4: High content of polyunsaturated fats: *if at least 45% of the fatty acids present in the product come from polyunsaturated fats and these polyunsaturated fats provide more than 20% of the product's total energy value; and v)* NC5: High content of unsaturated fats*: if at least 70% of the fatty acids present in the product come from unsaturated fats and these unsaturated fats provide more than 20% of the product's total energy value.* Taking the requirements into account, it can be said that both growth stage fishes of the three diets can be considered both a source and high in Omega-3 fatty acids. The CTRL300, CTRL300, and CTRL800 showed a high level of MUFA, while none of the treatments exhibit a high content of PUFA and/or SFA.

**Conclusions**

According to European Union regulations, fish raised with traditional feed is considered a healthy and nutritious option due to its beneficial levels of EPA, DHA, MUFA and omega 3 fatty acids. Furthermore, the use of the proposed alternative feeds does not compromise these properties, as the levels of these essential fatty acids remain within the recommended ranges for health benefits. This ensures that fish-fed with proposed alternative diets continue to provide the same nutritional advantages, making them a suitable and sustainable option without any detriment to their health and nutritious-promoting qualities.

# DEVELOPMENT OF SUSTAINABLE DIET FOR MALABAR GROUPER (*Epinephelus malabaricus*) USING OKINAWAN LOCAL RESOURCES

Taekyoung Seong*[1], Teruhisa Kojima[1], Siqi Lu[1], Makoto Takahashi[1], Yutaka Haga[2], Akihiro Takemura[1]

[1] University of the Ryukyus, Okinawa, Japan
[2] Tokyo University of Marine Science and Technology, Tokyo, Japan
E-mail: tk_seong@cs.u-ryukyu.ac.jp

## Introduction

Malabar grouper (*Epinephelus malabaricus*) is an economically important carnivorous fish species in Okinawa Prefecture, Japan. Aquaculture production in the region has been expanding steadily in response to rising domestic demand for high-quality marine fish. However, local farmers primarily rely on commercially available diets that may not fully meet species-specific nutritional requirements, resulting in suboptimal growth performance and feed efficiency. Furthermore, concerns regarding the environmental footprint of conventional feed ingredients and the vulnerability of supply chains have intensified interest in developing alternative feed resources. To enhance the sustainability and self-sufficiency of regional aquaculture, there is an increasing need to utilize locally available materials and promote a circular resource use approach that supports both economic viability and ecological resilience. This study aimed to develop sustainable diets for Malabar grouper by incorporating Okinawan fishmeal and livestock by-products as alternative protein sources to contribute to a regional circular resource utilization model.

## Materials and methods

Two feeding trials were conducted over 56 days in a flow-through system using 500 L tanks equipped with 45 L net baskets. Twelve fish per treatment group (initial mean weight 34.5 g) were hand-fed to near satiation. The first trial evaluated growth performance and nutrient digestibility of a diet formulated with Okinawan-produced fishmeal compared to a standard commercial fishmeal diet. The second trial assessed partial replacement of commercial fishmeal (75%) with pork-chicken meal at inclusion rates of 25%, 50%, and 75%. Apparent digestibility coefficients (ADC) of protein and lipid, body and muscle composition, and growth parameters were determined following standard analytical procedures.

## Results and discussion

The Okinawan fishmeal diet yielded slightly reduced growth (final body weight 80.1 ± 5.2 g) compared to the commercial fishmeal diet (85.4 ± 4.6 g). Protein digestibility remained high in both groups (Okinawan fishmeal: 89.3%; commercial fishmeal: 90.0%), whereas lipid digestibility was notably lower in the Okinawan fishmeal group (70.8% vs. 85.9%). In the livestock by-product replacement trial, substituting 25% of fishmeal with pork-chicken meal maintained growth performance (final weight 84.7 ± 5.1 g) and digestibility (protein ADC: 87.0%; lipid ADC: 86.9%). However, higher replacement levels (50–75%) resulted in significantly reduced protein digestibility (72.7–80.5%) and lipid digestibility (49.5–58.2%), indicating a threshold beyond which nutrient utilization declines. No adverse effects were observed on muscle proximate composition at moderate replacement levels.

These findings underline the importance of ongoing efforts to evaluate the nutritional optimization of locally sourced ingredients and to identify practical feed formulations that balance growth performance with environmental and economic sustainability. In particular, strategies to improve the lipid digestibility of Okinawan fishmeal and to refine processing techniques for livestock by-products are essential for maximizing the potential of regional resources. Future studies will also focus on conducting long-term feeding trials under commercial farming conditions to validate the efficacy of these diets and to assess their impacts on fish health and product quality.

## Conclusion

This study demonstrates that partial replacement of commercial fishmeal with locally produced livestock by-products can support satisfactory growth and nutrient utilization in Malabar grouper, highlighting the potential of Okinawan resources for sustainable aquafeed development. While further optimization of the nutritional quality of Okinawan fishmeal is required, these findings contribute to establishing a regional circular resource utilization model in line with the goals of the JST COI-NEXT project in University of the Ryukyus, which aims to promote integrated and sustainable aquaculture practices in Okinawa.

# APPLICATION OF GELATIN–CHITOSAN BASED SMART PACKAGING FILM CONTAINING ANTHOCYANINS IN FISH PACKAGING

Rezvan Shaddel[a,*], Tina Alighadri[a], Mahmood Alizadeh- Sani[b], Younes Zahedi[a], Jong Wham Rhim[c]

[c] Department of Food engineering and Bionanocomposite Research Institute, Mokpo National University

[*]Corresponding author: Email: r.shaddel@gmail.com

Smart biodegradable packaging films composed of gelatin (G) and chitosan (Cs) were developed for potential use in monitoring fish freshness. These films incorporated natural crosslinkers with antioxidant and pH-responsive properties. Anthocyanins extracted from *Echium amoenum* (EAA) were integrated as natural pH indicators, alongside citric acid (CA) and cinnamaldehyde (C) as crosslinkers. The resulting films exhibited excellent transparency and UV-blocking ability. Their color changed visibly in response to pH variation, a feature particularly useful for detecting spoilage in aquatic products. Notably, the G/Cs/CA5%/EAA film demonstrated enhanced physical and mechanical characteristics, including increased tensile strength, reduced water vapor permeability, lower elongation, and improved thermal stability, compared to the cinnamaldehyde-based film. Though the G/Cs/C5%/EAA film exhibited higher antioxidant activity (26.71%), the CA-based version showed smoother surface morphology and better overall performance. Most importantly, the films responded distinctly to chemical changes caused by fish spoilage and ammonia exposure, enabling real-time, non-invasive freshness monitoring. These findings highlight the potential of G/Cs/CA5%/EAA films as intelligent indicators in fish packaging, offering a sustainable and efficient solution for quality assurance in aquaculture and seafood distribution.

# STICK IT TO LACTOCOCCUS: DEVELOPMENT OF A POINT-OF-CARE DIAGNOSTIC ASSAY FOR PISCINE LACTOCOCCOSIS

Khalid Shahin

Pharmaq Analytiq UK Ltd (Part of Zoetis)
8B Solasta House, UHI-Inverness Campus
IV2 5NA, United Kingdom
Khalid.shahin@zoetis.com

Piscine lactococcosis is a critical bacterial disease impacting farmed fish, predominantly caused by species within the Lactococcus genus, including *Lactococcus garvieae, Lactococcus petauri*, and *Lactococcus formosensis.* Timely and accurate diagnosis is essential for effective outbreak management and mitigation of economic losses in aquaculture. While conventional diagnostic methods provide reliable results, they often necessitate specialized laboratory infrastructure and extended processing times, which limits their practicality in field conditions.

To overcome these limitations, we have developed a novel point-of-care (POC) diagnostic assay leveraging Recombinase Aided Amplification (RAA) technology combined with a lateral flow dipstick (LFD) detection system, enabling rapid and specific identification of piscine lactococcosis causative agents. Three species-specific RAA assays were designed, each targeting distinct genetic markers of *L. garvieae, L. petauri*, and *L. formosensis.* These assays exhibited high specificity, with no cross-reactivity detected among target species or other bacterial strains tested. Sensitivity analysis demonstrated a limit of detection between 10 and 20 genome copies, underscoring the assay's capability to detect low bacterial loads, which is critical for early diagnosis. Preliminary validation using field samples from infected fish yielded promising results, with each assay accurately detecting its corresponding pathogen without cross-detection. Ongoing efforts aim to broaden field validation across diverse geographical locations and aquaculture systems to further confirm assay robustness and reliability. Additionally, assay optimization is underway to enhance usability for non-specialist personnel, including simplified sample preparation and streamlined workflow.

In conclusion, the developed RAA-LFD diagnostic assays represent a rapid, sensitive, and specific POC solution for detecting Lactococcus species responsible for piscine lactococcosis. This advancement has the potential to significantly improve disease management in aquaculture by enabling decentralized testing, reducing dependence on centralized laboratories, and supporting sustainable fish production practices.

# DOMESTICATION STRATEGY OF THE MAJESTIC HUMPHEAD WRASSE (*Cheilinus undulatus*)

rossita@ums.edu.my

## Introduction

The humphead wrasse, also known as the Napoleon wrasse (*Cheilinus undulatus*), is a highly valuable marine fish species predominantly found in coral reef habitats across the Indo-Pacific region. Unfortunately, it is listed as Endangered on the International Union for Conservation of Nature (IUCN) Red List due to severe population declines caused by overfishing, particularly for the aquarium trade and the live reef fish food market (Sadovy & Vincent, 2002). Their slow growth rate and late sexual maturity make them highly susceptible to overexploitation, further exacerbating population declines. Given these challenges, conservation efforts are critical, including the establishment of marine protected areas (MPAs) and the implementation of sustainable fishing practices to ensure the species' long-term survival. Despite its high commercial value, aquaculture efforts for humphead wrasse remain rare, largely due to the difficulty in breeding and rearing the species in captivity. To date, only extremely rare instances of successful hatchery production of humphead wrasse seed have been documented. At the Borneo Marine Research Institute (BMRI), Universiti Malaysia Sabah (UMS), initiatives to domesticate the species began several years ago, yielding promising results in broodstock nurturing. The challenges of breeding this species stem from its complex reproductive behaviors, specific dietary requirements, and prolonged larval phase, all of which hinder large-scale aquaculture production. Additionally, its slow maturation rate presents further obstacles in achieving a sustainable breeding cycle. To advance aquaculture efforts, it is essential to establish a comprehensive baseline of biological and ecological information on this little-known species. This paper presents the ongoing strategies and early findings of humphead wrasse domestication, offering insights that could contribute to future aquaculture development and conservation management.

## Materials and Methods

A total of 65 tails of *C. undulatus* broodstocks reared in the captivity throughout six months of research period and fed daily with fresh squid (*Sepia sp.*) in a 150 ton tank at the Fish hatchery of Borneo Marine Research Institute, Universiti Malaysia Sabah, Kota Kinabalu, Sabah, Malaysia. Sex determination was carried out based on morphological assessment including the presence of eyeline, hump on head and genital papillae, of the *C. undulatus* were carried out to identify the sex (Tan et al., 2019). Another cohort of fish (30 fish; 700-1200g) were subjected to morphometric and meristic characterization, as well as nutritional profile (proximate analysis, amino acids, fatty acids, vitamins and minerals) using standards methods. In the weaning experiment fish were placed in a 30 ton round tank with different feeding regimes.

## Results and Discussion

Our preliminary findings show that *C. undulatus* exhibited an isometric growth pattern with more than half of the population being under the unknown status (neither male or female). Morphologically, females were distinguished by a less pronounced hump on the head and a visible eyeline behind the eyes, which was absent in males. Additionally, the study clearly revealed that male *C. undulatus* displayed an elongated genital papilla, whereas females had a rounded genital papilla with a distinct small egg hole. Induced spawning trials using hormone treatments have been conducted, with Ovaplant demonstrating the highest potential. Only ovaries were obtained from this fish cohort. On the other hand, nutritional analysis of *C. undulatus* has been done to provide valuable insights into the nutritional profile of the fish, which can be used to develop species-specific feeds. Significant differences were observed between the dorsal and ventral fillets of humphead wrasse, highlighting distinct nutritional strengths. The dorsal portion was higher in protein, essential amino acids, and minerals such as calcium and magnesium, making it ideal for consumers seeking muscle-building nutrients and bone health support. In contrast, the ventral portion contained higher fat content, particularly omega-3 fatty acids like DHA, as well as vitamin D, offering benefits for

*(Continued on next page)*

cardiovascular health, immune function, and energy. By-products from the fish also reveal a high potential nutritional profiling with high protein and mineral contents. Meanwhile, weaning from trash fish to formulated feed took at least about 2 month with a fasting-strategy. Survival rate during weaning period remains high with a flow-through culture system in round fiberglass tanks. An on-going feeding trial is conducted to evaluate the growth performance of humphead wrasse fed formulated feeds in captivity.

**Introduction**

Marine fish larvae face significant challenges during their early development. During this period, rapid growth, and intense metabolic activity make fish larvae highly vulnerable to oxidative stress; highlighting the critical role of nutrition (Xavier et al., 2021). Algal extracts are rich in bioactive compounds, therefore understanding how these molecules modulate digestive, and redox pathways in postlarval stages of fish is essential (Aragão et al., 2022). This work explores how dietary inclusion of micro- and macroalgae may support larval robustness and resilience through a modulation of growth performance, oxidative stress response, and gut integrity in *Solea senegalensis* postlarvae.

**Materials and methods**

In this experiment, sole larvae were fed one of three experimental diets: a commercial-like diet (COM) or two experimental diets supplemented with different combinations of algal products. These combinations used products of the macroalgae *Ulva* sp. and the microalgae *Phaeodactylum* (UPD), and *Tetradesmus* sp (UTD). The experiment lasted 24 days, from 25 days after hatching (DAH) to 49 DAH (Fig.1). After 49 DAH, sole previously fed with the experimental diets (COM, UPD, UTD) were fed with a new diet (Boost) for 5 days, until the end of the experiment (54 DAH).

During the experimental period, postlarvae (initial dry weight 1.24 mg) were reared in triplicate tanks in a recirculating aquaculture system. Throughout the nutritional trial, dissolved oxygen was maintained above 99.5%, temperature at 20.7°C, and pH at 8.1. Growth performance was assessed at 49 DAH. Key oxidative stress markers – superoxide dismutase (SOD), catalase (CAT), and total glutathione (GSH) – along with indicators of macromolecule damage like lipid peroxidation (LPO), as well as the expression of genes related to antioxidant defence (e.g. sod, cat), gut integrity (e.g. *cldn15*) and immune response (e.g. *il-1b*), were assessed at 49 and 54 DAH.

**Results & Discussion**

At 49DAH, the dietary treatments had no significant effects on growth, with larvae presenting a dry weight of 31.18 mg, a total length of 25.89 mm, and a condition factor of 0.89. The relative growth rate was 14.34 % $day^{-1}$, and the survival rate was 68.41%. After feeding the larvae with the COM and algae-supplemented diets, no clear trend in the antioxidant response was observed. However, after 5 days of feeding the larvae with the boost diet (at 54 DAH), LPO was significantly higher ($p < 0.05$) in larvae fed the UTD diet compared to those fed the control (COM). A higher LPO is not a positive response. However, as reported by Xavier et al. (2021), sole larvae when fed some doses bioactive compounds can exhibited higher cellular damage, nevertheless after a stressful event may lead to improved resilience. In the present trial, since larvae were not subjected to a challenge, it was not possible to determine whether the boost diet conferred an adaptive advantage. In terms of the molecular markers related to antioxidant defence, gut integrity and immune response, larvae fed the algae-supplemented diets seemed better prepared for a potential challenge, since the expression of genes such as *sod*, *cat*, *cldn15*, and *il-1b* was upregulated compared to larvae fed the COM diet.

**Conclusion**

Supplementing microdiets with algae products rich in antioxidants and other bioactive molecules may elicit both beneficial and adverse physiological responses. This dietary fine-tuning underlines the complexity of marine fish larvae nutrition and emphasizes the importance of tailoring diets to enhance larval resilience under hatchery production.

## Introduction

Jointly organised by the Brazilian Academy of Sciences (ABC), the German National Academy of Sciences Leopoldina, and the Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), the workshop "Sustainable Aquaculture – Environmental Impacts and Food Security", held in Berlin, Germany, in October 2023, brought together an interdisciplinary group of emerging scientists from Brazil and Europe to assess the potential and challenges of freshwater aquaculture in the face of rapid climate change and unprecedented loss of biodiversity. As a result of this workshop, a policy report was published by the German National Academy of Sciences Leopoldina and the Brazilian Academy of Sciences on 16 June 2025, emphasizing the prospects of especially freshwater aquaculture as a key component of a resilient, sustainable and increasingly circular global food production system, while considering the unique circumstances in Brazil and Germany and providing specific policy recommendations for both countries [1].

## Report summary

While acknowledging its many challenges, the aquaculture sector is growing rapidly and offers enormous potential to shift the global food system towards greater efficiency, sustainability and resilience. With the great variety of fish production methods, aquaculture has the ability to increase its importance as a sustainable global food source, both in terms of quantity and nutritional quality. Through the policy report, the author group aims to outline a path for aquaculture, especially freshwater aquaculture, to become a resilient, future-proof and increasingly circular mode of food production, focusing on available freshwater aquaculture technologies andoffering a comparative perspective on the fish farming sectors in Brazil and Germany.

Despite many differences, Brazil and Germany both share substantial potential for growth in the freshwater aquaculture sector. However, fish production and consumption in both countries fall below the global average, e.g., with Germany producing only 2% of domestically consumed fish. Both nations face similar challenges regarding the impacts of climate change, high production costs, negative public perception, labour shortages, and regulatory barriers. Expanding sustainable aquaculture requires strong political support, strategic measures, and efforts to enhance public awareness of its benefits compared to other animal production sectors. With the vision of expanding sustainable freshwater aquaculture, it is emphasised that research and technological advancements, as well as economic feasibility, are crucial in enhancing productivity, resource efficiency, and environmental sustainability.

*(Continued on next page)*

**Policy recommendations**

Aquaculture has great potential to contribute to a sustainable, circular, and resilient global food system. To unlock its ability to support healthy human diets, especially in regions with low self-sufficiency, three main objectives must be met.

1) Simplify regulatory procedures to support the sustainability of existing aquaculture enterprises and facilitate the creation of new ones.
2) Implement effective education and workforce development, while fostering consumer awareness about the sustainability and health benefits of modern aquaculture.
3) Translate scientific knowledge and innovations into practical, sustainable solutions.

To achieve these objectives, we recommend the following actions:

Policy and regulation

- Streamline bureaucracy: Limit the number of regulatory bodies responsible for licensing and controlling freshwater aquaculture facilities.
- Introduce aquaculture officers: These officers, located within regulating bodies, would guide prospective aquaculture entrepreneurs through the entire licensing and monitoring process, from initial concept to full implementation.

Consumer awareness and educating the future workforce

- Offer meals based on sustainable aquaculture products: Integrate domestically produced sustainable (freshwater) aquaculture products into public canteens, schools, and universities. This initiative can help support public health and promote the role of aquaculture in transforming the food production sector.
- Launch a mainstreaming programme: Raise societal awareness about the nutritional benefits of fish and the sustainable, secure, and transparent practices behind domestic freshwater aquaculture. Collaboration between governmental bodies, NGOs and the sector can help improve public perception and address prevailing biases against farmed fish.
- Intensify training programmes: Promote fish farming as a promising career path for young professionals. A skilled workforce is needed to scale up sustainable freshwater aquaculture, including:
    - Technical training for practitioners.
    - Academic training for research, education, and governance roles.

Science and innovation for practice

- Develop technological packages: These should be tailored to local needs and opportunities, focusing on sustainable technologies that offer economically viable solutions. These packages should include the selection of appropriate species, the re-use of by-products, and the implementation of effective waste management strategies to improve circularity.
- Co-develop local best management practices (BMPs): In collaboration with industry and government agencies, develop BMPs, guidance, and tools that encompass skills, knowledge, technology, services, infrastructure and governance. In this process, social and gender equity should also be considered.

# REPLACEMENT EFFECTS OF FISH MEAL WITH HIGH PROTEIN DISTILLERS DRIED GRAINS WITH SOLUBLES IN THE DIET ON GROWTH PERFORMANCE AND FEED AVAILABILITY OF OLIVE FLOUNDER (*Paralichthys olivaceus*)

Hae Chan Shin[1*] and Sung Hwoan Cho[2]

[1]Department of Convergence Interdisciplinary Education of Maritime & Ocean Contents, National Korea Maritime and Ocean University (Republic of Korea)
[2]Division of Convergence on Marine Science, National Korea Maritime and Ocean University (Republic of Korea)
E-mail: gocksv123@gmail.com

## Introduction

Olive flounder (*Paralichthys olivaceus*) was the most commercially important marine finfish species in korea in 2024 with the highest production volume of 40,125 metric tons (49% of the total) and value of 684 billion KRW (57% of the total) (KOSIS, 2025). Fish meal (FM) has become an expensive protein source for fishfeeds due to decreasing production and increasing demand worldwide (Index Mundi, 2025). Thus, it is essential to find an alternative protein source for FM in aquafeeds that are year-round available and inexpensive to reach sustainable aquaculture. High protein distillers dried grains with solubles (HPD), a by-product of the corn fuel ethanol production, is a possible plant-based alternative protein source for FM. Therefore, This study aims to evaluate the replacement effects of fish meal with HPD in the diet on growth performance and feed availability of olive flounder.

## Materials and methods

Five experimental diets with isoproteic (51.0%) and isolipidic (14.0%) were formulated (Table 1). In the control (Con) diet, 60% FM was contained. In the Con diet, 10%, 20%, 30%, and 40% of FM were substituted with HPD, referred to as the HPD10, HPD20, HPD30, and HPD40 diets, respectively. A total of 600 olive flounder (6.5 ± 0.04 g; mean ± SE) were randomly distributed into 15, 300-L flow through tanks (40 fish per tank) with triplicate. All fish were hand-fed to apparent satiation twice a day for 50 days. The proximate composition of the experimental diets and whole-body fish were analyzed using the standard methods. The amino acid and fatty acid profiles of the experimental diets were analyzed following the standard methods (AOAC, 1990). Also, The plasma parameters of fish were measured. One-way ANOVA, Duncan's multiple range test, orthogonal polynomial contrast and regression analysis were conducted by SPSS version 24.0.

**Table 1.** Ingredient and chemical composition of the experimental diets (%, DM basis).

| | Experimental diets | | | | |
|---|---|---|---|---|---|
| | Con | HPD10 | HPD20 | HPD30 | HPD40 |
| Fish meal | 60.0 | 54.0 | 48.0 | 42.0 | 36.0 |
| High protein distillers dried grains with solubles | | 8.8 | 17.6 | 26.4 | 35.2 |
| Fermented soybean meal | 13.0 | 13.0 | 13.0 | 13.0 | 13.0 |
| Wheat flour | 18.0 | 15.0 | 11.9 | 8.9 | 5.8 |
| Fish oil | 4.0 | 4.2 | 4.5 | 4.7 | 5.0 |
| Soybean oil | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 |
| Vitamin premix | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |
| Mineral premix | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |
| Choline | 0.5 | 0.5 | 0.5 | 0.5 | 0.5 |

*(Continued on next page)*

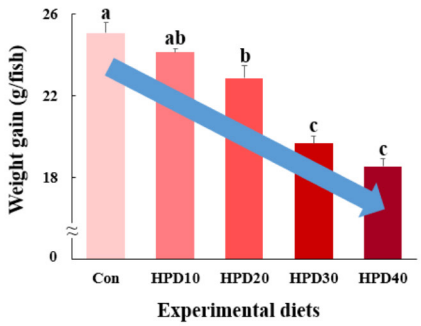

**Fig. 1.** Weight gain (g/fish) (Orthogonal polynomial contrast; **Linear = 0.0000**, Quadratic = 0.1877, Cubic = 0.1061) (**Y = – 0.174939X + 25.5451**, $R^2$ = 0.9049, $P$ < 0.0001) of olive flounder fed the experimental diets substituting increased level of FM with HPD for 50 days (means of triplicate ± SE) (***P* < 0.0001**).

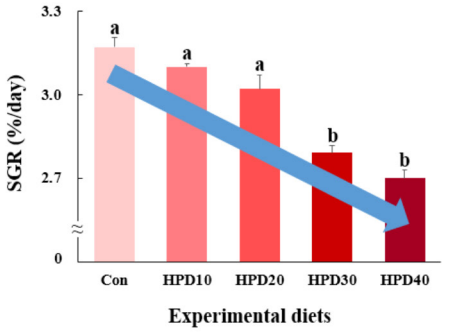

**Fig. 2.** Specific growth rate (SGR, %/day) (Orthogonal polynomial contrast; **Linear = 0.0000**, Quadratic = 0.1622, Cubic = 0.1853) (**Y = – 0.000123X + 0.0320**, $R^2$ = 0.8888, $P$ < 0.0001) of olive flounder fed the experimental diets substituting increased level of FM with HPD for 50 days (means of triplicate ± SE) (***P* < 0.0001**).

## Results

At the end of the 50-day feeding trial, Survival of olive flounder achieved over 95.8%, but it was not influenced by dietary treatments. Weight gain (WG) of olive flounder fed the Con diet was significantly ($P$ < 0.0001) higher than that of fish fed the HPD20, HPD30, and HPD40 diets, but not significantly ($P$ > 0.05) different from that of fish fed the HPD10 diet (Fig. 1). Specific growth rate (SGR) and feed consumption (FC) of olive flounder fed the Con, HPD10, and HPD20 diets were significantly ($P$ < 0.0001 and $P$ < 0.0009, respectively) higher than those of fish fed the HPD30 and HPD40 diets (Fig. 2). In orthogonal polynomial contrast, WG, SGR, and FC of olive flounder tended to linear ($P$ = 0.0001, $P$ = 0.0001, and $P$ = 0.0001, respectively) relationships with dietary increased substitution levels of FM with HPD. In regression analysis, linearly decreased relationship were determined to be the most suitable model between dietary FM substitution with HPD and WG (Y = – 0.174939X + 25.5451, $P$ < 0.0001, $R^2$ = 0.9049), SGR (Y = – 0.000123X + 0.0320, $P$ < 0.0001, $R^2$ = 0.8888), and FC (Y = – 0.126285X + 23.6996, $P$ < 0.0001, $R^2$ = 0.7421), respectively (Fig. 1 and 2, respectively). Feed utilization such as feed efficiency, protein efficiency ratio, and protein retention were not affected by dietary FM substitution with HPD. Condition factor and hepatosomatic index of olive flounder were not significantly affected by the dietary treatments. However, viscerosomatic index (VSI) of olive flounder fed the HPD30 and HPD40 diets was significantly higher than that of fish fed the Con diet. In orthogonal polynomial contrast, VSI of olive flounder tended to linear ($P$ = 0.0002) relationships with dietary increased substitution levels of FM with HPD. In regression analysis, linearly increased relationship were determined to be the most suitable model between dietary FM substitution with HPD and VSI (Y = 0.000287X + 0.064452, $P$ < 0.0002, $R^2$ = 0.6900). plasma parameters and proximate composition of whole-body fish were not affected by the dietary treatments.

## Conclusion

FM up to 10% and 20% could be substituted with HPD in the 60% FM-based diet without significantly deteriorating WG and SGR of olive flounder, respectively.

## Introduction

Fish feeds are typically more costly than feeds for livestock, primarily due to the high inclusion of fish meal (FM), which is one of the most expensive feed ingredients. However, the FM price has increased due to reduced FM production and increased global demand (Index mundi, 2025). Therefore, various animal by-products, such as meat meal, chicken by-product meal, and tuna by-product meal have been evaluated as an alternative protein source for FM in the olive flounder diets. Since DBM has high crude protein (61.5%) and crude lipid (10.6%) content, but is less expensive (USD 0.60/kg) than FM (USD 2.16/kg) (Islam et al., 2024), it can be used as a FM replacer in olive flounder diet. This study aims to evaluate the substitution effects of FM with DBM in the diet of olive flounder on the growth performance, feed availability, and economic analysis.

## Materials and Methods

The control (Con) diet contained 60% FM and 16% fermented soybean meal as the main protein sources, 4.0% fish oil and 2.5% soybean oil as the lipid sources, and 15.0% wheat flour as the carbohydrate source (Table 1). In the con diet, 20%, 40%, 60%, 80%, and 100% FM were substituted with DBM, and referred to the DBM20, DBM40, DBM60, DBM80, and DBM100 diets. All experimental diets were formulated at isoproteic (52.0) and isolipidic (12.0%). All experimental diets were assigned to triplicate groups of fish. A total of 450 juvenile (6.3 ± 0.07 g; mean ± SE) fish were distributed into 18 of 50-L flow-through tank (25 fish/tank) with triplicate. Fish were hand-fed to apparent satiation twice a day for 50 days. After the feeding experiment, growth performance, feed availability, biological indices and, plasma parameters were evaluated. Chemical composition of the experimental diets and fish were analyzed according to AOAC methods (1990). Also, Economic conversion ratio (ECR, USD/kg) and Economic profit index (EPI, USD/fish) were measured. One-way ANOVA and Tukey's post-hoc test were applied using SPSS version 24.0. Orthogonal polynomial contrasts and regression analysis were conducted to evaluate linear, quadratic, and cubic as the best fitable model between FM substitution levels with DBM and dependent parameters, respectively.

Table 1. Ingredient and chemical composition of the experimental diets (%, DM basis).

| | Experimental diets | | | | | |
|---|---|---|---|---|---|---|
| | Con | DBM20 | DBM40 | DBM60 | DBM80 | DBM100 |
| ***Ingredients* (%, DM)** | | | | | | |
| Fish meal (FM) (CP; 69.8%, CL; 7.8%, Ash; 14.6%) | 60.0 | 48.0 | 36.0 | 24.0 | 12.0 | |
| Duck by product meal (DBM) (CP; 61.6%, CL; 10.6%, Ash; 21.2%) | | 14.0 | 28.0 | 42.0 | 56.0 | 70.0 |
| Fermented soybean meal | 16.0 | 16.0 | 16.0 | 16.0 | 16.0 | 16.0 |
| Wheat flour | 15.0 | 13.5 | 12.0 | 10.5 | 9.0 | 7.5 |
| Fish oil | 4.0 | 4.0 | 4.0 | 4.0 | 4.0 | 4.0 |

| Ash | 10.3 | 12.4 | 13.9 | 15.5 | 16.5 | 17.0 |

*(Continued on next page)*

## Results

After 50-days feeding experiment, Weight gain (WG) and specific growth rate (SGR) of olive flounder fed the Con, and DBM20, and DBM40 diets were significantly ($P < 0.0001$ for both) higher than those of fish fed the DBM60, DBM80, and DBM 100 diets. In orthogonal polynomial contrast, WG and SGR of olive flounder showed linear ($P = 0.0001$ for both), quadratic ($P = 0.0001$ for both), and cubic ($P = 0.0001$ and $P = 0.001$, respectively) relationships with dietary substitution levels of FM with DBM. In regression analysis, cubic relationships were revealed to be the most suitable model between dietary substitution levels of FM with DBM and WG ($Y = 0.000043X^3 - 0.007713X^2 + 0.211515X + 21.5563$, $P < 0.0001$, $R^2 = 0.9566$, $Y_{max}$ = X value of 15.80%) and SGR ($Y = 0.000000033674X^3 - 0.000006X^2 + 0.000177X + 0.0299$, $P < 0.0001$, $R^2 = 0.9504$ $Y_{max}$ = X value of 17.22%), respectively. Feed consumption (FC) of olive flounder fed the Con, DBM20, and DBM40 diets were significantly ($P < 0.0001$) higher than that of fish fed the DBM60, DBM80, and DBM100 diets. In orthogonal polynomial contrast, FC of olive flounder showed linear ($P = 0.0001$), quadratic ($P = 0.0001$), and cubic ($P = 0.0001$) relationships with dietary substitution levels of FM with DBM. In regression analysis, cubic relationship was revealed to be the most suitable model between substitution levels of FM with DBM and FC ($Y = 0.000047X^3 - 0.008625X^2 + 0.275474X + 19.9047$, $P < 0.0001$, $R^2 = 0.9615$, $Y_{max}$ = X value of 18.88%). Condition factor (CF) of olive flounder fed the Con diet was significantly ($P < 0.0001$) higher than that of fish fed the DBM60, DBM80, and DBM100 diets, but not significantly ($P < 0.05$) different from that of olive flounder fed the DBM20 and DBM40 diets. However, there were no significant ($P < 0.05$) differences in feed utilization, biological indices expect for condition factor, chemical composition, and plasma parameters by dietary treatment. The highest economic conversion ratio (ECR) was observed in the Con diet ($P < 0.0001$). Economic profit index (EPI) of the Con, DBM20, and DBM40 diets was significantly ($P < 0.0001$) higher than that of the DBM60, DBM80, and DBM100 diets.

## Conclusion

DBM could substitute up to 40% of FM in the 60% FM-based diet without negatively affecting the growth performance, feed availability, and biological indices of olive flounder. The DBM40 diet maximize economic returns (EPI) for farmers.

The Manila clam, *Ruditapes philippinarum*, inhabiting the west coast of Korea, frequently experiences infections by protozoan and metazoan parasites, adversely affecting its growth and reproductive capacity. This study investigated seasonal fluctuations in the condition index (CI), reproductive stages, and parasite prevalence in clams sampled from four tidal flats near Anmyeondo Island. Histological examinations identified four major parasites: *Perkinsus olseni* infecting gill tissues, *Cercaria tapetis* within gonads, *Parvatrema duboisi* in the mantle tissue, and echinostomatoid encysted metacercaria infecting the foot muscle. Peak spawning activity occurred from July to September, corresponding to the period of highest sea surface temperatures (SST), with minimal variation across sampling sites. Significant spatial differences in clam condition indices were noted, with higher values recorded at Bangpo (120.9) and Janggok (119.1) compared to Gonam (113.4) and notably lower indices at Shinya (84.0). The intensity of *P. olseni* infection significantly varied between sites, showing elevated counts in muddy-sand habitats (Janggok: 2.219 × 10^6 cells/g, Gonam: 1.561 × 10^6 cells/g gill tissue) relative to sandy habitats (Shinya: 0.260 × 10^6, Bangpo: 0.057 × 10^6 cells/g). Despite high *P. olseni* prevalence, clams at Janggok exhibited superior fitness, possibly benefiting from greater nutritional resources associated with sediment organic enrichment. Conversely, Shinya clams displayed the poorest fitness outcomes, likely due to suboptimal feeding conditions in sandy substrates and intense trematode infestation of foot tissues.

# MORPHOLOGICAL CHARACTERIZATION, LARVAL DEVELOPMENT, AND MITOCHONDRIAL GENOME ANALYSIS OF *Rochia* AFF. *Nilotica* (GASTROPODA: TEGULIIDAE) FROM CHUUK ATOLL, FEDERATED STATES OF MICRONESIA, WITH INSIGHTS INTO GENETIC DISTINCTIVENESS

The button shell *Rochia nilotica* is economically valuable across Pacific Island nations, primarily due to its thick nacreous layer, widely utilized in button manufacturing and ornamental crafts. However, overfishing has led to significant population declines, necessitating detailed biological and genetic assessments to inform sustainable management practices. This study presents the first comprehensive examination of morphological characteristics, larval development, and mitochondrial genome sequencing of *R. nilotica* collected from coral reefs at a depth of 5 m near Weno Island, Chuuk Atoll, Federated States of Micronesia (FSM). Morphological analyses confirmed the characteristic features of *R. nilotica*, including an open umbilicus, distinct radial purple-red streaks, smooth columella, and variation in shell morphology with age. Eggs were approximately 50 μm in diameter, surrounded by a gelatinous layer within which fertilization and early differentiation occurred. At a water temperature of 29°C, embryos developed into veliger larvae approximately 10 hours after fertilization. Shell development and visceral torsion were observed 24 hours post-fertilization, and after 80 hours, the swimming velum disappeared, marking the transition to benthic juveniles. Furthermore, phylogenetic analyses using the COX1 partial gene and 13 mitochondrial protein-coding genes revealed significant genetic divergence of the Chuuk population compared to previously reported populations from New Caledonia and French Polynesia. Our newly assembled mitochondrial genome (17,664 bp) notably differed from existing unverified sequences. This genetic distinctiveness suggests that the Chuuk Atoll population may represent a genetically unique lineage or subspecies (tentatively referred to as *Rochia* aff. *nilotica*). The findings from this study provide essential baseline data for conservation and aquaculture strategies, emphasizing the need for regional management tailored to genetically distinct populations.

# ASSOCIATION BETWEEN GUT MICROBIOME COMPOSITION AND PARASITE INFECTION IN THE MANILA CLAM *Ruditapes philippinarum*: IMPLICATIONS FOR PROBIOTIC APPLICATIONS

E-mail: whdtjqtls@kiost.ac.kr

The gut microbiome plays a crucial role in bivalve immunity and resilience against pathogens. The Manila clam *Ruditapes philippinarum* has experienced production declines in Korea due to environmental changes and the protozoan parasite *Perkinsus olseni* infections. This study examined the relationship between gut microbiome composition and *P. olseni* infection across Incheon, Seocheon, and Jeju along the coast of Korea. Incheon had the highest infection intensity (1,454,425 ± 470,709 cells/g tissue), while Seocheon was lowest (310,889 ± 470,709). Amplicon sequencing revealed regional microbiome differences: Alphaproteobacteria dominated Incheon and Seocheon, whereas Mollicutes prevailed in Jeju. Pathogenic bacteriai *Vibrio splendidus* and Rickettsia-like organisms (RLOs) were more abundant in Incheon, aligning with higher infection levels. Conversely, Jeju and Seocheon showed higher proportions of *Mycoplasma* and *Metamycoplasma*, which were negatively correlated with parasite loads. Notably, Mycoplasma may suppress *Perkinsus* growth by competing for similar resources within the host and is more frequently found in healthy clams, suggesting its role as a symbiotic bacterium with potential probiotic applications to improve clam health and disease resistance.

# HIGH DESERT AQUACULTURE WORKFORCE EDUCATION

R.C. Shultz* and S. Gomez

Santa Fe Community College
S. Richards Ave
Santa Fe, 87508 USA
Email: richard.shultz@sfcc.edu

The Controlled Environment Agriculture (CEA) program at Santa Fe Community College (SFCC) in New Mexico, USA, trains students to be future technicians for aquaculture and indoor crop production facilities. With a focus on aquaponics, hydroponics and algae cultivation in recirculating aquaculture systems (RAS) Charlie Shultz and Steve Gomez have awarded more than 177 degrees over the past 10 years. They have spawned local businesses including New Mexico's first indoor vertical aquaponics farm and New Mexico's first commercial spirulina farm. The program collaborates with regional, national and international organizations like the Algae Foundation, the Algae Technology Educational Consortium, the Aquaponics Association, World Aquaculture Society, US Department of Energy, US Department of Defense, and many universities. Grants support student training and community support, many coming from the US Department of Agriculture. The facilities include an off-grid 1,100$m^2$ greenhouse with solar energy collectors and battery storage, at-scale hydroponic and aquaponic systems, algae cultivation systems from benchtop photobioreactors to farm scale production raceways, a Biofuels Center of Excellence, rainwater collection and storage, and other greenhouses and indoor production rooms. Students can earn degrees in CEA and Algae Cultivation as well as associated trades degrees like Water Technologies, Water Conservation Technologies, and Water Treatment Operation. Using RAS systems to produce nutritious food throughout the year is crucial in a region with very little freshwater resources like Santa Fe, NM. Aquaponic systems at SFCC operate with a daily recycle rate of >99%, requiring very little water to produce crops continuously. The program and facility have become a model for other schools and communities and provide tours for thousands of visitors each year. As a community college, our students and faculty engage with industry, creating pathways from college into employment.

# PHYSIOLOGICAL AND BIOCHEMICAL PERFORMANCE OF *ULVA* SPP. IN LAND-BASED RECIRCULATING AQUACULTURE SYSTEMS

Sickert, C. [1,2], Henschen, H.[1,3] and Hofmann, L. C.[1,3]

[1]Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany
[2]University of Bremen, Bremen, Germany
[3]Bremerhaven University of Applied Sciences, Bremerhaven, Germany
[*]chiara.sickert@awi.de

As marine space becomes increasingly limited and inland food systems face sustainability challenges, land-based seaweed cultivation in closed recirculating aquaculture systems (RAS) offers a promising alternative. Within the EU project NOVAFOODIES, we evaluate the feasibility of a closed, land-based *Ulva* spp. cultivation system (Fig. 1) using artificial seawater. The land-based RAS design (Fig. 1) allows for precise control of growth conditions, minimal water exchange, and potential integration with renewable energy sources, making it a model for sustainable production.

The objective of this study is to evaluate the physiological and biochemical performance of two *Ulva* spp. strains with different reproductive traits, cultivated under identical conditions across multiple 14-day cultivation cycles. The cultivation setup consists of two vertical shelving RAS units (~300 liter each), each containing six transparent 60-liter culture tanks (Fig. 1). Sampling is conducted at regular intervals (Day 0, 4, 7, 11, 14) within each cycle to monitor physiological development over time. Key data collected include growth rate, biomass (Fig. 2), yield, photosynthetic efficiency dissolved inorganic nutrient uptake (phosphate, ammonium, nitrate, nitrite), carbon and nitrogen content, total protein content, pigment composition, and specific leaf area. In addition, 24-hour nutrient uptake studies at early and late cultivation stages provide high-resolution data on nutrient dynamics and can be linked to physiological performance.

Preliminary results suggest characteristic changes in growth efficiency and nutrient assimilation across the harvest cycle, providing insight into optimal harvest timing, biomass quality and system efficiency. The findings contribute to the development of scalable and sustainable inland seaweed production systems and highlight the potential of land-based RAS as a viable component for the future of seaweed aquaculture.

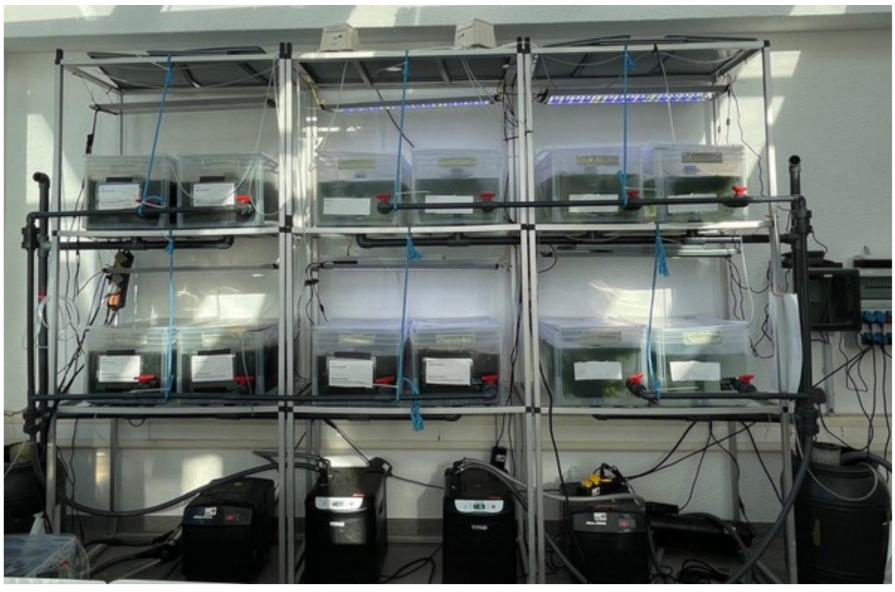

**Fig. 1:** NOVAFOODIES land-based recirculating aquaculture system (RAS) for seaweed cultivation. The setup includes two vertical shelving RAS units, each with six transparent 60 L culture tanks—System 1 (left) and System 2 (right). # PHOTOPERIOD MANIPULATION INDUCES CHANGES OF THE GUT MICROBIOTA IN ATLANTIC COD *Gadus morhua*

D.M.Silva [1*], I. Konstantinidis [2], P. Siriyappagouder [2], and Fernandes J.M.O.[1]

[1]Renewable Marine Resources, Institute of Marine Sciences (ICM-CSIC), Barcelona, Spain
[2]Faculty of Biosciences and Aquaculture, Nord University, Bodø, Norway
e-mail: danasilva@icm.csic.es

## Introduction

Microbiota is affected by environmental factors, including photoperiod, and this can have a profound effect on host physiology. However, little is known about the influence of sex on light-related changes in microbial composition. Our objective was to investigate sex-specific effects of photoperiod manipulation on gut microbiota in Atlantic cod (*Gadus morhua*).

## Materials & Methods

Juvenile Atlantic cod were divided into two experimental groups in triplicate tanks, which were kept under 24 h continuous light (CL) or 12 h light: 12 h dark (AL) for a period of 6 months. The microbiota of 60 samples collected from gut contents (15 males and 15 females from each photoperiod condition) was characterized by 16S rRNA V3-V4 region amplified on Illumina NovaSeq 6000 sequence (Siriyappagouder *et al*., 2018)"container-title":"Frontiers in Microbiology","volume":"9","abstract":"Establishment of the early-life gut microbiota has a large influence on host development and succession of microbial composition in later life stages. The effect of commensal yeasts - which are known to create a conducive environment for beneficial bacteria - on the structure and diversity of fish gut microbiota still remains unexplored. The present study examined the intestinal bacterial community of zebrafish (Danio rerio. The 16S rRNA sequences were first subjected to a quality control, trimming, merging and chimera removal procedure using the QIIME2 pipeline. Taxonomy was assigned to Amplicon Sequence Variants (ASVs) using the SILVA reference database and the feature table output was imported into Rstudio for further processing using the R package phyloseq  and pctax.

## Results

We identified a core microbiota consisting of 966 ASVs (99% sequence similarity), shared across all individuals. The most abundant taxa at phylum level were Spirochaetota, Bacteroidota and Proteobacteria, which were dominant in all samples. Proteobacteria dominated in both photoperiod groups and consisted mostly of the genera *Aliivibrio*, *Photobacterium*, *Psychromonas* and *Vibrio*. In the female and male groups exposed to CL there was an increase in the relative abundance of *Brevinema* and a concomitant reduction in the proportion of *Mycoplasma* in comparison to samples undergoing AL regime. Beta diversity analysis based on Bray–Curtis dissimilarity and Jaccard index revealed significant differences in community composition between AL and CL groups (PERMANOVA, $p = 0.003$), suggesting a strong effect of photoperiod on the gut bacterial composition in Atlantic cod. Alpha diversity indices (Shannon, Simpson and Chao1) showed significantly higher diversity in males under continuous light compared to their female counterparts ($P < 0.05$), while no significant differences with sex were observed under 12:12 photoperiod. In particular, Lefse analysis showed that Ruminococcoccaceae and Brevinemataceae were enriched in males and females exposed to continuous light, respectively.

## Conclusions

Our results show that photoperiod manipulation induces changes in the gut microbiota of Atlantic cod. Furthermore, higher alpha diversity was observed in males than in females exposed to continuous light. The differential taxon enrichment with sex may have implications in fish physiology, including sexual maturation.

## Acknowledgments

# IMPACT OF PARTIAL OR COMPLETE REPLACEMENT OF FISH MEAL WITH HIGH-QUALITY MEAT MEAL IN THE DIET OF RED SEA BREAM (*Pagrus major*) ON GROWTH PERFORMANCE AND FEED UTILIZATION

Yu Jin Sim[1*] and Sung Hwoan Cho[2]

[1]Department of Convergence Interdisciplinary Education of Maritime & Ocean Contents, National Korea Maritime & Ocean University (Republic of Korea)
[2]Division of Convergence on Marine Science, National Korea Maritime & Ocean University (Republic of Korea)
E-mail: dbfl1543@naver.com

## Introduction

Fish meal (FM) is often considered as neither eco-friendly nor sustainable. Therefore, feed nutritionists are actively seeking reliable and cost-effective protein sources to substitute for FM. Meat meal (MM) has a lower cost (USD 0.86/kg, USD 1 = 1400 KRW) compared to FM (USD 2.03/kg), and it is classified into low-quality [≤ 75% crude protein (CP)] and high-quality (≥ 80% CP) MM based on their protein content. Among them, high-quality MM has advantages including high CP and lipid content, and year-round availability as a FM alternative in fish diets.

Red sea bream (*Pagrus major*), a carnivorous fish species, is a valuable species of marine fish in Republic of Korea and Japan. Gunathilaka et al. (2023) proved that 50% of FM could be replaced with high-quality MM (CP: 84.2%) without compromising growth and feed consumption when fingerling (initial weight of 50.2 g) red sea bream were fed with a 60% FM-based diet or one of diets replacing 50% of FM with plants, animals, or their blends.

The size (or age) of fish can greatly influence the substitutability of FM by alternative proteins in diets. In general, smaller (younger) fish are less likely to tolerate higher level of FM substitution. However, no study on the substitutability of high-quality MM for FM in juvenile red sea bream diets has yet been performed.

Therefore, this study aims to evaluate the impact of partial or complete FM replacement with high-quality MM in the diet on the growth performance and feed utilization of red sea bream.

## Materials and Methods

The control (Con) diet contained 55% FM (Table 1). In the Con diet, the partial (20%, 40%, 60%, and 80%) or complete (100%) levels of FM were replaced with high-quality MM, referred to the MM20, MM40, MM60, MM80, and MM100 diets, respectively. All experimental diets were formulated to be isoproteic at 51.5% and isolipidic at 14.5%. A total of 450 juvenile red sea bream (7.9 ± 1.85 g; mean ± SE) were distributed into 18 of 50-L flow-through tank (25 fish per tank) with triplicate. All fish were hand-fed to apparent satiation twice a day for 8 weeks. At the end of the 8-week feeding trial, growth performance, feed utilization, blood chemistry, proximate composition, and amino acid and fatty acid profiles were analyzed.

Data were subjected to One-way ANOVA and Tukey's honestly significant difference test using IBM SPSS Statistics for Windows, version 24.0 (IBM Corp., Armonk, NY, USA).

## Results

Weight gain, specific growth rate (SGR), and feed consumption of fish fed the Con, MM20, and MM40 diets were significantly ($P < 0.0001$ for all) higher than those of fish fed the MM60, MM80, and MM100 diets (Fig. 1 and Fig. 2). In regression analysis, linear relationships were revealed to be the most suitable model between dietary elevated MM replacement for FM (X) and weight gain ($Y = -0.145434X + 31.6540$, $R^2 = 0.9253$, $P < 0.0001$), SGR ($Y = -0.008442X + 2.9195$, $R^2 = 0.9161$, $P < 0.0001$), and feed consumption ($Y = -0.133145X + 32.5305$, $R^2 = 0.9213$, $P < 0.0001$), respectively. In orthogonal polynomial contrast, weight gain and feed consumption of red sea bream revealed linear ($P = 0.0001$ for both), quadratic ($P = 0.002$ and $P = 0.014$, respectively), and cubic ($P = 0.030$ and $P = 0.019$, respectively) relationships with dietary MM replacement levels for FM, but SGR revealed linear ($P = 0.0001$) and quadratic ($P = 0.001$) relationships with dietary elevated MM replacement for FM. However, blood chemistry, proximate composition, and amino acid profiles of fish were not significantly ($P > 0.05$) influenced by dietary FM replacement with MM.

**Table 1.** Ingredients and chemical composition of the experimental diets (%, DM basis).

| | Experimental diets | | | | | |
|---|---|---|---|---|---|---|
| | Con | MM20 | MM40 | MM60 | MM80 | MM100 |
| *Ingredients (%, DM)* | | | | | | |
| Fish meal (CP: 73.4%, CL: 10.7%) | 55.0 | 44.0 | 33.0 | 22.0 | 11.0 | |
| Meat meal (CP: 83.9%, CL: 9.9%) | | 9.5 | 19.0 | 28.3 | 37.5 | 47.0 |
| Fermented soybean meal | 17.0 | 17.0 | 17.0 | 17.0 | 17.0 | 17.0 |
| Wheat flour | 17.5 | 18.8 | 20.1 | 21.6 | 23.2 | 24.5 |
| Fish oil | 4.0 | 4.2 | 4.4 | 4.6 | 4.8 | 5.0 |
| Soybean oil | 4.0 | 4.0 | 4.0 | 4.0 | 4.0 | 4.0 |
| Others | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 | 2.5 |
| *Nutrients (%, DM)* | | | | | | |
| Crude protein | 51.3 | 51.6 | 51.4 | 51.3 | 51.5 | 51.3 |
| Crude lipid | 14.6 | 14.7 | 14.5 | 14.5 | 14.6 | 14.4 |

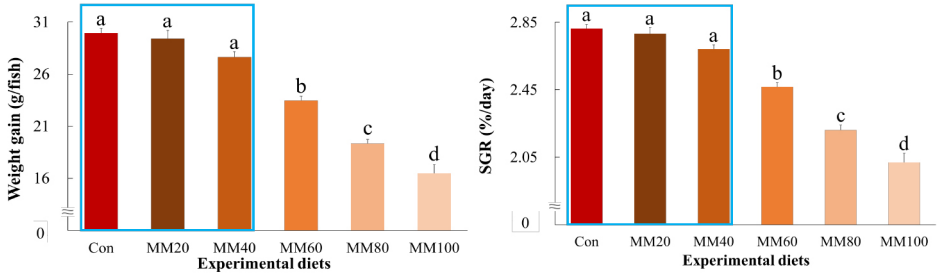

**Fig. 1**. Weight gain (g/fish) and specific growth rate (SGR, %/day) of red sea bream fed the experimental diets ($P < 0.0001$ for all).

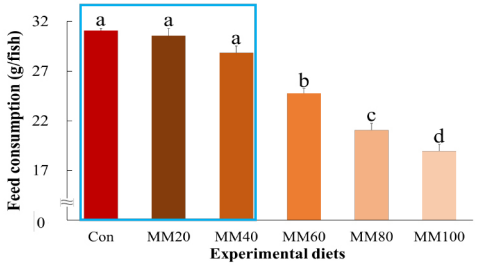

**Fig. 2.** Feed consumption (g/fish) of red sea bream fed the experimental diets ($P < 0.0001$).

## Conclusion

FM up to 40% could be replaced with MM in a 55% FM-based diet without significantly impairing the growth performance and feed utilization of juvenile red sea bream.

## Introduction

With stagnant production and high price of fish meal (FM), feed nutritionists are searching for a reliable and affordable source as a FM replacer. Corn gluten meal (CGM) and soy protein concentrate (SPC) are useful plant protein sources as a FM replacer in fish diets. Dietary 50% FM replacement with CGM led to lower growth of red sea bream (*Pagrus major*) than fish fed a 60% FM-based diet when fingerling (initial weight of 50.2 g) fish were fed with a 60% FM-based diet or one of diets replacing 50% of FM by CGM, SPC, meat meal, and chicken by-product meal as a single ingredient, and their combination (Gunathilaka et al., 2023). The authors stressed that the substitutability of CGM for less than 50% of FM should be assessed in the red sea bream diet. However, in that study, dietary 50% SPC replacement for FM achieved comparable growth of fingerling red sea bream to fish fed the 60% FM-based diet. Still, the substitutability of FM with SPC in the juvenile red sea bream diet has been unknown. The size (or age) of fish can influence the substitutability of FM by the replacers in fish diet.

The low-FM diets commonly cause poor palatability, decreased feed consumption by fish, and eventually deteriorate growth. In our previous study (Beak and Cho, 2024), jack mackerel meal (JMM) had the highest attractiveness to juvenile red sea bream among 18 protein sources, and 24% inclusion of JMM instead of FM in diets led to the greatest growth of red sea bream by improving feed consumption.

Therefore, this study investigates the effects of replacing FM with CGM and SPC in diets with or without JMM inclusion on the growth performance of juvenile red sea bream.

## Materials and Methods

A three-way {2 FM replacement source (CGM and SPC) × 2 FM replacement level (20% and 40%) × 2 JMM inclusion (without and with)} ANOVA experimental design was applied. Nine experimental diets were formulated to be isoproteic at 52.0% and isolipidic at 15.0%. The control (Con) diet contained 60% FM. In the Con diet, 20% and 40% of FM were replaced with CGM and SPC without or with inclusion of 24% JMM at the expense of FM, referred to the CGM20, CGM40, SPC20, SPC40, CGM20J, CGM40J, SPC20J, and SPC40J diets, respectively. Six hundred and seventy-five juvenile fish were assigned into 27 of 50-L flow-through tanks with triplicate. All fish were hand-fed to apparent satiation twice a day for 8 weeks. At the end of the 8-week feeding trial, growth performance, feed utilization, blood chemistry, proximate composition, and amino acid and fatty acid profiles were analyzed.

Data were subjected to Three-way ANOVA and Tukey's honestly significant difference test using IBM SPSS Statistics for Windows, version 24.0 (IBM Corp., Armonk, NY, USA).

## Results

Weight gain, specific growth rate (SGR), and feed consumption of red sea bream fed the CGM-replaced diets were significantly ($P < 0.001$ for all) higher than those of fish fed the SPC-replaced diets (Fig. 1A). Furthermore, dietary replacements of 20% FM achieved higher weight gain, SGR, and feed consumption in fish compared to those of 40% FM (Fig. 1B). Additionally, weight gain, SGR, and feed consumption of fish fed the all plant protein-replaced diets with JMM inclusion were significantly ($P < 0.0001$, $P < 0.001$, and $P < 0.001$, respectively) higher than those without JMM inclusion (Fig. 1C). Weight gain, SGR, and feed consumption of fish fed the Con diet were significantly ($P < 0.0001$ for all) higher than those of fish fed the CGM40, SPC20, SPC40, CGM40J, and SPC40J diets (Fig. 1D). However, feed utilization, blood chemistry, proximate composition, and amino acid profiles of red sea bream were not significantly ($P > 0.05$) influenced by dietary treatments.

*(Continued on next page)*

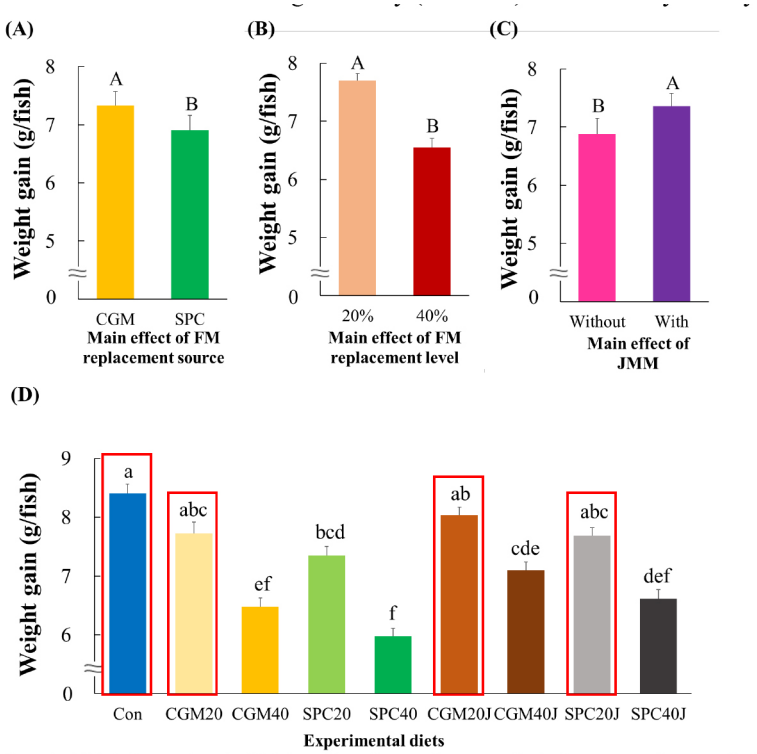

**Fig. 1.** Weight gain (g/fish) of red sea bream fed the experimental diets. The different uppercase and lowercase under numerical values indicate significant differences ($P < 0.05$) based on Three-way ANOVA and Tukey's honestly significant differences test, respectively.

## Conclusion

The CGM-replaced diets achieved better growth performance and feed consumption of red sea bream than the SPC-replaced diets. Moreover, dietary replacements of 20% FM attained better growth and feed consumption of fish than those of 40% FM. Additionally, better growth and feed consumption was obtained in fish fed the all plant protein-replaced diets with JMM inclusion compared to those without JMM inclusion. FM up to 20% could be replaced with CGM with or without JMM inclusion and SPC with JMM inclusion in the 60% FM-based diet of red sea bream without causing significantly negative effects on the growth performance and feed availability.

# MANIPULATION EFFECTS OF JACK MACKEREL MEAL IN LOW-FISH MEAL DIETS SUBSTITUTING FISH MEAL WITH VARIOUS ANIMAL PROTEINS ON THE GROWTH PERFORMANCE AND BIOCHEMICAL COMPOSITION OF ROCKFISH (*Sebastes schlegeli*), AND ECONOMIC ANALYSIS

Yu Jin Sim[1*] and Sung Hwoan Cho[2]

## Introduction

Fish meal (FM) has considered an unsustainable and costly feed ingredient, so feed nutritionists are actively seeking a cost-effective and consistently available alternative for FM. Chicken by-product meal (CBM), meat meal (MM), and tuna by-product meal (TBM) are popular a FM replacer in fish feeds. However, low-FM diets often result in reduced palatability and feed consumption by fish, ultimately leading to decreased growth performance. To resolve these issues, manipulation of feed ingredient exhibiting strong attractiveness to a target fish into the low-FM diets is one of the best options.

Therefore, this study aims to evaluate manipulation effects of jack mackerel meal (JMM) exhibiting strong attractiveness to rockfish (*Sebastes schlegeli*) in low-FM diets substituting 25% and 50% FM with various animal protein sources (CBM, MM, and TBM) on the growth and biochemical composition of rockfish, and economic analysis.

## Materials and Methods

A two-way [3 FM substitution source (CBM, MM, and TBM) × 2 FM substitution level (25% and 50%)] ANOVA experimental design was applied. The control (Con) diet included 55% FM. In the Con diet, 25% and 50% of FM were substituted with CBM, MM, and TBM with an additional inclusion of 22% JMM at the expense of FM, referred to the CBM25J, CBM50J, MM25J, MM50J, TBM25J, and TBM50J diets, respectively. All experimental diets were to be isoproteic at 51.5% and isolipidic at 14.5%. A total of 525 juvenile rockfish were randomly distributed into 21 of 50-L flow-through tanks with triplicate. All fish were hand-fed to apparent satiation twice a day for 8 weeks. At the end of the 8-week feeding trial, growth performance, feed utilization, blood chemistry, proximate composition, and amino acid and fatty acid profiles were analyzed.

The economic evaluation of the experimental diets for rockfish was conducted using formulas from the study by Martínez-Llorens et al. (2007): economic conversion ratio (ECR, USD/kg) = feed consumption of fish (kg/fish)/weight gain (kg/fish) × diet price (USD/kg) and economic profit index (EPI, USD/fish) = [final weight (kg/fish) × fish sale price (USD/kg)] − [ECR (USD/kg) × weight gain (kg/fish)].

Data were subjected to Two-way ANOVA and Duncan's multiple range test using IBM SPSS Statistics for Windows, version 24.0 (IBM Corp., Armonk, NY, USA).

## Results

Weight gain and specific growth rate (SGR) of rockfish fed the CBM- and TBM-substituted diets were significantly ($P < 0.005$ and $P < 0.004$, respectively) higher than those of fish fed the MM-substituted diets (Fig. 1A). Moreover, dietary 25% FM substitutions achieved significantly ($P < 0.0001$ for both) higher weight gain, SGR, and feed consumption in fish compared to dietary 50% FM substitutions (Fig. 1B). Weight gain and SGR of rockfish fed the Con, CBM25J, TBM25J diets were significantly ($P < 0.0001$ for all) higher than those of fish fed the CBM50J, MM50J, and TBM50J diets (Fig. 1C). Feed consumption of rockfish fed the MM25J diet was significantly ($P < 0.01$) higher than that of fish fed the Con, CBM50J, MM50J, and TBM50J diets. However, the dietary treatments did not significantly ($P > 0.05$) affect biological indices, plasma and serum parameters, proximate composition, and amino acid profiles of rockfish. The highest EPI was observed in the CBM25J diet (Table 1).

*(Continued on next page)*

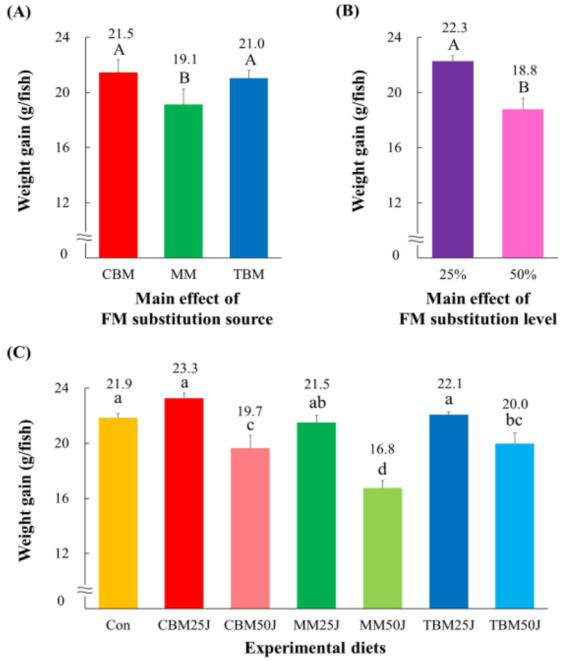

**Fig. 1.** Weight gain (g/fish) of rockfish fed the experimental diets. The different uppercase under numerical values indicate significant differences ($P < 0.05$) based on Two-way ANOVA.

**Table 1.** Economic parameters of the feeding trial.

| Experimental diets | Diet price (USD/kg) | ECR (USD/kg) | EPI(USD/fish) |
|---|---|---|---|
| Con | 1.63 | $1.43 \pm 0.008^{bc}$ | $0.97 \pm 0.008^{ab}$ |
| CBM25J | 1.59 | $1.40 \pm 0.037^{c}$ | **$1.02 \pm 0.013^{a}$** |
| CBM50J | 1.42 | $1.39 \pm 0.043^{c}$ | $0.90 \pm 0.032^{c}$ |
| MM25J | 1.60 | $1.57 \pm 0.063^{ab}$ | $0.96 \pm 0.019^{abc}$ |
| MM50J | 1.44 | $1.63 \pm 0.087^{a}$ | $0.81 \pm 0.016^{d}$ |
| TBM25J | 1.64 | $1.50 \pm 0.014^{abc}$ | $0.98 \pm 0.009^{ab}$ |
| TBM50J | 1.52 | $1.42 \pm 0.029^{bc}$ | $0.92 \pm 0.023^{bc}$ |
| *P*-value | | $P < 0.02$ | $P < 0.0001$ |

The two-way ANOVA results were excluded from the table due to space constraints.

## Conclusion

The CBM- and TBM-substituted diets achieved greater weight gain and SGR compared to the MM-substituted diets. Moreover, dietary 25% FM substitutions achieved greater weight gain, SGR, and feed consumption of rockfish than dietary 50% FM substitutions. Furthermore, 25% FM could be substituted with CBM, MM, and TBM in the 55% FM-based diet with 22% JMM inclusion without deteriorating the growth performance, feed consumption, and biochemical composition of rockfish. Finally, the CBM25J diet produced the highest weight gain and SGR of rockfish, and economic return (EPI) to farmers.

# IMPACTS AND ECONOMIC ANALYSIS OF JACK MACKEREL MEAL INCLUSION IN LOW-FISH MEAL DIETS SUBSTITUTING 50% OF FISH MEAL WITH HIGH-QUALITY MEAT MEAL ON THE GROWTH PERFORMANCE OF OLIVE FLOUNDER (*Paralichthys olivaceus*)

Yu Jin Sim[1*] and Sung Hwoan Cho[2]

## Introduction

The global market value of fish meal (FM) has been consistently increasing because of the rapid growth of aquaculture worldwide. Therefore, efforts are needed to look for an alternative source that is both sustainable and inexpensive for FM in fish feeds. High-quality meat meal (MM), an animal by-product, is considered a suitable FM replacer in olive flounder (*Paralichthys olivaceus*) diet. However, low-FM diet commonly deteriorates its palatability and eventually leads to reduced feed consumption and growth of fish. The incorporation of feed ingredient with strong attractiveness to a target fish into low-FM diets is an effective fish culture technique to improve palatability of low-FM diet and feed consumption by fish.

This study thus aims to evaluate the impacts and economic analysis of jack mackerel meal (JMM), which exhibits strong attractiveness to olive flounder, inclusion in low-FM diets substituting 50% of FM with high-quality MM on the growth performance of olive flounder.

## Materials and Methods

The control (Con) diet included 60% FM (Table 1). In the Con diet, 50% of FM was substituted with high-quality MM, and then 0%, 10%, 20%, 30%, 40%, and 50% of JMM were included at the sacrifice of FM, referred to the $MJ_0$, $MJ_{10}$, $MJ_{20}$, $MJ_{30}$, $MJ_{40}$, and $MJ_{50}$ diets, respectively.

Data were subjected to One-way ANOVA and Duncan's multiple range test using IBM SPSS Statistics for Windows, version 24.0 (IBM Corp., Armonk, NY, USA).

## Results

Weight gain of olive flounder fed the Con, $MJ_{40}$, and $MJ_{50}$ diets was significantly ($P < 0.02$) greater than that of fish fed the $MJ_0$ and $MJ_{10}$ diets (Fig. 1). Specific growth rate (SGR) of fish fed the Con, $MJ_{30}$, $MJ_{40}$, and $MJ_{50}$ diets was significantly ($P < 0.02$) greater than that of fish fed the $MJ_0$ and $MJ_{10}$ diets.

In regression analysis, linear relationships were shown to be the most suitable model between inclusion levels of JMM (X) in low-FM diets substituting 50% of FM with MM and weight gain ($Y = 0.026534X + 14.0555$, $R^2 = 0.5486$, $P < 0.0001$) and SGR ($Y = 0.002625X + 2.6140$, $R^2 = 0.4800$, $P < 0.001$), respectively. In orthogonal polynomial contrast, weight gain and SGR of fish revealed linear ($P = 0.0019$ and $P = 0.0036$, respectively) relationships with dietary inclusion levels of JMM in low-FM diets substituting 50% of FM with MM. Feed consumption of fish fed the MJ40 diet was significantly ($P < 0.001$) higher than that of fish fed the $MJ_0$, $MJ_{10}$, and $MJ_{20}$, diets. However, the dietary treatments did not significantly ($P > 0.05$) influence feed utilization, plasma and serum parameters, proximate composition, and amino acid profiles of olive flounder. The EPI of the Con and $MJ_{50}$ diets was significantly ($P < 0.04$) higher than that of fish fed the $MJ_0$, $MJ_{10}$, and $MJ_{20}$ diets (Table 2).

## Conclusion

Incorporation of 20%–50% JMM into low-FM diets substituting 50% of FM with high-quality MM attained comparable weight gain, SGR, and feed consumption to fish fed a 60% FM-based diet. Linear relationships between weight gain and SGR of olive flounder vs inclusion levels of JMM in low-FM diets were the most suitable model in regression analysis. Finally, the $MJ_{50}$ diet was the most recommendable treatment to farmers because of the highest EPI.

# PHYSIOLOGICAL AND MOLECULAR INSIGHTS INTO TRANSPORT STRESS IN SEA BASS: TOWARDS NON-INVASIVE CORTISOL MONITORING

Paula Simó-Mirabet[1,*]; Leandro Rodríguez-Viera[1]; Gonzalo Martínez-Rodríguez[2]; Juan Antonio Martos-Sitcha[1]

**Introduction**

The welfare of farmed fish is a growing concern, driven by both increased mortality and reduced productivity linked to stress, as well as ethical considerations. Transportation of fish, a necessary practice in aquaculture, represents a significant challenge by exposing fish to multiple stressors. Assessing welfare depends on understanding stress responses, and physiological and molecular markers provide crucial insights into an animal's state. Cortisol, a key indicator of hypothalamic–pituitary–interrenal axis (HPI) activity, is extensively studied in aquaculture to assess fish stress. This hormone serves as a reliable indicator of acute stress in plasma. However, the blood collection procedure itself can induce stress, necessitating the identification of less invasive matrices for cortisol measurement (Sadoul & Geffory, 2019). Consequently, this study will assess cortisol correlations across plasma, skin mucus, scales, and water in European sea bass (*Dicentrarchus labrax*) following an acute transport stress. The aim is to identify reliable, less invasive, or non-invasive stress markers, with findings supported by molecular markers from HPI-related tissues (brain, pituitary, and head kidney).

**Materials and methods**

Following a one-week acclimation period, European sea bass juveniles, fasted overnight, were transferred into 10 L plastic bags saturated with oxygen (density: 30 kg/m$^3$) and transported for 4 hours by a transport van. Immediately after transport, half of the transported fish were sampled (transported group, TRANSP) while the rest were returned to their original tanks, to serve as a recovery group (RECOV), with sampling conducted 24 hours later. Non-previously disturbed fish were sampled at each sampling point as controls of transported (CTRL1) and recovery groups (CTRL2). Plasma, skin mucus, scales, and water samples were collected for cortisol analyses. Additionally, the brain, pituitary, and head kidney were extracted for molecular studies.

**Results and discussion**

Transported fish exhibit increased cortisol levels in plasma, skin mucus, scales, and water, confirming cortisol's efficacy as an acute stress marker in all analysed matrices. Notably, the strongest positive correlation (rho=0.8) was observed between scales and mucus, suggesting a similar reflection of cortisol concentration, likely due to their proximity. Moderate yet strong correlations were observed between water and mucus (rho=0.56), water and scales (rho=0.54), mucus and plasma (rho=0.52), and scales and plasma (rho=0.51). Therefore, both mucus and scales may be useful matrices for evaluating cortisol levels in fish due to their strong relationship with plasma levels, as previously reported in other studies (Samaras et al., 2021; Franco-Martinez et al., 2022). The presence of cortisol in water and its positive correlation with mucus and scales reinforces the idea that cortisol is released into water via mucus or skin, supporting the notion that levels in the water reflect those in external body matrices. The weakest correlation, though still positive, was noted between water and plasma (rho=0.38), likely due to their greater physiological distance. Therefore, mucus and scales show strong correlations with each other and with plasma, indicating their potential as non-invasive biomarkers for systemic cortisol levels. While water cortisol is a valid measure, it is a less direct indicator. This may be due to a delayed release of excess cortisol into the external environment after plasma levels normalise post-stressor. Thus, water cortisol can reflect a stressful event in the animal's recent past, even if the acute stressor is no longer present.

*(Continued on next page)*

On the other hand, transcriptional changes following transport stress revealed a consistent and significant molecular response across all examined tissues. In the brain, the transported group showed a significant upregulation of *hsp70* and *crfbp*, suggesting activation of cellular stress pathways and *crf* modulation. Conversely, glucocorticoid receptors *gr1* and *gr2* were downregulated in transported fish, suggesting altered sensitivity or feedback to manage prolonged or intense stress. A similar response was observed in the pituitary, with an increase of *hsp70* and a decrease of *gr1* expression in transported fish. All these gene expression changes in both brain and pituitary returned to baseline within 24 hours post-transport, indicating physiological recovery. Surprisingly, *pomca* expression in the pituitary did not rise after transport but showed a significant temporal increase after 24 h of transportation in both CTRL2 and RECOV fish. A similar, but inverse, trend was noted for *gr2* expression. This suggests additional regulatory factors beyond transport stress, potentially influenced by the cumulative fasting period experienced by the animals. In the head kidney, *hsp70, il10*, and *cxcr4* were significantly upregulated in transported fish, reflecting the activation of immune regulatory mechanisms to control the stress response. A comparable pattern, although without significant differences, was observed for *star* expression, which enhances the metabolism of cholesterol, the precursor of cortisol. These findings collectively demonstrate a robust endocrine-immune response to transport in European sea bass, with partial recovery at the transcriptional level in the post-transport phase.

**Conclusions**

Transporting sea bass triggers a coordinated tissue-specific neuroendocrine and immune stress response at both physiological and molecular levels. Marked changes in the expression of genes associated with stress (*hsp70*, *crfbp*), glucocorticoid regulation (*gr1*, *gr2*), and immune modulation (*il10*, *cxcr4*) were observed in the brain, pituitary, and head kidney. These molecular shifts, along with increased cortisol levels after transport, reflect the activation of systemic stress and immune pathways, which partially reverse during recovery. Finally, to address the need to assess animal welfare in such scenarios, the strong correlations found between cortisol levels in plasma, scales, skin mucus, and even water suggest that these matrices offer effective and less stressful alternatives for monitoring cortisol in fish.

## Introduction

Vaccination is an indispensable tool in aquaculture, serving as a critical prophylactic measure against infectious diseases that can significantly affect fish health and welfare, leading to substantial economic losses for the industry (Kumar et al., 2024). Despite its benefits, the vaccination process itself presents a suite of stressors, both acute and chronic, that can negatively impact the physiological status of farmed fish. These stressors range from handling and injection to the inflammatory response triggered by the vaccine adjuvant. Therefore, it is imperative to understand and mitigate these stressors to optimise fish welfare, enhance vaccine efficacy, and promote the sustainability of aquaculture production (Ma et al., 2019). This research focuses on characterising vaccination as a quantifiable and relevant stress model within aquaculture systems. We investigated the physiological and metabolic responses to dip vaccination in two commercially significant species: rainbow trout (*Oncorhynchus mykiss*) and European sea bass (*Dicentrarchus labrax*). Plasma levels of energy metabolites and stress markers were assessed in both species at baseline and at different time points within 24 hours post-vaccination. The goal is to identify reliable biomarkers to improve fish health and aquaculture productivity.

## Materials and methods

The vaccination trials were conducted at the Interdisciplinary Centre of Marine and Environmental Research (CIIMAR) in Portugal. Juveniles of rainbow trout and European sea bass were allocated in triplicates into two separate systems, acclimated for one week at an initial stocking density of 4.5 kg/m³. Environmental conditions were kept constant for each species: sea bass at 20°C and 35 ppt salinity, and rainbow trout at 16°C and 0 ppt. Before the dip vaccination, baseline samples (pre-challenge) were collected. Subsequently, fish from each system were netted and transferred to smaller tanks with strong aeration, containing a commercially available vaccine solution for the vaccine group or only water for the sham group, and remained there for 60 s. After exposure, fish were returned to their original tanks. Post-treatment samples were collected at 1, 6, and 24 hours. Plasma samples served for the comprehensive analysis of stress and metabolic biomarkers, while the pituitary gland and brain were employed for molecular analyses.

## Results and discussion

Principal Component Analyses (PCA) performed on metabolites in sea bass showed that the first two components explained 68.8 % of the variance, with glucose and triacylglycerides (TAG) being the main contributors. The results suggest that time is a more influential factor than vaccination in sample separation. Specifically, cortisol levels increased in both the vaccinated and sham groups 1 hour post-vaccination, being only significant in vaccinated fish. The rapid increase in cortisol levels after vaccination, followed by a subsequent decline, indicates that both the procedure and the vaccine itself contribute to the overall stress response, establishing cortisol as a reliable biomarker for measuring this effect. Glucose exhibited a similar pattern to cortisol, but remained higher in the vaccinated group compared to the sham group after 6 hours before returning to baseline at 24 hours. Lactate levels, influenced by time and vaccination, increased significantly 1 hour post-vaccination in both groups, being more pronounced in vaccinated fish. These findings indicate an immediate acute stress response to the procedure, with lactate serving as a more reliable marker for differentiating the immediate effects of the vaccination procedure, while glucose discriminates the longer-term effects or recovery. Cholesterol levels in the vaccinated group were significantly lower 24 hours post-vaccination, which could be related to its role as a precursor for cortisol synthesis. TAG levels also showed a significant decrease, but temporal variations between vaccinated and sham fish suggest differential regulation in the activation

of TAG synthesis depending on the source of stress. Finally, preliminary gene expression analysis in sea bass revealed that the stress response in the pituitary gland and brain was regulated primarily by time rather than by vaccination. However, specific vaccination-related effects were observed, including changes in the expression of *pomca* and *gh* in the pituitary, and *crf* in the brain.

In contrast, in rainbow trout, more metabolites (glucose, TAG, and proteins) participate in the separation of the first two principal components, which together contribute to explaining 75.5 % of the total variance. Again, the effect of time is the most influential factor, regardless of the effect of vaccination. Cortisol and glucose appear to have the greatest influence 1 hour post-vaccination, while cholesterol, proteins, and TAG levels are better indicators of the recovery response. After the vaccination procedure, cortisol levels increased in both groups, although a statistically significant increase was only found in the vaccinated group after 6 hours. Glucose and lactate levels showed a similar pattern, increasing after the procedure, with the vaccinated group displaying significantly higher levels of both parameters compared to the sham group at 6 hours post-vaccination. Again, the increase in cortisol suggests that the vaccination procedure induces an acute stress response, although it was slower than in sea bass. Regarding metabolic parameters, TAG levels increased over time, showing significant differences after 24 hours, while cholesterol began rising after 6 hours post-vaccination. The opposite metabolic response observed in sea bass suggests physiological and metabolic differences between the species, likely due to distinct adaptations to stress and the use of energy reserves.

**Conclusions**

The vaccination procedure induced a significant and species-specific physiological stress response in both fish species. Cortisol and glucose levels consistently increased following the vaccination procedure, confirming their use as reliable biomarkers for the overall acute-stress response. Glucose and TAG were particularly useful for monitoring the longer-term recovery phase. Ultimately, the results demonstrated that time, rather than the vaccination itself, is a more influential factor in regulating the overall physiological and molecular responses. This suggests that the stress generated by the entire procedure, including handling and vaccine administration, has a significant impact on the animal.

# A DISH WITH NO FISH: HOW DHA-FREE MICROALGAE CAN BE AN ALTERNATIVE FATTY ACID SOURCE IN DIETS FOR RAINBOW TROUT (*Oncorhynchus mykiss*)

Anna Simon [1,2,*], Flora Suess [1], Sebastian Lippemeier [3] and Carsten Schulz [1,2]

## Introduction

Aquaculture is a rising sector and to maintain increasing fish production, an equal increase in feed production is necessary (Tacon, 2020). Especially fish meal and oil play an important role as protein and omega-3 fatty acid source in fish nutrition (Tocher, 2015). However, regarding sustainability and limiting wild fish stocks, alternative feed materials are currently of high interest. EPA (20:5 n-3) and DHA (22:6 n-3) are known as important long-chain polyunsaturated fatty acids (LC-PUFA) derived from fish in human nutrition as well as important fatty acids for the fish health itself. As fish are not able to produce omega-3 PUFA de novo, these fatty acids must be supplied by their diet. Despite to most saltwater fish species, rainbow trout are capable of biosynthesising the LC-PUFA EPA and DHA if enough ALA (18:3 n-3) as precursor is provided (Henderson and Tocher, 1987). Microalgae as primary producers in the marine food chain bring a broad offer of different nutrients and fatty acid profiles. The microalgae *Tetraselmis chui* showed a good potential as fatty acid source (Simon et al., 2024). It contains no DHA but low amounts of EPA and additionally offers ALA and SDA (18:4 n-3), an intermediate of the n-3 biosynthesis. In this study different n-3 PUFA profiles with increasing algae inclusion were evaluated for their effect on this biosynthetic pathway.

## Material and Methods

To test if *T.chui* could be an suitable fatty acid source in fish diets, a feeding trial with rainbow trout was conducted to evaluate growth performance and fatty acid utilisation of the fish. Fish oil was partially (0 %, 33 %, 66 %, 100 %) substituted by the microalgae resulting in decreasing DHA concentrations in the diets. Additionally, two diets (fish oil 0 % and 100 %) were enriched with ALA by adding linseed oil. Triplicates of groups of 20 fish per diet were fed daily with 1.9 % of their body weight for 12 weeks following a 2-week faecal collection period to determine digestibility.

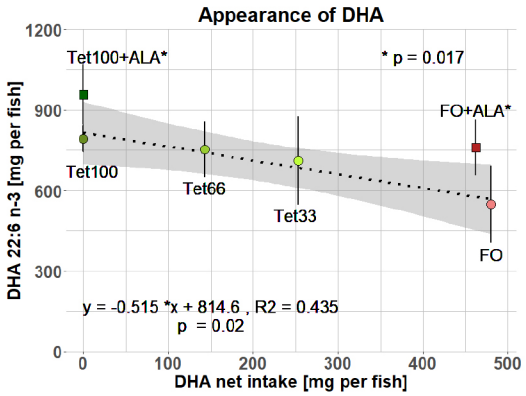

*Fig. 1: Appearance of DHA in rainbow trout whole body after 12-week feeding with different dietary DHA intake*

*(Continued on next page)*

**Results and Discussion**

The algae diets resulted only slightly in lower growth performance of the fish, although showing a lower digestibility in accordance with other studies of microalgae (Cardinaletti et al., 2018; Sarker et al., 2020). No significant effect was observed regarding health parameters of the fish as well as no effect in the whole-body nutrient composition. However, with increasing algae inclusion the DHA contents in the fish are decreasing as fatty acid composition of the fish mostly mirrors diet composition. But following the n-3 pathway an increasing proportion of biosynthesised DHA (Fig. 1, circles) can be seen, underlining the ability of rainbow trout to produce this fatty acid from precursors (Sargent et al., 2002). The addition of ALA did not influence the growth performance but increased the DHA production (Fig. 1, rectangles).

**Conclusion**

*T.chui* showed great potential as alternative fatty acid source in fish nutrition although lacking in DHA. Rainbow trout could compensate this lack by DHA biosynthesis and the increase of dietary ALA additionally promoted the DHA production. Understanding the physiological fatty acid pathways in the fish is essential for future feed formulations as sustainable use of important fatty acids is needed.

# TRANSGENE DELIVERY STRATEGIES TO INTEGRATE CATHELICIDIN DISEASE RESISTANCE GENE IN CHANNEL CATFISH GENOME BY CRISPR/CAS9 KNOCK-IN SYSTEM

R. M. Simora[1]*, D. Xing[2], W. Wang[2], X. Ma[2] and R. Dunham[2]

Email: rcsimora@up.edu.ph

**Introduction**

CRISPR/Cas9-based gene knock out in mammalian cells particularly in teleost has proven to be very efficient with mutation rates, but precise insertion of exogenous DNA or gene knock-in via the homology directed repair pathway remains elusive. While microinjection is more routinely used to introduce CRISPR components into fish embryos, it is labor-intensive and time-consuming, as embryos need to be injected individually. A common alternative to microinjection is electroporation, which uses a rapid and high-voltage electric pulse to deliver DNA into embryos. Here, we utilized microinjection, single electroporation, where CRISPR components were co-delivered with the donor DNA into fertilized eggs, and double electroporation, where both sperm and fertilized eggs received the CRISPR components and donor DNA.

**Materials and methods**

The microinjection experiment had three treatments pertaining to the three DNA constructs carrying cathelicidin gene, a disease-resistant gene derived from American alligator *Alligator mississippiensis*, designated in this study as: dsDNA-UBI-Cath for dsDNA construct driven by zebrafish ubiquitin promoter, dsDNA-BA-Cath for dsDNA construct driven by carp β-actin promoter and plasmid-UBI-Cath for plasmid DNA with zebrafish ubiquitin promoter. Three different concentrations for each of these constructs were used for microinjection namely 10, 20, and 40 ng/μL. For the electroporation experiment, there were three treatments: plasmid microinjection (20 ng/μL plasmid DNA construct), single electroporation and double electroporation. Integration rates were calculated as the number of positive individuals detected by PCR in a replicate or treatment/total number of individuals in the same replicate or treatment *100. Expression of cathelicidin transgene in positive P1 individuals was determined by reverse transcription (RT)-PCR and quantitative real-time PCR (QPCR) analyses.

**Results**

As shown in Table 1, highest integration rates were found using microinjection, both in dead fry with plasmid Ubi as donor DNA (61.5%) as well as in alive fingerlings with dsDNA Ubi donor (31.8%). Moreover, electroporation also proved to be an efficient method to deliver transgene as revealed by 44.4 % integration rate in dead fry and 12.5 % in alive fish using single electroporation technique.

**Discussion**

We succeeded in integrating with high efficiency an exogenous cathelicidin gene into chromosome 1 of channel catfish genome. Effective design of a donor template incorporating the zebrafish ubiquitin promoter, presence of a 250-bp homologous arms at each end of the construct and a sgRNA designed to cleave at the exact insertion site, all contributed to increased homology directed repair (HDR) rate leading to precise integration of the transgene construct into the chromosome 1 of channel catfish genome. The 61.5% integration rate of plasmid Ubi is comparable to the insertion rate of 60 to 90 % using ssDNA donor templates in human cell lines (Sakuma et al., 2016; Aird et al., 2018) and mouse models (Gu et al., 2018). Microinjection remained more effective than electroporation in delivering the transgene construct into the embryos of channel catfish. But electroporation also proved to be an efficient method for transgene delivery. Integration rates were also higher in dead fry than in fingerlings, indicating either off-target effects, pleiotropic effects or lethal overexpression. Additionally, a sensitive area of the genome may have been targeted, although our hypothesis was that this would not be a sensitive area.

Overall, we have successfully generated a CRISPR knock-in transgenic channel catfish carrying cathelicidin gene using microinjection and electroporation strategies.

*(Continued on next page)*

**Table 1**. Integration rates of cathelicidin gene constructs in dead fry and surviving fingerlings that were microinjected and electroporated using CRISPR/Cas9 system.

| Delivery Method | Donor DNA construct | Dead fry | | | Alive fingerlings | | |
|---|---|---|---|---|---|---|---|
| | | Total analyzed | Positive fish | Integration rate (%) | Total analyzed | Positive fish | Integration rate (%) |
| Microinjection | dsDNA β-actin | 30 | 6 | 20.0 | 46 | 4 | 8.7 |
| | dsDNA Ubi | 31 | 6 | 19.3 | 22 | 7 | 31.8 |
| | Plasmid Ubi | 13 | 8 | 61.5 | 17 | 3 | 17.6 |
| Single Electroporation | Plasmid Ubi | 9 | 4 | 44.4 | 24 | 3 | 12.5 |
| Double electroporation | Plasmid Ubi | 25 | 5 | 20.0 | 20 | 2 | 10.0 |

# DEVELOPMENT AND VALIDATION OF A 70K SNP GENOTYPING ARRAY FOR ATLANTIC HALIBUT (*Hippoglossus hippoglossus*)

Valentina Krivenjeva Sinani, Cryogenetics AS, Storhamargata 44, 2317 Hamar, Norway
Email: valentina.sinani@inn.no

Robert C. Wilson, Ujjwal Acharya, Elisabeth Kommisrud, CRESCO, Centre for Embryology and Healthy Development, Inland Norway University of Applied Sciences, Hamar, Norway

Matthew P. Kent, Torfinn Nome, Centre for Integrative Genetics, NMBU, Ås, Norway
Marte Wetten, Aninova, Hamar, Norway

**Introduction**
Genetic improvement in Atlantic halibut has been limited by the lack of comprehensive genomic tools. To address this, we developed a mid-density SNP genotyping array for this species [1]. This array supports genomic selection and other advanced genetic applications, facilitating improved breeding outcomes in halibut aquaculture.

**Materials and Methods**
Whole genome sequencing (WGS) data from 40 individuals were used for SNP discovery. Following rigorous filtering [2], 70,824 SNPs were selected and used to design a custom Affymetrix Axiom array. This array was validated on 1152 samples using the Axiom Best Practices Workflow. Genotyping accuracy, SNP performance metrics, and gender determination probes were evaluated to assess array robustness.

**Results**
Sequencing of 40 individuals generated over 8 million variants, including 6,224,375 SNPs and 2,131,436 INDELs. Following stringent quality control filtering, 70,824 high-confidence SNPs were selected for inclusion on a custom Affymetrix Axiom array, including 697 loci informative for sex determination, as females are generally preferred by producers due to their superior growth rate and larger final body size. The array achieved an average sample call rate of 99.64%, and the majority (84%) of SNPs were classified within the top-performing Polymorphic High Resolution (PHR) category. Comparison of array-based genotyping results with WGS-derived genotypes in 36 individuals showed a concordance rate of 99.0% for PHR SNPs [1]. Approximately 95% of SNPs exhibited a minor allele frequency (MAF) greater than 0.05, confirming the array's utility for population-level genomic studies (Figure 1).

The extent and decay of linkage disequilibrium (LD) across the genome was also evaluated, revealing an average $r^2$ of 0.083 for SNPs within 0.1 Mb. LD decayed rapidly with increasing physical distance, dropping to an average $r^2$ of 0.017 at 10 Mb, suggesting high recombination rates and broad genetic diversity within the analyzed populations. Chromosome-specific differences in LD patterns were observed, with chromosomes 3, 5, 7, 8, 13, and 14 exhibiting relatively elevated LD levels [1]. These results indicate the SNP array is well-suited for genome-wide association studies (GWAS) and genomic selection applications in Atlantic halibut. The array also incorporated sex-associated SNPs and structural markers located in and around the gsdf gene, demonstrating robust performance in differentiating genetic sex.

**Discussion and Conclusion**
The development of a robust 70K SNP genotyping array represents a major advancement in the genomic toolkit available for Atlantic halibut, enabling high-resolution analyses across the genome. The array demonstrated excellent technical performance, with high call rates, strong concordance with whole-genome sequencing data, and informative marker distribution across the genome [1,2]. These features support its suitability for applications such as genome-wide association studies (GWAS), pedigree reconstruction, and genomic selection in breeding programs [3].

The array's ability to capture population-wide genetic variation, as evidenced by minor allele frequency distribution and linkage disequilibrium (LD) analyses, underscores its value for studying genetic diversity and structure. LD decay patterns were consistent with high recombination rates and a relatively diverse breeding population [1], indicating that the array offers sufficient marker density for fine-scale mapping and selection strategies.

*(Continued on next page)*

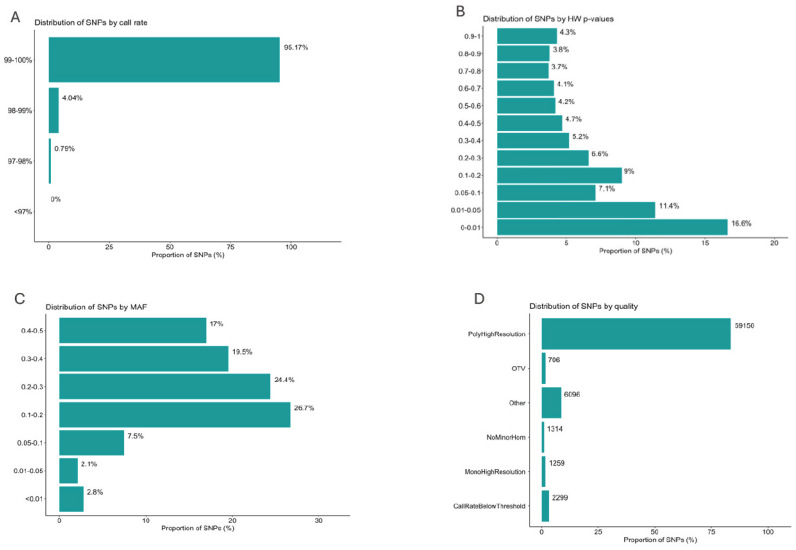

Figure 1. Summary of SNP metrics based on 70,824 SNPs in 1138 Atlantic halibut samples, showing SNP call rate, Hardy-Weinberg equilibrium, minor allele frequency, and SNP classification.

In addition to genome-wide applications, the inclusion of sex-determination markers targeting the gsdf region and associated structural variants provides a practical tool for assigning genetic sex. This is particularly relevant in aquaculture, where female halibut are often preferred due to their faster growth and larger size at harvest [1,4]. The ability to genetically identify sex early in development offers breeders a non-invasive and reliable method to support population management and production efficiency.

Collectively, the performance and design of this mid-density SNP array provide an important resource for advancing genomic research, selective breeding, and management of Atlantic halibut in both commercial and conservation contexts.

paul@nexttuna.com

## Introduction

The development of artificial diets for rearing Atlantic Bluefin Tuna (ABT) is crucial for several reasons. Overall, it will support sustainability, economic viability, and reduced environmental impact in tuna aquaculture.

Availability of a commercial feed program for ABT on the market is mandatory for successful ABT aquaculture. The commercial feed should be at least as good performing as feeding based on bait fish, sustain the fish health and performance under aquaculture conditions, and open the opportunity to reduce the amount of marine ingredients in ABT feeding and reduce the trophic level of ABT aquaculture.

A full feeding program should offer solutions for all development and age stages in the aquaculture lifecycle of ABT, starting from weaning over grow-out to brood-stock diets.

The trial presented here aimed to continue the very successful weaning trials with readily available commercial weaning diets, performed in 2023 and presented at WAS conference in 2024, where fish were successfully fed a commercial diet up to 150g. The target of the trial presented here, was to rear juvenile ABT from about 150g onwards to the end of the growth season in winter with a readily available Skretting diet, developed for Tuna.

## Material & Methods

Over 16.5 weeks, an ABT feeding trial was conducted at the Instituto Oceanográfico de Murcia (IEO). A group of 1175 ABT juveniles with a mean weight of 20g at 60 days post hatch (dph) was split into two groups. One group of 520 fish was fed artificial diets from Skretting (Comm. feed group), the other group of 625 fish was re-weaned from artificial diets to bait and continued fed bait fish (sardine and squid) (Bait group). The detailed feeding regime is listed in Table 1.

For the first three weeks of the trial both groups were fed Gemma Silk (GS) a commercial starter diet for marine fish.

Then from about 85dph onwards the Comm. feed group was transferred to Magro diet (M). The Bait group was transferred at the same time (85dph) to natural diets consisting of pieces of sardine and small squid.

Table 1.: Feeding regime of the two ABT groups in the trial.

| Group | 60-84 dph | 85-95 dph | 96-122 dph | 123-152 dph | 153-175 dph |
|---|---|---|---|---|---|
| Comm. feed | GS | M 3mm | M 6mm | M 7mm | Feed paste |
| Bait | GS | Bait | Bait | Bait | Bait |

*(Continued on next page)*

For the Comm. feed group, the size of the pellet was successively increased. At 96 dph the fish were changed from 3mm to 6mm Magro, at 123 dph to 7mm Magro. For every size change, there was a period of at least 3 days of co-feeding with both feed sizes.

At 153 dph (after 3 month) the Comm. feed group was changed to a wet diet produced on site, consisting of hydrated Vitalis feed, enriched with Ori-N3 DHA enrichment.

**Results & Discussion**

Both groups showed unusual and very high mortality rates. By the end of the trials (mid-December) both groups were left with less then 25 fish per group and a mortality rate of 95.9 and 96.7% for the Comm feed and bait fish group respectively. These abnormal mortalities were attributed to a previous bacterial infection, not fully overcome.

What became apparent already in the first and second feeding period from 60 and 85 dph onwards is the lower growth performance of the Comm. feed group. While the Bait group reached already 125g at 91 dph, the Comm. feed group only had 68g. The lower performance of the Comm feed group continued until 153dph. During all this time the specific growth rates (SGR) of the Comm. feed was 0.9% lower compared to the bait group.

Only during the last feeding period from 153-175 dph the Comm. feed group had a 0.4% higher SGR. However, by the end of the trial the size difference between the two groups was huge. While the Comm. feed group reached a mean weight of 452g by day 175 post hatch, the Bait group was more then double the size with 987g.

This preliminary trial delivered two main results:

1. The group offered the commercial feed Magro was much worth performing compared to the bait fish reference. In addition, the fish showed also a lower performance then experienced in the previous trials, where the fish were fed the Magro diet up to 150g. The Magro feed was optimized for high growth rate with corresponding high protein levels in the feed.
2. When the fish from the Comm. feed group were offered a different diet, the performance increased.

Additional data evaluation on the whole-body composition of the fish from both groups is planned, however, the results are not available yet. It is expected that these analysis may reveal a specific nutrient deficiency in the Comm feed group.

The preliminary results lead to the following conclusions:

- Offering ABT a high protein diet during the critical growth period of 50g onwards, seems to the wrong strategy.
- Based on the assumption that starting from 50g onwards, ABT is developing its internal temperature regime, a different feeding strategy, less focusing on growth and rather on key physiological changes in the fish might be more promising.
- Additional trials and more in-depth research are needed to understand the specific requirements of ABT in this vulnerable life stage, to develop an adequate feeding strategy for Atlantic Bluefin Tuna.

# FUTURE OF OFFSHORE-BASED CIRCULAR ECONOMY MARITIME PLATFORM FOR SUSTAINABLE FISH PRODUCTION

P. G.Sinn

SINN Power G.m.b.H
philipp.sinn@sinnpower.com

## Introduction

This initiative envisions a scalable, offshore circular economy maritime platform for sustainable fish production, centered on a fully enclosed fish farming pool that ensures biosafety and environmental protection by isolating operations from the marine environment. Integrating all stages of aquaculture from hatchery to logistics, the platform includes living quarters and supply docks and is powered mainly by renewable energy. It tackles key challenges such as energy autonomy, nutrient recycling, and global scalability, offering a resilient, sustainable alternative to coastal aquaculture systems.

## Vision

The envisioned platform redefines offshore aquaculture by introducing a circular, autonomous supply system operating entirely at sea. Central to this vision is the use of fully enclosed fish rearing pools that maintain complete separation from the ocean. These systems prevent any interaction with open water, thereby eliminating the risk of pathogen intrusion and ensuring there is no environmental degradation, such as seabed contamination from waste. The design allows for the integration of all stages of production—from hatchery to grow-out, processing, and logistics—into one self-sufficient system. Energy supply is almost entirely renewable, leveraging solar, wind, and wave energy, and supported by redundant backup systems for operational security.

## System Architecture

The system architecture is based on a modular network of platforms designed for various operational functions. Production modules house enclosed liner pools, which support controlled exchange of seawater or freshwater, regulated feed content, and oxygenation. These are complemented by living and working modules that accommodate permanent on-site personnel. Docking stations enable the seamless arrival and departure of vessels for supply and transport. The entire infrastructure is powered by a hybrid renewable energy system composed of wind, wave, and solar sources. Backup diesel generators ensure the protection of livestock and maintain essential systems during unfavorable conditions.

*(Continued on next page)*

**Environmental Protection & Biosafety**
At the heart of the environmental protection strategy is the use of an enclosed offshore liner pool that operates without any direct exchange with surrounding sea water. This design creates a robust barrier against pathogens and external contamination, ensuring biosecure conditions for fish farming. Furthermore, internal wastewater treatment systems and the ability to monitor and adjust water parameters result in minimal environmental footprint. The platform protects natural ecosystems by avoiding contact with marine life and eliminating waste discharge into the ocean. These features also significantly reduce the need for antibiotics or medications, enabling organic aquaculture practices.

**Development Priorities**
Key development priorities focus on building scalable, energy-autonomous offshore platforms that integrate diverse systems into a coherent whole. This includes advancing biosafe aquaculture technologies that ensure environmental isolation while enabling controlled rearing conditions. The integration of energy, supply logistics, housing, and food processing into a single marine facility is a complex challenge, demanding interdisciplinary innovation. Additionally, minimizing waste through a circular economy approach—such as the on-site generation of fertilizers and complete resource utilization—remains a central goal.

**Global Relevance**
This offshore platform model presents a globally relevant solution to the increasing strain on coastal environments. By moving sustainable fish production into offshore zones, it alleviates pressure on nearshore ecosystems and supports global food security. The design is particularly suitable for deployment in regions facing climate stress or lacking adequate coastal infrastructure. Its adaptability allows for use even in tropical zones by employing technologies for controlled oxygenation and thermal regulation. Overall, it sets a precedent for next-generation marine food systems that are sustainable, resilient, and ecologically responsible.

# GREEN ENERGY FOR BLUE MARKETS – SUSTAINABLE AQUACULTURE WITH A FUTURE

P. G. Sinn

SINN Power GmbH
philipp.sinn@sinnpower.com

**Management Summary**
Aquaculture operations are undergoing structural transformation. Rising energy costs, increasing regulatory pressure, and growing demands for sustainability are putting conventional operating models under serious strain. At the same time, the deployment of maritime floating solar systems is opening new solution spaces. Integrating these technologies significantly improves environmental performance, reduces operational costs, and enhances infrastructure resilience. This trend is rapidly evolving into a new industry standard—independent of any single manufacturer—and represents a key pillar for the future viability of global aquaculture.

**Vision**
A hybrid energy model for aquaculture facilities that combines fluctuating renewable sources with energy storage systems—transforming diesel generators from primary energy sources into backup solutions. This system is embedded in a scalable infrastructure that can be integrated into existing operations without additional permitting, ensuring long-term compliance with regulatory sustainability requirements.

**Opportunities**
Aquaculture facilities stand to gain energy autonomy and improved supply security by integrating floating solar systems that directly feed into onboard battery storage. Diesel generators can still be used but with significantly reduced runtime, boosting resilience to supply disruptions. Operational costs drop dramatically due to reduced fuel use and maintenance, resulting in annual savings in the five-digit euro range per site, even with fluctuating $CO_2$ taxes. Sustainability improves markedly, enabling compliance with EU decarbonization standards and offering enhanced market appeal through certifications and green labels. Integration is straightforward, using existing infrastructure and avoiding new permitting procedures. This builds on proven technology from freshwater solar applications. Insurance benefits further strengthen the business case, as floating systems can be covered by marine insurers and standardized components reduce operational risks—offering greater investment security to all stakeholders.

**Threats**
Despite these opportunities, many aquaculture sites still rely heavily on diesel generators, resulting in high $CO_2$ emissions and risks of marine pollution. This dependence threatens long-term viability as environmental regulations become stricter. Electricity from diesel generators is costly and inefficient. It also exposes facilities to changing fuel prices and possible fuel shortages, making it hard to plan for the future. Regulatory pressure is mounting, with EU directives demanding tangible decarbonization and energy efficiency efforts. Non-compliance may lead to exclusion from key markets and subsidy programs. Moreover, traditional aquaculture operations that rely on diesel are increasingly facing criticism from both environmental groups and society. At the same time, consumer demand is shifting toward more transparent and sustainable production systems, putting additional pressure on industry to adapt. Without innovation in energy use, these facilities risk losing public trust and market relevance, potentially leading to stagnation or decline in support.

# NURSERY CULTURE AS A SOLUTION TO HIGH SPAT LOSSES IN NEW ZEALAND'S GREENSHELL™ MUSSEL INDUSTRY

Brad Skelton* and Andrew Jeffs

Institute of Marine Science
University of Auckland
New Zealand
Brad.Skelton@auckland.ac.nz

New Zealand's Greenshell™ mussel (*Perna canaliculus*) industry is one of the most inefficient mussel aquaculture industries in the world. The industry harvests over 350 billion spat each year to seed its farms, yet only a fraction of these (< 1%) are retained in production from seeding through to harvest, representing an enormous constraint on growth and production. This presentation will provide an overview of research that has been carried out to develop alternative approaches to nursery culture of Greenshell™ mussels to reduce spat losses and improve production efficiency. It will include results from trials seeking to adapt commonly used bivalve nursery culture systems (FLUPSYs) to mussels and provide insights from studies that aimed to identify the nutritional requirements of Greenshell™ spat so that cost-effective alternatives to live phytoplankton for land-based nurseries can be developed. The presentation will conclude by outlining the next steps required to commercialize these approaches to nursery culture, which will facilitate the transformation of the Greenshell™ industry.

# INITIAL INSIGHTS INTO THE POTENTIAL FOR A SCALLOP *Pecten novaezelandiae* AQUACULTURE INDUSTRY IN NEW ZEALAND

Brad Skelton*, Leonardo Zamora, and Andrew Jeffs

Institute of Marine Science
University of Auckland
New Zealand
Brad.Skelton@auckland.ac.nz

New Zealand's aquaculture industry is currently dominated by three key species – mussels, oysters, and salmon – and as such, there is growing interest in diversifying the sector. Over the past few decades, wild scallop populations throughout the country have been depleted, resulting in several regional fisheries closures. This decline in wild populations combined with the cultural significance of this species makes it a promising candidate for aquaculture in New Zealand. This presentation will provide an overview of the results from an initial study seeking to determine the feasibility of scallop aquaculture in the Coromandel, in northern New Zealand. It will discuss the key factors limiting the development of scallop aquaculture in New Zealand at each stage of production, namely biofouling and mortality, and suggest some approaches to overcoming these challenges. The presentation will then conclude by providing a summary of the workstreams underway from a recently funded project that seeks to build on the initial results and overcome these challenges to support the development of a scallop industry in New Zealand.

# DIFFERENCES IN THE MINERAL COMPOSITION OF THE TWO MOST COMMONLY FARMED FISH SPECIES IN THE ADRIATIC SEA

Skendrović H.*, Pleadin J., Zrnčić S., Kudumija N., Krešić G.

Croatian Veterinary Institute
Savska Cesta 143
10000 Zagreb, Croatia
E-mail: skendrovic@veinst.hr

## Introduction

Global aquaculture production reached a record high of 130.9 million tons in 2022, of which finfish accounted 65%. Predominant finfish products in Mediterranean countries include European seabass (*Dicentrarchus labrax* L.) and sea bream (*Sparus aurata* L.), which are valued for their high protein and mineral content and contribute to the increase in annual per capita consumption. In this study, the proximal mineral composition of farmed sea bass and gilthead sea bream from the Adriatic Sea was determined over a one-year period to assess possible species-specific differences in mineral content ($p < 0.05$).

## Materials and methods

Seven representative individual samples per species were analyzed to determine the eight minerals (Na, Ca, K, Mg, Zn, Fe, Cu and P). They were quantified (mg/kg) using flame atomic absorption spectroscopy (200 Series A4 with SPS 4 Auto-Sampler, Agilent Technologies, USA). Normality was tested using the Shapiro-Wilk test and homogeneity of variance using the Levene test. As all minerals showed homogeneity of variance ($p > 0.05$), with the exception of phosphorus, the Welch test was used for this mineral. Due to deviations from normality, the Mann-Whitney U-test was used for zinc and phosphorus, while the Student's t-test was used for all other minerals.

## Results

No statistically significant differences in mineral content were found between the two species ($p > 0.05$), indicating a comparable mineral profile and general richness in essential minerals in both species (Table 1). These results are consistent with previous studies and confirm the comparable nutritional value of these two economically important marine species and the variability in their composition throughout the year.

# ADULT BLACK SOLDIER FLIES (IMAGINES, *Hermetia illucens*) AS A REPLACEMENT FOR FISH MEAL IN DIETS FOR PACIFIC WHITELEG SHRIMP, *Penaeus vannamei*

E. Fricke*, H. Udeh, T. Galonska, C. Behrendt, R. Saborowski, M. Slater

Alfred Wegener Institute
Helmholtz Centre for Polar and Marine Research
Am Handelshafen 12
27570 Bremerhaven, Germany
Email: enno.fricke@awi.de

## Introduction

Large-scale insect farming holds significant potential for transforming biogenic waste into high-value protein for use in animal feed and human food. The black soldier fly, *Hermetia illucens*, is one of the most cultured insects worldwide. Imagines, the adult life stage of the insect, are only cultivated for reproduction and are arising as novel and unused by-product of industrial black soldier fly larvae production (Soetemanns et al., 2020). Utilization of this side stream as feed ingredient for high value species like *Penaeus vannamei* would reduce waste, create by-product value, and promote a circular economy. In this work, an in-depth chemical analysis of meal prepared from the adult black soldier fly was made and the apparent digestibility of key nutrients was determined *in vivo* in *P. vannamei*. A consecutive growth trial was conducted to assess effects of replacing fish meal with imago meal on weight gain, feed utilization, digestive enzyme activities, and immunological parameters of *P. vannamei*.

## Materials and methods

Dead adult black soldier flies were collected from a local insect farm, dried, and ground to homogenous meal (< 500 µm). Composition of gross nutrients, amino acids, fatty acids, selected minerals, chitin and, cholesterol were determined. Full-fat and partially defatted imago meals were used in a digestibility trial with juvenile *P. vannamei,* using a reference and test diet with yttrium as an inert marker. Based on these findings, experimental diets replacing 50% (I50), 75% (I75), and 100% (I100) of the fish meal content with defatted imago meal were formulated on digestible protein and energy levels. Experimental diets were used for an acceptability trial and a 40-day growth trial with juvenile shrimp (5.4 ± 1.0 g). At the end of the growth trial, digestive enzyme activities were measured in crude extracts made from shrimp midgut glands. Glucose, protein, total hemocyte counts, phenol-, and prophenoloxidase activities were measured in the hemolymph. Shrimp muscle and midgut glands were analyzed for dry matter, lipid, and protein content.

## Results and discussion

Full fat imago meal contains 52% protein, 36% lipid, and moderate levels of chitin (5%). Considerable amounts of amino acids are present with an essential amino acid index of 1.8, referring to the ideal protein for penaeid shrimp (NRC, 2011). Cholesterol and copper were detected at moderate concentrations of 2.8 $g \cdot kg^{-1}$ and 16 $mg \cdot kg^{-1}$, respectively. Defatting the imago meal (IM) reduced the lipid content to 23% and increased protein levels to 60%. Results of the digestibility trial showed, that defatting significantly increased the bioavailability of protein and energy ($p < 0.05$). This is likely related to the low tolerance of shrimp to high levels of dietary lipids and the high content of saturated fatty acids present in imago meal (NRC, 2011; Glencross et al., 2002). However, protein and energy apparent digestibility remained moderate in defatted IM with approximately 60% and 53%, respectively. The acceptability of the defatted IM containing diets was reduced, leading to significantly lower apparent feed intake of the I75- and I100-diets during the growth experiment ($p = 0.001$). Shrimp growth was reduced in all defatted IM-containing diets ($p = 0.0005$). Defatted IM-containing diets caused lower dry matter contents in shrimp muscle ($p = 0.0136$) and lower lipid contents in midgut glands compared to the control diet ($p = 0.0169$; FIGURE 1).

Survival, digestive enzyme activities, and hemolymph parameters were not affected by the diet, implying no adverse effects of defatted IM on general shrimp health. Based on these findings, defatted imago meal is not suitable to replace dietary fish meal at the levels tested in this study. Lower IM inclusion rates (< 100 $g \cdot kg^{-1}$), more efficient defatting of IM, and addition of attractants are suggested to improve the nutritional quality and palatability of imago meal.

*(Continued on next page)*

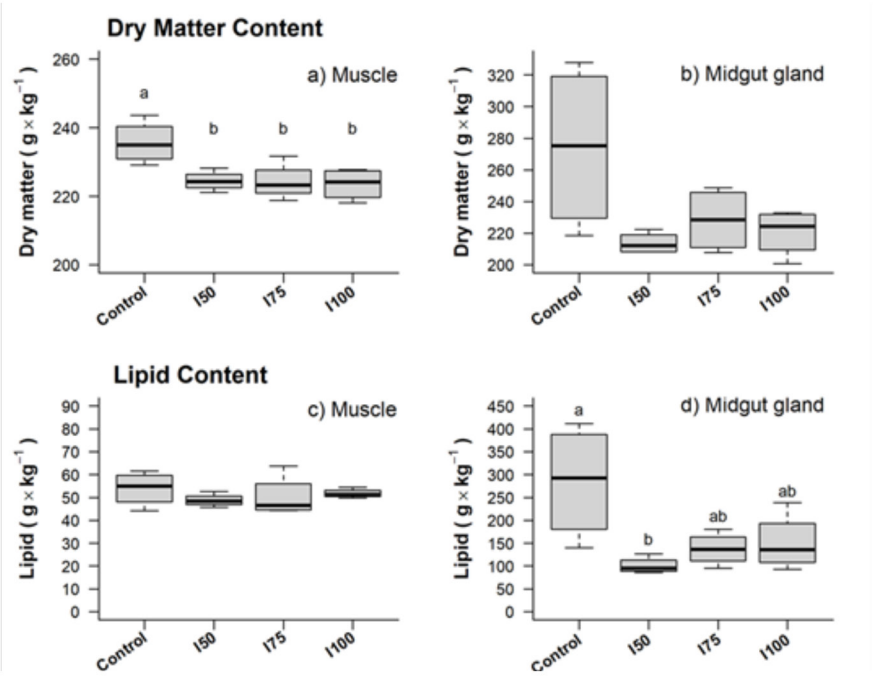

FIGURE 1. Dry matter and lipid contents measured in the muscle (a, c) and midgut gland (b, d) of *P. vannamei* fed a fish meal-based control diet, and three diets in which 50% (I50), 75% (I75), and 100% (I100) of the fish meal was replaced with defatted imago meal (n=4).

# THE RELATION BETWEEN AQUACULTURE OPERATIONS AND BIOSAFETY IN THE FUTURE OF MARINE FISH FARMING – NEW PRODUCTION STRATEGIES AND PRODUCTION SYSTEMS ON THE RISE

HT Slette*, AU Misund

SINTEF Ocean
7465 Trondheim, Norway
Email: hans.slette@sintef.no

## Introduction

In 2024 over 100 million Atlantic salmon over 3 grams died in hatcheries and fish farms in Norway. Diseases and parasites are the main root causes, with the most common cause of death being infectious diseases. At the same time, Norwegian aquaculture is largely regulated based on the production of sea lice and how it affects wild salmon. Recently, the authorities put forward a white paper presenting their vision for future regulation of the industry (Meld. St. 24 (2024–2025)) – still largely based on sea lice numbers. Even though it is early to say how this will turn out and ultimately affect the industry, it is reasonable to expect significant changes to production strategies and prevalence of new production systems.

Changes to production strategies and use of production systems following Meld. St. 24 (2024–2025) will potentially affect biosafety. One central consideration is how vessel activities and operations at fish farms are adapted to new regulatory conditions and use of new technology.

## Material and methods

This study investigates how changes to production strategies and production systems for marine farming of Atlantic salmon can affect the biosafety in the industry. The approach is two-folded; i) cases for future scenarios are described and discussed in expert panels, this covers exploring how the industry might look in 20 years and what this means for biosafety, ii) detailed choices for production strategies and production forms are listed and the literature is reviewed for knowledge on the effects of the choices on biosafety, and for possible measures for improvement.

## Results

The study is not yet fully completed, however some preliminary results and details on the structure of the study are available. Case studies are divided into segments for land-based facilities, sea-based facilities and transportation. Choices for production strategies and production forms are further divided into five segments; broodstock, hatcheries, grow-out, slaughter and transport. This is necessary due to the magnitude of choices that can be made from selecting water temperature, geographical placement of facilities, to operations routines and use of stun and bleed vessels.

Extensive literature on risks and measures exists for some choices and alternatives, but there is also a number of choices for which no relevant literature has been identified. This might indicate knowledge gaps with respect to how decision making in aquaculture can affect biosafety. The resulting overview can therefore help guide decision makers in terms of informing them about the risk/consequences related to choices they make.

Further results will be finalized in time for the presentation at Aquaculture Europe 2025.

# PROTEOMIC INSIGHTS INTO TAURINE-INDUCED CHANGES ON EUROPEAN SEA BASS MYOTUBES

Roger Solà*[1], Manel Montblanch[1], Isabel García-Pérez[1], Mar Vilanova[2], Marta Vilaseca[2], Daniel Garcia de la serrana[1], Joaquim Gutiérrez[1], Josefina Blasco[1], Miguel Martin-Perez[1]

[1]Department of Cell Biology, Physiology and Immunology, University of Barcelona, Spain
[2]Institute for Research in Biomedicine (IRB Barcelona), The Barcelona Institute of Science and Technology (BIST), Barcelona, Spain
E-mail: rogersola@ub.edu

**Introduction**

European sea bass (*Dicentrarchus labrax*) is one of the most commercially valuable species in the Mediterranean aquaculture. However, the use of highly substituted diets for European sea bass is hampered due to the high carnivorous habits of this species. The non-protein amino acid, taurine, has been previously reported as a potential dietary supplement in fish aquaculture, enhancing both growth and antioxidant capacity (D. Montero et al., 2023; P. Salze and Allen Davis, 2015). Here, to better understand the signalling response triggered by taurine in muscle, proteomic and phosphoproteomic analyses were carried out on cultured myotubes from European sea bass.

**Methodology**

European sea bass juveniles (10 ± 2 g of body weight) provided by Culmarex (Mallorca, Spain) were maintained in our indoor facilities at the University of Barcelona. Muscle cells were extracted from 11-12g of white epaxial muscle from juveniles and cultured in quadruplicate (n=4) for 13 days until myotube development stage (García-Pérez et al., *under review*). Cells were treated 24h with 10mM taurine (showed no effects on cell viability) and protein extracted with 8M urea buffer containing a mix of proteases and phosphatases inhibitors. Samples were reduced, alkylated, and digested with LysC and trypsin. Digested peptides were desalted with reverse phase C18 columns, keeping an aliquot for proteome analysis and using another aliquot for phosphopeptide enrichment by IMAC using Fe-NTA magnetic beads. Data acquisition was performed by nano LC-MS/MS using Evosep One chromatograph coupled to an Orbitrap Eclipse mass spectrometer with DDA methods. MaxQuant software was used to identify and quantify the proteome and phosphoproteome using European sea bass database from Uniprot, whereas Perseus and R software were used for bioinformatic analyses.

**Results and discussion**

We quantified 2643 proteins, of which 267 (10.1%) showed significant changes in abundance between taurine and control groups. Hierarchical cluster analysis of z-score normalized changes in proteome abundance allowed to discriminate between control and treatment groups (Fig.1a). Downregulated proteins upon taurine treatment were enriched in gene ontology biological process terms (GOBP) related to cell development (Fig.1b), while mostly protein translation processes were upregulated. We identified 7259 phosphosites, of which 1179 (16,2%) displayed significant differences in intensities between the two groups (Fig.2). Several targets of the mTOR signalling pathway showed increased phosphorylation upon taurine treatment, such as AKT, 4EBP1, and EIF4EBP1, as well as transcriptional factors (e.g., EIF3A) involved in protein synthesis. These findings support a proteinogenic stimulus of taurine in muscle cells by enhancing mTOR signalling and ribosomal activity, thus indicating its potential as a dietary additive for stimulating muscle growth in European sea bass.

*(Continued on next page)*

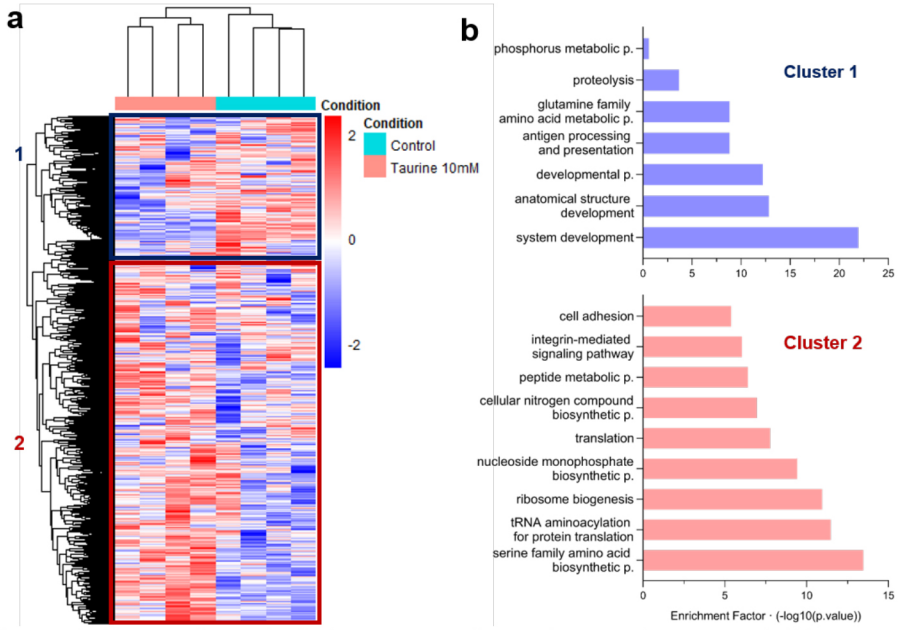

**Figure 1**. Proteomic analysis between taurine and control groups. a) Heatmap and hierarchal clustering of total proteins detected. b) Significantly enriched GOBP terms from main clusters of heatmap.

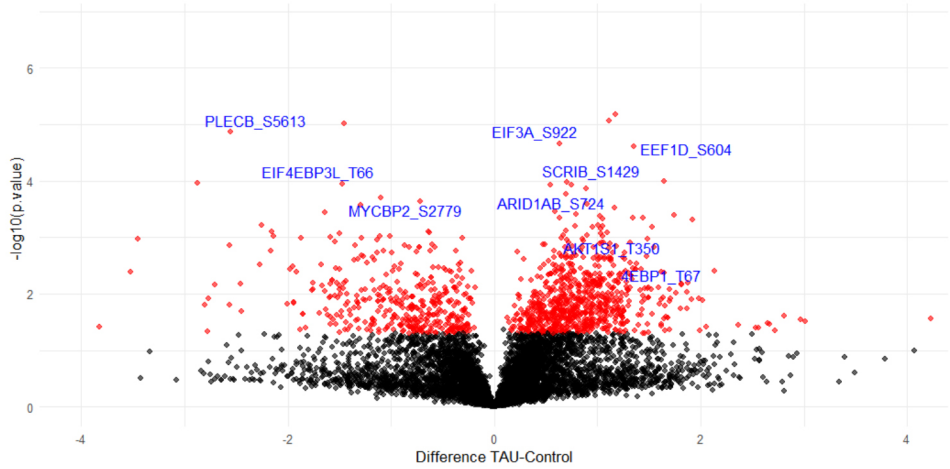

**Figure 2.** Volcano plot comparing taurine and control groups from phosphoproteomic data. (n=3, t-test p-value < 0.05). Highly significant phosphosites involved in mTOR signalling are indicated.

[3]Instituto de Bioingeniería, Universidad Miguel Hernández, Avenida de la Universidad s/n, 03202 ELCHE (Alicante)

**Introduction**

Carnivorous fish species such as gilt-head seabream (Sparus aurata) require long-chain polyunsaturated fatty acids (LC-PUFA) of the n-3 and n-6 series, including eicosapentaenoic acid (EPA; 20:5n-3), docosahexaenoic acid (DHA; 22:6n-3), and arachidonic acid (ARA; 20:4n-6), crucial both for their optimal health and development and for nutritionally enhancing of products for human consumption (Calder, 2020). EPA and DHA are vital for neurological development during the fetal stage, infancy, and early childhood (Innis, 2007; Lauritzen et al., 2016). Reflecting this, the European Commission has authorized several health/nutritional claims (Regulation (EC) No. 1924/2006).

In parallel, the presence of metal(loid) contaminants in fish-based foods must be minimized due to their carcinogenic and genotoxic potential. Legislative efforts have been made to reduce exposure, including the establishment of maximum limits (Regulation (EC) No. 2023/915). Recent EFSA assessments continue to highlight fish as a major contributor to exposure to arsenic species such as DMA and MMA, particularly in toddlers and elderly populations. Additionally, methylmercury (MeHg) remains a key concern. In contrast, health benefits associated with fish consumption must also be considered.

Ensuring essential nutrient content and minimizing contaminant levels poses a considerable challenge for the food industry. Careful selection of fish species and production methods is therefore critical when designing fish-based products for vulnerable groups. Toddlers' nutrition has become a central concern for the scientific community, the food industry, and general consumers. This study aims to support the development of safer, more sustainable, and nutrient-rich fish products, particularly for toddlers.

**Materials and methods**

As part of an experiment framed within the ThinkInAzul GVA project, three types of feed formulations (n=3, CTRL: fish meal-based diet, PAP: processed animal protein-based diet, and ALT: alternative protein-based diet) were evaluated on fatty acid and mineral profiles of *Sparus aurata* fillets. A Gas Chromatograph coupled to a Flame Ionization Detector (GC-FID) was used for fatty acid detection and semi-quantification, and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) was used for metal(oid) quantification.

On the other hand, all the published literature on the comparison of metal(oides) in aquaculture fish and wild fish was analyzed using the PRISMA methodology. Thirty-one studies that met the eligibility criteria were selected (Casanova-Martínez et al 2025).

In addition, fish-based pureed baby food, available in Spanish supermarkets and hypermarkets, was evaluated. Product labeling information was collected, including the list of ingredients, nutritional information, and possible health claims.

*(Continued on next page)*

**Results and discussion**

*Preliminary background*

According to EU regulations, fish raised with traditional feed is considered a healthy and nutritious option due to its beneficial levels of EPA, DHA, MUFA, and omega-3 fatty acids. The use of the proposed alternative feeds did not compromise these properties and, in addition, had a positive impact on the metal(oid) content of the fish fillets. This ensures that fish-fed with these alternative diets can be considered a suitable option for reducing metal(oid) exposure without compromising their health and nutritional qualities. Thus, the differences between formulations, particularly in As and Hg levels, emphasize the need for careful selection of feed ingredients to minimize metal(oid) exposure in aquaculture. Further research is needed to better understand the metabolism of these compounds and to evaluate the potential health risks associated with their accumulation in farmed fish.

*Literature review*

A higher concentration of metal(oids) such as Hg and As was found in wild fish than in aquaculture fish, although most of the elements were within the limits established for safe consumption by the general population. Even so, it is necessary to reduce the concentrations of these contaminants, especially in foods intended for vulnerable populations. Even so, with the data available in the scientific literature, it is difficult to determine the effect of the fish production system on metal(oid) contamination, since several factors interact in a complex way. The differences found in some research papers are probably not solely attributable to the production system. In addition to species, factors such as size, age, feed type, physiological state, habitat, degree of environmental pollution, diet, or growth rates of aquatic organisms seem to have a greater effect.

*Baby food based on fish and open pathways*

The ingredients of pureed baby foods available on the Spanish market are sources of metal(oids) as they include rice, roots, tubers, and/or fish/shellfish. The study found that fish-based pureed baby foods from the Spanish market account for only 12.04-13.13% of all pureed baby foods, with fish content around 8%. Hake was present in over 50% of these products. Only 28% of products specified the production method, with wild-caught hake frequently identified. This low proportion of fish-based products contrasts with the scientific evidence supporting the need to increase fish consumption during infancy to promote neurodevelopment, particularly in relation to LC-PUFA intake, specifically EPA and DHA. None of the products included nutrition or health claims. Therefore, the development of baby foods with a higher percentage of fish would be desirable to meet the requirements of these claims and ensure benefits for the target population. Careful selection of the fish species to be included in these formulations is recommended. Aquaculture-derived fish could be a suitable option, as it offers more control over the raw material and facilitates regulation of both desirable and undesirable compound levels.

**Conclusions**

This study highlighted the feasibility of using alternative protein-based feeds in aquaculture without compromising the nutritional quality of *Sparus aurata*, particularly in terms of essential LC-PUFA such as EPA and DHA. Moreover, these alternative feeds can contribute to lowering metal(oid) contamination in fish fillets, supporting the development of safer and more sustainable products. The literature review indicated that while wild fish often show higher concentrations of metals(oids), multiple confounding factors complicate direct comparisons with aquacultured fish. Additionally, current commercial fish-based baby foods in Spain underrepresent fish content and lack authorized nutritional claims despite scientific evidence supporting early-life intake of EPA and DHA. Therefore, enhancing fish content in these products -especially from aquaculture sources with better contaminant control- could help meet regulatory health claim criteria and support the nutritional needs of vulnerable populations like toddlers. Further research and regulatory efforts should focus on optimizing both nutrient and contaminant profiles in fish-based foods for early childhood nutrition.

# WHAT A META-ANALYSIS MAY SHOW US ABOUT THE ONTOGENY OF DIGESTIVE ENZYMES IN FISH LARVAE?

M. Solovyev*, A. Gusenkov, E. Kashinskaya, E. Gisbert

Institute of Systematics and Ecology of Animals of SB RAS
Novosibirsk, Russia
E-mail: yarmak85@mail.ru

## Introduction

Digestion is a complex multi-level process consisting of physicochemical breakdown and absorption of a large number of organic and inorganic substances entering the body. The key role in this process is played by digestive enzymes, which differ in many parameters: origin (pancreas, stomach, intestine, food objects, symbiotic microbiota, etc.), substrate specificity (proteins, carbohydrates, lipids, etc.), localization (stomach and intestinal cavity, brush border of enterocytes, intracellular), dependence on pH, activators, inhibitors, etc. For fish, the most important enzymes include pepsin, trypsin, chymotrypsin, amylase, lipase, aminopeptidase, maltase, alkaline phosphatase and some others, responsible for the hydrolysis of food substrates in both gastric and non-gastric (except pepsin) fish. Most enzymes (except pepsin) are found in the digestive system of fish in the first days after hatching and can demonstrate several peaks of activity during ontogenesis. Despite the decisive role of these enzymes in the hydrolysis of proteins, lipids and carbohydrates in the digestive tract, the issue of the coupled development of these enzymes in the early ontogenesis of fish remains poorly understood.

The aim of this work is to conduct a meta-analysis of changes in the activity of key digestive enzymes in the early ontogenesis of different fish species.

## Materials and Methods

The data used in this study were obtained from a bibliographic search using the Dimensions application (https://app.dimensions.ai/discover/publicationtool). The following keywords in various combinations were used for this bibliographic search: “trypsin”, “chymotrypsin”, “alkaline proteases”, “fish”, “larva”, “ontogeny”, and “development”. The retrieved articles were carefully screened for descriptions of developmental activity of digestive enzymes, in particular: pepsin (gastric), lipase, trypsin, amylase, chymotrypsin, total alkaline proteases, carboxypeptidase A (pancreatic), N aminopeptidase, alkaline phosphatase, maltase (brush border), leu-ala peptidase and acid phosphatase (intracellular). From the list of analyzed articles (105), a total of 69 studies were selected for correlation analysis (Pearson), including 63 fish species and 2 fish hybrids. The remaining articles were excluded from the analysis due to insufficient number of sampling points for correlation analysis or lack of data on sampling dates.

## Results

Based on the correlation analysis we have found that pepsin (gastric protease) has shown low correlation ($r$ = 0.25-0.50) with trypsin, chymotrypsin, amylase and carboxypeptidase A (pancreatic enzymes) but moderate correlation ($r$ = 0.50-0.75) with alkaline phosphatase (brush border) and strong negative ($r$ = -0.75-1.00) correlation with leu-ala peptidase (intracellular) enzymes. Regarding to intestinal enzymes, we have detected that in 75 and 79% of cases, total alkaline proteases (TAP) correlated moderately ($r$ = 0.50-0.75) or strongly ($r$ = 0.75-1.00) with trypsin and chymotrypsin, correspondingly. Also, the TAP showed a strong correlation ($r$ = 0.75-1.00) with amylase in 80%, lipase in 85%, and carboxypeptidase in 100% of cases.

Using the special data set of papers where the activity of all three enzymes was available (trypsin, chymotrypsin and TAP), we identified four groups of fish based on correlation analysis: 1) a significant positive correlation ($r$ = 0.61–0.97) between chymotrypsin activity and TAP (28.6% of fish species); 2) significant positive correlation between trypsin activity ($r$ = 0.59–0.97), chymotrypsin ($r$ = 0.78–0.97) and TAP (52.4% of fish species); 3) significant positive correlation ($r$ = 0.65) between trypsin activity and OAP (4.8% of fish species); 4) negative correlation between trypsin ($r$ = -0.38 to -0.57), chymotrypsin (r = -0.22 to -0.49) and TAP (14.3% of fish species). Of particular importance is the fact that all species with high activity of

*(Continued on next page)*

only chymotrypsin (group 1) and trypsin (group 3) compared to TAP belonged to gastric fish species with a predominance of predatory species. However, all fish species from group 2, in which the effect of both enzymes (trypsin and chymotrypsin) on the TAP was significant and similar, belonged to both gastric and agastric species with different types of nutrition. Group 4, characterized by a negative correlation between the studied proteases, included only Amazon catfish (family Pimelodidae). All correlations will be discussed in the presentation.

**Conclusion**

Due to known limitations related to the impossibility of direct comparison of enzyme activity obtained by different researchers, correlation analysis nevertheless allows one to search for dependencies in such results. This meta-analysis based on a large array of data allows one to identify various relationships between digestive enzymes and to test previously proposed hypotheses.

Meta-analysis of the articles was carried out with the support of the Russian Science Foundation, project No. 23-74-101-01.

# HABITAT CHARACTERISTICS AND PHYTOPLANKTON FOOD SOURCES OF TWO VENERID CLAMS (*Ruditapes philippinarum* AND *Venerupis aspera*) IN JEJU ISLAND, KOREA

Chi-une Song[1]*, Jong-Seop Shin[2], Hyun-Sung Yang[2], Seong-il Eyun[1], Kwang-Sik Choi[3]

[1]Department of Life Science, Chung-Ang University, Seoul 06974, Republic of Korea
[2]Marine Biotechnology & Bioresource Research Department, Korea Institute of Ocean Science and Technology, Busan 49111, Republic of Korea
[3]Department of Marine Life Science (BK 21 FOUR), Jeju National University, Jeju 63243, Republic of Korea
E-mail: lowmemory93@gmail.com

Venerid clams, including the Manila clam (*Ruditapes philippinarum*) and the Venus carpet shell (*Venerupis aspera*), are commercially valuable bivalves. Historically, these two closely related species have shown different distributions based on climatic conditions. *R. philippinarum* is widely distributed in temperate waters, whereas *V. aspera* tolerates warmer, subtropical to tropical regions. As sea surface temperatures rise, both species are expanding its range and both venerid species now coexist on Jeju Island. Our study assessed habitat characteristics, sediment composition, and potential food sources of the two species at three sites in Jeju (Seongsan, Oeido, Seogwipo) to provide baseline data for selective breeding and genetic resource exploration. We found that the distribution of these clams varies by site. Seongsan hosted only *R. philippinarum*, Oeido had only *V. aspera*, and Seogwipo supported both. Sediment analysis showed that Seongsan had a sandy substrate, while Oeido had higher gravel content. Using psbA-targeted metabarcoding, we identified 120 phytoplankton taxa. Seongsan had the highest phytoplankton diversity and was dominated by diatoms, while Oeido and Seogwipo were dominated by cyanobacteria. These findings suggest that the distribution of these clams is influenced by sediment type and food availability, in addition to climate. This information is valuable for future aquaculture and climate change adaptation strategies.

# HARNESSING NATIVE MARINE BACTERIOPHAGES FOR POST-SURGICAL HEALING IN PEARL OYSTERS: A SUSTAINABLE SHIFT FROM ANTIBIOTICS

Dr. Ajai Kumar Sonkar

Pearl oyster farming is a critical industry in marine aquaculture, relying heavily on the surgical implantation of a nucleus and mantle tissue to induce pearl formation. However, this delicate process comes with the risk of post-surgical infections, which can compromise oyster health, survival rates, and the quality of pearls produced. To mitigate the risk of bacterial infection, antibiotics such as oxytetracycline, chloramphenicol, and kanamycin have been used in aquaculture systems. Despite their effectiveness in infection control, the widespread and often indiscriminate use of antibiotics has led to the alarming rise of antimicrobial resistance (AMR), creating both ecological and public health threats. The aquaculture sector, therefore, urgently requires sustainable, effective alternatives to antibiotics, especially in environmentally sensitive systems like pearl oyster farms.

This study aims to present an innovative solution to this growing challenge by exploring the use of naturally derived bacteriophages—viruses that specifically infect and lyse bacteria—as a post-operative treatment in marine pearl oyster culture. Bacteriophages, in contrast to broad-spectrum antibiotics, offer a highly targeted and eco-friendly alternative, with minimal risk of disrupting non-target microbiota and no harmful residue left in the environment. In this research, bacteriophages were extracted from pristine seawater collected from an uncontaminated coastal region of the Andaman Sea, known for its abundant and diverse marine microbial population. The primary objective was to determine the efficacy of these native bacteriophages in promoting post-surgical healing and preventing bacterial infections in the pearl oysters *Pinctada margaritifera* and *Pteria penguin*, which are native to the Andaman Sea.

The experimental design involved a randomized control trial with 400 oysters subjected to surgical implantation of nucleus and graft tissue. The oysters were divided into three groups: a phage-treated group (n=150), an antibiotic-treated group (n=150), and a control group (n=100). The phage-treated oysters were immersed in bacteriophage-enriched seawater for 72 hours, while the antibiotic-treated oysters were exposed to oxytetracycline at 1.5 ppm for the same duration. The control group was maintained in untreated filtered seawater. Several parameters were monitored, including mortality rates, wound healing times, shell closure rates, nacre deposition quality, microbial load at the wound site, and histological tissue analysis.

The results revealed striking differences between the treatment groups. The phage-treated oysters exhibited significantly faster wound healing, with recovery times ranging between 48 and 72 hours, compared to the antibiotic-treated group, which took 72 to 96 hours to recover. Mortality in the phage-treated group was markedly lower (5%) compared to the antibiotic-treated group (12%) and control group (18%). Histological analysis further corroborated these findings, showing reduced inflammation and superior tissue regeneration in the phage-treated oysters. The microbial analysis revealed that phage therapy effectively reduced pathogenic *Vibrio* spp., particularly *Vibrio harveyi* and *Vibrio alginolyticus*, without negatively affecting the beneficial microbial communities essential for oyster health.

One of the key advantages of phage therapy was its specificity—phages only targeted harmful bacteria while leaving beneficial microbes intact. Furthermore, phage therapy demonstrated the ability to self-replicate at the infection site, providing sustained antimicrobial activity without the environmental persistence associated with antibiotic residues. This self-amplifying property ensures a long-lasting effect, making phages an ideal candidate for sustainable aquaculture management.

In contrast, the antibiotic-treated oysters showed moderate healing times and higher levels of pathogen load. This inefficiency could be attributed to the emergence of antibiotic-resistant bacterial strains within the aquaculture system. Additionally, the use of antibiotics raised concerns about potential residual contamination in the final product, which can pose risks to both consumer health and the broader environment.

This study highlights the potential of bacteriophage therapy as a sustainable, environmentally friendly alternative to antibiotics in pearl oyster farming. By reducing mortality rates, accelerating wound healing, and enhancing nacre quality, phage therapy offers a compelling solution to some of the most pressing challenges in the aquaculture industry. Moreover, the study demonstrates the practicality of phage-based interventions, which can be seamlessly integrated into existing pearl farming practices without the need for major infrastructure changes or new regulatory approvals.

In addition to offering a promising alternative to antibiotics in pearl oyster aquaculture, this research opens up avenues for further investigation into the use of phage therapy in other bivalve species and aquaculture systems worldwide. The findings of this study also contribute to the global effort to combat AMR, providing a model for responsible and sustainable aquaculture that aligns with the increasing demand for antibiotic-free seafood production.

# THE NAUI MONITORING AND FORECASTING SERVICE TOOL IN SUPPORT OF AQUACULTURE MANAGEMENT IN THE EUROPEAN NORTHEAST ATLANTIC AND THE MEDITERRANEAN

MG Sotillo[1]*, O Ballesteros[1], M Fernandez-Tejedor[2], M Garcia-Leon[1], T Dabrowski[3], C Ramos[1], M. Espino[4], S Piedracoba[5], M. Moros[1], V. Pérez-Muñizuri[6], E. Bielsa[1], P Montero[7], J.M Garcia-Valdecasas[1]

4) LIM/UPC
5) CETMAR
6) USC
7) Intecmar

NOW Systems: marcos.sotillo@nowsystems.eu

NAUI is the latest User Interface Application developed by NOW Systems, designed as a service aggregator to facilitate access to a wide range of met-ocean information in coastal environments. It delivers Early Warning Systems (EWS) and drives forward the concept of smart coasts by enhancing environmental management and data-based decision making.

Several deployments of NAUI are currently supporting diverse coastal services across the European Northeast Atlantic and the Mediterranean Sea, showcasing how coastal monitoring and forecasting data can contribute to the protection and restoration of coastal biodiversity, while also support a more sustainable aquaculture management. Notable examples of services using the NAUI tool in support of local aquaculture include the e3HOPE in the Ebro Delta zone, the BIODIVER-COAST in Galway Bay, and the MOLL-e MALONE in the Ria de Arousa. All of which have been, or are currently, supported by the Copernicus Marine User Engagement Program as national coastal pilot services.

The Ebro Delta, a protected area of high ecological significance for local biota -recognized as a EU Natura 2000 Site, a Natural Park and a UNESCO Biosphere Reserve-, is also a hotspot for aquaculture. Its inner Bays -Fangar and Alfacs- host the highest annual production of mussels (*Mytilus galloprovincialis*) along the Spanish Mediterranean coast, along with some oyster farming. The region is under pressure due to anthropogenic activities (extensive rice agriculture in the delta), and there were significant mussel production decreases in recent years due to high water temperature peaks. The e-3HOPE Service, codeveloped by NOW, LIM/UPC and IRTA, target the area and includes a new operational coastal forecast system that incorporates freshwater inputs from both the Ebro River and the agriculture drainage canals discharging into the inner Bays. This system supports environmental protection and sustained management of aquaculture production in the Ebro Delta. To this aim, the e3HOPE service features a NAUI application that acts as service aggregator, providing visualization of all available coastal forecasts and observational data, including key indicators and an EWS for extreme events mitigation. This NAUI service enables traffic lights-style warning system, indicating local conditions as safe (green), minor concern (orange), or of a major concern (red) for various essential variables. Users can fully customize these alerts by setting specific threshold values for each warning level at each site according to their needs. This local deployment of NAUI in the Ebro Delta, admin by IRTA, eases coastal management, and helps address challenges to the sustainable development of local bivalve mariculture -such as mussel mortality risks linked to marine heatwaves-. It also supports biodiversity conservation in the area, by helping to monitor the suitability of habitat conditions for *Pinna nobilis,* a Mediterranean endemic species listed as Critically Endangered on the IUCN Red List of Threatened Species and whose presence in Fangar Bay is highly sensitive to changes in salinity. Finally, as part of the on-going FLORETHA Project, the e3HOPE service will be upgraded with new modules for coastal flooding and HAB prediction, further enhancing the existing IRTA HAB forecasting system.

**Galway Bay** hosts some of the last remaining populations of native oyster in Ireland, along with multitude of bivalve mariculture production sites. To support sustainable oyster farming in the bay, it is essential to provide timely information on unfavorable environmental conditions, enabling oyster farmers to take preventive actions to protect their stocks. One of the major concerns is the low salinity events, which significantly increase oyster mortality. To address this challenge, Marine Institute partnered

*(Continued on next page)*

with NOW Systems are developing the **BIODIVER-COAST Service**, delivered through a NAUI online platform. This service provides EWS for low salinity events in the bay. The warning system has been co-designed with local end users, and salinity thresholds are established based on a combination of oyster farmers' local knowledge, laboratory experiments exposing oysters to varying salinities and temperatures, and model hindcast analysis. In addition to near-real-time alerts based on the 3-day local forecast and the last month hindcast, the NAUI platform provides access to observational data from local monitoring stations, along with maps displaying monthly, seasonal, annual and decadal (2012-2021) statistics for Galway Bay. This comprehensive system allows identifying the spatial distribution of suitable habitat for native oysters, promoting a local sustainable bivalve mariculture and contributing to the preservation of biodiversity in the Bay.

The most recent deployment of NAUI in support of aquaculture is taking place in the **Ria de Arousa**, as part of the **MOLL-e MALONE Project** developed by a consortium grouping USC, NOW Systems, CETMAR, and that target as key stakeholder to the Coastal Observatory of the Xunta de Galicia. Shell fishing is a key activity along the Galician coast, and particularly in the Ría de Arousa, where edible cockle (*Cerastoderma edule*) holds both ecological and economic significance. Sedentary bivalves like cockles are highly vulnerable to abrupt changes in water conditions -especially to sudden extreme variations in salinity and temperature- often triggered by severe weather events. Despite cockles can tolerate short periods of low salinity, prolonged exposure can cause physiological stress and even mortality. Heavy rainfall and sudden river dam discharges, coincident with high tidal conditions, can significantly reduce salinity levels in the Ría, leading to mass mortality events. To address this, a tailored NAUI module to assess cockle mortality risks due to salinity-driven following Parada et al. (2012), is being implemented for all the production zones in the Ria. The service will contribute to enabling data-driven decision-making for shellfish gatherers and authorities, helping to reduce potential economic losses of shellfish harvesters, and to support more resilient shellfish harvesting practices.

The NAUI service aggregator, through its ad-hoc modules and integrated early warning systems associated with the existing local monitoring and forecasting data, leverages the identification of upcoming unfavorable conditions that may negatively impact on the health of bivalve species, such as oysters, cockles, and mussels. It provides short-term forecasts for key parameters, including salinity, temperature and currents, as well as time series from the past month and relevant historical climate data. By offering this integrated, data-driven insight, the NAUI service contributes to addressing critical challenges in achieving sustainable bivalve mariculture, supporting nature-based solutions focused on restoration, and preserving coastal biodiversity, as exemplified through its application in the here showcased services.

## Introduction

The washing process of synthetic textiles is one of the main sources of microplastics (MPs) pollution in different environmental compartments, including seawater (1). Polyester (PES) is the most common synthetic polymer in the textile industry and it is characterised by high persistence in the environment since it cannot be easily degraded (2). The fate of PES microfibers depends on both environmental and textile parameters. Photodegradation is considered one of the most common and effective (3). Laboratory simulations of this type of degradation are time-consuming and, thus, accelerated protocols are preferred (3). The aim of this study is the determination of the effect that washing and different manufacturing steps may have on the degradation of PES fibres.

## Materials and methods

Three different types of polyester textiles were used: undyed polyester (U-PES), dyed polyester (D-PES), a polyester commercial garment (G-PES). Fibres from differently manufactured PES fabrics were obtained by cutting the textiles or by washing them in a household washing machine, and collecting the fibres released. Hence, our study provides a realistic approach to examine textile degradation. D-PES and G-PES fabrics were washed under domestic washing conditions (40$^{o}$C, non-bio detergent, 1200 spin) and the fibres were collected from the drainpipe using a 1μm pore PP filter. The degradation of the prepared PES fibres was studied using an accelerated hydrolytic degradation protocol proposed by Sarno et al, 2021 (3), which mimics the processes occurring, for example, in marine environment. Monitoring of the degradation was performed at: $T_0$ (before degradation), $T_1$ (1 hour), $T_3$ (3 hours), and $T_5$ (5 hours). Fibres were analysed by Scanning Electron Microscopy (SEM), micro- FTIR (μFTIR) and Pyrolysis- Gas Chromatography- Mass Spectrometry (Py-GC-MS). The degradation solution used in the simulation was collected and neutralized. For non-target High Pressure Liquid Chromatography- High Resolution Mass Spectrometry (HPLC-HRMS) analysis, the solution was analysed either directly (diluted) or after solid- phase extraction (SPE).

## Results and discussion

Degradation of the samples was evident, with colour and fibre mass loss increasing throughout the process. As far as the fibre weight loss is concerned, washed garment fibres (G-PES) showed higher levels (71% mass loss at T5). SEM analysis showed degradation of all types of PES fibres, already starting at T1. SEM indicated that the washing process did not affect the morphology of the fibres degradation pattern. Py-GC/MS analyses showed a more substantial degradation of the commercial clothing garment fibres released from laundering, with total ion currents (TICs) of D-PES and G-PES at $T_0$ and $T_5$, showing a drastic decrease in the relative intensity of the marker peaks for G-PES samples after 5 h of degradation. Non-target analysis indicated that the release of leachates including dyes, and additives such as 4-nitrophenol, disperse orange 3, phenyldiethanolamine, and acetoacetanilide depended upon textile manufacturing process. Extraction of the degradation solution by SPE before non- target analysis led to the identification of 79 chemicals.

## Conclusion

The fibres released from the commercial clothing garment showed a higher degradation than the fibres from the textile fabric after 5 h. SEM, Py-GC/MS and PES degradation product concentrations in their degradation solutions, supported this result. Different morphology of the clothing garment fibres (napped on the surface), as well as, manufacturing steps and additives could be the cause of their more substantial degradation and the different leachates that were detected by non-target screening and that could reach the sea. Further research is needed to assess the environmental impact of fibres release and degradation, as this may be of great interest for assessing their potential toxicity while preserving ocean biodiversity.

## Introduction

The accelerated growth of marine aquaculture created an urgent need for sustainable and quality ingredients to maintain the performance and nutritional value of farmed species. Marine gammarid amphipods can be an excellent source of essential fatty acids, namely long-chain *n*-3 polyunsaturated fatty acids (LC-PUFA). However, their potential contribution to the formulation of aquafeeds still remains largely unexplored. The present work evaluated the effect of mono-specific macroalgal diets on the fatty acid composition of the offspring of *Gammarus locusta* fed on these macroalgae and compared it with the offspring of wild conspecifics.

## Materials and methods

*Gammarus locusta* breeding pairs were fed one of five mono-specific macroalgal diets (*Ulva* sp., *Fucus* sp., *Laminaria* sp., *Gracilaria* sp., and *Chondrus* sp.), and their broods were collected to determine their fatty acid composition using gas chromatography-mass spectrometry (GC-MS). Subsequently, their FA composition was compared with that displayed by the offspring of conspecifics from the wild.

## Results

The offspring from wild *G. locusta* showed the highest amount of polyunsaturated fatty acids (PUFA) (4.95 ± 0.31 μg $mg^{-1}$ DW), as well as essential fatty acids, namely eicosapentaenoic acid (EPA, 20:5*n*-3) and docosahexaenoic acid (DHA, 22:6*n*-3), with an abundance of 2.49 ± 0.21 and 0.87 ± 0.16 μg $mg^{-1}$ DW, respectively. The algal treatment that promoted the highest PUFA content in offspring was *Fucus* sp. (4.46 ± 0.31 μg $mg^{-1}$ DW), but those derived from broodstock fed with *Chondrus* sp. showed the highest DHA levels (0.56 ± 0.10 μg $mg^{-1}$ DW). However, no significant differences in fatty acid composition were found between offspring from broodstock fed with the different mono-specific macroalgal diets. On the other hand, the abundances of stearic acid (18:0) and DHA were significantly higher in the offspring of adults from the wild when compared to those fed on algal-based diets.

## Discussion

These findings suggest that *G. locusta* selectively conserves and biosynthesises essential fatty acids for growth and reproduction, particularly LC-PUFA. However, this process remains to be demonstrated in marine gammarids, as the presence of genes encoding the front-end desaturases necessary to LC-PUFA biosynthesis is yet to be described in their genome. Moreover, this experiment highlighted the importance of maintaining optimal diet properties for gammarid cultivation, as some mono-specific diets may negatively impact their reproductive yield. Nonetheless, all the offspring analysed present a balanced fatty acid composition with potential applications for aquaculture.

## Conclusion

*Gammarus locusta* offspring present a balanced FA profile with potential applications for aquaculture, as they demonstrate a remarkable trophic plasticity by being able to feed on a wide variety of substrates. Further research is needed to fully elucidate the mechanisms underlying trophic upgrading in gammarids. By using both marine and non-marine diets, as well as nutritional programming and selective breeding, it is possible to establish lineages that match or even surpass the fatty acid composition of wild conspecifics.

*(Continued on next page)*

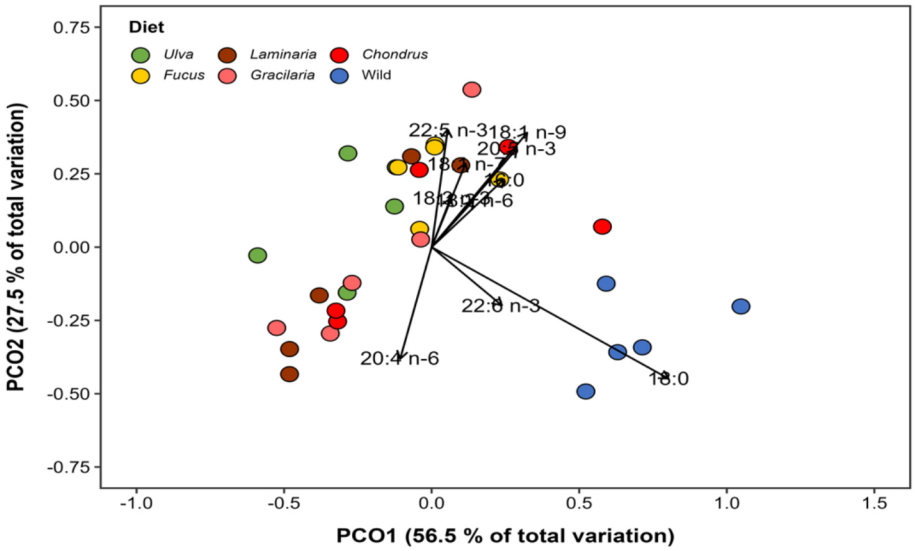

**Figure 1.** Principal Coordinate Analysis (PCoA) illustrating the variation in the fatty acid composition of *Gammarus locusta* offspring from breeding pairs fed with a mono-specific macroalgal diet (*Ulva* sp., *Fucus* sp., *Laminaria* sp., *Gracilaria* sp., and *Chondrus* sp.) or from specimens sourced from the wild. Analysis was restricted to fatty acids in the samples accounting for more than 1% of the total fatty acid abundance.

# HOUSEMATES IN AQUACULTURE: INTEGRATING *Ulva lactuca* INTO AN IMTRAS WITH *Holothuria arguinensis* FED WITH FISH WASTE

J. Sousa [a], P.M. Félix [b], A. Vieira [c], T. Mouga[a], A. Pombo [a]

[c] Piscicultura Vale da Lama, 8600-258 Lagos
Email: joao.t.sousa@ipleiria.pt

## Introduction

Integrated Multitrophic Aquaculture (IMTA) stands as a viable avenue to pursue an increase and more sustainable production of marine resources while diversifying commercial output by little to no additional costs. In this regard, sea cucumbers, such as *Holothuria arguinensis*, are deposit feeders that can grow from organic matter deposited at sea floor, making them prime candidates as organic extractors in IMTA systems. However, the circular IMTA concept requires additional agents, like inorganic extractors from the water column like amonia ($NH_3$), nitrites ($NO^-_2$) and nitrates ($NO^-_3$). Macroalgae are strong candidates for this role. The present study sought to determine the viability of producing *Ulva lactuca* in the same recirculating system (RAS) as *H. arguinensis* growing, in turn, in fish waste enriched sediment, in an Integrated Multitrophic Recirculating Aquaculture System (IMTRAS).

## Materials and Methods

To determine the efficacy of *U. lactuca* as an inorganic extractor for aquaculture production, two experimental RAS were put in place, one with the macroalgae (U treatment) and one without (control). Each system was comprised of an individual sump and 3 flat bottom tanks with 50L capacity and substrate enriched with fish waste, provided by Piscicultura do Vale da Lama (Lagos, Portugal). Each tank housed 30 *H. arguinensis* and connected to the respective system's sump. The two sumps were supplied with mechanical and biological filtration, but no protein skimmer. Each sump was then connected to 3 kreisels with 2.9 L capacity, where one system (U treatment) had *U. lactuca* at a density of $1 g \cdot L^{-1}$ and the other system (control) had empty kreisels. Water would then flow into the sea cucumber tanks, closing the circular system. This way, both RAS had the same water volume to better establish comparisons between them. Water quality parameters, mainly nitrogen compounds ($NH_3$, $NO^-_2$ and $NO^-_3$) were measured daily and, once per week, all sea cucumbers had their biometrics registered, such as submerged length, fresh weight, and specific growth rate (SGR). The density ($g \cdot L^{-1}$) of *Ulva* in the U treatment system was also registered in the same weekly interval, to monitor macroalgae growth over time.

## Results

After a period of 6 weeks, while there were no differences between treatments regarding *H. arguinensis* SGR (C = 0.23 ± 0.09 $\% \cdot day^{-1}$; U = 0.24 ± 0.11 $\% \cdot day^{-1}$), sea cucumbers grown with *U. lactuca* presented a higher mean survival rate (U = 97.78 ± 1.92 %) than the ones without (C = 84.44 ± 8.48 %). The inorganic compounds detected in the RAS system with *U. lactuca* were, inversely, at smaller concentrations (U: $NH_3$ = 0.03 ± 0.03 $mgL^{-1}$, $NO^-_2$ = 0.20 ± 0.31 $mgL^{-1}$ and $NO^-_3$ = 1.26 ± 1.42 $mgL^{-1}$) than the one without the macroalgae (C: $NH_3$ = 0.05 ± 0.05 $mgL^{-1}$, $NO^-_2$ = 0.58 ± 0.75 $mgL^{-1}$ and $NO^-_3$ = 2.67 ± 2.18 $mgL^{-1}$).

*U. Lactuca* reared in IMTRAS reached a peak of 2.44 ± 1.99 $g \cdot L^{-1}$ four weeks into the trial, with a maximum SGR of 2.77 ± 0.92 $\% \cdot day^{-1}$.

## Discussion

Sea cucumbers like *Holothuria arguinensis* have continuously demonstrated their aptitude for growth as organic extractors in IMTA settings. However, to reach a circular design and a more sustainable and resilient production system, macroalgae like *Ulva lactuca* are excellent inorganic extractors, mitigating the by-products of animal species in production, thus, improving water quality and showing positive effects on other organisms in the system. Furthermore, the lack of nutritional costs to produce additional trophic levels (commercial sea cucumbers and macroalgae) adds significant value to current production systems.

# DEVELOPMENT AND CHARACTERIZATION OF PLA-BASED ACTIVE FILMS WITH $TIO_2$ NANOPARTICLES AND THYMOL FOR EXTENDING GILTHEAD SEABREAM SHELF-LIFE

## Introduction

Active and antimicrobial food packaging is a rapidly emerging field, driven by the growing demand for safer, longer-lasting food products, while maintaining food quality, freshness, and safety (Wu et al., 2014). Polylactic acid (PLA), a commercial biodegradable polymer derived from renewable resources, has gained significant attention for food packaging applications due to its transparency, mechanical strength, eco-friendly profile and GRAS (generally recognised as safe) status (Mulla et al., 2021; Sharma et al., 2023). However, neat PLA suffers from brittleness and poor barrier properties, limiting its practical applications (Sharma et al., 2023). To address these limitations, PLA reinforcement with inorganic nanoparticles (NPs), particularly titanium dioxide ($TiO_2$), can enhance mechanical, thermal, and barrier properties, while also providing strong antimicrobial activity through reactive oxygen species generation (Mulla et al., 2021; Nikolic et al., 2021; Nayak et al., 2024). In parallel, thymol, a natural phenolic compound from thyme essential oil, serves as both an effective antimicrobial agent and a plasticizer, enhancing film flexibility (Kazemi-Pasarvi et al., 2020; Wu et al., 2014). The combined incorporation of $TiO_2$ nanoparticles and thymol into PLA matrices has not been extensively investigated and represents a promising strategy for developing multifunctional, eco-friendly active packaging systems aimed at reducing microbial spoilage, improving barrier properties, and extending the shelf life and quality of perishable products such as fresh fish.

## Materials and methods

Films were prepared by the solvent casting method using neat PLA pellets (10% $w/v_{solvent}$) dissolved in the film-forming solution (chloroform), with $TiO_2$ nanoparticles incorporated at concentrations of 0, 1.5, and 3% $w/w_{polymer}$ and dispersed by ultrasonication for 30 min. A fixed 12% $w/w_{polymer}$ concentration of thymol was added to one series of PLA-NPs films. Solutions were cast into 14 cm Petri dishes to achieve films with a thickness of approximately 100 μm.

The produced films were evaluated for mechanical (tensile strength, elastic modulus, elongation at break; ASTM D882-02), optical (color, opacity, light transmittance, UV barrier), and barrier properties (water vapor permeability, WVP; ASTM E96/E96M). Antimicrobial activity was assessed *in vitro* via disk diffusion assay against specific foodborne pathogens (*Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Enterococcus faecalis*, *Escherichia coli*, *Salmonella typhimurium* and *Listeria monocytogenes*). Surface microstructure and chemical composition were characterized using Scanning Electron Microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR) (4000–400 $cm^{-1}$), respectively, while crystallinity was determined by X-Ray Diffraction (XRD). Finally, a shelf-life study was conducted on gilthead seabream (*Sparus aurata*) fillets stored at 2 °C for 11 days, to evaluate the films' preservation capacity, by monitoring Total Viable Counts (TVC), *Pseudomonas* spp. counts, and pH levels.

## Results

Thymol addition reduced tensile strength and elastic modulus but significantly increased elongation at break (%), while $TiO_2$ NPs had no notable impact on mechanical properties. Both thymol and $TiO_2$ NPs increased the total color difference, with higher $TiO_2$ concentrations also raising opacity values; thymol did not affect opacity. Films containing $TiO_2$ NPs exhibited excellent UV-Vis barrier properties, with 0% transmittance at 280 and 320 nm and less than 1% at 400 nm. Water vapor permeability (WVP) was significantly reduced by thymol, while $TiO_2$ NPs had little effect. All active films, particularly those with thymol, showed antimicrobial activity against all tested pathogens, notably inhibiting the growth of *E. coli*, *S. aureus*, and *P. aeruginosa*. Regarding the shelf-life assessment, PLA films containing 3% $TiO_2$ NPs and thymol achieved optimal results, reducing microbial counts by at least 1 log CFU/g and extending fish shelf life by 2 days.

email: synne.spjelkavik@sintef.no

## Introduction

To meet the rising demand for sustainable feed ingredients in aquaculture, new, alternative sources must be explored. Gammarids represent a promising low-trophic option due to their favorable protein and fatty acid profiles, as well as their role as a natural food source for many fish species (Harlıoğlu and Farhadi, 2018). They are also well-suited for high density cultivation and can be reared on a variety of marine and terrestrial side streams (Ribes-Navarro et al., 2022, Alberts-Hubatsch et al., 2019). For efficient production in intensive systems, it is crucial to understand how different diets and feeding strategies influence their growth and survival to be able to optimize production.

## Materials and methods

In this study, juvenile marine *Gammarus* were fed over a six-week period with one of three diets: fresh *Fucus* sp., commercial fish feed, or dried sugar kelp *Saccharina latissima*. Each diet was provided at two feeding frequencies, with feed supplied *ad libitum* once and three times weekly. The experiment was conducted in quadruplicates for each treatment, with 30 individuals assigned randomly to each beaker. The experimental units, filled with 700 mL of seawater (35 ppt, 99% DO, pH 8.1), were kept at a constant temperature of 12.3 °C and a 12L:12D light regime. Approx. 50% of the seawater was changed three times a week for all beakers.

Gammarids were sampled at the beginning and at the end of the experiment to obtain data on survival, total lengths, as well as the corresponding individual dry weight (DW) and carbon and nitrogen (CN) samples. Moreover, data on length measurements and survival was collected bi-weekly.

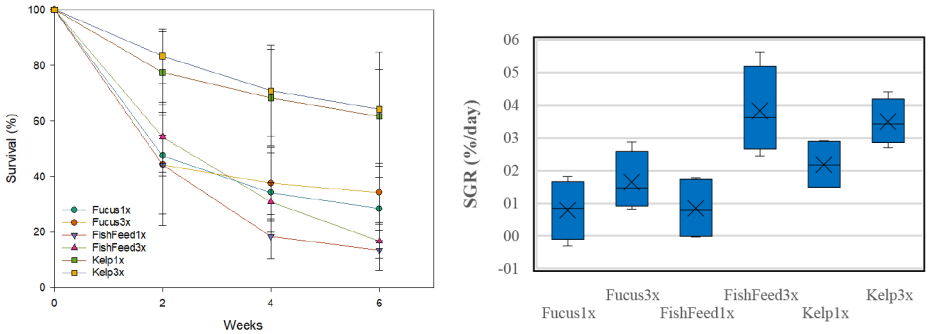

*Figure 1: Temporal survival (%, left) and specific growth rate (% per day, right) of gammarids provided three different diets over a 6-week period.*

*(Continued on next page)*

## Results and discussion

Preliminary results from the feeding experiment show that gammarids fed with sugar kelp had the highest survival rates across both feeding frequencies, and that the feeding interval had no significant effect on the survival of *Gammarus* across the dietary treatments. Gammarids fed with fish feed three times per week exhibited a significantly higher specific growth rate (SGR) compared to those in the Fucus treatment at the same feeding frequency. The juveniles in the fish feed treatment provided three times a week also had significantly higher SGR than the ones who were fed once a week. Otherwise, no significant differences in SGR were observed between the other diets or feeding frequencies.

## Conclusion

Overall, the diet had a stronger impact on the survival of the gammarids than the feeding frequency. A higher feeding frequency promoted higher growth, although not significant, and a further increase in feeding frequency (e.g. daily) could be explored. Fish feed fed three times a week resulted in a high growth rate, but overall poor survival. Thus, it can be concluded that the dried sugar kelp had the best effect on both growth and survival among the tested diets.

## Introduction

Anguillid herpesvirus 1 (AngHV-1) (recently renamed Cyvirus anguillidallo 1) is the etiologic agent of a lethal disease that affects several eel species. It is thought to be one of the main infectious agents causing a population decline in wild eels and economic loss within the eel aquaculture sector. Since the first report of AngHV-1 in the 1980s, it has been detected globally, affecting different anguillid eel species from temperate to tropical countries. To date, there is no vaccine against AngHV-1 available on the market. Current measures to prevent AngHV-1 disease within aquaculture settings mainly rely, when possible, on shifting water temperatures outside of the range (below 22 °C) associated with efficient lytic replication. However, it promotes latent infection thereby increasing the risk of transmission when latently infected eels are cohabiting with naïve eels under stressing conditions. Recently, we developed an attenuated recombinant vaccine against CyHV-3 using prokaryotic recombination technologies and in vivo bioluminescent imaging system (IVIS). The development of this vaccine relied on the deletion of CyHV-3 ORF57. Orthologues of CyHV-3 ORF57 exist in CyHV-1 and CyHV-2 (ORF57) and in AngHV-1 (ORF 35). Therefore, this study demonstrates the effect of ORF35 deletion on the ability of AngHV-1 to replicate in cell culture and on its virulence after inoculation in European eels (yellow eel stage) by different routes.

## Materials and methods

Eel kidney (EK-1) cells were cultured. The AngHV-1 isolate (UK strain) was used as a parental strain to produce recombinant AngHV-1 UK Luc strain, UK ORF35 Del and UK Luc ORF35 Del by homologous directed recombination (HDR). Luc strain encodes a LucGFP (luciferase and copGFP) cassette inserted in the intergenic region ORF32–ORF33 of AngHV-1 genome. ORF35-deleted recombinants were produced by replacing ORF35 with a sequence encoding mCherry. All the recombinants in this study were confirmed by SacI restriction fragment length polymorphism (RFLP) and transcriptional analyses. Indirect immunofluorescence staining, viral growth and plaque-area assay for recombinant AngHV-1 strains were investigated. These recombinants were inoculated in eels by intraperitoneal injection or intradermic infection or immersion. At specific days post infection, the eels were euthanized to measure the bioluminescence radiance using IVIS for the both sides of the body, gills and internal organs. We tested the potential of different concentrations of AngHV-1 UK ORF35 Del strain as a vaccine candidate for the mass vaccination of yellow eels by immersion (primary infection) along with a group of eels exposed to psoralen/UV inactivated AngHV-1 ORF35 Del strain (highest dose) to test the hypothesis of infectivity of the virus, acting like an inactivated vaccine. At 36 days post-exposure, eels were challenged with the AngHV-1 UK Luc strain and analysed it in IVIS at specific time points.

## Results

The replication kinetics of ORF35-deleted recombinant strains (UK ORF35 Del and UK Luc ORF35 Del strains) reached high and comparable titers with no significant statistical differences detected with parental strains (UK and UK Luc strains). The UK Luc and the UK Luc ORF35 Del strains expressed both luciferase bioluminescence and copGFP fluorescence, while mCherry fluorescence correlated with ORF35 deletion. Plaque-area assays revealed that the two ORF35 Del strains produced significantly smaller plaques than the wild-type parental strains. AngHV-1 ORF35-deleted strains using this approach demonstrated that ORF35 is not essential for viral replication in cell culture. For IP inoculation in eels, UK Luc ORF35 Del strain expressing

*(Continued on next page)*

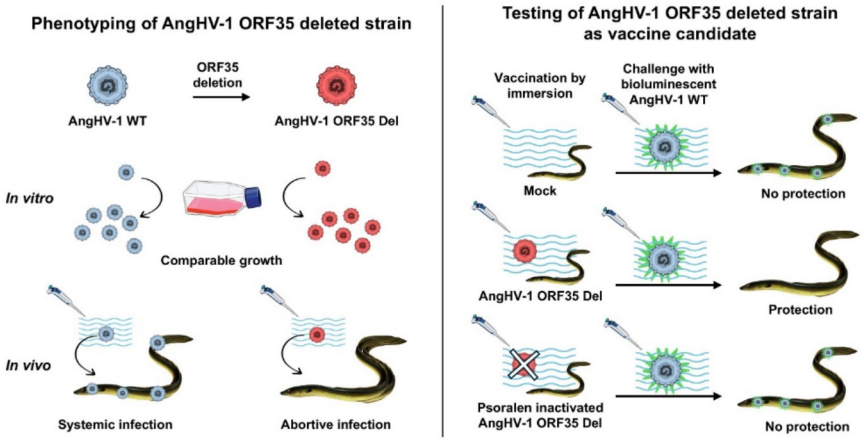

Figure: Graphical illustration of research findings

either much lower or no bioluminescence signals when compared with UK Luc strain. Similar to IP, immersion infection revealed significant differences between parental and ORF35 Del strains. While intradermal inoculation showed that the fish infected with either the UK Luc or UK Luc ORF35 Del strains showed positive signals at 2 dpi but only in the skin then these signals reduced at later time points in eels infected with UK Luc ORF35 Del. This suggested that the inoculation led to an erratic and abortive infection despite the artificial systemic mode of infection used. In the case of different concentrations of UK ORF35 Del strain as a vaccine candidate, at 6 dpi and at later timepoints, all the eels from mock and Psoralen/UV-inactivated groups expressed infection in the skin, gills and also in the other organs tested (brain, heart, and gut–liver). A significant effect of UK ORF35 Del was observed for all doses tested for the skin and the gills, while a significant effect was observed for the brain, the heart, and the gut–liver at doses of 50,000 pfu/mL or higher. It shows the ability of ORF35 Del strain to confer a protective immunity against a wild-type challenge.

**Conclusion**

The present study investigated, using recombinant strains and bioluminescent imaging, the effect of AngHV-1 ORF35 deletion on virus replication in vitro, virulence in vivo, and the potential of AngHV-1 ORF35-deleted recombinants as vaccine candidates for the mass vaccination of eels by immersion. The results suggest that the AngHV-1 ORF35 expresses singular and essential properties in vivo compared to its orthologues encoded by CyHV-2 and CyHV-3. This study supports the potential of AngHV-1 ORF35-deleted recombinants as vaccine candidates for the mass vaccination of eels by immersion.

# MITIGATION OF POST-HARVEST CONTAMINATION IN FISH BY A METHYL-CELLULOSE COATING INCORPORATING BACTERIOPHAGES TARGETING *Vibrio alginolyticus*

C. A. Stafyli[1]*, E. Athanasopoulou[1], M. Tseperka[2], D. Skliros[2], E. Flemetakis[2], T. Tsironi[1]

[1]Laboratory of Food Process Engineering, Department of Food Science and Human Nutrition

Email: chris.an.sta@aua.gr

**Introduction**

Post-harvest contamination poses a significant challenge in aquaculture, directly affecting the microbiological quality and shelf life of fish products. *Vibrio alginolyticus* is among the predominant microorganisms in marine fish. In the pursuit of sustainable and targeted antimicrobial interventions, bacteriophages have emerged as promising biocontrol agents. This study investigates the application of the lytic bacteriophage Athena 1, incorporated into a methyl-cellulose-based edible coating, for the control *V. alginolyticus* V1 on fresh fish. The investigation focuses on assessing the phage's stability, lytic efficacy, and antimicrobial efficacy within the coating matrix under conditions that simulate post-capture handling and storage.

**Materials and Methods**

The lytic bacteriophage Athena 1, specific to *Vibrio alginolyticus* strain V1, was evaluated for its stability across a range of pH values and temperatures to confirm its viability during coating preparation. Subsequently, Athena 1 was directly applied to surface-contaminated *Argyrosomus regius* fillets to evaluate its standalone antimicrobial activity. A phage bioactive coating (PBC) was formulated by incorporating Athena 1 (~$10^9$ PFU/mL) into a 2% (w/v) methyl-cellulose solution. The coating was applied to fish fillets by immersion, and its in vivo efficacy against *V. alginolyticus* was evaluated over a 48-hour incubation at 25°C. Microbiological analysis included enumeration of Total Viable Counts and *Vibrio* spp., while phage persistence was monitored through plaque assays and absolute quantification via RT-qPCR. Furthermore, a predictive growth model was employed to estimate the kinetic parameters of *V. alginolyticus* under each treatment, providing a deeper understanding of the inhibitory effects of the coating and the growth dynamics of the target bacterium on fish fillets.

**Results**

Athena 1 exhibited strong lytic activity under the condition required for coating preparation, demonstrating its stability and robustness. Direct application of the phage onto fish fillets resulted in a significant reduction of *Vibrio alginolyticus* V1 growth compared to untreated controls, indicating effective antimicrobial activity even withing the complex matrix of fish tissue (Figure 1).

The *in vivo* application of the phage incorporated into a methyl-cellulose-based bioactive coating (PBC) effectively delayed bacterial growth by 1.68 $\log_{10}$ CFU/mL, supporting previous findings. To further validate its performance, an accelerated shelf-life study was conducted. The growth rate of *V. alginolyticus* V1 was significantly lower in the PBC-treated group (0.395 ± 0.0791) compared to the coating without phage (0.748 ± 0.0973) and the untreated control (1.026 ± 0.163) (Figure 1). Additionally, absolute quantification of bacteriophage Athena1 during the accelerated shelf-life study demonstrated a time-dependent increase in phage levels following coating application. A statistically significant exponential rise (approximately $10^4$-fold) in PFU levels was observed within the first 8 hours post-application, followed by a plateau phase that persisted for at least 16 hours.

These findings highlight the potential of Athena 1 as an effective antimicrobial agent within methyl-cellulose-based biodegradable coatings for fish, further supporting the promising role of bacteriophages in mitigating spoilage and extending the shelf life of aquaculture products.

# RESOLVING SPECIES-SPECIFIC FUNCTION IN MICROBIOME ANALYSIS IS KEY TO ENVIRONMENTAL MANAGEMENT DECISIONS IN AQUACULTURE

Julianna Stangroom*, Melissa Allen, Jason Stannard, Jordan Poley

*Onda
20 Hope St
Souris, PE, Canada C0A 2B0
jstangroom@onda.ca

The functional dynamics within bacterial communities are increasingly recognized as crucial to the sustainability and health of cultured aquatic species. Interest in microbiome analysis has soared in response and, consequently, a number of studies have examined the bacterial composition of land- and sea-based aquaculture sites. The majority of investigations use NGS platforms to sequence the hypervariable V3/V4 region of the bacterial 16s rRNA gene, providing identification and relative abundance data for all genera. While the V3/V4 region can also provide species-level differentiation in some cases, the necessary resolution for accurately defining closely related species or detecting uncommon or recently identified genera is lacking. Bacterial metabolism, growth strategies, and capacity for beneficial or antagonistic microbial interactions are broadly species dependent. The work presented here represents a compilation of data from our custom full-length (FL) 16S rRNA gene sequencing platform and database. We describe species-specific bacterial functions related to recirculating aquaculture system (RAS) environmental management and the monitoring of open-water sites, including: nitrification, the metabolism of eutrophication-relevant nutrients, and off-flavour chemical or cyanobacterial toxin production.

We find that full-length 16S rRNA identification of important bacterial groups such as Cyanobacteria is key to avoid overrepresenting production risk from benign species and for the selection of appropriate management methods of undesirable species. Furthermore, we have identified bacterial storage and subsequent release of nutrients as a hidden risk for water quality management and reporting in open water shellfish sites. Lastly, the prediction of biofilter establishment, maturation, function, and tolerance to change is poorly represented at a genus level, particularly amongst nitrite-oxidizing bacteria, such as Nitrospira. These examples and others will display the scientific value of full-length 16S rRNA sequencing in environmental surveillance of land and open water aquaculture sites and, therefore, critical management decisions for all aquaculture producers.

# BALANCING COMMON CARP (*Cyprinus carpio*) PRODUCTIVITY AND SUSTAINABILITY IN WATER-SCARCE POND AQUACULTURE SCENARIOS

## Introduction

Freshwater aquaculture, particularly pond-based systems, is increasingly challenged by the growing prevalence of water scarcity, an issue compounded by climate change, population growth, and competing demands for freshwater resources. Projections indicate that climate-induced variability in precipitation, increased evapotranspiration, and declining surface water availability will disproportionately impact traditional aquaculture regions reliant on open water systems. In this context, the sustainability of pond aquaculture is under scrutiny, prompting the need for adaptive management strategies that can maintain productivity without exacerbating environmental stress. Intensification has emerged as a key strategy to increase output per unit of water, often through increased stocking densities and enhanced feeding practices. However, the transition from extensive or semi-intensive to more intensive systems introduces complex trade-offs. Higher biomass densities and nutrient inputs can lead to water quality deterioration, elevated fish stress, and greater susceptibility to diseases, particularly under water-limited conditions. This study aimed to evaluate how the interactive effects of water supply level, stocking density, and feeding regime influence growth performance, environmental parameters, and physiological stress responses in common carp (*Cyprinus carpio*) juveniles during the first production season in ponds.

## Materials and Methods

A full factorial experiment ($2^3$ design) was implemented to assess the individual and interactive effects of three key variables: Water supply: optimal (standard replenishment based on evaporative loss) vs. limited (restricted input mimicking drought conditions), Stocking density: low (standard semi-intensive density) vs. high (intensive commercial-level density), Feeding regime: traditional (plankton enhancement + cereal grains) vs. commercial (Aller Aqua formulated feeds).

Juvenile common carp (mean initial weight: 2.5 g) were stocked into twelve experimental earthen ponds (~300 m² each), with each treatment combination replicated in triplicate. The trial spanned over a three-month ongrowing period during the primary production season. Key metrics included: weight gain, specific growth rate (SGR), feed conversion ratio (FCR), survival rate, and plasma cortisol levels. Water quality: temperature, dissolved oxygen (DO), total ammonia nitrogen (TAN), and chlorophyll-a concentrations. Environmental and physiological data were collected biweekly, while growth performance metrics were recorded at the start, mid-point, and end of the trial. Statistical analysis was performed using a three-way ANOVA to detect main effects and interactions, followed by Tukey's HSD for post hoc comparisons ($\alpha = 0.05$).

## Results and Discussion

The study revealed significant main and interactive effects among the three tested variables. Water supply limitation had a consistently negative impact on fish performance across treatments, reducing both growth rate and survival. However, the extent of these effects varied significantly depending on the stocking density and feeding strategy employed.

Under limited water conditions, high-density ponds with traditional feeding showed the lowest performance in terms of growth and survival, accompanied by elevated levels of TAN and critical DO dips, especially during early morning hours. These conditions correlated with increased stress markers, including elevated cortisol levels and frequent surface gasping behavior. Conversely, the use of commercial feed under the same high-density, water-limited scenario mitigated many of these negative effects. Fish in this treatment group maintained significantly better FCR and growth rates compared to those on traditional diets, with more stable DO profiles and reduced behavioral stress indicators.

*(Continued on next page)*

Interestingly, under optimal water conditions, the difference between feeding regimes was less pronounced, suggesting that the benefits of formulated feed are most evident when environmental conditions are suboptimal. The commercial diet appeared to not only improve nutrient assimilation but also reduce organic loading, thereby alleviating oxygen stress and minimizing toxic metabolite accumulation.

Water quality trends supported these observations: ponds with traditional feeding showed significantly higher chlorophyll-a and TAN levels, particularly under high density and limited water supply. This suggests a synergistic effect of increased nutrient loading and poor flushing, which likely exacerbated algal blooms and microbial respiration, further lowering oxygen availability. In contrast, the commercial feed contributed less to water quality deterioration, likely due to its higher digestibility and nutrient density.

**Conclusion**

While higher stocking densities are often viewed as ecologically risky, they can be viable when aligned with high-efficiency feeding strategies and proactive water quality management. Traditional feeding approaches, though cost-effective in the short term, may exacerbate eutrophication and compromise fish welfare, particularly under drought-prone conditions.

In the context of climate change and increasing resource limitations, adaptive aquaculture practices based on factorial insights like those presented here will be essential to future-proof the sector. These results contribute to the development of more resilient freshwater production systems and inform decision-making around feed formulation, density management, and water use efficiency in the face of environmental uncertainty.

# A GLIMPSE INTO OFFSHORE AQUACULTURE – FIRST INSIGHT INTO BLUE MUSSEL (*Mytilus edulis*), OYSTER (*Ostrea edulis*), AND ALGAE (*Saccharina latissima*) GROWTH AT THE ULTFARMS PROJECT PILOT SITE FINO3 IN THE NORTH SEA

Tim Staufenberger*[1,2], Eva Strothotte[1], Jacob Nimz[1], Jakob F.M. Becker[1]

[1]R&D Center University of Applied Sciences Kiel GmbH; Schwentinestr. 24; 24149 Kiel
[2]Kieler Meeresfarm GmbH & Co. KG; Jaegeralle 15: 24159 Kiel

e-mail: Tim.Staufenberger@fh-kiel-gmbh.de

ULTFARMS is an EU Horizon project dedicated to unlocking the potential of sustainable offshore aquaculture by developing and testing cultivation systems for low-trophic species in co-location with offshore wind infrastructure. At the FINO3 test site in the North Sea, near the DanTysk wind farm, three systems were deployed for the cultivation of *Saccharina latissima* (kelp), *Mytilus edulis* (blue mussel), and *Ostrea edulis* (European oyster). Preliminary results demonstrate promising growth performance: mussels achieved flesh content up to 47%; kelp grew up to 1.3 mm/day despite a short cultivation period; and oysters are under continued observation (results expected by September 2025). These findings validate the technical feasibility and biological viability of offshore aquaculture and offer a foundation for further development of multi-use marine sites.

## Introduction

The European Union's blue economy strategy emphasizes climate-neutral food production, optimized marine spatial planning, and co-use of ocean infrastructure. ULTFARMS directly contributes to these goals by designing and validating aquaculture systems for low-trophic species that can coexist with offshore wind farms. The project aims to overcome technical, biological, and economic barriers to offshore farming while supporting circularity, biodiversity enhancement, and regional economic value chains, contributing to the Ocean Mission Baltic & North Sea Lighthouse. The FINO3 pilot site, located adjacent to the DanTysk wind farm in the North Sea, offers a challenging but strategic setting for testing aquaculture prototypes under real offshore conditions. The project's goal is to assess biological viability, system resilience, and scalability of co-located farming of macroalgae and filter feeders, paving the way for environmentally and economically sustainable offshore aquaculture operations.

## Materials and Methods

Three aquaculture systems were installed at the FINO3 offshore research site:
The study was conducted at the FINO3 research platform, located in the German Bight of the North Sea, adjacent to the DanTysk offshore wind farm. This location offered a high-energy offshore environment ideal for testing robust aquaculture infrastructure under real marine conditions. Within the ULTFARMS project, three cultivation systems were installed to evaluate the growth potential of *Saccharina latissima* (sugar kelp), *Mytilus edulis* (blue mussel), and *Ostrea edulis* (European oyster).

The algae cultivation system consisted of a net structure that extended from the sea surface down to a depth of two meters. It was anchored on both ends using delta flippers connected to chain links and reinforced by concrete blocks for additional stabilization. *S. latissima* specimens were sourced regionally and propagated in a laboratory setting. Two seeding approaches were employed: a direct seeding method, where spores were applied directly onto the net, and a twine-seeding method in which pre-seeded twine was attached to vertical lines flanking the net structure. The entire net system was assembled and seeded at the harbor shortly before being deployed at the offshore site. Due to unforeseen technical complications, the algae had to be harvested after only three months of growth.

The mussel cultivation system featured a submerged backbone composed of a polypropylene tube suspended approximately seven meters below the water surface. Attached to this backbone were nets. Buoyancy was provided by flotation buoys, which were evenly spaced and connected to the backbone. The structure was anchored similarly to the algae system, using delta flippers, chain, and concrete weights. Different net materials were deployed in early spring to encourage natural mussel spatfall. The system remained at sea also during winter to allow a natural grow-out phase of up to two years. Subsamples were collected periodically during routine inspection and maintenance to monitor settlement and growth progression.

*(Continued on next page)*

For oyster cultivation, a novel system was developed consisting of small, commercially available oyster baskets arranged within a steel cage frame. Each cage included a weighted base for stability on the seafloor. The entire unit was equipped with an acoustic remote control (ARC) retrieval mechanism mounted on the upper frame. This system could be triggered remotely, deploying a buoy attached to a retrieval line, which enabled surface access to the submerged cage. The baskets were filled with hatchery-reared European oysters verified to be free of *Bonamia* infection in order to protect the trial site from potential pathogen introduction. The oyster system was fully assembled and stocked before offshore deployment in May 2024 and shall remain on site until September 2025. Growth data is expected after the current cultivation cycle concludes.

This comprehensive setup allowed for simultaneous testing of different species, materials, and deployment strategies under the same environmental conditions, providing valuable early data for offshore multi-use aquaculture development.

**Results**

*Algae (Saccharina latissima)*
The kelp cultivation trial, despite being limited to a three-month period due to technical constraints, showed encouraging biological performance. Growth rates of up to 1.3 mm per day were observed, aligning with published benchmarks for early-stage development in offshore kelp farming. However, growth was uneven. The central and lower sections of the net exhibited moderate to good growth, while the uppermost zone showed little to no growth. This absence of biomass in the top section suggests adverse effects from high surface turbulence and wave-induced mechanical stress. No substantial difference in growth performance was observed between the direct seeding and pre-seeded twine methods.

*Mussels (Mytilus edulis)*
Mussel settlement and growth were patchy, with clear differences in performance among different tested net materials. The standard polypropelene mesh netting supported the highest spat density and showed the best results . In contrast, fuzzy rope nets had poor results. Subsamples taken during mid-season inspections and final autumn maintenance revealed well-developed mussels on the nets, with flesh content reaching up to 47%. This figure reflects excellent meat yield and is comparable to quality standards for commercial mussel production. However, variability within and between net types highlights the need for improved design.

*Oysters (Ostrea edulis)*
The oyster system is still deployed last visual inspection revealed system robustness under offshore conditions. Growth data was not available at Abstract submission time but is expected to be presented during the conference.

**Discussion**

These preliminary trials at the ULTFARMS FINO3 pilot site provide a foundational proof-of-concept for integrated, offshore aquaculture in co-location with wind energy infrastructure. Although the biological results were mixed in uniformity, each of the systems showed technical feasibility and species-specific success indicators that merit further investigation and upscaling.

The short duration of the kelp trial limited conclusions on seasonal yield, yet the observed growth rates suggest that *S. latissima* can develop efficiently in exposed sites. The absence of growth in the upper net layers likely results from physical abrasion and motion during heavy seas, indicating a need to adapt net design or focus seeding below the wave-affected zone. Future efforts should investigate longer grow-out durations.

Mussel cultivation showed high potential for biomass yield and quality. The high flesh content of up to 47% supports commercial interest, but patchy settlement highlights need for further research.

Oyster growth data remains pending. But the structural setup and ARC retrieval system look promising. This technology can drastically reduce offshore maintenance costs by removing the need for diver-based operations. Assuming acceptable growth and survival rates continue, this system may serve as a model for future offshore shellfish farming infrastructure.

These results represent a promising first step toward a scalable and environmentally compatible model for offshore aquaculture within Europe’s evolving blue economy framework.

# APPLYING A STANDARDIZED RISK-EVALUATION TO ALIEN SPECIES IN AQUACULTURE

Kathrin Steinberg*, Michiel Fransen and Giovanni Vimercati

*Aquaculture Stewardship Council
Daalseplein 101, 3511 SX Utrecht
The Netherlands
kathrin.steinberg@asc-aqua.org

Aquaculture is a global industry that relies upon the culture of alien species – either referring to non-native species that were introduced through human activities or species resulting from selective breeding, hybridization or domestication that are now genetically or phenotypically distinguishable from their ancestors.

The (possible) biodiversity consequences of these species escaping into the natural environment are rarely studied, nor quantified in a consistent or standardised way. This is largely due to variability in how ecosystems respond, the delayed emergence of ecological effects, and the complexity of interacting factors that influence biodiversity. Despite this, clear cases of severe biodiversity impacts are known, e.g. crayfish introductions in Europe or (big head) carp introductions in the USA.

Policy makers, including aquaculture third-party certification schemes, are challenged with regulating the culture of alien species as considerable resources and efforts are needed to intervene in controlling these species. This has resulted in the clear need for scientific risk assessments to evaluate, compare, and predict the magnitudes of the impacts of alien taxa and to determine and prioritise appropriate measures where necessary.

The Environmental Impact Classification of Alien Taxa (EICAT) is a unified assessment method based on the mechanisms of impact used in the International Union for Conservation of Nature (IUCN) Global Invasive Species Database. EICAT evaluates alien species against thirteen potential Impact Mechanisms (e.g. competition, hybridisation) based on evidence of observed harm and classified according to five Impact Categories (Minimal, Minor, Moderate, Major, Massive). Taxa categorised in the latter three categories are considered "harmful". In addition, the Methodology also has a category for taxa that are data deficient, when no alien populations are found, or not (yet) evaluated. Based on the outcome of the Impact Mechanism and Impact Category, policymakers are better informed regarding which interventions are relevant – and justifiable towards the industry.

Here we outline the use of the EICAT methodology as part of the Aquaculture Stewardship Council (ASC) Certification Programme. We draw upon several examples of assessed species to demonstrate how scientific risk assessments can inform policy setting.

# NUTRIENT DIGESTIBILITY, FAECAL CHARACTERISTICS, AND OXYGEN CONSUMPTION IN PIKEPERCH (*Sander lucioperca*) FED UNCONVENTIONAL FEED INGREDIENTS

V. Stejskal[1]*, F. Cerjak[2], R.M. Mass[2], S. Prakash[2], F. Kokou[2], J.W. Schrama[2], H.Q. Tran[1]

## Introduction

Pikeperch (*Sander lucioperca*) is an emerging species in aquaculture, valued for its high meat quality and increasing market demand (Stejskal et al., 2023). In its natural habitat, this carnivorous species primarily consume crustaceans, insects, and fish. Under commercial farming conditions, pikeperch are typically fed formulated diets with high protein levels ranging from 43% to 50% (Policar et al., 2019). These diets often require substantial inclusion of fishmeal sourced from marine environments – a practice that raises concerns regarding long-term sustainability due to declining fish stocks and the ecological impact on marine ecosystems. In this context, alternative protein sources such as insect meal derived from yellow mealworm (*Tenebrio molitor*) and krill meal (*Euphausia superba*) have gained attention as promising ingredients for aquafeeds. These ingredients are characterized by high protein content, a well-balanced amino acid profile, and high palatability for carnivorous fish species (Tran et al., 2022; Tran et al., 2025). The present study assessed the digestibility of nutrients and energy from these alternative feed ingredients in pikeperch. The findings aim to provide insights that support the development of future feed formulations for this species.

## Materials and methods

Two ingredients, including defatted yellow mealworm (*T. molitor*) (TM), and krill meal (*E. superba*) (KM) were evaluated for nutrient digestibility. A control diet (CON) was formulated, containing 50% crude protein, 15% lipid, and 22 MJ/kg with fishmeal as a dominant protein source, in order to meet the nutrient requirements of pikeperch (Nyina-Wamwiza et al., 2005). The other two test diets contained 80% of CON, diluted by 20% with the corresponding test ingredients (TM and KM), abbreviated diets as TMD and KMD, respectively. To these diets, 0.2% yttrium oxide ($Y_2O_3$) was added as an inert marker to determine nutrient digestibility. Experimental diets were produced by a 2-mm die extruder by Research Diet Services, Netherlands. Fish were fed with the respective diets at 2% body weight for a duration of 8 weeks. During the last four weeks of the experiment, nutrient digestibility (dry matter, ash, crude protein, fat, carbohydrate, energy, phosphorus and calcium), waste production, and faeces recovery of the eight diets was determined. Moreover, oxygen consumption and ammonia production were determined from week 3 to week 7. Faeces particle size (quality) was determined from week 6 to week 8; faeces recovery was determined during week 8 after a 72-hour faeces collection.

## Results

### *Growth performance*

Dietary treatment did not significantly affect survival rate, growth indices, and feed utilization in pikeperch (Table 1).

### *Nutrient and energy digestibility*

Nutrients and energy in KM appeared to be significantly better digested by pikeperch than TM ($P < 0.05$) regarding dry matter, protein, lipid, total carbohydrate, and energy (Table 2).

### *Faecal characteristics*

There was no significant difference on faecal size distribution and recovery of pikeperch fed experimental diets (Table 3).

Collected faeces samples of pikeperch fed three diets are presented in Figure 1.

*(Continued on next page)*

Table 1. Survival rate and growth performance of pikeperch fed three diets for 8 weeks.

| | Experimental diets | | | SEM | ANOVA P-value |

Table 4. Oxygen consumption of pikeperch fed three experimental diets

| | Experimental diets | | | SEM | ANOVA P-value |
|---|---|---|---|---|---|
| | CON | KM | YMW | | |
| Oxygen consumption (mg $O_2$/kg$^{0.8}$/min) | 1.61 | 1.60 | 1.65 | 0.02 | 0.54 |
| Oxygen consumed/DM feed (g/kg) | 384.60 | 383.13 | 373.92 | 4.04 | 0.55 |
| Oxygen consumed/Digestible Energy (mg/kJ) | 20.41 | 19.92 | 19.34 | 0.23 | 0.14 |

***Oxygen consumption***

There was no significant difference in oxygen consumption of pikeperch fed experimental diets (Table 4).

## Conclusion

Inclusion of 20% unconventional protein sources in the diet did not significantly influence the survival rate, growth performance, or feed utilization of pikeperch (*S. lucioperca*), indicating that this species can accept such protein sources without adverse effects on performance or palatability. Digestibility assessments demonstrated that nutrients and energy derived from krill meal are efficiently utilized by pikeperch, highlighting its potential as a dietary protein source. However, the use of mealworms should be approached with caution due to their relatively low protein digestibility. The inclusion of both mealworm and krill meal did not result in significant differences in faecal characteristics or oxygen consumption when compared to the control diets. These findings have important implications for the commercial aquaculture of pikeperch, particularly in the context of future feed formulation, as well as the management of waste collection and oxygen consumption in recirculating aquaculture systems.

## Introduction

The SAFE (SmartAqua4FuturE) project aims to revitalise EU freshwater aquaculture through a circular economy model that cuts emissions, protects biodiversity, supports sustainable feed, improves profitability, and generates jobs. It focuses on converting waste from recirculating (RAS) and integrating multi-trophic aquaculture (IMTA) into valuable resources: dried sludge for mushroom cultivation, liquid effluents for microalgae, duckweed, and watercress, which feed mealworms and redworms. These biomasses enrich feeds for European freshwater species. This study examines mealworm frass as a substrate for *Pleurotus ostreatus*, producing both edible mushrooms and protein-rich stems for aquaculture feed.

## Materials and Methods

Substrates containing 0–15% mealworm frass were prepared for *P. ostreatus* cultivation. Fruiting bodies and stems were harvested separately. Chemical analyses included determination of crude protein, amino acid profile, and fatty acid composition, with emphasis on polyunsaturated fatty acids (PUFAs). β-glucan content was quantified, and antimicrobial activity of dichloromethane extracts from stems was tested against *Tenacibaculum maritimum*, a major bacterial pathogen in aquaculture.

## Results

Increasing frass inclusion significantly enhanced the protein content of both mushroom stems (from 7.78% to 22.31%) and fruiting bodies (from 24.74% to 30.99%), with enrichment in essential amino acids at 12.5–15% frass levels. PUFAs were predominant in both tissues across treatments. β-glucan content decreased with higher frass inclusion. Antimicrobial assays revealed that dichloromethane extracts from stems cultivated on 12.5–15% frass inhibited *T. maritimum* growth.

## Conclusion

Mealworm frass is a promising sustainable substrate for *P. ostreatus* cultivation, enhancing nutritional and functional properties of mushrooms while providing protein-rich biomass for aquaculture feed. This approach supports environmental and economic sustainability in EU freshwater aquaculture by closing nutrient loops and generating value-added products from waste streams.

# NEITHER MATURE NOR NEW BIOCARRIERS INFLUENCE THE ESTABLISHMENT OR PERSISTENCE OF YERSINIA RUCKERI

K.T. Stiller*, E. Burgerhout, H. Brenne, C. C. Lazado

Nofima AS, Tromsø, Norway
Kevin.Stiller@nofima.no

## Introduction

The biological removal of nitrogen compounds such as ammonium and nitrite in recirculating aquaculture systems (RAS) is primarily facilitated by nitrifying bacteria residing within the biofilter. This structure is often referred to as an "ecosystem within an ecosystem" due to the diverse microbial assemblages it supports—each with distinct metabolic and physiological traits—which collectively convert toxic ammonium excreted by fish into the less harmful nitrate through a two-step nitrification process. Monitoring studies have revealed that the biofilter represents a unique microbial niche, characterized by a notably low abundance of pathogen-related species, such as *Moritella viscosa, Psychrobacter immobilis,* and *Aeromonas salmonicida*. One plausible hypothesis is that the resident microbial communities exert inhibitory effects on the colonization of these pathogens, thereby maintaining a protective microbiological environment within the biofilter. However, the mechanisms governing pathogen establishment and the influence of various environmental and operational factors on this process remain largely unexplored. It is further hypothesized that the introduction of pathogens into the biofilter—potentially triggered by disease outbreaks or microbial imbalances in the RAS—could disrupt the native microbial community. Such disturbances may negatively impact both the diversity and functional performance of the biofilter, thereby impairing nitrification efficiency and leading to suboptimal water quality characterized by elevated levels of toxic ammonium and nitrite. Additionally, many mechanical components within RAS are not easily accessible, often leading to the generalized assumption that uniform cleaning and disinfection protocols are effective across the system. In reality, spatial heterogeneity can significantly influence the efficacy of these disinfection practices. A deeper understanding of pathogen establishment pathways is therefore essential for the development of targeted and effective disinfection strategies.

## Material and methods

A 30-day biofilter experiment was conducted under controlled environmental conditions at Nofima Tromsø, with the system maintained at 12 °C and a salinity of 12 ppt within an environmental chamber. The study was designed to evaluate the effects of *Yersinia ruckeri* introduction on biofilter function, using three treatments as part of an infection challenge. The first treatment involved waterborne exposure to Y. ruckeri at a defined concentration (XY concentration). The second treatment consisted of biomedia inoculation, wherein biofilter media were submerged for 24 hours in a Y. ruckeri suspension, subsequently rinsed with phosphate-buffered saline (PBS), and transferred to the experimental culture bottles. A preliminary laboratory trial confirmed that Y. ruckeri successfully adheres to autoclaved biocarriers after 24 hours of exposure. A third group, serving as a control, remained unexposed to Y. ruckeri. Nine 1-liter Schott bottles were used for the experimental setup, each filled with a mix of 85% mature biomedia and 15% autoclaved biomedia. Continuous aeration was provided via air stones connected to membrane pumps. Every three days, total ammonia nitrogen (TAN) levels were elevated to 4 mg $L^{-1}$ to simulate nitrogenous waste input, and removal efficiency was assessed after six hours. During the first two weeks, biomedia samples were washed with PBS and marine broth, then plated on Y. ruckeri-selective agar to quantify colony-forming units (CFUs). Concurrently, microbial communities present in the water phase were analyzed by filtering the culture water and extracting microbial DNA for further analysis. At the conclusion of the 30-day experiment, a pH-shift disinfection protocol was applied to evaluate whether disinfected biomedia could act as a reservoir for Y. ruckeri, thereby ensuring that desinfection measures effectively eliminate any remaining pathogenic bacteria.

## Results

Yersinia ruckeri was confirmed to attach to autoclaved biomedia within 24 hours of exposure. Among the experimental groups, the highest denitrification performance was observed in the treatment where the inoculated biomedia were washed with PBS buffer prior to their introduction into the system. Over the course of the experiment, a gradual decline in colony-forming units (CFUs) of Y. ruckeri was observed, indicating a reduction in the presence of the pathogen over time.

## Discussion

The results indicate that Yersinia ruckeri does not actively proliferate within the biofilm of the biomedia but can still be detected more than one week after a single infection event. While the presence of Y. ruckeri had no measurable impact on the denitrification performance of the biofilter, the PBS-washing of biomedia prior to use significantly enhanced nitrogen removal efficiency. This improvement may be attributed to the removal of older or inactive biofilm layers, thereby promoting more effective colonization by active nitrifying communities. Results from the disinfection phase of the experiment are still under analysis at the time of writing.

# VIBRIOS IN BIVALVES AND CRUSTACEANS – A SURVEILLANCE GAP FOR SEAFOOD SAFETY?

J. E. Storesund*, K. C. Grøndal, F. Håkonsholm, J. Øyro, B. T. Lunestad, C. S. Svanevik

Institute of Marine Research
Bergen, Norway
Email: julia.storesund@hi.no

## Introduction

Bacteria in the genus *Vibrio* are naturally found in marine and brackish waters and represent one of the main challenges to microbial seafood safety, where four species are of particular concern to human health; *V. cholera*, *V. parahaemolyticus*, *V. alginolyticus* and *V. vulnificus*. However, no regulations currently address the threat posed by human pathogenic vibrios. This is of particular concern for seafood products that are typically consumed without heat-treatment, such as oysters, where the presence of vibrios can lead to gastrointestinal infections of varying severity. Products meant to be heat-treated may also be an issue, as bacteria on these products can contaminate other food-items during preparation. In addition, products imported from countries with frequent use of antibacterial agents may contain resistant bacteria and contribute to spreading antibiotic resistance.

## Materials and Methods

In 2021-2024, 96 samples of fresh or frozen bivalves and crustaceans were analysed for the presence of vibrios as part of a monitoring programme by the Norwegian Food Safety Authority (NFSA) for veterinary control on seafood products imported to Norway from countries outside EU/EEA [1–5]. In addition, in 2025, 32 samples of fresh bivalves collected along the Norwegian coast, were analysed. Samples were analysed according to the NMKL method no. 156. Further, two isolates of *V. parahaemolyticus* from imported shrimp were phenotypically tested for antibiotic resistance, genome sequenced and analysed for the presence of genes associated with antibiotic resistance.

## Results

From the imported seafood samples, 12 of 96 samples contained one or more of the four target vibrio-species[1–5]. Of these, five consisted of fresh oysters, whereas the remaining seven vibrio-positive products consisted of frozen shrimp and oysters. Oyster samples were positive for *V. alginolyticus*, whereas shrimp samples were positive for *V. parahaemolyticus* or *V. cholera*. Two *V. parahaemolyticus* isolates examined further expressed phenotypic resistance and harboured resistance genes against clinically important antibiotics, including antibiotics banned in aquaculture. For the samples of Norwegian produced bivalves, 30 of 32 were positive for *Vibrio* spp., with preliminary analyses indicating the presence of *V. alginolyticus* and *V. parahamolyticus*. The two *V. parahamolyticus* strains tested further expressed phenotypic resistance, and harboured resistance genes against several clinically important antibiotics[6].

## Conclusion

These findings highlight the need to strengthen the surveillance and regulatory framework for pathogenic *Vibrio* spp. in seafood.

anja.striberny@nofima.no

## Introduction

Atlantic salmon smolt production in Norway has been intensified over the past years and has led to concern about increasing prevalence of life-style diseases in cultured Atlantic salmon (Frisk et al. 2021). Temperature and water salinity are critical rearing parameters that differ between smolt hatcheries (Kristensen et al. 2011) and directly affect Atlantic salmon physiology. While several studies have examined these factors in short-term experiments (Handeland et al. 1998, Handeland et al. 2000), there is limited documentation on how smolt rearing history changes long-term growth, welfare, and slaughter quality. In this study, we evaluated the short- and long-term effects of four temperature groups: 8°C, 12°C, 14°C, and a group with temperature increased from 8°C to 12°C. We hypothesized that lower rearing temperature in fresh water would result in better growth at sea. In addition, we evaluated the potential benefits of acclimatizing smolts to salinity prior to seawater transfer. All treatments were assessed in both flow-through (FT) and RAS systems.

## Material and Methods

The experiment consisted of a smolt production phase, when treatment groups were established, followed by seawater grow-out until slaughter (Fig. 1). The first phase of the experiment was conducted simultaneously in flow-through and RAS systems at Nofima's Research Station for Aquaculture in Sunndalsøra, Norway. A total of 4800 parr (10 g) were distributed across 32 rearing units and pit-tagged after reaching 20 g. All fish were exposed to a photoperiodic regime consisting of over 5 weeks of 12 hours of light and 12 hours of darkness, followed by 350 degree-days of continuous 24-hour light to induce smoltification. After smoltification, water salinity was either increased directly to 32 ppt (A), or gradually over a three-week period (B). Thereafter, 2560 smolts were and stocked in net pens at a seawater facility for grow-out. During the seawater period, the fish were kept in a common garden design. Fish and water samples were collected multiple times throughout phase 1, and at the end of the seawater phase. The analysis of response variables included water quality characterization, growth, survival, and several morphological and lab-based welfare indicators (Noble et al. 2018).

## Results and discussion

Throughout the experiment, the fish from the different treatments had low mortality and a seemingly good welfare status. During the freshwater phase, all groups developed typical smolt characteristics, indicated by an increased Na+, K+-ATPase (NKA) activity in gills, kidney, and intestine in response to 24 hours light underlining the importance of photoperiod for smolt development, irrespective of temperature. Even though the NKA development was similar in all groups, overall lower levels of NKA activity in fish held at 8°C and a less pronounced reduction in condition factor, suggest that these fish may have needed more time than the 350 degree-days to complete smoltification. Yet, serum analyses after seawater challenge tests before seawater transfer showed good and similar hypoosmoregulatory ability in all groups. Interestingly, there were distinct differences in water quality between FT and RAS systems, with an accumulation of major cations and $CaCO_3$ seen in RAS, irrespective of temperature regime, over time. This finding can potentially explain differences seen in kidney NKA activity between FT and RAS.

*(Continued on next page)*

Surprisingly, salmon from the 12°C and 14°C had a significantly higher thermal growth coefficient, and larger final body mass (4.4 *vs* 3.3 kg) than their conspecifics from the 8°C and 8-12°C groups. Also, the slaughter quality score was higher in these groups. Yet, there was a tendency for smaller hearts in the fish of the 12°C and 14°C groups at the end of the experiment, and it can be speculated if this could have compromised these fish in case of a disease outbreak or during strong stress exposure, however, no disease outbreak occurred, and all groups handled exposure to lice treatments equally well. During the seawater phase the fish experienced almost ideal growth conditions, with low stress and high-quality feed. Under favorable conditions, early rearing temperatures up to 14°C lead to faster production of high-quality salmon for consumption. However, potential effects on robustness should be investigated in future studies.

**Ethical statement on animal welfare**

The experiment was conducted following the EU legislation on animals in science and was approved by the Norwegian Food Safety Authority (ID#29982).

# TESTED OFFSHORE NATURE INCLUSIVE DESIGN AS A NATURE RESTORATION MEASURE BASED ON A FILTER APPLICATION CONCEPT SHOWCASING THE POTENTIAL VALORISATION OF EXISTING AND PLANNED OFFSHORE INFRASTRUCTURE

Eva Strothotte[1]*, Tim Staufenberger[1], Jacob Nimz[1], and Jakob F. M. Becker[1]

**Introduction:**
The biodiversity crises, habitat degradation along with a rapidly increase use of marine areas are major challenges worldwide and especially within the EU. The associated start of implementation of the EU Nature restoration regulation in aquatic environments fuels the discussion on suitable measures. These urgent requirements and rapidly progressing demands also affect aquaculture operations and cannot ignored by them. Offshore multi-use projects are currently developing concepts and testing different solutions to find and push useful measures. Nature inclusive design (NID) and artificial reefs (AR), have raised significant attention, as being a potential valuable marine ecosystem management tool, compensating human induced habitat destruction and its consequences for marine wildlife. However, a positive impact for the environment, can only be ascertained to very few installations. Missing concepts, insufficient data of sound experimental design, quantifiable objectives, monitoring strategy and data accessibility or analysis are the main reasons why the vast AR/NID-installations are not reliable to demonstrate an impact due to recent metadata analysis studies (Paxton et al., 2020). While this research gap has been increasingly acknowledged in recent years, still only a few approaches addressed the missing points for an objectively successful AR/NID-installation. Due to the ongoing expansion of marine infrastructure and offshore wind industry the pressure on habitat situation is growing but also new options arise for potentially novel installation opportunities and multi-use efforts. Within the offshore multi-use project ULTFARMS a concept with a filter-based approach has been developed and applied based on proven installations to conceptualize a species- and site-specific AR/NID-installation. The results of first tests in offshore conditions provided invaluable technical insights for future upscaled scenarios. A novel, in-house developed attachment technique, enables a non-disruptive, flexible positioning of add-ons for both existing and future offshore infrastructure, such as monopiles.

**Methodology:**
The filter approach concept builds on three sequential steps, containing multiple interrelated aspects (non-hierarchical) found in literature (see figure 1)

1. Background analysis:
The ULTFARMS Baltic Sea German offshore pilot, the research platform has been investigated before the design phase to deliver the baseline for habitat developments, cumulative human pressures, historic record of past species abundances and the current status of populations. To be an effective management tool, NID installations must employ SMART objectives prior to the installation as specific, measurable, achievable, realistic and time-bound (Higgins et al. 2022). The dramatic decline of fish populations has been identified as one of the most obvious negative changes for this area. Therefore, this restoration measure focuses to provide lost habitat for juvenile fish.

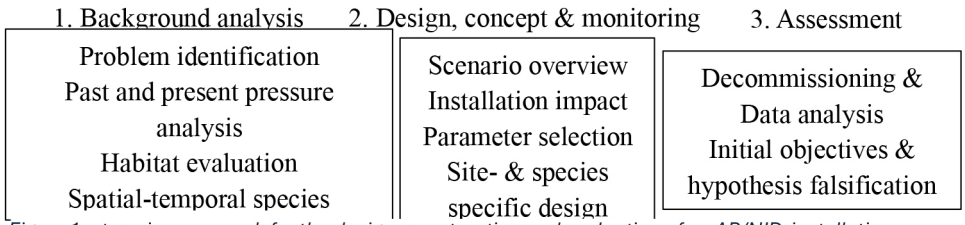

*Figure 1: stepwise approach for the design, construction and evaluation of an AR/NID-installation.*

*Figure 1: Nature inclusive design (NID) installation equipped with species-specific materials attached to the monopile of FINO2, Baltic Sea, Germany*

2. Design, concept & monitoring

A total of 42 studies have been selected, to fine-tune the site- and species-specific design. While there are limitations in predictability recent studies found good correlation between specific design requirements and population development. Fish diversity has proven to be enhanced via the provision of three-dimensional habitat that incorporates a wide range of microhabitat sizes and types (Taira et al., 2024).

3. Assessment

Stationary underwater cameras fulfil a range of requirement for offshore monitoring as very low maintenance schedules, automatic self-cleaning, continuous data over a longer period of time for monitoring fish and options for AI based automatic species identification.

**Results & discussion:**

Throughout this pilot-scale deployment, substantial amounts in both quantity and quality of fish assemblages have been observed in and around the installation. The data show a first proof of effectiveness of this NID-installation, the technical and logistical feasibility of a novel attachment technique within an existing windpark. Future experimentally sound studies shall incorporate the above-mentioned filter approach to implement, site- and species-specific AR/NID-installations.

Based on these transferable results of a modular, flexible and scalable NID design tested on an existing offshore monopile future upscaled scenarios for numerous offshore windparks are feasible.

# THE IMPACT OF REARING ENVIRONMENT ON LARVICULTURE IN PIKEPERCH (SANDER LUCIOPERCA) UNDER COMMERCIAL CONDITIONS – IMPROVEMENTS BY MODIFYING PHOTOPERIOD, ARTEMIA ENRICHMENT, AND TEMPERATURE

Marcus Stüeken*, Ferenc Zoltán Demény, Jelena Stanivuk, Uroš Ljubobratović

## Introduction

Intensive pikeperch larviculture presents a challenging task and is still the limiting factor for the expansion of successful production. In addition to a high level of cannibalism, which causes high mortality rates, this is primarily due to the quality of the fingerlings produced. The loss of quality is significantly reflected in the deformation rate, which in turn increases cannibalistic behavior. In pikeperch, it is known that this phenomenon mainly occurs between days 19 and 39 post-hatch, depending on the rearing temperature, which is a rather long period from a production point of view. In addition to an existing dark period, cannibalism is also promoted by the habituation to commercial dry feed, as the nutrient composition changes drastically and the prey stimulus changes due to a lack of agility. However, the drastic change in the nutrient composition, especially if no appropriate biosynthesis of enzymes has taken place, caused by live food reduction, can lead to nutritional deficiencies and consequently to deformities. Nevertheless, the rearing temperature is a success-determining factor in addition to those already mentioned being decisive for the rate and quality of metabolism, but can also detriment development. Overall, it is evident that all effects have common factors and interact among each other.

## Material & Methods

Besides the effect of two different photo regimes (16/L:8/D vs 24/L:0/D), two different rearing temperatures (16 °C vs 19 °C) were examined in two identical recirculated systems. Simultaneously, we compared the influence of the dietary enrichment of *Artemia* (enriched vs non-enriched). The trial was conducted in a multi-factorial design and groups were duplicated (model: $2^{\wedge 3}$; 8 combinations; 16 tanks). During 47 days, multiple variables were followed: growth parameters - body weight (g) and length (mm) and their coefficients of variation, condition factor and specific growth rate. In addition, the occurrence of jaw and spine deformities, survival and swim bladder inflation dynamics were assessed. Main effects and interactions were analyzed with SPSS 29.0 (IBM Co., Armonk, NY, USA) in the General Linear Model, Univariate ANOVA. Afterwards, Principal Component Analysis and Pearson correlation (n-1) were applied to compare the strength of factors. (XLSTAT, Long Island: New York, NY, USA, 2023).

## Results

Our findings revealed that a higher temperature had significant positive effect on the speed and efficacy of swim bladder inflation at day 12 ($p = 0.003$), day 23 ($p = 0.002$), and 47 ($p < 0.001$) post hatch, as well as on the total length ($p < 0.001$) and wet weight ($p < 0.01$) on day 47 post hatch. Furthermore, a higher rearing temperature improved homogeneity in growth, visible by a lower coefficient of variation (CV wet weight: $p = 0.014$). Considering photoperiod, it became apparent that it positively influenced growth shown in a higher wet weight ($p = 0.037$) at final sampling time. The third factor investigated, the enrichment of the *Artemia*, had a significant effect on the survival rate ($p = 0.005$). These results indicate that rearing pikeperch larvae at a relatively higher temperature of 19 ºC could improve the rearing success, while the enrichment of *Artemia* nauplii seems necessary. To reach a stable juvenile production, further investigations are required to determine the most efficient conditions with all crucial parameters e.g. a practical photo regime, algae product and its application rate (i.e. turbidity level), as well as applying older stages of *Artemia* (i.e. Instar II) aiming for reliable, efficient and universally applicable protocol.

# POPULATION DYNAMICS OF *Auchenoglanis occidentalis* FROM DADIN-KOWA DAM, GOMBE STATE, NIGERIA

Fish and its resources has been an integral component of food security in many countries across the world, this is not limited to only coastal areas but also encompasses inland water bodies (Ahamed, Akter, Hasan, & Chakma, 2024). Human nutritional requirements depends also largely upon the resources obtained from fish such as lipids, high quality proteins (Nazeef, Ja'afaru, Ka, & Kabiru, 2021), and numerous minerals such as iodine and phosphorous (Ahamed *et al*., 2024).

The population dynamic parameters of *Auchenoglanis occidentalis* from Dadin-Kowa reservoir were studied. Population dynamic parameters such as growth, mortality and recruitment patterns were analyzed using length frequency data over 12-month period employing FiSAT II software. Findings revealed that **LWR** (***b*** constant) = 2.88, **K** = 0.72 $^{-yr}$., **L∞** = 40.91 cm and $\mathbf{T_{max}}$ = 3.57 years and **Θ' =** 3.14.

Mortality indices revealed that natural mortality (**M** = 1.39), fishing mortality (**F** = 0.22) and exploitation ratio (**E** = 0.14), **Lc/L∞ =** 0.48, **Emax** = 0.64, while **Lopt** = 26.4 cm. Uni-modal recruitment peak observed with **Lm** = 27.3 cm. Restocking program is suitable to ensure its continuous existence as it seems to have low population.

# QUANTIFYING THE IMPACT OF SUBOPTIMUM TEMPERATURE AND LOW DISSOLVED OXYGEN ON THE PRODUCTION BIOLOGY OF POST-SMOLT ATLANTIC SALMON *Salmo salar* USING PROTEOMICS

Atshaya Sundararajan*[a,b], Chris G. Carter [a,b], Gianluca Amoroso [a,b], Richard Wilson [c] and Maxi Canepa [a,b]

[a]Blue Economy Cooperative Research Centre, PO Box 897, Launceston, Tasmania, Australia
[b]Institute for Marine and Antarctic Studies (IMAS), University of Tasmania, Australia
[c]Central Science Laboratory, College of Science and Engineering, University of Tasmania, Hobart 7001, Australia
E-mail: Atshaya.Sundararajan@utas.edu.au

**Introduction**

Temperature is the master abiotic factor for salmon growth. Atlantic salmon has a wide thermal range for growth, ranging from 12-18°C. Tasmania, which produces the majority of Atlantic salmon in Australia, is a global hotspot for ocean warming, and water temperatures exceed 18°C for extended periods during marine heat waves, which are predicted to become more frequent. Suboptimum water temperature and low dissolved oxygen (DO) are key drivers of reduced feed intake and growth during summer, yet their impact on salmon production biology remains poorly understood at the proteome level. This study used proteomics to investigate the cumulative impact of sub-optimum temperature and low DO on the growth performance and nutritional physiology of post-smolt Atlantic salmon.

**Materials and Methods**

A total of n = 1144 post-smolts with a mean weight of 419.4 ± 3.2 g were distributed across 12 indoor RAS tanks and were exposed to simulated summer conditions (19°C; 80% DO) followed by an autumn recovery (15°C; 100% DO) for 84 and 42 days, respectively. Liver and white muscle tissue samples were collected from targeted individuals for label-free quantitative proteomics (from known genotypic groups of the Tasmanian Selective Breeding Program) expected to show high, medium and low growth performance (n = 8 samples per group per time point; n = 24 per tissue per time point) after summer stress and autumn recovery, referred to as post-thermal and post-recovery time points, respectively.

**Results**

Proteomic analysis of liver and white muscle protein extracts identified ~6300 and ~1800 protein groups, respectively, and t-test analysis (FDR < 0.05) identified 3650 and 257 differentially abundant proteins (DAPs) between different time-points. Bioinformatic analysis of the liver revealed that proteins increased in the post-thermal group were associated with functional terms, including endoplasmic reticulum stress, proteasome activity, heat-shock response, antioxidant defence, amino acid catabolism, fatty acid degradation, carbohydrate metabolism, and oxidative phosphorylation Significant proteins included SERPINh1, previously identified as a key biomarker of thermal stress in Atlantic salmon (Mendoza-Porras et al., 2024). In contrast, functional terms associated with the proteins increased in the post-recovery group included ribosome biogenesis, cholesterol, and unsaturated fatty acid biosynthesis. In white muscle, enriched terms were directly or indirectly related to protein turnover processes at both time points. Statistical analysis for high vs low performance groups identified 306 and 273 DAPs in the liver between timepoints, respectively, and 81 DAPs ($p < 0.05$) at both time points in the white muscle. Enrichment analysis revealed differential mechanisms across the groups tested in this experiment.

**Conclusion**

Overall, this study provides an improved understanding of the physiological mechanisms operating in Atlantic salmon under suboptimum environmental conditions, with protein turnover being the most differentially affected process across tissues. Our findings also indicate that post-smolt salmon have biological capacity to recover and achieve compensatory growth at the protein level. Additionally, proteomic signatures across different genotypic groups were identified, offering a scope for future research towards climate-proofing the selectively bred Tasmanian salmon.

# BENCHMARKING ATLANTIC SALMON *Salmo salar* PERFORMANCE TO TEST TRANSLATION OF RESEARCH FROM EXPERIMENTAL TO COMMERCIAL SYSTEMS USING PROTEOMICS

Atshaya Sundararajan*[a,b], Chris G. Carter [a,b], Gianluca Amoroso [a,b], Richard Wilson [c] and Maxi Canepa [a,b]

[a]Blue Economy Cooperative Research Centre, PO Box 897, Launceston, Tasmania, Australia
[b]Institute for Marine and Antarctic Studies (IMAS), Taroona, University of Tasmania, Australia
[c]Central Science Laboratory, College of Science and Engineering, University of Tasmania, Hobart 7001, Australia
E-mail: Atshaya.Sundararajan@utas.edu.au

## Introduction

Temperature regulates all aspects of growth and physio-metabolic processes in Atlantic salmon. In Tasmania, the production of Atlantic salmon is highly exposed to the effects of climate change due to the increasing prevalence of marine heatwaves. However, further research on the accuracy of experiments in controlled conditions in predicting farmed fish response to natural conditions is highly recommended. In this study, the cumulative effects of suboptimum environmental conditions on large salmon production biology were investigated using proteomics, and by comparing two genetically equivalent populations with similar size: one grown in an experimental recirculating aquaculture system (RAS) and the other in a commercial pen.

## Materials and Methods

In the RAS, n = 631 large salmon (mean weight ~2.5 kg) were exposed to a simulated summer of 19°C and 80% DO for 84 days, followed by 40 days of autumn recovery at 15°C and 100% DO, referred to as post-thermal and post-recovery time points, respectively. The liver and white muscle tissue samples were collected from targeted individuals (from known genotypic groups of the Tasmanian Selective Breeding Program) expected to show high, medium and low growth performance (n = 8 samples per group per time point; n = 24 per tissue per time point). In addition, this study collected same type and number of tissues (n = 24) from genetically equivalent individuals from a commercial pen at the end of a natural summer (~16.75°C; 78.92 % DO) to compare the proteomic response with the RAS simulated summer.

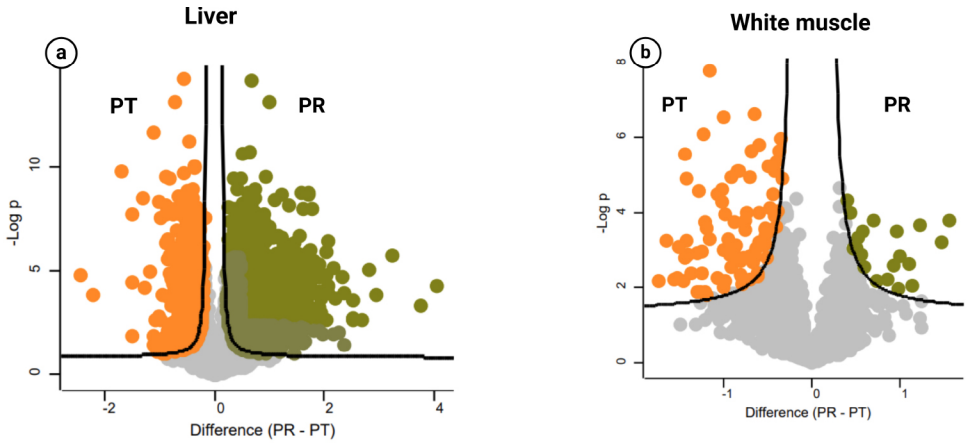

Figure 1: Volcano plots displaying the differentially abundant proteins (DAP) expressed in liver and white muscle at PT vs. PR, using FDR < 0.05 and S0 = 0.1. PT; Post-thermal PR; Post recovery.

*(Continued on next page)*

**Results**

In the RAS, proteomic analysis of the liver and white muscle identified ~6900 and ~1900 protein groups, respectively. Statistical analysis (FDR < 0.05) of the liver and white muscle proteomics data identified 2614 and 119 differentially abundant proteins (DAPs), respectively, between the two timepoints (Figure 1). When comparing simulated with natural summer, 3983 and 357 DAPs distinguished RAS from the pen. In the RAS, gene ontology analysis of the liver identified terms related to protein folding, SERPINh-1, and lactate metabolism among the proteins increased in the post-thermal group, and lysosomes, ribosome biogenesis, and unsaturated fatty acid biosynthesis in post-recovery. In white muscle, glucose and pyruvate metabolism, were enriched in both timepoints, with protein folding enriched only at post-thermal. In the pen, gene ontology analysis revealed shared cardinal markers (SERPINh-1), and mechanisms (endoplasmic processing, protein turnover) related to thermal stress with the RAS, while immunomodulatory proteins of innate and humoral responses were enriched only in the pen, capturing the different nature of commercial environment.

**Conclusion**

Overall, the results showed increased energy reallocation during suboptimum environmental stress and prolonged physiological recovery in large Atlantic salmon. Additionally, the findings support the use of an experimental RAS as a potential translational tool for commercial applications.

# STUNNING NEWS: EFFECTS OF IN-WATER ELECTRICAL EXPPOSURE ON BRAIN FUNCTION IN NILE TILAPIA (*Oreochromis niloticus*) AND AFRICAN SHARPTOOTH CATFISH (*Clarias gariepinus*)

Erika Sundell[1]*, Ulla Saarinen[1], Jeroen Brijs[2], and Albin Gräns[1].

[1] Department of Animal Environment and Health, Swedish University of Agricultural Sciences
[2] Institute of Zoology, University of Innsbruck, Innsbruck, Austria

Email: erika.sundell@slu.se

**Background**

Nile tilapia (*Oreochromis niloticus*) and African sharptooth catfish (*Clarias gariepinus*) are two important aquaculture species whose global production have increased significantly over the last decades (FAO, 2022). Ensuring a humane end of life for these species is essential for a number of interconnected reasons, spanning ethical, legal, scientific, and societal considerations. Common slaughter methods for these fish, such as asphyxiation, gill cutting, decapitation and/or evisceration, fail to meet the standards of humane slaughter, which require the use of an effective stunning method prior to killing (EFSA, 2004; Lines and Spence, 2011; Robb and Kestin, 2002; WOAH, 2019). Electrical stunning has been proposed as a more humane alternative (WOAH, 2019) and species-specific laboratory studies have demonstrated that if enough electrical energy is delivered it can induce a loss of sensibility for at least one minute in both tilapia and catfish. Further, when combined with throat cutting and immersion in ice slurry, no signs of recovery were observed for either species during a 30 min post-stunning period (Brijs et al., 2021; Sundell et al., 2024). While these findings highlight a potential of electrical stunning, the effectiveness and feasibility at scale warrants further validation under commercial conditions. Therefore, we designed a study to assess the effectiveness of in-water electrical stunning of these commercially important species at the farm level.

**Material and methods**

In-water electrical stunning was tested on tilapia and catfish at a commercial RAS farm in Skåne, Sweden, using a custom-built electrical stunner (Ace Aquatec Ltd., UK; AC source, 50 Hz). Fish were captured and subjected to an electrical stunning protocol under controlled conditions (785 ± 5 $\mu$S cm$^{-1}$, 21 ± 0.3 °C), after which they were instrumented with electroencephalography (EEG) electrodes to measure brain activity for 10 min. Stunning effectiveness was assessed via the presence or absence of visually evoked responses (VERs) in the EEG. Four stunning protocols, with regards to electrode configuration and electric intensity, were tested: (*i*) head-to-tail (HT) standard intensity, (*ii*) side-to-side (SS) standard intensity, (*iii*) SS high intensity, and (*iv*) SS high intensity combined with exsanguination and ice slurry immersion. The stun duration was 40 s for catfish and 30 s for tilapia. Low intensity was 11.63 ± 0.05 V cm$^{-1}$ (0.979 ± 0.025 A dm$^{-2}$) and 10.10 ± 0.04 V cm$^{-1}$ (0.870 ± 0.029 A dm$^{-2}$) for catfish and tilapia, respectively, while high intensity was 17.48 ± 0.04 V cm$^{-1}$ (1.696 ± 0.038 A dm$^{-2}$) and 13.52 ± 0.04 V cm$^{-1}$ (1.135 ± 0.014 A dm$^{-2}$) for catfish and tilapia, respectively.

**Results**

A Kaplan meier analysis of time until recovery of sensibility post-stunning revealed no significant differences between treatment groups for tilapia ($\chi^2(3)=3.856$, P=0.277) but a significant effect for catfish ($\chi^2(3)=41.586$, P=<0.001; Figure 1). In catfish, 100 % insensibility was achieved in the combinational group (*iv*) while all other treatments (*i.e.,* groups *i-iii*) reached only 0-20 % (Figure 1). With the high intensity SS stunning, 25 % of tilapia recovered VERs within 54-77 s, and 80 % of catfish within 43-269 s. Duration of VERs differed significantly between groups for both species (tilapia: $\chi^2(3)=8.657$, P=0.034; catfish: $\chi^2(3)=31.119$, P<0.001). In tilapia, the combinational group (*iv*) differed significantly from both HT (*i;* P=0.007) and SS low intensity (*ii;* P=0.042). In catfish, the combinational group (*iv*) differed from all other treatments (*i-iii;* P<0.001), and SS high intensity (*iii*) had shorter VER duration than SS low intensity (*ii;* $\chi^2(3)=5.145$, P=0.023).

**Conclusion**

In contrast to the results of our recent laboratory studies, the combination of electrical exposure, exsanguination and ice slurry immersion failed to prevent recovery in tilapia. While the same procedure achieved 100% insensibility in catfish, the rapid return of VERs, in some cases as early as within 43 s post-stunning, show that both throat cutting and immersion in ice slurry must occur immediately after stunning to prevent recovery during exsanguination and chilling. Until a clearly defined and practically feasible stun-to-stick interval can be established, the in-water electrical stunning as tested here cannot be recommended for either Nile tilapia or African sharptooth catfish. These findings highlight the need to refine stunning protocols under commercial conditions using species-specific parameters and precise timing to ensure humane slaughter of warm-water fish.

*(Continued on next page)*

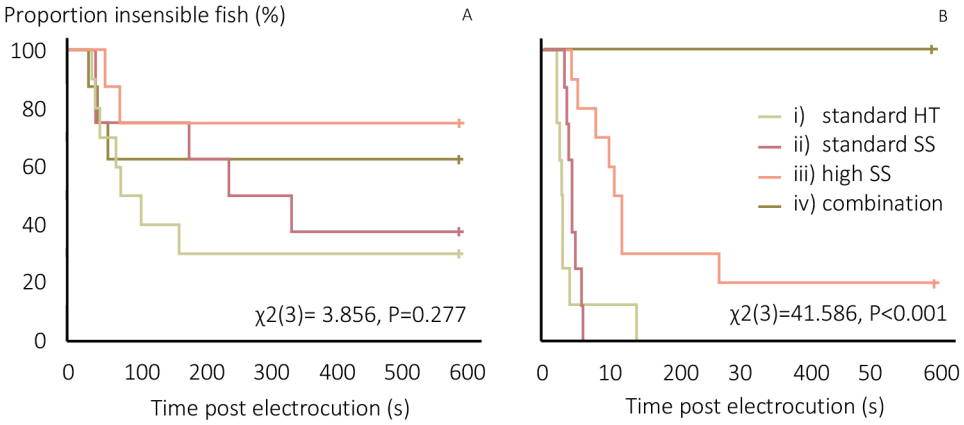

Figure 1. Kaplan meier curves showing the proportion of insensible fish post-stunning using 4 different protocols in A) Nile tilapia (*Oreochromis niloticus;* n=34) and B) African sharptooth catfish (*Clarias gariepinus;* n=36). The protocols (i-iv) refer to electrode configuration (head to tail=HT, and side to side=SS), and electrical intensity (standard or high). In the combination, electrocution was followed by exsanguination and ice slurry immersion. Cases were censored if no recovery occurred 10 min post-stunning (*i.e.,* at time 600 s), as indicated by the vertical line at time 600 s.

# THE NORDIC MASTER'S PROGRAM IN SUSTAINABLE PRODUCTION AND UTILISATION OF MARINE BIORESOURCES: A MODEL OF SUCCESSFUL INTER- AND TRANSDISCIPLINARY COLLABORATION IN HIGHER EDUCATION

Jonathan Roques*, Viviane Verlhac-Trichet, Camille Leblanc, Barry Costa Pierce, Kristina Sundell

SWEMARC
The Swedish Mariculture Research Center
University of Gothenburg
Gothenburg 413 90, Sweden
Jonathan.roques@bioenv.gu.se

In 2019, the Nordic master's program in Sustainable Production and Utilization of Marine Bioresources (MAR-BIO) was established by 4 Nordic universities: Gothenburg (Sweden), Nord (Bodø, Norway), Akureyri (left in 2022) and Hólar (both Iceland) in collaboration with the University of New England (Maine, USA). This unique trans- and interdisciplinary program aims to educate the next generation professionals in sustainable blue bioeconomy by combining natural sciences with environmental and social sciences, as well as economics and law. It introduces students to key aspects of the blue bioeconomy and its main industries in each partners' country. In Norway, focus is on salmon farming, in Iceland on the fishing industry and its sustainable use of natural resources and in Sweden on low-trophic aquaculture. All 3 countries jointly teach technical development of sustainable and innovative aquaculture systems, novel alternative feed ingredients and fish health and welfare in circular systems.

The program places strong emphasis on mobility and requires at least 30 ECTS to be earned outside the home university. The first course (15 ECTS) is a mandatory and hybrid course consisting of 3 modules of 1-2 weeks online, each followed by 1 week of on-site visits to each country. These visits include study tours to industrial partners and presentations of ongoing research (Fig.1). In the second semester, students apply for classes at 1 or more of the partner universities (15 ECTS) and the program is finalized by a 60 ECTS master's thesis course at any of the partner universities.

Now entering its 6$^{th}$ year, the master's program has grown from 5 students in the first cohort to 25. In this presentation, we will provide a detailed overview of the program, highlighting the transdisciplinarity and the future within this most rapidly growing and diversifying area of sustainable food production. We will show how the program offers a diverse network of contacts to the students both within the established industry, among innovative entrepreneurs and with authorities in the 3 partner countries. You will see the unique curriculum of the first mandatory course that lay the foundation for this successful cross-country collaboration in higher education, with potential to expand beyond the Nordic countries.

# NUTRITIONAL REPROGRAMMING OF HEPATIC IMMUNOMETABOLISM IN JUVENILE SPOTTED WOLFFISH (*Anarhichas minor*)

Joshua L. Superio[*1,2], Kathrine R. Bakkemo[3], Atle Foss[4], Jorge Galindo-Villegas[1]

## Introduction

Nutritional inputs can reprogram immunometabolic pathways, reshaping the balance between energy metabolism and immune function in cultured fish species. Modern aquafeeds differ markedly from natural diets, with protein and lipid sources increasingly derived from alternative ingredients. In parallel, functional feeds are being developed to enhance disease resistance and recovery, positioning nutrition as a central tool for health management. Advances in omics technologies now enable detailed characterization of diet-induced changes in immune and metabolic pathways, yet such knowledge remains limited in emerging cold-water species such as the spotted wolffish (*Anarhichas minor*). Here, we provide the first integrative evidence that protein-optimized diets reprogram hepatic immunometabolism in juvenile wolffish, revealed through combined histological, biochemical, metabolomic, and transcriptomic analyses.

## Materials and Methods

A seven-month feeding trial was conducted with juvenile wolffish (251.3 ± 22.1 g; 27.4 ± 1.7 cm) obtained from in-house breeding at Akvaplan-Niva (Tromsø, Norway). All procedures complied with Norwegian animal welfare regulations and were approved by the internal committee and the Norwegian Food Safety Authority (FOTS ID: 30374). Fish were assigned to three dietary groups: a control feed and two proprietary protein-optimized diets (Feed 1 and Feed 2, Skretting, Tromsø, Norway), each with two replicate tanks. Five fish per treatment were sampled at three time points, in addition to five baseline livers collected pre-trial. At each sampling, fish were euthanized with MS-222, and ~0.2 g of liver tissue was dissected, cleaned, weighed, and snap frozen. Semi-polar metabolites were extracted in methanol–water and analyzed by UPLC (Vanquish, Thermo Fisher Scientific) coupled to a high-resolution Orbitrap Exploris 240 MS under polarity switching. Stable isotope standards and pooled quality-control (QC) samples were included, with QC injections every sixth run. Data were processed with Compound Discoverer 3.3 and Skyline 23.1, and compounds annotated at three confidence levels (1–3) using accurate mass, isotope patterns, and MS/MS spectra. Statistical analyses combined univariate testing (Box-Cox transformation, t-tests, Benjamini–Hochberg FDR 0.05) with multivariate analysis (PCA) to identify diet-dependent clustering. Shotgun RNA sequencing, biochemical, and histological assays were also performed, with analyses still ongoing.

## Results and Discussion

Control fish achieved the highest growth (final weight 959.4 ± 84.2 g; length 53.0 ± 7.9 cm), while those fed protein-optimized diets displayed slightly lower final weights (832.8–869.0 g) and lengths (47.9–52.0 cm). Semi-polar metabolite profiling detected 1,739 compounds. Of these, 98 were confidently identified (Level 1), 78 annotated by accurate mass and retention time (Level 2a), 89 by MS/MS fragmentation (Level 2b), while 632 were assigned at lower confidence (Level 3) and 842 remained unclassified. PCA revealed clear separation of dietary groups, with Feed 2 producing the most distinct hepatic metabolic profile. QC samples clustered tightly, confirming high analytical reproducibility and that biological variance exceeded technical noise. Univariate analyses identified significant shifts in key metabolic pathways. Central energy metabolism was affected, with variation in pyruvic acid, lactic acid, glyceric acid, and glyoxylic acid pointing to altered glycolysis and TCA cycle activity. Several amino acids (alanine, glycine, threonine, valine) and derivatives (e.g., β-hydroxyisovaleric acid) were diet-responsive,

*(Continued on next page)*

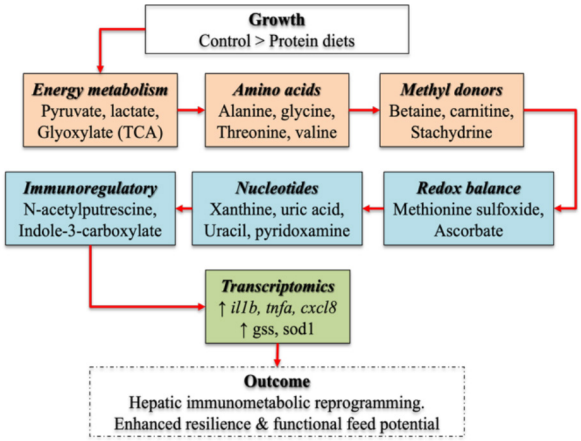

**Fig. 1** Diet-Induced Hepatic Immunometabolic Reprogramming in Spotted Wolffish

reflecting adjustments in protein turnover and nitrogen metabolism. Methyl donors and osmolytes such as betaine, carnitine, and stachydrine were strongly modulated, consistent with remodeling of one-carbon metabolism and lipid oxidation. Markers of redox balance, including methionine sulfoxide, methionine sulfone, and ascorbic acid, indicated enhanced oxidative stress buffering in fish fed experimental diets. Nucleotide derivatives such as xanthine, uric acid, uracil, and pyridoxamine were also affected, suggesting changes in nucleotide turnover and antioxidant defense. Furthermore, variation in polyamines (N-acetylputrescine) and tryptophan metabolites (indole-3-carboxylate) highlighted a potential dietary influence on immunoregulatory signaling. Preliminary transcriptomic screening supported these findings, with upregulation of pro-inflammatory cytokines (*il1b, tnfa, cxcl8*) and antioxidant regulators (*gss, sod1*), suggesting activation of cytokine signaling and redox defense pathways. Overall, protein-optimized diets modestly reduced growth but induced distinct hepatic immunometabolic reprogramming (**Fig. 1**). These metabolic signatures suggest prioritization of immune competence and physiological resilience over maximal biomass gain, supporting the potential of functional feeds for sustainable wolffish aquaculture.

## Conclusion

Protein-optimized diets reprogrammed hepatic immunometabolism in juvenile spotted wolffish, altering amino acid utilization, methyl donor pathways, redox balance, and immunoregulatory metabolites. While growth performance was slightly reduced, these nutritional interventions elicited distinct metabolic signatures associated with enhanced resilience and immune competence. To our knowledge, this represents the first integrative metabolic and transcriptomic evidence of diet-driven immunometabolic reprograming in spotted wolffish, providing a foundation for the development of functional feeds to support sustainable cold-water aquaculture.

# LONG-CHAIN POLYUNSATURATED FATTY ACID BIOSYNTHESIS IN THE SALMONIDS *Salmo trutta* AND *Thymallus thymallus*

Ida Djurdjevič, Simona Sušnik Bajec*

University of Ljubljana
Biotechnical Faculty
Ljubljana, Slovenia
e-mail: simona.susnik@bf.uni-lj.si

**Introduction**

Long-chain polyunsaturated fatty acids (LC-PUFAs) play a crucial role in brain and eye development and function, form essential components of cell membranes, and possess anti-inflammatory properties. The main biologically active LC-PUFAs are arachidonic acid (ARA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3). In the absence of enzymes required for the synthesis of LC-PUFAs from oleic acid (18:1n-9), vertebrates must obtain PUFAs from their diet (1). However, some vertebrates can convert C18 PUFAs, such as alpha-linolenic acid (ALA, 18:3n-3) and linoleic acid (LA, 18:2n-6), into biologically active LC-PUFAs.

The capacity for this conversion is species-specific and depends on the presence and expression of genes encoding fatty acid desaturases (Fads) and elongases (Elovl) (2). In fish, the ability to meet physiological demands for LC-PUFAs through elongation and desaturation of C18 PUFA precursors varies among species. This variability is influenced by both genetic factors and environmental conditions, including diet.

In aquatic food webs, the distribution of LC-PUFAs—particularly n-3 LC-PUFAs—follows a clear gradient from nutrient-poor headwater streams to lakes rich in n-3 LC-PUFAs. However, in freshwater ecosystems, the availability of prey rich in n-3 LC-PUFAs is rapidly declining due to anthropogenic impacts such as climate change and land-use alteration. Consequently, the ability to biosynthesise n-3 LC-PUFAs is of critical importance for the long-term survival of species.

**Material and methods**

Our model species are brown trout (Salmo trutta), represented by two ecotypes (lake and stream trout), and grayling (Thymallus thymallus), which inhabit distinct habitats. To evaluate the potential for LC-PUFA biosynthesis, we examined the genomic presence and tissue-specific expression of candidate genes in hatchery-reared individuals maintained under identical conditions to minimise environmental effects. The analysed tissues included brain, pyloric caeca, liver, heart, and muscle.

Candidate genes (FADS2, FADS6, Elovl2, Elovl4a, Elovl4b, Elovl5, Elovl8a, Elovl8b, ehhadh, Hacd1) were selected based on previous literature. Their presence and copy number were first determined using Ensembl (Release 111) for brown trout and BLAST searches against the available grayling genome. For most candidate genes, multiple copies were identified in both genomes. Where possible, gene expression analyses were conducted separately for each copy.

**Results and conclusions**

The genomes of S. trutta and T. thymallus contain multiple copies of genes that encode enzymes involved in fatty acid synthesis. The expression profiles of these gene copies are tissue-specific in both species.

Some candidate genes showed a similar pattern of expression across different copies, while others showed clear overexpression of one copy. Differences in the expression profiles of certain genes/gene copies were observed between the two S. trutta ecotypes, which may indicate adaptation to different environments (stream versus lake) and the diets of wild populations.

Multiple amino acid (AA) substitutions were found between gene copies in the aligned protein sequences. For example, three copies of the FADS2 gene are present in S. trutta, with pairwise distances between them ranging from 6.6% to 8.5%. AA substitutions were also found in conserved regions, such as haem-binding motifs, the cytochrome b5-like domain and transmembrane motifs.

# ESTIMATING THE WATER FOOTPRINT OF FISH FEED IN CLOSED-LOOP AQUAPONIC SYSTEMS (CLA SYSTEM)

S. Symeonidou [1,*] and E. Mente [2]

[1] Faculty of Engineering, School of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki GR-54124, Greece

## Introduction

Closed-loop aquaponic water recirculation systems (CLA) are innovative, integrated food production systems that combine recirculating aquaculture with hydroponic plant cultivation, using the same water in a continuous loop. In these systems, nutrient-rich wastewater from fish tanks is biologically filtered and recirculated to hydroponic units, where plants absorb dissolved nutrients, thereby purifying the water before it returns to the fish tanks (Maucieri et al., 2017). This symbiotic relationship enables efficient nutrient recycling, minimizes water consumption—often reducing usage by 90–99% compared to traditional aquaculture—and significantly lowers environmental discharge and pollution (Ahmed et al., 2024; Badiola et al., 2012). CLA systems maintain optimal water quality for both fish and plants through advanced filtration, oxygenation, and real-time monitoring technologies, supporting high-density fish production and robust plant growth (Lal et al., 2024). The closed-loop design not only enhances resource efficiency and sustainability but also offers economic and environmental benefits, such as lower chemical use, and the potential for local food production in urban or resource-limited settings (Lal et al., 2024). Fish feed water footprint is a critical component in the sustainability of aquaponics. Production-weighted average feed water footprints for commercial aquafeed, for the major farmed species, were estimated at 1629 $m^3/t$ (green), 179 $m^3/t$ (blue), and 166 $m^3/t$ (grey), with common carp among the top contributors to global aquafeed water use (Pahlow et al., 2015). The current study aims to assess the blue, green, and grey water footprint of fish feed (indirect water consumption) in a closed-loop aquaponic water recirculation system (CLA) containing common carp (Cyprinus carpio) and lettuce (Lactuca sativa), following the Water Footprint Network methodology.

## Material and Methods

Common carp (*C. carpio*) grown in a laboratory CLA system with lettuce (*L. sativa*) was fed four meals per day at six-hour intervals. The 45-day trial was carried out at the laboratory of Aquaculture and Aquatic Animal Diseases, School of Veterinary Medicine at Aristotle University of Thessaloniki. Three different diets were used: the control diet (C), which contained 15% fishmeal, the *Hermetia illucens* diet (B), which substituted 50% of the protein in fishmeal with *Hermetia* meal, and the plant residues diet (F), which substituted 50% of the protein in fishmeal with a 2:1:1 mixture of *Hermetia* meal, *Hermetia* frass, and hydroponic by-products. By calculating the water footprints of the feed ingredients used to create the three distinct fish diets, the blue, green, and grey water footprints of fish feed (indirect water consumption) of the different diets were assessed. More precisely, fishmeal, Hermetia meal, Hermetia frass, dried hydroponic by-products, poultry meal, rapeseed meal, soybean meal, sunflower meal, corn gluten meal, wheat meal, and rapeseed oil were the primary feedstuffs utilized for the diet compositions.

## Results and Discussion

The Water Footprint Assessment Manual (Hoekstra et al., 2011) following the Water Footprint Network approach, enables spatially explicit quantification of water consumption and pollution associated with crop-derived feed ingredients, considering the three components of the water footprint (blue, green and grey) (Mekonnen and Hoekstra, 2011). Integrating these estimates into closed-loop aquaponic systems highlights the importance of feed sourcing and nutrient management for minimizing indirect water consumption and environmental impact, supporting the development of more sustainable aquaponic production of carp and lettuce.

## Introduction

While biofilm formation in biofilters has been extensively studied, microbiota attached to other surfaces within recirculating aquaculture system (RAS), such as tank walls, remain largely unexplored. This is particularly relevant, as sloughed biofilm can contribute to microbial dispersal throughout the system via water recirculation. Gaining insights into the factors influencing biofilm development is therefore crucial for managing system microbial dynamics and potential pathogen reservoirs. To this end, this study investigated the effects of system type and diet on the temporal dynamics of tank biofilm over an eight-week period.

## Materials & Methods

Three mariculture systems with different water refreshment rates were examined: a flow-through system (FTS), a high refreshment (HR-RAS), and a low refreshment RAS (LR-RAS). Each system consisted of four tanks evenly stocked with juvenile gilthead seabream (*Sparus aurata*). To assess the effect of diet, fish in each tank were fed restrictively one of two aquafeeds in duplicate: a diet rich in non-starch polysaccharides (NSP-DIET) or a starch-rich diet (S-DIET). Water quality and biofilm development were analyzed at the tank level at Week 0, 2, 5, and 8. Water samples were filtered at 0.22 μm immediately after collection, and biofilm samples were obtained by swabbing tank walls. Water physicochemical parameters were assessed using standard analytical methods. Microbial abundance was measured via quantitative polymerase chain reaction (qPCR). Microbial community composition was determined through full-length 16S rRNA gene sequencing using the ONT MinION device; sequences were taxonomically assigned using the SILVA v148.1 database and further analyzed with the R microeco package.

## Results & Discussion

By the end of the trial, tank biofilm in the LR-RAS showed the highest microbial abundance and a trend toward higher organic carbon levels, indicating that nutrient accumulation promotes biofilm growth. Alpha diversity also varied most in the LR-RAS, with a short-term decline linked to the NSP-DIET. This contrasted with trends observed in the tank water—where alpha diversity fluctuated more under higher water refreshment rates—suggesting that biofilm and water microbial dynamics are likely independent of each other. Beta diversity in tank biofilm shifted over time across all systems, with each maintaining distinct prokaryotic communities throughout. Despite these shifts, the relative abundance of dominant taxa remained stable and included no known gilthead seabream pathogens (Fig1A), even though potentially pathogenic bacteria (e.g. *Vibrio*, *Coxiella*) were detected in water from the two RAS. Differences among systems were partly explained by physicochemical water quality parameters, with organic carbon and nitrogen levels strongly shaping biofilm prokaryotic communities in the two RAS. In the LR-RAS, diet also influenced biofilm community structures (Fig1B). Nonetheless, it did not promote the presence of common sulphate-reducing (i.e. Desulphobacteroda) or off-flavor producing (e.g. *Oscillatoria perornata*, *Anabaena spp.*, and *Pseudanabaena*) bacteria, which remained at low relative abundances in all systems, despite their frequent presence in previous biofilm studies (Houle et al., 2011; Rojas-Tirado et al., 2021). Overall, the present findings highlight that environmental conditions are the primary drivers of biofilm development in aquaculture systems, while diet plays a secondary but notable role under low water exchange.

*(Continued on next page)*

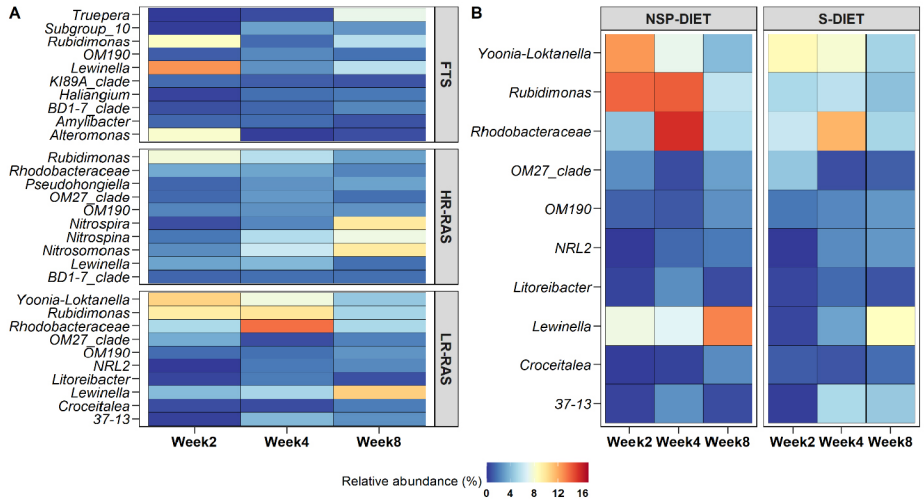

Fig1. Temporal mean relative abundances of the 10 most prevalent genera in the tank biofilm A) as observed across systems, with samples from both diets being pooled together, and B) as found in the LR-RAS, with samples being grouped per diet.

## Introduction

As global water stress intensifies, optimizing water management becomes critical. In this context, the CisWEFE-NEX project seeks to integrate innovative solutions that optimize the interconnections between water, energy, food, and ecosystems, promoting the sustainable use of natural resources. In this framework, a low-footprint recirculating aquaculture system (RAS) will be engineered to produce whiteleg shrimp at high stocking densities. The system will operate with minimal water exchange, with inputs and outputs linked to onsite operations to ensure resource circularity.

## Materials & Methods

The ~40 $m^3$ RAS (Fig.1A) will be installed at the CisWEFE-NEX demonstration site in Algarve, Portugal, and will consist of three culture tanks (10$m^3$). Tanks will feature a multi-platform setup connected to an air-lift pump (Fig.1B), providing increased surface area for shrimp colonization and efficient in-tank water circulation. At a system level, high water recirculation will be achieved via a state-of-the-art water treatment unit, including a drum filter (60 μm), a moving-bed bioreactor (1.5 $m^3$ RK plastic bio media; 750$m^2/m^3$), a custom packed-column degasser (0.14 $m^2$), a sump (0.7 $m^3$), and a low-head oxygen cone (max 50 $m^3$/h). Discharge water will be directed to an onsite prototype farm for seaweed cultivation, while collected sludge will be supplied to an onsite biogas plant for heat and energy production, which will in turn power the RAS. Under this setup, shrimp will be grown from post-larvae (~1gr) to market size (~25 gr) in three annual batches using a commercial feed. Throughout the project, production metrics, including survival and growth rates, will be monitored to assess the system's capacity. Additionally, both CAPEX and OPEX will be analyzed to evaluate the economic viability of the system.

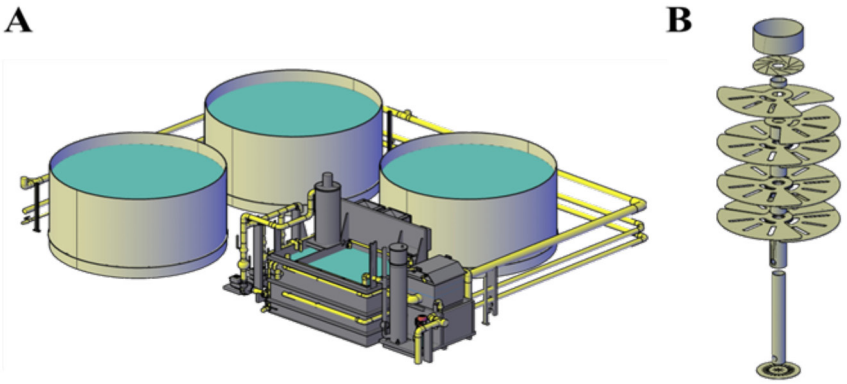

Fig1. A) 3D schematic of the RAS outlining its key components. B) Top-down layout of the in-tank platform arrangement, showing the centrally positioned air-lift pump.

*(Continued on next page)*

**Expected outcome**

This technologically adapted system for shrimp farming aims to achieve stocking densities of up to 20 kg/m$^3$, which is twice the level typically applied in conventional shrimp systems to suppress cannibalism (Romano & Zeng, 2016). Growth and survival are expected to be on par with those observed in intensive operations (Thakur et al., 2018), as high-quality feeds will be used and optimal water quality standards will be maintained. Due to the continuous solids removal, the system's oxygen demand is projected to be lower compared to common biofloc systems with high microbial, heterotrophic activity. The high production capacity per unit volume of water is expected to reduce capital costs per unit of shrimp produced, offering a cost-efficient solution to shrimp farming in RAS. Operational costs will also be minimized through the use of energy-efficient equipment and local, circular energy resources. Overall, the proposed system seeks to enhance both the efficiency and profitability of RAS shrimp farming while aligning with emerging sustainability and circular economy principles.

**Funding**
The present work is conducted within the CisWEFE-NEX project, which has received funding from the European Commission programme Horizon Europe (HORIZON-CL6-2023-CircBio-02-1-two-stage), under Grant Agreement no. 101135062.

For many years now, diet has been identified as a pivotal conditioner of health and immune status in both mammals and fish. Yet the extent to which diet composition or diet supplementation with immunostimulants affects the response to vaccination has been scarcely studied. In this study, we have carried out a series of different feeding experiments in rainbow trout (Oncorhynchus mykiss) to determine how diet composition can affect the antibody response to vaccination. For this, fish were fed the different supplemented diets or a control diet for 30 days. At that point, fish were immunized with different antigenic models through different administration routes and at day 30 post-immunization, fish were sacrificed and systemic specific antibody responses analyzed by ELISA. Antibody affinity was also determined in some cases. These experiments included diets supplemented with methionine or enriched with β-glucans or the probiotic microorganism Bacillus subtilis. The diets tested were selected based on preliminary in vitro experiments that demonstrated the capacity of these substances to increase B cell function in rainbow trout. Our results demonstrate that an optimized diet can improve the performance of vaccines in fish, being this especially useful for underperforming mucosal vaccines. The results presented will be useful for the design of holistic vaccination protocols that will not only focus on antigen optimization or administration regimes, but that will also include diet composition as an important factor to influence the outcome of the immunization strategy.

# EFFECTS OF PRODUCTION TEMPERATURE, WATER CURRENT VELOCITY, AND THEIR INTERACTION ON FARMED ATLANTIC SALMON (*Salmo salar*) STRESS RESPONSES AND WELFARE

P. Tang*[1], N. Gilannejad[1], D. Røise[1], S. Menanteau-Ledouble[1], M. Gorissen[2], M. Nilsen[1], N. Gharbi[1]

## Introduction

Farmed Atlantic salmon (*S. salar*) mortalities have increased in recent years, occurring during both the freshwater (FW) and seawater (SW) production phases. Meanwhile, suboptimal rearing and transfer strategies between FW and/to SW can greatly influence fish resilience. For instance, seasonal mismatches in the thermal environment during transfer can have pronounce effects on fish welfare and challenge abilities to adjust to the novel SW environment. At the same time, high water velocities are increasingly favoured in aquaculture settings due to reported benefits on fish health, including improved stress coping and cardiovascular fitness. However, the interactions between such training procedures and temperature and their effects on stress functions critical for farmed salmon welfare is still poorly known. Therefore, this study aimed to evaluate how temperature, water current velocity and their interaction influences farmed salmon welfare by monitoring stress responses and key neural markers of brain plasticity, with special reference to the sensitive FW-SW production phase.

## Materials and methods

Atlantic salmon parr (initial body weight ~ 40g) were allocated in duplicates between two water velocities (body length [BL] / second [s]): **1)** H (1.2 BL/s) and **2)** L (0.6 BL/s). The fish were maintained under these conditions at 10°C in FW RAS for 8-weeks. During this period fish were smoltified according to standard industry practice, followed by SW transfer of smolts in the same respective water velocities. To investigate the effect of abrupt temperature changes that often results from transfer from land-based sites to sea-cages, we investigated three distinct temperature regimes (**1)** 8°C [8-H & 8-L], **2)** 10°C [10-H & 10-L] and **3)** 14°C [14-H & 14-L]). The fish remained under these conditions for an additional 8-weeks before final sampling. At the end of both FW and SW phases, 20 fish from each treatment (N=5 per tank) were sampled for blood and brain tissue. In each treatment, 10 fish were immediately euthanized (pre-stress) and the other 10 were subjected to an acute challenge test (ACT), by high density, to monitor stress response capacities (ACT; 15 min. at 300 kg. $m^{-3}$, followed by 45 min. recovery). Plasma levels of cortisol were measured using ELISA, and ions (e.g., sodium, chloride) and energy metabolites (e.g., glucose, lactic acid) analysed using Horriba Pentra 400. These were compared to telencephalic expression changes in genes involved in the stress response (mineralocorticoid receptor; *mr*, glucocorticoid receptors; *gr1* and *gr2*) and neural plasticity (e.g., neurogenic differentiation factor; *neurod*, e.g., immediate early gene [IEG]; *c-fos*). Data was subjected to one- and two-way ANOVAs ($p < 0.05$).

## Results & Discussion

**Effect on growth performance:** Fish final average body weight was ~ 415 g. In FW, the specific growth rate (SGR) was unaffected by water velocity. In SW, SGR increased towards higher temperature regimes (8°C:~1.61, 10°C: ~1.68, 14°C:~1.86). Only at 14°C was the SGR further improved using high-water velocity (1.2 b/s).

**Plasma ions and metabolites:** In FW, plasma glucose, lactic acid, and $Na^+$ levels were lower in response to the high-water velocity (Fig. 1). This may indicate larger energetic demands and disturbed ion-homeostasis, effects consistent with osmo-respiratory compromise. In SW, the pre-stress 10-H group at 10°C showed a general elevation in plasma ions suggesting increased osmoregulatory challenges (Fig.1). Conversely, lactic acid levels were highest in the 14°C group following the ACT, while the high-water velocity seemed to elevate lactic acid build-up at pre-stress status in the 14-H group (Fig. 1). This build-up in lactic acid may be a consequence of thermal increases in metabolic rate alongside higher energetic demands to sustain swimming activities that elevate anaerobic forms of metabolism.

*(Continued on next page)*

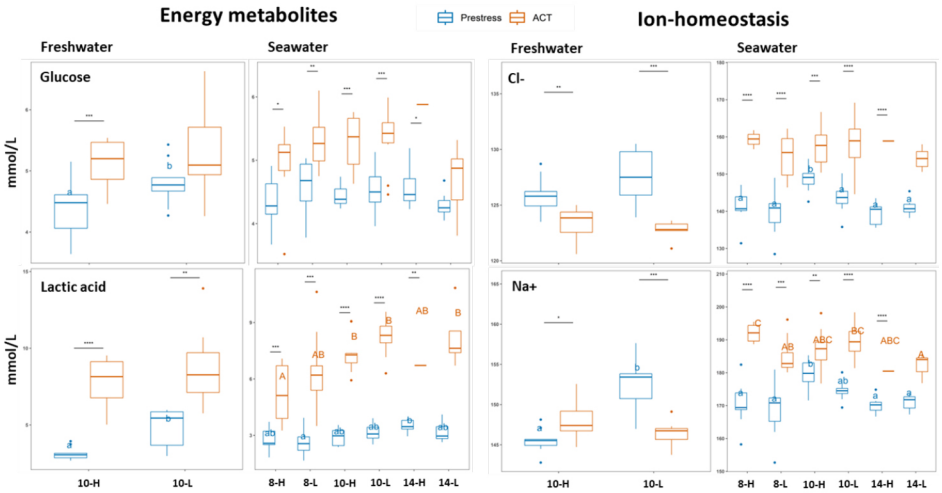

**Fig. 1.** Plasma stress responses at the end of the FW and SW phases. Lower- and upper-case letters denote significant differences among treatments, while asterisks indicate significant differences between the two stress states within each diet (*, **, ***, **** denote $p < 0.05$, 0.01, 0.001, and 0.0001, respectively).

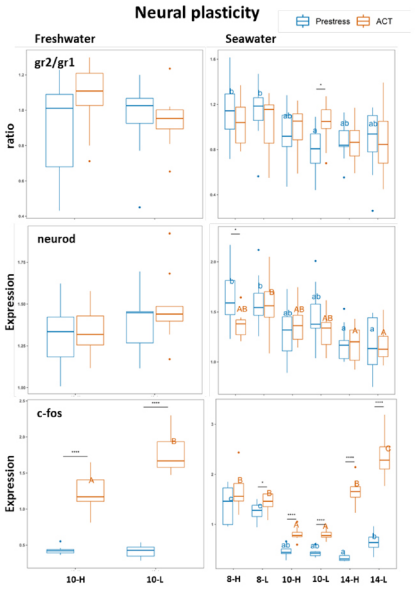

**Fig. 2.** Neural responses in the telencephalon at the end of the FW and SW phases. The rest of the legend is as in Fig. 1.

**Neural functions:** A gradual suppression in corticosteroid receptors (*mr*, *gr2*) and neural plasticity (*neurod*) was observed with increasing temperature, consistent with our prior findings (Fig. 2) (Tang et al., 2022). However, the effect of water current velocity was less apparent. In FW, the response of *c-fos* to the ACT appeared lower in the fish that had experienced the highest velocity strength, which could suggest reduced stress coping, while, in SW, this difference was only observed at the highest temperature that agrees with the more stressful effects seen in plasma lactic acid levels in the 14-H group.

**Conclusion:** The effect of water velocity in SW was less apparent compared to that of temperature. Since growth was maintained well throughout all treatments, this suggests that farmed salmon still handled the tested temperature-water velocity treatments well without marked effects on welfare status.

fzanuzzo@onda.ca

*Yersinia ruckeri*, the causative agent of enteric redmouth disease (ERM), is a common pathogen that causes substantial economic losses in salmonid aquaculture. This study evaluated the efficacy a thymol-based blend – Prototype TCS – in reducing mortality on juvenile rainbow trout in following immersion challenge with *Yersinia ruckeri*. Two practical diets were manufactured to contain 2000 ppm of Prototype TCS and no additive (Control) and fed to 320 trouts divided in 16 tanks ($n$=8). After four weeks of feeding, the fish were challenged with *Y. ruckeri*. Fish fed diets containing Prototype TCS effectively reduced post-challenge mortality by 15.6% and hazard ratio by 29.3% (P<0.05 -Figure 1). Additionally, fish fed Prototype TCS had a significantly lower prevalence (P<0.05) of pathological signs in survivors, supporting enhanced disease robustness. Our results demonstrated that including Prototype TCS in rainbow trout diets significantly increased resistance against ERM. This additive could therefore serve as promising alternatives to reduce antibiotic reliance and support more sustainable aquaculture practices.

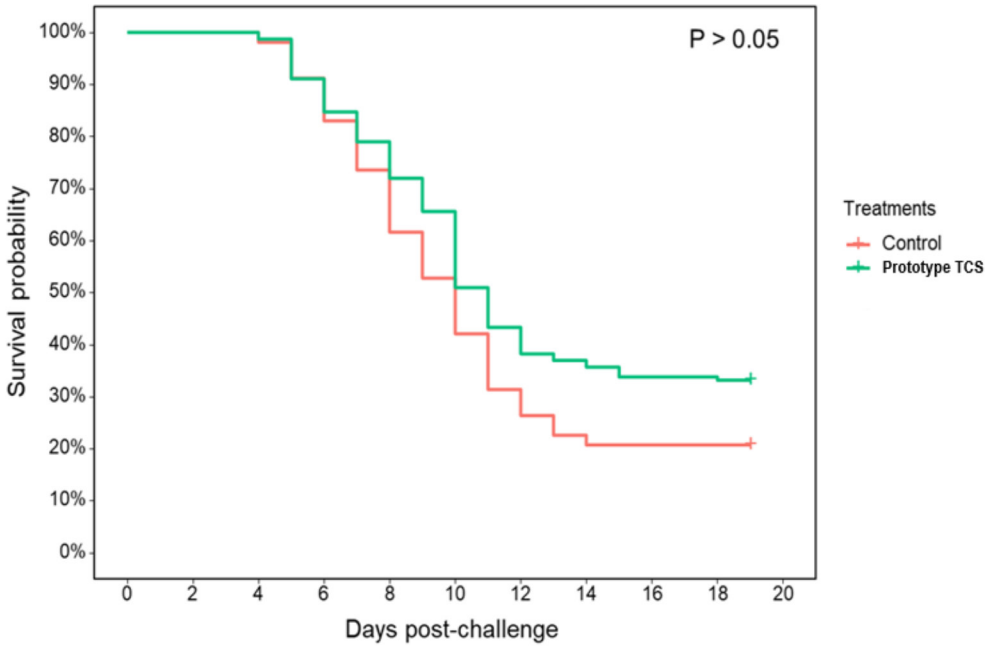

Figure 1. Survival curves of rainbow trout challenged with *Y. ruckeri* fed diets containing botanical-based blend.

# UNLOCKING PROTEIN DIGESTIBILITY IN EUROPEAN SEABASS (*Dicentrarchus labrax)* WITH PLANT EXTRACTS TO REDUCE FEED COSTS

Nicolas Tanrattana*, Sophie Reys, and Pierre Fortin

TECHNA
41 Rte de St Etienne de Montluc
44220 Couëron, France
nicolas.tanrattana@groupe-techna.com

Fishmeal (FM) is the primary protein source in aquaculture feeds, but its price has risen due to overfishing and climate change reducing supply. Alternatives like plant-based proteins, insect meals, and single-cell proteins are being explored, but their lower digestibility can hinder growth and feed efficiency. Enhancing their digestibility is key to meeting the nutritional needs of farmed species.

Economix is a plant-based feed additive produced by TECHNA (Couëron, France) that aims at enhancing protein digestibility. It offers a promising solution for reducing FM use and substituting it with more affordable plant proteins.

A digestibility trial was held at Sparos, Portugal, to evaluate the effect of Economix on apparent digestibility coefficients (ADC) of nutrients in European seabass (*Dicentrarchus labrax*). The trial comprised two experimental diets, both containing 0.02% yttrium oxide as an inert digestibility marker.
Control diet: 30% FM
Economix diet: 28% FM + 0.2% Economix

The Economix diet reduces FM by 2% compared to the Control diet, replacing it with plant proteins (soybean meal, wheat) and 0.2% Economix additive. This reformulation achieves a cost reduction of -1.78% compared to the Control diet.

Each diet was tested in triplicate groups of 13 fish (mean body weight: 73 ± 5 g), maintained in 60 L tanks at a constant water temperature of 20.0 ± 0.43°C. Feces were collected in tanks equipped with a fecal decantation column (Guelph system).

The results showed that the inclusion of 0.2% Economix significantly improved the amino acids digestibility of 13 out of the 17 analyzed amino acids, including lysine, methionine, and threonine ($p < 0.05$). This trial also indicated numerically higher values, although not statistically significant, for protein, fat and energy digestibility.

To conclude, Economix, with its ability to enhance amino acid digestibility, offers a viable solution by enabling the reduction of fishmeal and the incorporation of cheaper, more sustainable protein sources, while maintaining optimal performance in fish and shrimp.

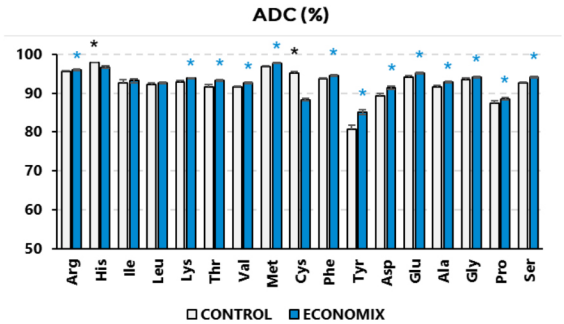

Figure 1. Effect of Economix on amino acid digestibility of European seabass *Dicentrarchus labrax* at Sparos, Portugal

# LONG-TERM COMPARISON OF GREEN AND RED MACROALGAE EXTRACTS AND β-GLUCANS ON THE DISEASE RESISTANCE, GILLS INTEGRITY AND GROWTH PERFORMANCE OF RAINBOW TROUT

Garcia-Suárez M.[1*], Pereira R. T.[1], Sutili F. J.[2], Battisti E. K.[2] , Rodriguez, M. A.[1], Marzin D.[1]

[1]OLMIX SA, ZA du Haut du Bois, 56 580 Bréhan, France
[2]ELOAQUA, Research Facility, Brazil
*mgarcia@olmix.com

This study aimed to evaluate the efficacy of green and red macroalgae extracts and β-glucans on the disease resistance, gills integrity, and growth performance of rainbow trout (*Oncorhynchus mykiss*) in long-term use. An algae-based marine sulphated polysaccharides (MSP) extracts, from Ulva sp. and Solieria chordalis, and 60% purified yeast-based β-glucans available in the market were used in the feeding trial. Fish weighting 27.6 g were reared at 14-17 °C, and average dissolved oxygen above 6 mg/L. Fish were divided into four different dietary treatments and 6 replicates (tanks of 70 L): Control, Algae MSP 0.3%; β-Glucan A 0.1% and β-Glucan B 0.1% produced as pelleted feed of 3mm. Fish were stocked at a density of 12 fish per tank (72 fish per treatment) and fed twice a day for 100 days. At the end of the feeding trial, 8 fish per treatment were sampled for blood-based innate immune response analysis. Another 6 fish per treatment were exposed to a bacterial solution containing *Aeromonas hydrophila* and *Pseudomonas anguilliseptica* via immersion for 24 hours, and gills were sampled after 72 hours for histopathological evaluation by a specialized laboratory using a diagnostic scoring system. Additionally, a third group of 30 fish per treatment was intramuscularly challenged with the same bacterial solution, and survival was monitored for 7 days. Data were analyzed using one-way ANOVA followed by SNK post hoc test ($p<0.05$), and survival was analyzed using the Kaplan-Meier method (SIGMA PLOT 11.0, Systat Software, San Jose, CA, USA). Trout fed the Algae MSP exhibited the best overall performance, with a 13% higher weight gain (45.8 g vs. 40.5 g; $p=0.017$), increased lysozyme activity (117 vs. 79 U/mL; $p=0.016$), and enhanced complement activity (40.5% vs. 2.4%; $p <0.001$) and were the only group which differed from control for survival 40% and 10%, respectively (+400%). Likewise, higher complement hemolytic activity was also observed in fish fed β-Glucan B (45.7%). Fish fed Algae MSP showed the lowest gills histopathological score among the challenged groups, indicating a 38% reduction in gill damage, 0.85, 0.53, 0.65, and 0.71, respectively. In conclusion, Algae MSP demonstrated the most consistent overall performance, excelling in growth, innate immunity, survival and gills integrity. The results highlighed the algae-based solution as a tool for strengthening natural defenses in aquaculture due to its broader benefits in long-term use.

# SOURCES OF HEPATIC GLYCOGEN TRACED BY $^{13}$C-NMR IN FRUGIVOROUS AMAZON TAMBAQUI (*Colossoma macropomum*)

## Introduction

The use of plant-based feed ingredients proportionally increases the amounts of plant-derived carbohydrates, including digestible carbohydrates, starches and sugars in aquafeeds. Despite not being essential, the energy derived from carbohydrates can potentially have protein-sparing effect. However, carnivorous fish display several digestive, enzymatic or hormonal limitations in the metabolism of carbohydrate-rich feeds. Tambaqui is an Amazon fish species (*Colossoma macropomum*) with herbivorous/frugivorous feeding habits, very different from the marine carnivorous species commonly farmed (Ferrari et al., 2022). The study aims to assess how carbohydrates are assimilated at the hepatic glycogen of tambaqui through the injection of an intraperitoneal [U-$^{13}$C]glucose or [U-$^{13}$C]fructose load (2g kg-1). $^{13}$C-NMR analysis of hepatic glycogen was used to determine the contribution of the load to glycogen synthesis via direct and indirect pathways at 24h post-injection under fed and fasted conditions.

## Materials and methods

All animal procedures for handling and sampling were performed as previously described (Ferrari et al., 2022). Briefly, a total of 90 fish were randomly distributed into nine 900 L tanks with average body weight per tank 157.8 ± 5.2 g in a closed freshwater circulation system. The fish were acclimated for 10 days and fed to satiation 3x day with a commercial feed. Six tanks were assigned for fed fish (FED, 60 fish, 10 fish per tank): three for IP-injected with glucose (GLU, 30 fish, 10 fish per tank), and three for IP-injected with fructose (FRU, 30 fish, 10 per tank); these continued the feeding regime for another 10 days. Three tanks were assigned for fasted fish (FAST, 30 fish, 10 fish per tank); these were feed-deprived for 10 days prior to injection with [U-$^{13}$C]glucose or [U-$^{13}$C]fructose load (2g kg-1) Fish were processed 24h after injection, under anaesthesia, weighted, sampled for blood (Ferrari et al., 2022), and sacrificed by cervical section. The liver was excised, weighed, freeze-clamped in liquid nitrogen, and stored at -80ºC until further processing. Hepatic glycogen was extracted after MTBE extraction and derivatisation for NMR experiments was performed as previously described (Viegas et al., 2012).

## Results

Enrichment of the load with [U-$^{13}$C]glucose or [U-$^{13}$C]fructose will generate glycogen 13C-isotopomers that can be attributed to direct and indirect pathways activities (Viegas I et. al 2022). The 10-day fasted tambaqui, synthesized more hepatic glycogen from the [U-$^{13}$C]glucose load than fed tambaqui ($p<0.001$, 24.9±7.9% vs. 11.5±3.8%, respectively). The indirect pathway fluxes were similar in both fasted and fed conditions (ns, 6.1±1.7% vs. 6.4±2.9%, respectively). Considering the [U-$^{13}$C]fructose load, an indirect pathway substrate, can provide information regarding fluxes originating at triose-P level or arising from Krebs cycle. In both fluxes, the fasted tambaqui significantly increased the fluxes towards hepatic glycogenesis (triose-P level $p<0.001$, 55.1±7.3% vs. 31.0±8.2%; Krebs cycle level $p<0.05$, 12.8±2.1% vs. 10.0±2.6%). In both assays we were able to quantify the fraction of direct pathway glucose and fraction of indirect pathway fructose metabolized by pentose phosphate pathway.

**Discussion and Conclusion**

Our results clearly show that the direct pathway contributed more to glycogen synthesis than indirect pathway contributed less to glycogen synthesis from a glucose load in fasted tambaqui. The results show a clear contrast with carnivorous fish, which rely almost exclusively from indirect pathway (Viegas I et al. 2012). Furthermore, tambaqui is able to metabolize large amounts of fructose towards glycogenesis through indirect pathway. Such results offer great insight on the mechanisms employed by tambaqui to assimilate carbohydrates and will allow to optimize fructose-rich ingredients for aquaculture.

E-mail: mtejero@ub.edu

## Introduction

*Tenacibaculum maritimum* is a Gram-negative filamentous bacterium that accounts for the majority of tenacibaculosis cases in marine fish species (Mabrok et al., 2023). Although biofilm formation is presumably a necessary step in the establishment of the infection by *Tenacibaculum* (Levipan et al., 2019), biofilms have not been usually included in studies assessing the antibacterial activity of fish skin mucus against this pathogen. In this context, the present study aimed to establish a simple and reproducible protocol for the formation and quantification of *T. maritimum* biofilms that will allow a more realistic approximation when studying the antibacterial properties of different compounds against this pathogen. For this purpose, a first attempt to elucidate the effects of gilthead seabream (*Sparus aurata*) skin mucus on *T. maritimum* planktonic and biofilm growth was included.

## Materials and methods

This study developed an evaluation of skin mucus antibacterial activity on planktonic cultures, on biofilm formation and on mature biofilms of *Tenacibaculum maritimum* (CECT 4276 strain from the Spanish Type Culture Collection University of Valencia, Spain). To do this, an experimental setup for the biofilm formation has been developed. A pool of homogenized skin mucus of gilthead seabream juveniles (*S. aurata*) was created and three different dilutions were tested in the antibacterial assays. The activity of skin mucus on biofilms was monitored through Crystal Violet staining (biomass) and resazurin assay (metabolic activity).

## Results

The results obtained demonstrated that seabream mucus significantly impairs the planktonic growth of *T. maritimum* in a concentration-dependent manner: non-diluted mucus (9.6 mg $ml^{-1}$) completely inhibited *T. maritimum* growth, 1:2-diluted mucus initially caused high inhibition that was reduced during the later hours of culture, and a 1:5 dilution of the mucus resulted in an almost complete loss of antibacterial activity (Figure 1).

The antimicrobial effect of the fish skin mucus on the biofilm formation showed similar results to those obtained with planktonic cells. Non-diluted mucus strongly inhibited biofilm formation: a high reduction in biofilm biomass was observed and no metabolic activity was detected. The inhibitory effect decreased when 1:2-diluted mucus was used and lost with the 1:5-dilution. Undiluted gilthead seabream skin mucus demonstrated significant effects on mature biofilms, promoting substantial biofilm biomass dispersion (40%) and reducing the metabolic activity by approximately 50%. In contrast, diluted mucus appears not to affect biofilm biomass and viability in the dispersion assay.

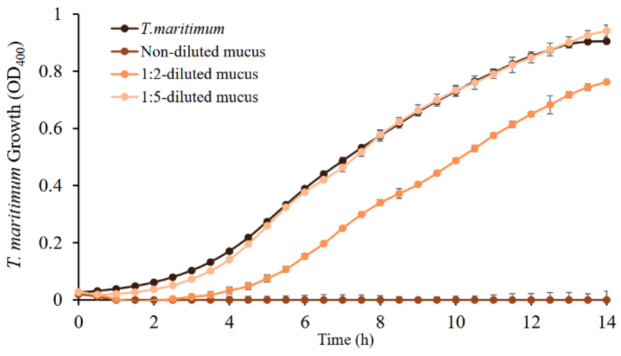

**Figure 1.** Skin mucus antibacterial activity against planktonic cultures of *T. maritimum*. Growth of *T. maritimum* incubated without or with different dilutions of gilthead seabream skin mucus.

*(Continued on next page)*

**Discussion and conclusions**

Bacterial biofilms constitute significant challenges in medical and ecological contexts due to their remarkable ability to resist antibiotic treatments, leading to persistent infections (Flemming et al., 2016). This study aimed to provide a platform for studying the potential antimicrobial effects of fish skin mucus on the formation and dispersion of biofilms of *T. maritimum*. The results showed that the mucus inhibited biofilm formation in a concentration-dependent manner. Considering the effect of skin mucus on planktonic growth, the inhibition of biofilm formation observed could be a consequence of the inhibition of total bacterial growth in the presence of the skin mucus. Our results demonstrated that, in addition to inhibit biofilm formation, seabream skin mucus could alter previously formed *T. maritimum* biofilms. However, as expected, the impact of skin mucus on the disaggregation of *T. maritimum* pre-formed biofilms was found to be less pronounced, evidencing the high resistance that these structures confer to the bacterial cells. Assessing how fish culture conditions influence the host's vulnerability to bacterial infections is essential to prevent economic losses in fish farms. The protocols developed here will provide functional and reliable tool to monitor fish vulnerability to this pathogen and to study '*ex vivo*' the benefits of functional feeds. In addition, gilthead seabream skin mucus could represent a potential source of new therapeutic compounds for treating biofilms of this pathogen, due to its effect on established biofilms.

## Introduction

Aquaculture systems generate sludge continuously and inevitably. This sludge consists of indigestible feed components, uneaten feed, and microbial biomass and contains high amounts of nutrients. It can thus be treated as valuable side stream under the circular economy paradigm, being useful for e.g., aquaponics to reduce reliance on inorganic fertilizer. In any case, it must be regarded as a residual material whose disposal entails costs. Within this context, aerobic sludge stabilization is a fast and simple process that offers high nutrient recovery efficiency and nitrogen availability. While the process is more energy-intensive than anaerobic digestion (Chen et al., 1997), it offers the advantage of a lower hydraulic retention time (HRT), making it potentially more cost-effective as bioreactors of large volume require high additional investment. However, there are no studies that assessed the optimization potential and the economic side of aerobic sludge stabilization in aquaculture, let it be as a means of end-of-pipe treatment or a method for nutrient mobilization, targeting aquaponic systems.

Against the outlined background, this study aimed at optimizing aerobic sludge stabilization by investigating the influence of pH, temperature, duration, and presence of PSB on the reduction of organic matter and nutrient leaching. The obtained results were then validated on pilot-scale to assess scale-effects.

## Material and Methods

A series of experiments was conducted to identify the maximum solids load, hydraulic retention time, and the effect of PSB and commercial enzymatic products for sludge treatment. Sludge for the experiments originated from the drum filter backwash of a RAS stocked with *Clarias gariepinus* and fed with Skretting Meerval throughout sludge collection. 1 L glass bottles equipped with a cap and aerated through PVC pipes served as bioreactors. The bottles were placed in a water bath with temperature regulation.

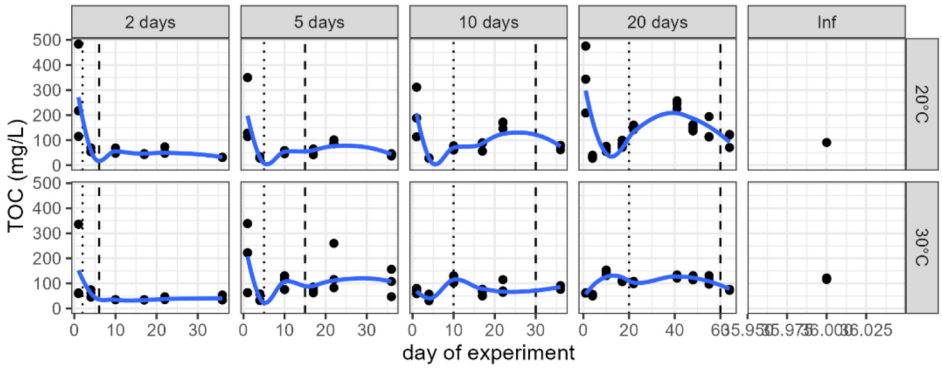

Figure 1: Total Organic Carbon (TOC) concentration in continuous aerobic sludge reduction reactors (n = 3) operated at different hydraulic retention times (HRT). Blue line: Moving average. Dotted line: 1x HRT. Dashed line: 3x HRT. Batch reactor (HRT = inf.) was used as control.

*(Continued on next page)*

The maximum solids load was determined by mixing sludge with a known amount of total solids (TS) with deion. $H_2O$ to achieve TS loads from 5 to 25 mg $L^{-1}$. The reactors were then aerated over seven days and the oxygen saturation determined daily. Eventually, the effect of the maximum solids load on sludge reduction performance with and without addition of PSB was assessed in batch experiments. The respective amount of TS was added and the reactor kept under continuous aeration over 14 days.

The optimum hydraulic retention time (HRT) for continuous sludge reduction was determined at two different temperatures (20°C and 30°C) and four HRT levels (2 d, 5 d, 10 d, 20 d), with a batch treatment as control. Water exchanges were carried out daily with exchange water set to the pre-determined maximum TS concentration. Experiments were run until at least 3 times HRT was reached.

Abiotic parameters were determined daily in the batch experiments and in increasing time intervals in the continuous experiment. Water and sludge samples for C, N, and P analyses were analysed according to standard methods.

Results and Discussion

The maximum TS load under which the reactor remained aerobic was 10 g $L^{-1}$. This is five to ten times lower than the loads reported in aquaponics literature (Goddek et al., 2018; Monsees et al., 2017). As expected, temperature had a significant effect on the remineralization process in aquaponic sludge treatment. In batch experiments, the pH reached its minimum after approx. 6 days at 30°C, compared to 14 days at 20°C, indicating accelerated microbial activity. Similarly, the degradation of total organic carbon (TOC) showed a decline around day 4–5 across most treatments, except at higher HRT (10 and 20 d) at 30°C. While TOC concentrations were lowest (~50 mg $L^{-1}$) in treatments with shortest HRT, they increased with longer HRT, ranging from 75 to 150 mg $L^{-1}$. Total nitrogen concentrations in solution increased over time, reaching their inflection point faster at 30°C (~7 days) compared to 20°C (~14 days). Higher nitrogen concentrations were associated with longer HRT and warmer conditions. A 5-day HRT appears optimal, balancing pH reduction and system feasibility. At this duration, pH dropped to 5.2 at 20°C and 4.5 at 30°C, which is sufficient to mobilize plant nutrients due to shifts in speciation.

In practical terms, a small recirculating aquaculture system (RAS) with a total volume of 5 $m^3$ and a daily sludge production of about 3 L/d (50 g/L DM) would require a 75 L tank (based on the 5-day HRT and 10 g/L TS target) for sludge stabilization. However, an improved solid-liquid separation is necessary to achieve optimum performance.

**Introduction**

Monitoring benthic biodiversity in harbours and human-impacted areas is essential for assessing environmental status, detecting changes due to pollution, and managing ecological risks associated with anthropogenic activities.

Benthic communities are key indicators of environmental health, as they respond sensitively to pollutants and shift in their composition and diversity may signal environmental degradation *(Chatzinikolaou et al*., 2018).

Continuous monitoring helps to quickly detect the introduction of harmful species, allowing effective responses to prevent their spread and minimize ecological and economic damage. Degraded environments facilitate the spread of unwanted species and are associated with an increase in invasive species, which can affect ecosystem functionality (Bayley *et al.*, 2024; Chatzinikolaou *et al*., 2021; Tamburini *et al*., 2020)they can affect biodiversity, industry, ecosystem function, and both human and wildlife health. Isolated areas with sensitive or highly specialised endemic species can be particularly impacted. The global increase in the scope of tourism and other human activities, together with a rapidly changing climate, now put these remote ecosystems under threat. In this context, we analyse invasion pathways into South Georgia and the South Sandwich Islands (SGSSI.

For this reason, the development of standardised accessible methodologies for environmental monitoring of biodiversity, such as ARMS-MBON (Autonomous Reef Monitoring Structures of the Marine Biodiversity Observation Network), is crucial, because they allow more accurate, rapid and large-scale data collection on biological diversity, overcoming many limitations of traditional methods (Daraghmeh *et al*., 2025; Obst *et al.*, 2020)we present the data of our first sampling campaign comprising 56 ARMS units deployed in 2018–2019 and retrieved in 2018–2020 across 15 observatories along the coasts of Europe and adjacent regions. We describe the open-access data set (image, genetic and metadata.

The present study aims to use these standardised environmental monitoring methodologies to observe variations in biodiversity among different types of ports in the Gulf of Valencia (marina, fishing and international cargo) and evaluate their applicability to study other types of marine areas affected by anthropogenic activities.

**Material y methods**

Three ports located in the Gulf of Valencia (Spain) are being studied: Pobla de Farnals (marina), Denia (fishing port), and Valencia (international cargo port).

Three ARMS have been placed in each of these ports, where they will remain submerged for around three months (July 2025-October 2025). Once the immersion time has elapsed, they will be extracted and processed in the laboratory as specified in the methodology proposed by Obst *et al*. (2020), to extract the surrounding biological material.

Subsequently, molecular genetic analyses will be carried out on the material scraped from the ARMS plates, which will be compared with DNA databases (COI, 18S and 16S metabarcoding).

**Expected results**

The results of the molecular genetic analysis of each of the ARMS are expected to enable the characterisation of the biological communities in each port and their differences. These are predicted to focus on indicator species of different levels of pollution, species typical of enclosed waters, and even non-indigenous species that may have been brought in by different types of marine traffic. It will also be possible to evaluate the performance of this methodology for monitoring areas of direct anthropogenic impact, such as ports or aquaculture farms.

*(Continued on next page)*

**Future lines**

One of the objectives of the study is to draw up a future strategy for monitoring and characterising local impacts and biodiversity hot-spots. For this reason, we are testing this methodology in confined environments such as ports. Afterwards, we would apply the same methodology to monitor the impact of aquaculture facilities, evaluate the effect of marine nature reserves, or control the biological diversity of areas with special characteristics for the conservation of endangered species.

**Acknowledgements**

This project has been developed in collaboration between the groups OCECOSVAL of the IMEDMAR-UCV and RNM-213 and RNM-214 of INMAR (University of Cadiz) funded under the project ThinkinAzul of both the Valencian Community (GVA-THINKINAZUL/ 2021/033) and Andalusia (PCM_00025, co-financed by the Ministry of University, Research and Innovation of the Junta de Andalucía and by the European Union via the Next Generation EU funds of the Recovery, Transformation and Resilience Plan (C17. I1)).

Email: josetena@ucv.es

**Introduction**

The Mediterranean Sea is suffering from multiple pressures affecting severely its biodiversity. The region is warming faster than any other sea, causing marine heat waves and ecosystem degradation (Klaoudatos et al., 2024). Phenomena such as 'tropicalisation' and 'meridionalisation' are altering the distribution of species, benefiting warm species and displacing native ones. Corals and gorgonians forests are suffering from bleaching and mortality (Ghanem et al., 2021; Kersting et al., 2023). In Spain, the Plan Complementario de I+D+I en Ciencias Marinas ThinkInAzul (Government of Spain, 2012) has been promoted and one of its objectives is the monitoring of the marine environment. Fish monitoring is crucial, and methods such as the Underwater Visual Census (UVC) have been improved (Azzurro et al., 2022), but it is necessary to standardize the use of sustainable techniques to assess the health of the marine ecosystem.

**Materials and methods**

A protocol for monitoring impacts of climate change was standardized by Izquierdo-Muñoz, et al. (2024) and has been implemented for 2-years monitoring of benthic biocenosis and singular species in 4 stations (Oropesa, Pobla de Farnals, Albufera and Calp) along the coast of the Valencian Community, Western Mediterranean Sea. The monitoring protocol was established by conducting Underwater Visual Census (UVC) at rocky bottom locations, coupled with sensible sessile species monitoring (e.g., hard and soft corals) covering a 250 $m^2$ of sampled area in each census under the criteria of presence of the species selected of interest by ThinkInAzul.

**Results**

A total of 4887 specimens were sighted in the UVC surveys. Differences in the fish composition of the rocky bottom communities show significant differences in relation to season of the year.

Environmental deterioration recorded in the 2084 coral colonies observed in the surveys show mostly healthy specimens with little deterioration. Seasonal variations in the colonies examined showed not significant differences for most of the sample areas.

**Discussion and conclusion**

The protocol for monitoring impacts of climate change has been applied for a period of 2-years to establish a baseline for comparison in future surveys. The results show indicators of resilience so far to the impacts of marine warming as observed in the low levels of coral bleaching and the dominance of *Coris julis* over *Thalassoma pavo*. A shift in proportions between the two species is expected, reducing the abundance of *C. julis* and increasing *T. pavo*, linked to the increase in temperature (Azzurro et al., 2022). Future surveys will provide an early warning system thanks this bioindicators that will allow the detection of climate change trends and its adaptation to other areas of the Mediterranean, with variation and criteria and community species. It is therefore essential to continue the challenges of ThinkInAzul to understand the trends of change in the Mediterranean Sea.

# EFFECTS OF TEMPERATURE AND SALINITY ON THE GROWTH OF EARLY LIFE STAGES OF THE JELLYFISH *Pelagia noctiluca*: OPTIMIZING AQUACULTURE TECHNIQUES FOR SUSTAINABLE CULTIVATION

J. Tena-Medialdea[1]*, J. Igual[1], R. Torres-Cardenal[1,2] and A. Ballesteros[1]

## Introduction

Jellyfish have been recognized as valuable sources of novel natural products with a wide range of biotechnological applications. However, the spatiotemporal variability of their life cycles makes them an occasional resource, whereas aquaculture can offer a continuous and reliable supply. *Pelagia noctiluca* is an ideal candidate for research in the biomedical, cosmetic, and pharmaceutical industries due to the potential value of bioactive compounds found in its venom (Frazão et al., 2017). Despite its importance in marine biotechnology, the cultivation of *P. noctiluca* is considered a challenge by the scientific community, aquariums, and industry. This is primarily due to its holoplanktonic life cycle (Canepa et al., 2014), which lacks a polyp stage—an element that, in jellyfish with metagenetic life cycles, serves as an inexhaustible source of young jellyfish (ephyrae and metaephyrae). In this context, this study aimed, for the first time, to investigate the effects of temperature and salinity on the growth of early life stages of *P. noctiluca*, with the goal of optimizing aquaculture techniques.

## Materials and methods

Fertilized eggs from mature *P. noctiluc*a medusae at Loro Parque Aquarium (Tenerife, Spain) were incubated in filtered seawater with aeration until they reached the ephyra stage on day 3 post-fecundation. Experiments were conducted in 18 containers combining two temperatures (18 °C, 24 °C) and three salinities (32, 36, 40 PSU), with three replicates per treatment. The initial number of ephyrae per culture was 30, and they were acclimated using a drip method. Ephyrae and metaephyrae were fed daily with 20,000 rotifers and containers were cleaned twice weekly to maintain water quality. Morphological descriptions and the total body diameter (TBD) of 6 live individuals per treatment and replicate were recorded weekly (Ballesteros et al., 2022a). TBD values were converted into carbon weight (CW) to calculate growth rates (GR) according to Lilley et al. (2014) and, life cycle stages were classified according to Ballesteros et al. (2021). A two-way ANOVA assessed the effects of temperature and salinity on GR, with post hoc Tukey's tests applied ($p < 0.05$). The experiments were finished at day 24 post-fecundation.

## Results

A two-way ANOVA revealed significant effects of temperature, salinity, and their interaction on GR ($p < 0.01$). The highest GR was observed at 24 °C/32 PSU ($0.23 \pm 0.03$ d$^{-1}$) where jellyfish exhibited fully developed marginal tentacles and a high number of nematocyst batteries by day 24 post-fecundation (mean TBD of $1.42 \pm 0.22$ mm). At 36 PSU, GR at 24 °C ($0.21 \pm 0.03$ d$^{-1}$) was significantly higher than at 18 °C ($0.14 \pm 0.03$ d$^{-1}$), highlighting the positive effect of increased temperature at moderate salinity. However, individuals from both treatments were classified as metaephyra stage 3, with mean TBDs of $1.25 \pm 0.16$ mm and $0.78 \pm 0.13$ mm, respectively, at day 24 post-fecundation. Finally, jellyfish in the 18 °C/40 PSU and 24 °C/40 PSU cultures did not show tentacle buds and were classified as ephyra stage 2 with mean TBD values of $0.65 \pm 0.12$ mm and $0.77 \pm 0,19$ mm at day 24 post-fecundation, respectively.

## Discussion

Despite the importance of *P. noctiluca*, few studies have focused on optimizing its life cycle in aquaculture (Lilley et al., 2014; Ramondenc et al., 2019; Ballesteros et al., 2022a, 2022b)causing considerable problems to tourism and aquaculture. Little is understood about the drivers of its periodic presence and absence or how it survives unfavourable periods. Studying the effect of starvation, we evaluated the main metabolic expenses (reproduction, respiration and excretion, and the combined effects of temperature and salinity have never been investigated at any stage of its life cycle with the specific aim of improving aquaculture practices. Previous captivity studies identified 18°C the optimal temperature for the culture of *P. noctiluca* (Lilley et al., 2014;

Ramondenc et al., 2019)causing considerable problems to tourism and aquaculture. Little is understood about the drivers of its periodic presence and absence or how it survives unfavourable periods. Studying the effect of starvation, we evaluated the main metabolic expenses (reproduction, respiration and excretion, and indicated that higher temperatures induced stress in the individuals. However, Ballesteros et al. (2022a) recommended a temperature of 22 °C as more suitable for promoting healthy growth without inducing visible signs of stress in captivity. In this study, we demonstrated that temperature and salinity had a significant effect on the growth of *P. noctiluca* ($p < 0.01$), with 24 °C and 32 PSU identified as the optimal combination for proper development. Cultivating the species at high salinities, such as 40 PSU, is not recommended, as it does not exhibit proper growth under these conditions, regardless of temperature. These guidelines, together with dietary recommendations for the species (Ballesteros et al., 2022a) and the implementation of new breeding systems (Ballesteros et al., 2022b), represent a significant advance in the development of cultivation protocols for the mauve stinger *P. noctiluca*.

**Introduction**

The Albufera is to the south of the city of Valencia, (Fig. 1), which is currently a coastal lake of fresh to brackish water (Sanchis Ibor, 2010) regulated by three systems of watergates called the Pujol, Perellonet and Perelló (from north to south). At the beginning of the 17th century, Escolano (1611) described the Albufera with a single water channel connecting with the sea, the Albufera Gola, which was different from the current ones, near Casa del Rey (the current Rey Beach, Sanchis Ibor, 2010). It was wide enough to admit salt water, and was artificially closed with logs, branches, and sand so that the Albufera could function as a large fish farm that supplied abundant and constant fish to the city of Valencia. By closing off the communication with the sea, the level of the lagoon could vary with respect to sea level. A mark was required to monitor the water level in the Albufera, and this corresponded to the so-called "Fita," which translates as "The Milestone." Although it seems that one existed before, king Jaume I rebuilt it (it was in place by 1250), marking it with his royal coat of arms (Sanchis Ibor, 2010). The Fita had marks located at a distance of Valencian palms (approximately 22.5 cm). When the Albufera was connected to the sea, the Fita protruded one palm, and when the level of the Albufera dropped during the summer, it could drop three palm marks (66 cm). If the water level dropped further, in ancient times the channel had to be opened (Sanchis Ibor, 2010) or the Albufera had to be filled with waters from the Turia and Jucar rivers. This way, the fishing was not lost. If the level was higher than the "Fita", the dam that closed the inlet could break, losing all the possible fishing, so when the level rose, the dam must be opened in a controlled manner to capture the fish.

The Fita's position is only marked on a map by Pedro Torbé (commissioned by the Crown to carry out a new boundary marking of the Albufera) from 1752. Its original location is marked in the Fishermen and Farmers Society of Sueca maps by Toni Carrasquer (1984). Around 1760, the original Fita with the royal coat of arms was missing, and the mention of "Fita" disappears from maps and archives (Sanchis Ibor, 2010).

The maps by Toni Carrasquer García (1984) show the position of the Creu de la Llonga, which was found as scattered ruins on a terrace. It has appeared in the area since the 18th century, which coincides with the destruction/relocation of the "Fita" of the Albufera as deduced from the Torbé map (1752). The Creu de la Llonga is identified as the Fita with the palm marks. The place name *la Llonga* does not appear on the Torbé map (1752) but it does appear on the recent maps.

**Discussion and conclusions**

Between 1755 and 1756, two tsunamis occurred in the Mediterranean: on November 30, 1755, the Lisbon earthquake tsunami affected the western Alboran Sea (Silva et al., 2019), and on January 31, 1756, the Santanyí tsunami in Mallorca (Roig-Munar et al., 2023). For Roig-Munar et al. (2023), the tsunami blocks in Mallorca seem to have shifted around the late 18th and early 19th centuries, with the Santanyí tsunami being the main candidate. Roselló Verger (1979) described several blocks of a cemented Tyrrhenian dune in the Perellonet area of the Albufera sandbank and these could be the product of the mid-18th-century event.

*(Continued on next page)*

The original position of the “Fita” in the Albufera, taken from the Toni Carrasquer García maps (1984), and the current position of the Creu de la Llonga are 4,300 m apart in a heading of approximately N250°E.

The old “Fita” of the Albufera, which was used to control the lake level when it was connected to the Mediterranean Sea, is identified as the Creu de la Llonga. It is proposed that its displacement may have been caused by a tsunami like the one that hit Santanyí in Mallorca in 1756. This event may also have displaced blocks from the underwater sandbank to the beaches of La Dehesa.

## Introduction

Functional diets play a pivotal role in aquaculture by enhancing fish health, resilience, and performance under the various stressors encountered throughout the production cycle, such as handling, transport, or high stocking densities. The integration of functional additives (e.g. prebiotics, probiotics, amino acids, and bioactive compounds from micro- and macroalgae) into aquafeeds has shown potential to mitigate oxidative stress and support immune responses. Among these additives, algae-derived compounds have gained particular attention for their richness in natural pigments, antioxidants, and polysaccharides. These ingredients may contribute to health status and help maintain gut integrity, which is essential for nutrient absorption and overall resilience. Species such as gilthead seabream (*Sparus aurata*), a key species in Southern European aquaculture, can particularly benefit from these dietary strategies. However, the successful implementation of functional diets requires a rigorous process of fine-tuning through controlled trials to determine optimal formulations and dosages. These trials are essential to ensure efficacy, cost-effectiveness, and compatibility with existing farming practices, while supporting the development of a range of reliable and sustainable aquafeed products for the market. As part of this effort, the Vertical Algae project aims to develop algae-derived products for a range of applications. Specifically, sub-project 5 is dedicated to aquaculture, focusing on the formulation of functional diets that incorporate algal biomass or extracts, with the goal of enhancing fish resilience through improved nutritional support.

## Materials and Methods

**Trial 1:** A 3-week feeding trial was conducted to evaluate the effect of microalgal extracts on the resilience of juvenile gilthead seabream (± 18 g) to stress and bacterial challenge. Fish were fed one of three diets: a commercial-like premium control diet supplemented with immunostimulants (CTRL+), or the same diet further supplemented with either a low (LOW) or high (HIGH) dose of *Tetraselmis chui* extract. At the end of the feeding period, fish were sampled to assess physiological and molecular biomarkers related to antioxidant status, gut health, and immune function. Subsequently, fish were exposed to an acute stress challenge involving handling, crowding, and transport. Six hours after the onset of the stressor, additional samples were collected to evaluate the fish response to the challenge. Following this, fish were infected with *Photobacterium damselae* subsp. *piscicida*, and mortality was monitored for 10 days.

**Trial 2:** In a second trial, early juvenile seabream (± 6.5 g) were fed for 7 days. The dietary treatments included the same commercial-like premium diet used in Trial 1 (CTRL+), a control diet without immunostimulants (CTRL−), and two additional diets based on the CTRL− formulation, supplemented with a low dose of *Tetraselmis chui* extract combined with either *Ulva* extract (Low+UL) or processed *Euglena* biomass (Low+EU). At the end of the feeding period, fish were sampled as before. Afterwards, they were subjected to the same stress protocol, followed by infection with *P. damselae* subsp. *piscicida*. Additional samples were taken 6 hours post-infection to assess the early fish response to this challenge, and mortality was monitored over the subsequent 10 days.

## Results and Discussion

**Trial 1:** Following the stress challenge, fish fed the LOW diet exhibited significantly higher hepatic total antioxidant status (TAS) than those fed CTRL+ or HIGH, suggesting a protective effect of the lower *Tetraselmis* dose against oxidative stress. Both LOW and HIGH diets appeared to buffer oxidative stress effectively, as lipid peroxidation (LPO) levels remained stable post-stress, unlike in the CTRL+ group, which showed a significant increase. Despite these physiological effects, no significant differences in mortality were observed between groups following the *P. damselae* subsp. *piscicida* challenge.

*(Continued on next page)*

**Trial 2:** Following the stress and bacterial challenge, liver catalase (CAT) activity was significantly higher in fish fed the LOW+UL and LOW+EU diets compared to the CTRL− but not the CTRL+ groups, indicating enhanced antioxidant responses with algal supplementation. In the intestine, fish fed the LOW+EU diet showed upregulated expression of *il1b* and *cldn12* compared to those fed the CTRL+ diet. The elevated expression of *il1b*, a key pro-inflammatory cytokine, suggests an activated local immune response, potentially modulated by the algal supplementation. Simultaneous upregulation of *cldn12*, a tight junction protein, may reflect a strengthening of the gut barrier, which is critical during infection. These findings point to a potential synergistic effect between *Tetraselmis* and *Euglena* in supporting intestinal immune responses and maintaining barrier integrity under stress and pathogen challenge. As in Trial 1, no differences in mortality were observed between treatment groups during the post-infection period.

**Conclusion**

Both trials highlight the potential and the challenges of using functional diets to improve fish resilience. While some algal extracts showed positive effects on antioxidant status and gut health, these changes did not lead to improved survival after bacterial infection. Functional diets can produce specific effects in different tissues, and results often depend on context, making it difficult to rely on single biomarkers. This reinforces the need for broad datasets and multivariate analyses to fully understand the impact of these diets. In the end, developing effective functional feeds requires a careful, data-driven approach that considers species, ingredients, and farming conditions.

## Introduction

The global climate of our planet is undergoing a rapid warming phase, characterized by a sustained increase in atmospheric and surface water temperatures The annual mean temperature is continuously rising also in Hungary, resulting in a surface water temperature increase of 0.32°C by average per decade over the past four decades. This warming is particularly significant in shallow lakes. The increase of temperature in the winter months is almost twice as high as in the summer (Li Huan et al., 2024).

Climate change is increasingly affecting pond aquaculture as well, with challenges including rising and fluctuating water temperatures. Additional emerging risk factor is higher water temperature during overwintering with associated metabolic impacts, and the emergence of various infections. These direct and indirect stressors negatively affect the welfare and immune systems of traditionally farmed species, influencing fish viability and production outcomes. The digestion capacity and appetite are primarily temperature-dependent in case of our most important farmed fish species common carp (*Cyprinus carpio*). In winter, natural food disappears in the lakes, but fish show active periods following weather fluctuations. Recent studies have shown measurable activity even at temperatures below 4°C. (Bauer & Schlott, 2004). Some studies suggest that carp not only moves but actively feeds at 6°C, with increasing feed intake as temperatures rise (Chen Song-bo et al., 2012). Active feeding behaviour typically occurs during milder winter periods, during which nutrient supply can only be managed through feeding. The primary goal during this period is to maintain condition and minimize weight loss, which is essential for sustaining a healthy stock in spring. Under these conditions, we aimed to determine feed intake at low temperatures, with a particular focus on identifying the lowest temperature at which the fish stop feeding. Our experiment focuses on reducing the vulnerability of carp farming technology to external stress factors.

## Materials and Methods

Four 160 L aquaria were used in the experiment: three with a feeding regime and one control without feeding. Each aquarium was stocked with five one-summer-old carp (average weight: 89.5 ± 23.9 g). The aquariums were filled with aerated tap water, with salt (NaCl) added at a concentration of 4 mg/L to prevent the spread of white spot disease (*Ichthyophthirius multifiliis*). Filtration was provided, with integrated heating, and adequate oxygen levels were maintained using an air pump.

The acclimation period lasted 17 days, during which water temperature fluctuated between 6–7°C. After acclimatization, measures were taken (standard and total length, body weight) of each fish. The experiment started at 4°C (3.4–4.4°C) and was maintained for 10 days using natural atmospheric cooling. For the subsequent temperature ranges (6°C and 8°C), the heaters were used to achieve the desired temperatures. Water temperature and oxygen levels were measured daily. Feeding was carried out once a day using Aller Master (Aller Aqua A/S Denmark) 4.5 mm feed pellets. Uneaten pellets were collected and counted after 24 hours, because of the pellets' good water stability and distinctive shape and size, which differed sufficiently from fish faces, allowed accurate counting. The trial lasted totally 56 days, when the fish biometric indices were assessed.
Feed intake was calculated using the following formula:
Feed provided (pcs) – uneaten feed (pcs) = feed consumed (pcs)
Feed consumed (pcs) * unit weight of the pellet (g) = feed consumed (g)
Feed consumed (g) / total fish biomass (g) = feed intake (%)
The average oxygen level measured during the experiment was 89.7 ± 9.3%.

*(Continued on next page)*

**Results and Discussion**

The fish were inactive at 4°C with minimal feed intake (0.031%). With increasing temperatures to 6°C, feed intake increased to 0.3% in all three aquaria. After two days, feed consumption decreased, presumably due to satiety, followed by a slower, steadier increase in feeding up to 0.160%. By further increasing the temperature to 8°C, feed intake reached 0.431%. Feed consumption showed significant differences between temperature levels (4–6–8°C) and a strong positive correlation was observed between water temperature and feed intake.

A slight increase in body weight was observed in fed fish across the temperature ranges. The initial average weight of 81.4 ± 23.5 g increased to 82.5 ± 25.4 g after eight weeks (56 days) treatment period, while the unfed control group showed decrease from 100.0 ± 28.7 g to 94.7 ± 27.4 g. As the temperature was higher the body weight loss of unfed fish was higher.

**Conclusion**

We demonstrated that at 4°C, the fish either did not consume feed or fed only minimally. However, feed intake was observed at 6°C and became more pronounced at 8°C, showing a strong positive correlation with increasing water temperature. Additionally, a slight increase in fish body weight was observed. Overall, the results indicate that targeted winter feeding can reduce body weight loss during overwintering, resulting better condition of the fish, which may enhance disease resistance and improve production efficiency.

# EFFECTS OF EXTREMELY LOW FREQUENCY ELECTROMAGNETIC FIELDS ON GROWTH, PHOTOSYNTHESIS AND ANTIOXIDANT ACTIVITY IN MARINE MICROALGAE

José María Terrer[1]*, José Antonio García Gamuz[2], María Ángeles Esteban[1], Marina Aboal[3]

[1]Department of Cell Biology and Histology, Faculty of Biology, University of Murcia, 30100 Murcia, Spain

## Introduction

The increasing use of technologies that emit extremely low frequency electromagnetic fields (ELF-EMF), such as submarine cables and electronic tagging systems, raises concerns about their potential ecological effects in marine ecosystems. Although the biological impacts of ELF-EMF on humans have been widely studied, their effects on marine primary producers, especially microalgae, remain poorly understood. Microalgae play essential roles in aquatic ecosystems and can synthesize protective molecules such as carotenoids and phenolic compounds in response to stress. This study evaluates the effects of ELF-EMF exposure on growth, photosynthetic performance, and antioxidant activity in marine microalgae strains from both anthropized and pristine environments.

## Materials and Methods

Six strains of microalgae from four taxonomic classes (Cyanobacteria, Porphyridiophyceae, Bacillariophyceae, and Chlorophyceae) were cultivated in liquid medium and exposed for five days to ELF-EMF (50 Hz, 100 ± 20 μT) generated by Helmholtz coils. Cultures were maintained under controlled temperature and light conditions. Cell density was monitored daily using a Neubauer chamber, and trypan blue was added to assess cell viability. Total antioxidant capacity was measured using the Sigma-Aldrich® MAK334 kit, and photosynthetic performance was assessed with a LiCor 6800 system by measuring net $CO_2$ assimilation, electron transport rate, PSII quantum yield, and dissolved carbon. Strains were grouped based on their collection sites: the anthropized Mar Menor lagoon (acclimated group) and the minimally impacted Moratalla mountains (non-acclimated group).

## Results and Conclusion

No significant differences in cell density (Figure 1) or total antioxidant capacity were observed between control and ELF-EMF-treated groups. However, growth trends varied by strain, with slightly higher final densities in controls. Photosynthetic responses showed significant interspecies differences: Tetraselmis sp. exhibited altered $CO_2$ assimilation and electron flow; Erythrolobus sp. and Scenedesmus sp. showed significant changes in dissolved carbon, and the latter also in PSII quantum yield. Acclimated strains tended to respond differently than non-acclimated ones in antioxidant activity, suggesting possible adaptive responses. Overall, short-term ELF-EMF exposure did not cause strong physiological changes in the strains tested, but species-specific photosynthetic responses and environmental history may modulate sensitivity. Further long-term studies are recommended to assess cumulative or delayed effects.

# ESTABLISHMENT OF IDENTIFICATION METHOD OF SEA CUCUMBER SPECIES TRADED IN KOREAN MARKET USING MULTIPLEX PCR AND PEPTIDE-NUCLEIC ACID (PNA) BASED REAL-TIME PCR METHOD

## Introduction

The expansion of Free Trade Agreements (FTAs) has significantly increased seafood imports, raising concerns about mislabeling of country of origin and consumer safety. Sea cucumbers are imported in substantial quantities, exceeding 1,000 tons annually, in various forms such as dried, frozen, salted, or preserved in brine. The emergence of incidents involving origin fraud underscores the necessity for accurate and efficient molecular identification tools. This study aimed to develop and validate multiplex PCR and peptide nucleic acid (PNA)-based real-time PCR assays for species-level identification of imported and distributed sea cucumbers in the domestic market.

## Materials and methods

A total of 32 sea cucumber samples were collected from various retail sources, including domestic supermarkets, traditional markets, and online shopping platforms. Species identification was carried out using small subunit ribosomal RNA (SSU rRNA) gene sequencing, which identified four species: *Cucumaria miniata* (Red sea cucumber), *Stichopus horrens* (Ruby cucumber), *Apostichopus japonicus* (Japanese sea cucumber), and *Holothuria spinifera* (Brown sea cucumber). Based on these results, four species-specific primer pairs were designed for multiplex PCR, along with four corresponding PNA probes for real-time PCR analysis.

## Results and discussion

The developed multiplex PCR assay demonstrated high specificity, with each primer set amplifying only the target species without cross-reactivity. The detection sensitivity ranged from $1 \times 10^3$ to $1 \times 10^4$ copies/µL. Similarly, the PNA-based real-time PCR assay showed specific amplification with distinct Tm values for each species, also within the sensitivity range of $1 \times 10^3$ to $1 \times 10^4$ copies/µL. These findings suggest that both methods are robust and reliable for species identification. The assays developed in this study are expected to provide effective tools for the authentication of sea cucumber species and for preventing country-of-origin mislabeling in the seafood market.

# CONSUMER AND PRODUCER PREFERENCES FOR ORGANIC AQUACULTURE PRODUCTS: THE CASE OF GREECE

I. Theodossiou,[1,*] E. Mente[2] and A. Zangelidis[1]

theod@abdn.ac.uk

## Introduction

Organic aquaculture has witnessed notable expansion and gained increasing scholarly and commercial interest, largely driven by escalating consumer demand for sustainably and organically certified aquaculture products. (Lembo and Mente, 2019). In the European Union, despite the growing demand for organic aquaculture products, evidence suggests a deceleration in the sector's growth, varying across countries and species. As environmental concerns and preferences for sustainable food sources increasingly influence consumer behavior, it becomes essential to understand consumer perceptions and purchasing patterns. Of particular importance is consumers' willingness to pay (WTP) for organic aquaculture products, as it serves as a critical incentive for producers to adopt organic farming practices—practices that typically incur higher production costs than conventional methods.

Previous research conducted in Greece indicates that younger consumers with higher levels of education and income tend to be more aware of the benefits associated with organically farmed fish and seafood (Polymeros et al., 2014; 2015).

This study examines both the WTP among Greek consumers and the willingness of Greek producers to engage in the organic cultivation of seabream, seabass, and mussels.

## Materials and Methods

This study utilizes data collected from structured surveys administered to both consumers and producers. Employing contingent valuation methodology, the research assesses consumers' willingness to pay (WTP) for seafood products derived from three distinct production systems: conventional aquaculture, organic aquaculture, and wild capture. The analysis investigates the influence of consumers' knowledge of organic aquaculture practices, their environmental attitudes, and their awareness of ecological issues on their purchasing preferences. Parallel to the consumer analysis, the study also examines producers' willingness to engage in the production of seabream, seabass, and mussels under conventional and organic prodaction system, aiming to identify potential alignment or divergence between consumer demand and producer intent.

## Results and Discussion

Altintzoglou et al. (2025) found that consumer awareness of aquaculture production systems remains generally low among European populations, despite widespread favourable attitudes toward sustainability in aquaculture. Their findings suggest the presence of a "halo effect," whereby positive perceptions of organic food in general may be extending to organic aquaculture products, leading to increased acceptance despite limited knowledge. The present study adds to this discourse by offering a focused analysis of the Greek seafood market, elucidating key demand-side dynamics. The results provide insights for stakeholders—particularly producers, retailers, and policymakers—who are aiming to foster the development and adoption of sustainable organic aquaculture practices in Greece.

**Introduction**

The European edible sea urchin, *Paracentrotus lividus* (Lamarck, 1986) is one of the most harvested invertebrate species in the Iberian Peninsula and other European regions, due to the high market price of its gonads (Toso *et al*., 2025). Populations of *P. lividus* in the wild undergo an annual gonadal cycle. In the southern of Spain, their gonads reach their highest gonadosomatic index (GSI) from January to March, aligning with their commercial availability period (Sánchez-España *et al*., 2004). Although aquaculture of *P. lividus* began in the early 1990s, challenges persist, particularly in regulating the gonadal cycle to ensure year-round production of marketable gonads. Daily and seasonal changes in light are key signals in the synchronisation of the circadian system and in the initiation, progression, and coordination of gonadal maturation in vertebrates (Mishra & Kumar 2017). In *P. lividus*, shortening day length (autumnal equinox) boosts gametogenesis rate and trigger the first spawning event, whereas extended daylight hours reduce it (Sphigel *et al*., 2003). To investigate whether this pattern is linked to photoperiod-entrained biological rhythms, we examined the gonadal circadian transcriptome of wild and sexually mature *P. lividus* (male and female) during their reproductive period.

**Materials and methods**

Wild, sexually mature *P. lividus* of commercial size were collected in March in Aguadulce (Almeria, Spain) and maintained in 60 L tanks (25 sea urchins/tank) at the facilities of the SCI-CM (University of Cadiz). The sea urchins were kept under natural photocycle (12L:12D) and temperature (~ 15 °C), and fed *ad libitum* with a mix of ulva (70%) and kelp (30%). They were then divided into 2 groups: one kept in 12L:12D (LD group) until the sampling day, and a second group exposed to 24 h of darkness (24D) prior to the sampling day. Gonads from 4 males and 4 females were collected every 4 hours over 24-hour, immersed in liquid nitrogen and stored at -80 °C. RNA was extracted using Quick-RNA™ Miniprep Kit, purified using OneStep™ PCR Inhibitor Removal kit (Zymo Research) and sent to Novogene to obtain the transcriptome using the *P. lividus* genome as query. Analysis of rhythmicity was performed using normalized TPM as input in the DiscoRhythm web application (Carlucci *et al*., 2021) and R Studio was used for data representation and gene clustering.

**Results**

All the gonads were fully mature, containing eggs and sperm, with an average GSI of around 3 in males and females in both photocycle groups (LD and 24D). Cosinor analysis of 24,337 genes from the transcriptome revealed daily rhythmic expression in 3.8% of male genes and 4.5% of female genes under LD, with only 1.6% of these rhythmic genes being shared between sexes. These percentages increased to 9% in males and 5% in females under 24D, with only 3.8% of these genes exhibiting rhythmicity in both sexes. Comparison of LD and 24D groups showed that only 3.5% of rhythmic genes in males and 3% in females were present in both conditions. Clustering of rhythmic genes according to their peak of expression (acrophase) revealed that, in the LD group, 46% of male genes peaked around dusk, while 59% of female genes peaks at night. In males under 24D, 36% of the genes maintained their original timing of maximal expression, 59% were delayed, and 5% were advanced. In females under 24D, only 8% of genes maintained their expression peak, 51% genes were delayed and 41% were advanced. Target analysis of the canonical genes of the molecular clock only showed significant rhythmic expression of *bmal2* in females and *timeless* in males under LD condition but none under 24D.

*(Continued on next page)*

**Discussion**

The animals were healthy and had ova and sperm, with a GSI whitin the expected range for this time of year (Sánchez-España *et al.*, 2004). The genome of *P. lividus* and the transcriptome of its gonads have recently been obtained. The findings suggest variations in the transcriptome related to sex and maturation (Machado *et al*., 2022). Accordingly, cosinor and clustering analyses revealed distinct sexual differences in the diel rhythmic expression of the analysed genes. Notably, only 1.6% and 3.8% of rhythmic genes were shared between sexes under LD and 24D, respectively. Moreover, clustering analysis showed that females appear to be more nocturnal and males more crepuscular under LD. Under 24D, gene expression phases shifted in a sex-specific manner: most genes were delayed in males and a substantial proportion were advanced in females. Interestingly, the percentage of rhythmic genes in both sexes increases under 24D. These results suggest that other synchronisers, in addition to light, may also be present, but their effects could be masked by the light cues in the LD group. The lack of rhythmic expression of canonical clock genes suggests that the diel rhythms in the gonads may be driven or maintained by central or systemic signals rather than by an autonomous oscillator within the gonads. Alternatively, different genes than those found in vertebrates may be involved in the functioning of the clock in sea urchins. In summary, our findings provide novel evidence suggesting that the circadian expression rhythms of sea urchin gonads appear to be photoperiod-responsive and sex-specific. Further research is required to determine whether central/systemic cues are the main drivers of these rhythms and how they interact with the seasonal reproductive timing of sea urchins.

# EVALUATION OF CANOLA MEAL AS A FEED INGREDIENT FOR ATLANTIC SALMON (*Salmo salar* L.)

Ivan Tankovski*, Angela Liu, Van Pham Thi Ha To, Saeed Khoramian, André Dumas, Essi Evans, Ellen McNabb, Chris Manchur, Curtis Rempel

ONDA
20 Hope Street
Souris, C0A 2B0, PE, Canada
itankovski@onda.ca

## Introduction

With a favourable nutritional profile and consistent supply, canola meal (CM) stands out as a promising ingredient for salmonid feeds. While several studies have examined CM inclusion in feeds for rainbow trout and Chinook salmon, its application in Atlantic salmon remains underexplored. The objective of this study is to assess the nutritional value of solvent-extracted CM by evaluating its digestibility, effects on the growth and health of Atlantic salmon, and environmental impact when used in salmon feeds.

## Materials and methods

A freshwater digestibility trial was conducted to determine the apparent digestibility coefficient (ADC) of the nutrients in CM. A reference diet was blended with CM at 90:10, 80:20, 70:30, and 60:40 ratios to create a series of test diets. Each diet was fed to triplicate groups of juvenile fish (49.0 ± 1.3 g), reared in 100-L tanks equipped with passive-feces collecting columns.

In a saltwater grow-out trial, four diets containing 0, 5, 10, or 15% CM were randomly assigned to three replicate 700-L tanks and hand-fed to post-smolt fish (245.6 ± 2.8 g) for 103 days. At the study's conclusion, a pooled sample of five fish per tank was collected for whole-body composition analysis. Blood, liver, and distal intestine samples were obtained from an additional five fish per tank to assess plasma biochemistry, liver and intestinal histology.

A life cycle assessment (LCA) following ISO and PAS 2050 standards was performed to evaluate the environmental impacts of salmon production across four scenarios: cage systems without and with 10% CM in the feed, and recirculating aquaculture systems (RAS) without and with 10% CM.

## Results

Results from the digestibility trial indicated that the ADC of nutrients was positively correlated with CM inclusion. At 40% CM, energy, protein, and essential amino acids ADC were 57.7%, 77.1%, and 83.0–93.9%, respectively. The feeding trial showed good growth performance across dietary treatments, with fish nearly tripling in body weight and maintaining a favorable feed conversion ratio (FCR) of approximately 1.0. Fish fed diets containing 5 and 10% CM had similar feed intake, growth, and FCR compared to the control, whereas 15% CM inclusion resulted in reduced growth and poorer FCR. Whole-body composition (i.e., protein, lipid, and ash) and plasma chemistry (i.e., immunoglobulin, lysozyme, glutathione peroxidase, catalase, and thyroid hormones) were similar across all diets ($P>0.05$). Intestinal and liver histology remained largely normal in all treatments. The LCA indicated that incorporating 10% CM into the diet, compared to a CM-free diet, led to 17% and 5% reduction in $CO_2$-equivalent emissions during salmon production in cage (1,683 vs. 1,390 kg $CO_2$-eq/MT salmon live weight) and RAS (5,763 vs. 5,460 kg $CO_2$-eq/MT salmon live weight) systems, respectively. Similar trends were observed for water use and land use, with impacts decreasing when CM was included. In conclusion, CM can be incorporated in salmon feed at levels up to 10% without compromising growth or health performance, while offering potential environmental benefits.

# NUTRITIONAL EVALUATION OF REDUCED ANTI-NUTRIENT FACTOR SOLVENT-EXTRACTED SOYBEAN MEAL AND MECHANICALLY PRESSED SOYBEAN CAKE IN DIETS OF ATLANTIC SALMON (*Salmo salar* L.)

Van Pham Thi Ha To*, Ivan Tankovski, Amanda Smith, Treasa Pauley, Alain Letourneau, Sylvain Legay, David Hendrick

ONDA
20 Hope Street
Souris, C0A 2B0, PE, Canada
Email: itankovski@onda.ca

**Introduction**

In salmon diets, soy protein concentrate (SPC) is considered a safe and commonly used plant-protein ingredient, though its high cost is a drawback. In contrast, although more affordable, conventional soybean meal (cSBM) is restricted due to the presence of anti-nutritional factors (ANFs) that can reduce digestibility, impair growth, and cause gut inflammation. To overcome these challenges, a new non-GMO soybean variety with reduced ANFs has been bred and processed using two common methods: solvent extraction to produce SBM (~55% crude protein (CP) on dry matter basis) and mechanical pressing to produce soybean cake (SBC: ~53% CP). The objective of this study is to evaluate the nutritional value of SBM and SBC by assessing their digestibility, growth performance, and effects on the gut histology of Atlantic salmon.

**Materials and Methods**

In the freshwater digestibility study, juvenile Atlantic salmon (60.2 ± 0.7 g) were randomly assigned to 12 100-L tanks in groups of 25, with four replicate per group. The fish were fed with one of three diets: a reference diet and two test diets. The test diets consisted of an 85:15 blend of the reference diet and test ingredients (SBM or SBC). Fecal material was collected using the passive column method to determine the apparent digestibility coefficient (ADC) of the ingredients' nutrients.

In the saltwater feeding study, post-smolt Atlantic salmon (166 ± 2.9 g) were randomly allocated into 17 700-L tanks at 50 fish per tank. The fish were fed one of six diets: Diet A (12% SPC: positive control), Diets B and C (5% and 15% SBM), Diets D and E (5% and 15% SBC), and Diet F (15% cSBM: negative control). Each diet had three replicates, except for Diet F which had two replicates. The fish were hand-fed three times daily for 84 days. At the study's conclusion, fish body weights were recorded, and whole-body (5 fish/tank) and distal intestine samples (5 fish/tank) were collected.

**Results**

The digestibility study showed that SBM and SBC were highly digestible, with the ADC for protein and essential amino acids (EAAs) ranging from 83.8-97.2% and 78.7-96.6% for the former and latter, respectively. In the feeding trial, no significant differences were observed in growth performance or feed conversion ratio between diets. Whole-body nutrient composition and nutrient retention (e.g., moisture, protein, lipid, ash, gross energy and EAAs) were comparable across all dietary treatments. Histopathological examination showed no apparent differences between fish fed novel reduced ANFs SBM and SBC compared to those fed SPC, while improvement trends were observed when compared to those fed conventional SBM. Based on these findings, the novel soy, whether processed through solvent extraction (SBM) or mechanical pressing (SBC), is considered digestible, nutritious, and promising protein alternatives that can be included up to 15% in salmon diets.

# DEVELOPMENT OF FUNCTIONAL ANTIOXIDANT AQUACULTURE FEED INGREDIENTS FROM POULTRY WASTE VIA ENZYMATIC HYDROLYSIS

## Introduction

The poultry industry generates large volumes of by-products such as carcasses, feet, viscera or skin, which are generally destined for low value-added purposes. However, these by-products are rich in proteins and constitute an important source for obtaining bioactive peptides of interest in animal nutrition (Fontinha et al., 2021). Through enzymatic hydrolysis, it is possible to valorise these materials by transforming them into protein hydrolysates with a high content of free amino acids and functional peptides. The aim of this work was to study the single or double enzymatic hydrolysis of chicken legs and carcasses to obtain new ingredients with antioxidant properties for aquaculture nutrition, contributing to the development of a more sustainable aquaculture and the efficient use of poultry waste.

## Materials and Methods

First, a characterisation of the sample was performed by determining its moisture, protein, fat and ash content. Chicken by-products consisting of carcasses (C) and feet (F) were diluted 1:2 with bidistilled water. Subsequently, simple hydrolysis was carried out with an endoprotease (C1, F1) for 1h at 55ºC, and sequential hydrolysis by adding an exoprotease after the action of the endoprotease (C2, F2), leaving it to act overnight at the same temperature. After that, the enzymes were inactivated by heating in a water bath (85°C, 15 min). The degree of hydrolysis of the samples was determined and then an ultrafiltration was carried out using filters with cut-offs of 30, 10 and 3kDa to study the peptide profile according to their molecular weight. The free amino acid content was determined according to Flores et al. (1997). Finally, the antioxidant activity of all extracts was measured through four different methods: ABTS radical scavenging capacity, oxygen radical absorbance capacity assay (ORAC), DPPH radical scavenging and ferric-reducing antioxidant power (FRAP).

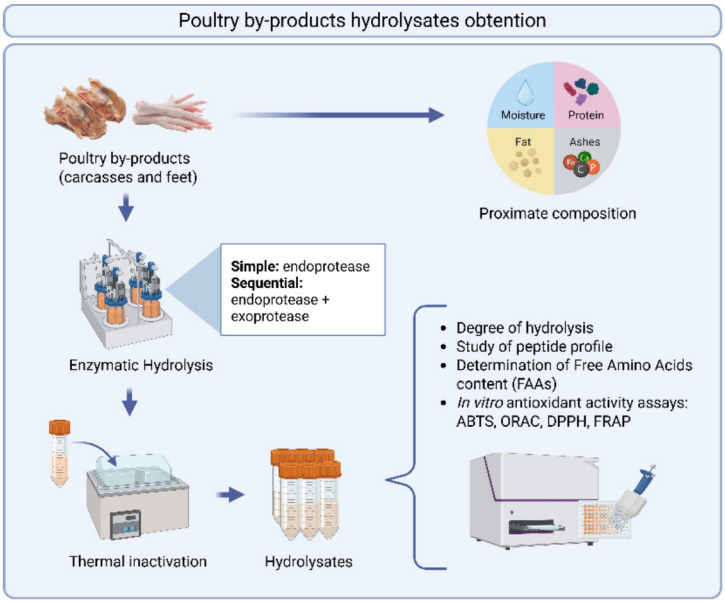

**Figure 1.** Graphical summary for the obtention of poultry by-products (carcasses and feet) hydrolysates (created in https://BioRender.com).

*(Continued on next page)*

**Results and Discussion**

Statistical analysis of the results obtained in the different trials revealed significant differences between the use of one or two enzymes to obtain hydrolysates from these by-products, as well as differences between the use of either carcasses or feet. Regarding the degree of hydrolysis, carcasses presented higher values than legs in both treatments, being hydrolysate C2 the one that reached the highest value (66.41 ± 5.47%). Peptide profile analysis showed a higher proportion of low molecular weight peptides (<3 kDa) in the hydrolysates with exoprotease incorporation (C2 and F2), with values of 78.35 ± 3.88% and 65.28 ± 2.32%, respectively. Similarly, the concentration of free amino acids was significantly higher in C2 and F2 compared to C1 and F1, with C2 standing out, where approximately 55% of the content corresponded to free amino acids. Finally, the analysis of antioxidant activity showed significant differences between carcass and leg hydrolysates, attributable to the characteristics of their peptides. Hydrolysates from chicken carcasses showed higher antioxidant activity in the ABTS and ORAC assays, while those obtained from feet were higher in the FRAP and DPPH assays. In all cases, hydrolysates obtained by sequential hydrolysis showed better results than those obtained by simple hydrolysis, which is related to a higher proportion of small peptides (< 3 kDa), widely associated with a higher antioxidant capacity (Ajibola et al., 2011).

**Conclusions**

Chicken by-products, such as feet and carcasses, can be efficiently exploited to obtain hydrolysates with bioactive properties, especially antioxidant activity. Sequential hydrolysis favoured the generation of low molecular weight peptides and a higher release of free amino acids, which resulted in higher antioxidant activity. These findings highlight the potential of revalorisation of poultry by-products through the use of enzymatic processes for the development of new functional ingredients and its application in aquaculture feeds.

**Funding**

This study forms part of the ThinkInAzul program and was supported by MCIN with funding from European Union NextGenerationEU (PRTR-C17.I1) and by Generalitat Valenciana (GVA/THINKINAZUL/2021/023, IP1: F. Toldrá, IATA). The Accreditation as Center of Excellence Severo Ochoa CEX2021-001189-S, funded by MCIN/AEI/10.13039/501100011033, is also acknowledged.

## Introduction

Exogenous environmental factors, such as temperature and light, significantly influence fish growth. As poikilotherms, fish exhibit a direct correlation between temperature and metabolic rate. Light is another major factor that may affect physiology, behaviour and growth performance in indoor aquaculture systems. Specifically, variations in light wavelength and intensity can modulate metabolism and welfare status (Karakautsoli et al., 2008). This study aimed to evaluate the combined effect of light and temperature on the growth performance of rainbow trout (*Oncorhynchus mykiss*).

## Material and methods

Three different colours of light emitting diode (LED: white, 380-750 nm; green, 495-570 nm; or blue, 450-494 nm; Fig 1) were tested at two different culture temperatures (15 and 20ºC). The experimental design was 3x2 with two replicate tanks for each experimental condition. A total of 70 fish per tank, with an initial weight of 3.7 ± 0.3 g, were randomly distributed into 500 L cylindrical tanks connected to separate recirculating aquaculture systems according to temperature condition. Trout were maintained under a 12L:12D photoperiod. For 45 days, fish in all tanks were hand-fed once daily with a commercial diet to apparent satiation (two hours after the start of the light cycle) up to a maximum of 3% of daily feed intake. Fish weight was monitored every 15 days, sampling 16 fish per tank to adjust feed intake. Statistically analysis was performed using a two-way ANOVA, including the interaction effect of temperature x light. For each light condition, a Student's t-test was performed to compare temperatures. A significance level of $P < 0.05$ was considered for all tests.

## Results and discussion

There were no significant effect of light colour nor interaction with temperature on growth performance by two-way ANOVA. However, there was a significant effect of temperature by the ANOVA analysis that affected growth in a different way depending of light (evidenced when T-test was applied to compare fish weight at 15ºC and 20ºC under the same light). Fish cultured at 20ºC exhibited lower growth efficiency than those maintained at 15ºC. This growth reduction was significant for final weight (g), weight gain (WG), and specific growth rate (SGR), which decreased at 20ºC, and for feed conversion ratio (FCR), which increased, in fish exposed to green light (Fig 2). Fish under white light showed a similar trend to those under green light, though without statistically significant differences. Conversely, fish exposed to blue light maintained similar growth under both temperature conditions. Mortality remained very low (<2%) in all experimental conditions. Within an optimal range, an increase of temperature may impact on the metabolic rate, leading to increase of activity and faster feeding. In this study, all the fish ate the maximum daily feed intake stablished (3%). However, fish cultured at 20ºC showed higher activity levels during the feeding, suggesting an increase of metabolic rate. This increased energy expenditure, not compensated by additional energy intake, may have contributed to their lower growth. Other authors have demonstrated the influence of light colour on fish metabolism, stress and immune response (Chen et al., 2022). Blue light, in particular, has been shown to improve feed utilization and growth performance in other teleosts (Villamizar et al., 2009; Sierra-Flores et al., 2016) and even reduce stress levels (Wu et al., 2021). In this study, we observed that blue light could mitigate the negative effects of increased temperature on growth, compared to the reduced growth observed in fish reared under green or white light at the same feeding rate. Future results funded by this project will explore homeostatic mechanisms and welfare to draw further conclusions about how the light colour can regulate the impact of elevated temperatures in indoor aquaculture systems.

## Introduction

The sustainability of aquaculture is essential for its long-term viability. As such, a significant research area focuses on finding more sustainable alternative ingredients for aquafeeds. The circular economy plays a crucial role, particularly by using by-products as valuable feed inputs. In Spain, cider production reaches approximately 78 million litres annually, with 73% originating from Asturias. This industry generates large quantities of a residual by-product from fermentation and maturation of cider, known as cider lees, which could potentially be used in aquaculture feeds. Cider lees are characterized by their high content of insoluble dietary fibre and different compounds with antioxidant capacity (Rodríguez et al., 2017). The objective of the present study was to evaluate the effect of including cider lees in fish diets, specifically to assess their impact on fish growth and antioxidant capacity.

## Material and methods

To evaluate growth performance, fish were fed diets containing two different levels of cider lees (CL10: 10% and CL20: 20%; Table 1) and a control diet for 88 days in a recirculating aquaculture system. Each diet was tested in triplicate, with 30 fish per tank, and fed to apparent satiety once daily (up to 3%). Following the feeding trial, fish from each dietary group were split into two tanks per diet. One tank was subjected to an acute hypoxia challenge (4 ppm $O_2$/10 min; de Mercado et al., 2018), while the other served as a non-stressed control. Blood samples were collected from six fish per tank at four time points: pre-stress (BASAL), immediately post-stress (0H), and at 2- and 5-hours post-stress (2H; 5H). Samples were collected in heparinized syringes and centrifuged to recover plasma, which was stored at -80°C until analysis. Ferric-Reducing Antioxidant Power (FRAP) was measured in the plasma using the Benzie and Strain (1996) method, with results expressed as μM $Fe^{2}$□. Data were analyzed using a one-way ANOVA followed by Tukey's post hoc test, with a significance level of $P < 0.05$.

**Table 1. Composition of experimental diets**

| *% Ingredients (on dry weight)* | CONTROL | CL10 | CL20 |
|---|---|---|---|
| Fishmeal | 20.0 | 20 | 20 |
| Cider lees | 0.0 | 10 | 20 |
| Soy protein concentrate | 20.0 | 20 | 20 |
| Wheat gluten | 12.0 | 11.5 | 11.5 |
| Corn gluten | 6.0 | 6 | 6.5 |
| Chicken meal | 5.0 | 4.5 | 3 |
| Wheat meal | 18.0 | 9 | 0 |
| Fish oil | 11.0 | 11 | 11 |
| Fish soy | 5.2 | 5.2 | 5.2 |
| Vit & min premix | 1.0 | 1 | 1 |
| Monocalcium phosphate | 0.8 | 0.8 | 0.8 |
| Lysine | 0.3 | 0.3 | 0.3 |
| Threonine | 0.1 | 0.1 | 0.1 |
| Methionine | 0.6 | 0.6 | 0.6 |
| *% Proximal composition (on dry weight)* | | | |
| Protein | 45.6 | 45.1 | 45.5 |
| Fat | 20.2 | 20.9 | 21.4 |
| N-Free extract (NFE) | 26.7 | 26.2 | 25.2 |

## Results and discussion

At the end of the feeding trial, fish reached a final weight of 73.3 ± 2.6 g. No significant differences were found in final weight, specific growth rate (SGR), or feed conversion ratio (FCR) among the dietary groups. After the hypoxia challenge, all fish showed an increase in antioxidant capacity (FRAP) at time 0H, followed by a gradual decrease at 2H and 5H post-stress. However, this decrease was only statistically significant in the control group, suggesting a depletion of the antioxidant system after 5H post-stress. In contrast, fish fed the 20% cider lees diet (CL20) maintained higher FRAP levels throughout the recovery period, showing a significantly higher antioxidant capacity than the other groups at 5 hours post-stress (Fig 1). Non-stressed fish maintained stable FRAP levels over time, with higher values observed in fish fed with cider lees (data not shown). The preliminary results of this study show that including up to 20% cider lees in rainbow trout diets has no negative effects on growth performance and enhances the fish's antioxidant capacity, suggesting its potential as a functional ingredient. Other studies have explored the use of similar by-products, such as grape pomace (solid residues after juice; Peña et al., 2020) and wine lees (Martínez-Antequera et al., 2023) in aquaculture diets, without negative effects on growth and providing functional properties. To our knowledge, this is the first study to investigate the use of cider lees as a sustainable and alternative ingredient in aquaculture feed. While further analysis is needed to understand the effects on various physiological parameters, these preliminary results highlight the potential of cider lees as a functional and alternative ingredient for rainbow trout diets.

# LIVE FROM THE CAGE: GILTHEAD SEABREAM (*Sparus aurata*) RESPONSE TO OPERATIONAL AND ENVIRONMENTAL FACTORS IN A COMMERCIAL SEA FARM

L. Toomey[1,*], G. Lembo[1], C. Neglia[1], P. Carbonara[1]

[1] Fondazione COISPA ETS

In order to achieve sustainable and ethical aquaculture practices, it is imperative to gain a comprehensive understanding of the interactions between fish species and their environment. The aquaculture industry is in need of instruments capable of objectively and accurately monitoring fish health and welfare in real time, without disturbing the fish or interfering with standard management practices. Precision livestock farming is a subject that has gathered increased attention given its potential to enhance animal welfare, whilst concomitantly increase production and environmental sustainability (Føre et al. 2018; Brijs et al. 2021). The utilisation of biological sensors, capable of measuring diverse parameters (e.g. depth, acceleration, muscle activity, heart rate), has emerged as a pertinent tool to assess fish health and welfare in response to aquaculture environments and practices (e.g. Carbonara et al. 2019, 2021; Morgenroth et al. 2024; Toomey et al. 2025). The present study evaluated the effectiveness of wireless environmental and accelerometer/pressure sensors in monitoring fish welfare and in gathering insights into relationships between fish acceleration/depth and environmental/farm operational factors.

An experimental trial was conducted within a sea cage of industrial scale at the Rehomare S.r.l. farm in Torre Suda, Italy. In this trial, a variety of environmental sensors were deployed in the water to monitor environmental parameters, namely temperature, oxygen saturation, salinity, tilt (i.e. used as a proxy for water current), and turbidity. Furthermore, we implanted accelerometer or accelerometer/pressure sensors, with a tailbeat mode algorithm, in gilthead sea breams (*Sparus aurata*), thus enabling the measurement of fish acceleration ($m.s^{-2}$), which serves as a proxy for energy expenditure (Alfonso et al. 2021), and depth (m). The experiment was conducted over a period of 305 days, commencing in September 2023 and concluding in September 2024, the experiment being subjected to intermittent interruptions due to technical issues. A total of 40 fish were tagged at different periods during the experiment. All sensors provided real-time data visibility to the farmers, and a total of 1,855,363 detections (acceleration + environmental variables) were obtained after the data was cleaned (i.e. false detections were excluded). A comprehensive data set was compiled, encompassing the quantity of feed administered daily, in addition to any occurrence of disruptions (e.g., feeding, sensor maintenance, or the introduction of tagged fish into the sea cage). Linear mixed models were employed to assess the variation of acceleration according to the period (night/day), the different environmental variables (i.e. temperature, salinity, oxygen, sensor tilt, turbidity), as well as the amount of feed provided and the occurrence of disturbances. The effect of these factors on the switch between aerobic and anaerobic metabolism was also investigated using a binomial generalised linear model.

The utilisation of wireless technology allowed for the acquisition of precise temporal data on various pivotal environmental parameters to explore relationships with fish behaviour/physiology. A range of significant variations were observed across time for the environmental data. For instance, the mean temperature was found to be 27.7 ± 5.7°C, with a range between 13.6 and 29.7°C. Similarly, the levels of dissolved oxygen varied from 48.3 to 126.8%. Overall, fish exhibited clear differences in day/night patterns both in terms of acceleration and depth, with fish being in shallower waters and displaying lower acceleration values during the night. Furthermore, the observed pattern of acceleration across hours indicates a possible anticipatory behaviour in relation to feeding. The study also identified the influence of environmental parameters on fish acceleration. In addition to photoperiod, a significant positive correlation was observed between acceleration and temperature, tilt, turbidity, and dissolved oxygen. Conversely, an inverse correlation was observed between acceleration and salinity or feed supply. In the switch between aerobic and anaerobic metabolism, temperature and disturbances appeared to be particularly important factors. In terms of depth, a positive correlation was observed with turbidity and salinity, and fish were in deeper waters in the absence of disturbance. Conversely, a negative relationship was evident with temperature and oxygen. The results of this study are overall in agreement with those previously obtained for Gilthead seabream in other contexts (e.g. Alfonso et al., 2024; Muñoz et al., 2020; Toomey et al., 2025). However, we provide here various new insights on relationships with new environmental and farm operational parameters and over a longer time period. A more in-depth discussion of these findings is required, with particular emphasis on the season and the inherent variability among individual fish.

*(Continued on next page)*

This study provided preliminary insights into the complex interplay between environmental factors and Gilthead seabream acceleration and depth, which are useful information for future welfare prediction indicators. The next steps are the integration of growth data to facilitate the creation of predictive models. The integration of acoustic telemetry technology with environmental sensors provides fish farmers with real-time data, which could function as an alert system for adverse events, enabling timely adjustments to be made to management practices, thus enhancing productivity and fish welfare.

## Introduction

Marine mussels represent an important component of the intertidal and subtidal communities and estuaries, and also of considerable economic importance to aquaculture in many regions of the world (FAO, 2024). The issue regarding the recently published evidence of the presence and potential dissemination of alien mussel species in the Chilean coast, that could cause an impact on the coastal benthic biodiversity and a tremendous damage to the Chilean indigenous mussel (*M. chilensis*) aquaculture growing industry; is a potential problem. Among some of the main features of these *Mytilus* species is the well-known capability to naturally hybridize among them in locations where their distributions overlap (Comesaña et al., 1999; Gardner et al., 2021). Furthermore, a low percentage of "natural hybrids" between these mussels' species have been also described in the literature along the Chilean coast, Larraín et al. (2012), described, a few hybrids between *M. galloprovincialis* & *M. chilensis.* Jilberto et al. (2023) also described at the Strait of Magellan, some hybrids between *M. chilensis* & *M. platensis*. The study of the reproductive cycles of *M. chilensis* and *M. galloprovincialis* at Tumbes Cove where they are found sympatrically is important, to establish the amount of reproductive output of each mussel species and possible synchronous spawning which leads to potential formation of natural hybrids.

## Material and Methods

The recollection of mussels (*M. chilensis* and *M. galloprovincialis*) from the natural beds at Tumbes Cove (Fig 1), where then suspended from a long line in pearls nets 4 months before the experiment. During 17 months 30 mussels from each species were sampled. The samples were transported at 4°C to the laboratory and within 1 day following each field sampling, 20 mussels (38–42 mm s.l.) from each species, were dissected carefully to separate the mantle (and in some the mesosoma) from other soft tissues. The histological procedures were made following Comesaña et al., (1999) (fig. 2). A piece of mantle border (20–30 mg) from each individual was stored (95% ethanol at –20°C) for identification of the species using the diagnostic genetic markers (Illesca et al. 2018). Histological analysis and terminology for the stages of gametogenesis followed Oyarzún et al., (2018).

## Results

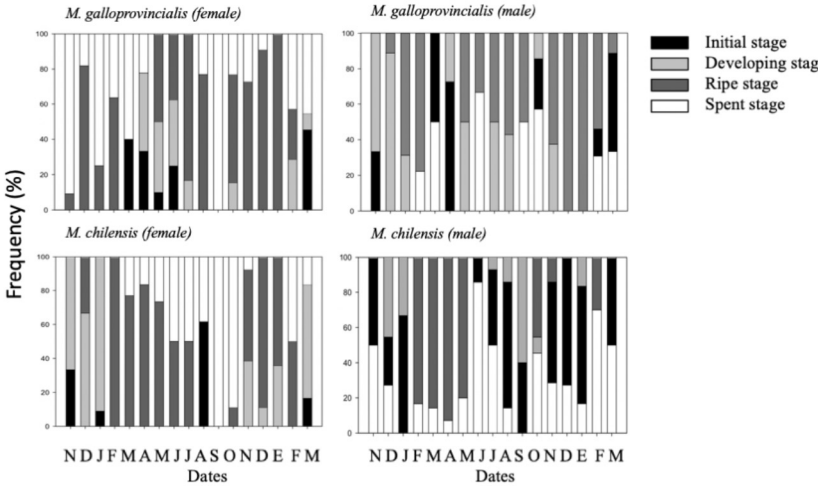

**Fig. 3**: *Mytilus* spp. Frequency distribution of gonad maturation stages in female and male *M. galloprovincialis* and *M. chilensis*.

*(Continued on next page)*

Fig. 1. Location sampled, Tumbes Cove.
Upper valves: *M. galloprovinciales*
Lower valves: *M. chilensis*

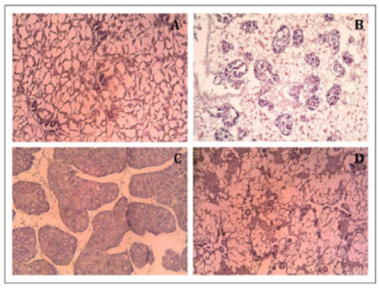

Fig 2. gonad maduration stages
A: Initial. B. Developing
C: Ripe. D: Spend

**Discussion and Conclusions:**

According to the results we observed a high synchronous spawning during winter (July) from both species (Fig. 3). The beginning of the gametogenic cycle for *M. galloprovincialis* was observed in November, just after the spawning (spring) reaching over 40% of individuals (male and female) at the Development stage. Then, towards winter (June) the stages moved from Development to Ripe Stages (Fig 3), having a spawning during July. During august-september, presented another short gametogenesis cycle with Development and Ripe stages following a Spend (spawning) stage during october-november. *M. chilensis*, showed two spawning periods, February-march (summer), and July (winter). The gametogenesis cycle of this species is over a larger period presenting individuals with at Ripe stage for a long period (Fig. 3). The gamete volume fraction (GVF) analysis showed a high prevalence of Ripe Stage gametes during several months sampled, while the a drastic reduction of these, shows spawning periods These results are in accordance to the literature Tarifeño et al. (2006).

# TURBULENCE AND SURFACE WAKES IN A COASTAL AQUACULTURE AREA: INSIGHTS FROM THE SIRENA PROJECT

J.S. Torres[1]*, A. Rodríguez-Santana[1], A.J. González-Ramos[1], A.M. Mancho[2], A. García[1], L. Yubero[2] and A. Marrero-Díaz[1]

[1]ECOAQUA, Universidad de Las Palmas de Gran Canaria, Edificio de Ciencias Básicas, 35017, Las Palmas de Gran Canaria, Spain
[2]CSIC, Instituto de Ciencias Matemáticas, C/ Nicolás Cabrera 13-15, Campus Cantoblanco 28049 Madrid, Spain
Email: jacob.torres@ulpgc.es

## Introduction

The SIRENA project aims to develop innovative monitoring tools for aquaculture farms in Gran Canaria, focusing on external and internal environmental processes. This study compares two oceanographic scenarios—one with an island wake and one without—using a multidisciplinary approach combining satellite imagery, high-resolution model data, and in situ turbulence measurements.

## Methods

Four seasonal oceanographic campaigns were conducted: March 5, April 7, June 30 and July 28; employing a free-falling turbulence profiler (VMP-250) and a multiparameter EXO2 probe to collect vertical profiles of physical and biogeochemical variables. Surface fields and subsurface profiles were obtained from the Puertos del Estado operational ocean forecast model (≈250 m resolution). Sentinel-2 imagery was used to detect and delineate island wake structures (Figure 1).

## Results

Vertical profiles of conservative temperature from in situ measurements and Puertos del Estado model outputs at Station 5 showed discrepancies across seasons (Figure 2). The model generally overestimated temperatures by about 0.3°C in March and surface temperatures in April but underestimated temperatures below 10 meters. On June 30, observed temperatures were up to 2°C higher than the model in upper layers, likely due to inaccuracies in the model's delineation of the island wake boundary. A similar, though less pronounced, pattern was seen on July 28, outside the wake area. Observations showed a warming trend toward summer with stronger stratification later in the year.

Profiles of potential density and turbulent dissipation rate (ε) indicated stronger stratification and higher turbulence below 20 meters on June 30 (with wake) compared to July 28 (without wake). Satellite imagery and model outputs differed notably in the spatial extent of the island wake, affecting sea surface temperature predictions. However, in situ turbulence data were consistent with the wake location observed in Sentinel-2 imagery, supporting the satellite's spatial positioning of the wake.

## Conclusions

The Puertos del Estado model shows limitations in accurately resolving island wake features, impacting environmental assessments. These findings underscore the necessity for higher-resolution models, such as the one developed in the SIRENA project, to improve monitoring and management of aquaculture farms in complex coastal environments.

## Acknowledgements

This project is developed with the collaboration of the Biodiversity Foundation of the Ministry for Ecological Transition and the Demographic Challenge, through the Pleamar Programme, and is co-financed by the European Union through the European Maritime, Fisheries and Aquaculture Fund.

## Introduction

The diversification of cultured species represents a promising strategy for enhancing the economic viability of the aquaculture industry. Within the European Union, this approach has emphasized the importance of some species, such as the grooved carpet clam (*Ruditapes decussatus*), due to its high potential from biological, economic, and gastronomic perspectives (FAO, 2024). Furthermore, sustainable clam aquaculture may contribute to the conservation of European natural populations of this mollusc species, which are currently in decline due to overexploitation, disease, and competition with other bivalve species, such as the Manila clam. These challenges may be exacerbated under global warming scenarios, making it critical to assess the effects of elevated temperatures on the culture of marine invertebrates, whose growth, metabolism, and overall welfare are closely linked to environmental thermal conditions (Rato et al., 2022). In this line, the objective of this study was to evaluate the impact of high environmental temperatures (28-30 °C) on the physiology and metabolism of *R. decussatus*, previously cultured under two conditions: with substrate and without substrate during all life cycle.

## Materials and Methods

*Ruditapes decussatus* specimens were obtained from thermal shock-induced spawning at the IFAPA-Agua del Pino facilities (Cartaya, Huelva, Spain). Juvenile clams were previously reared for 15 months under two distinct conditions: (i) with substrate and (ii) without substrate. Following this initial rearing period, a total of 240 clams were individually measured, weighed, and randomly allocated into 12 perforated rectangular baskets (20 clams per basket), maintaining the respective substrate conditions: 120 clams in six baskets with substrate and 120 clams in six baskets without substrate. These were assigned to four experimental groups (in triplicate): with and without substrate, each maintained at either control temperature (18 °C) or elevated temperature (28 °C) for 28 days. Clams were fed a mixed microalgae diet consisting of *Skeletonema costatum*, *Chaetoceros gracilis*, *Isochrysis galbana*, and *Tetraselmis suecica*. At the end of the thermal exposure period, biometric data were collected, and soft tissue samples from each experimental tank (n =12) were harvested and stored at -80 °C for subsequent biochemical analyses.

## Results and Discussion

Prior to the thermal challenge, clams reared with substrate exhibited superior growth performance and body condition compared to those cultured without substrate. After 28 days of exposure to elevated temperature, significant differences in growth parameters were observed among the experimental groups, with temperature emerging as a key factor. Under both rearing conditions (with and without substrate), high temperature negatively affected soft tissue weight (Table 1). In addition, individuals maintained at 28 °C (High) displayed reduced shell length compared to those held at 18 °C (Ctrl). This detrimental temperature effect was also reflected in the condition index, which reached its highest values in clams maintained at 18 °C, regardless of substrate presence. Concerning intermediary metabolism, no significant differences were detected in triglyceride, cholesterol, or glycogen concentrations among groups. However, glucose levels peaked in clams reared without substrate at the control temperature (Fig. 1A), suggesting increased carbohydrate mobilization to meet energy demands associated with growth, as supported by the elevated condition index in this group. Lactate accumulation was observed in clams exposed to high temperature, irrespective of substrate availability (Fig. 1B). Interestingly, under control temperature, clams reared without substrate also exhibited higher lactate levels than those with substrate. Although lactate is not the primary end-product of anaerobic glycolysis in bivalves (de Zwaan & Eertman, 1996), its accumulation is often associated with muscle fatigue and physiological stress, potentially induced by thermal stress and/or the absence of substrate. Total lipid content was significantly influenced by temperature, with the lowest levels observed in clams exposed to high-temperature conditions (Fig. 1C). This reduction likely reflects increased utilization of lipid reserves to meet the elevated energetic demands required to maintain homeostasis under thermal stress.

Data of growth parameters are shown as the mean ± SD (n=60). Different letters (a, b) in each row denote significant differences (one way-ANOVA and Tukey test, $P \leq 0.05$) among clams reared in $T_0$: Initial time; Ctrl: 18 °C; High: 28 °C for the same substrate condition (with or without). T.W.: Total weight; M.W.: Meat weight; S.W.: Shell Weight; S. L.: Shell length; C. I.: Condition Index = M.W./S.W*100; D.W: Dry weight.

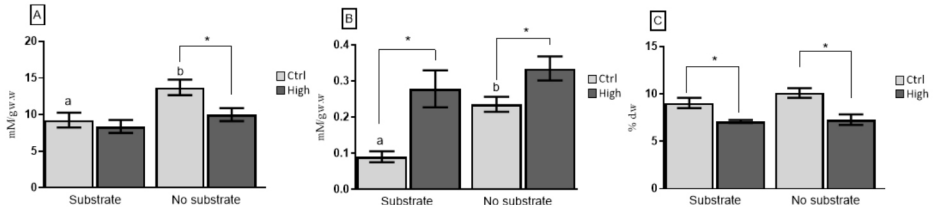

**Figure 1**. Glucose (A), lactate (B), and total lipids (C) values in whole meat of *R. decussatus* cultured with and without substrate, and submitted to different water temperatures (Ctrl: 18 °C; High: 28 °C) for 28 days. Asterisk (*) over the box denotes significant differences (t-Student, $P \leq 0.05$) between clams reared with the same substrate condition (with/without) at 18 °C or 28 °C. Different letters (a, b) over the box denote significant differences among clams reared with the same $T^a$, with or without substrate.

In summary, the results demonstrate that elevated environmental temperatures exert a detrimental impact on growth performance in *R. decussatus*, regardless of substrate availability. While further research is warranted, these findings provide valuable insights into the potential effects of climate change on clam aquaculture productivity.

## Introduction

Since the mid-1920s, when intensive harvesting of the grooved carpet shell (*Ruditapes decussatus*) began, its natural populations, despite having a high recovery capacity, have experienced a sharp decline. This has led the main producing countries, i.e., Spain, France, and Portugal, to focus on sustainable aquaculture as a key strategy to improve the economic sustainability of the sector, thereby reducing environmental extractive pressure (FAO, 2024). An optimized farming method is key to the culture's profitability. Thus, determining the optimum stocking density, maintaining a well-organized farming system, and ensuring the availability and quality of substrate are specific technical solutions that facilitate easier intervention in the event of any problem (e.g., pollution, parasitism, abrupt environmental changes, etc.). This study aimed to assess the effects of substrate and stocking density on the physiology and metabolism of *R. decussatus* throughout the entire culture cycle.

## Materials and Methods

*R. decussatus* specimens were obtained from thermal shock-induced spawning at the IFAPA-Agua del Pino facilities (Cartaya, Huelva, Spain). Clams were reared for 15 months in baskets with mesh sizes adapted to each developmental stage, under different culture conditions: (i) with substrate, and (ii) without substrate. Throughout the entire culture cycle, three stocking densities were maintained: Low Stocking Density (LSD; 1000 specimens/m²), Medium Stocking Density (MSD; 2000 specimens/m²), and High Stocking Density (HSD; 3000 specimens/m²). Clams were fed a mixed microalgal diet composed mainly of *Skeletonema spp*. and *Chaetoceros spp.* Rearing conditions, including flow rate, temperature, and oxygen saturation, were monitored weekly. Growth parameters were assessed monthly over the culture period. At the end of the experimental period, final biometric measurements were recorded, and soft tissue samples from each experimental tank (n = 18) were collected and stored at -80 °C for subsequent biochemical analyses.

## Results and Discussion

Clams reared with substrate exhibited enhanced growth performance and improved body condition compared to those cultured without substrate. This difference may be attributed to more favorable feeding conditions, as the presence of substrate facilitates proper shell opening for optimal microalgae filtration and ingestion (Zhang et al., 2023). When substrate is available, clams can rest their valves against the surrounding sediment, allowing the adductor muscles to relax during filtration. Conversely, clams cultured without substrate must maintain continuous adductor muscle contraction to ensure valve alignment, which may reduce filtration efficiency. Regarding stocking density, significant differences in growth parameters were observed among the experimental groups, with high density exerting a negative effect (Table 1). This effect was more pronounced in clams reared with substrate, which exhibited higher growth rates at low stocking density (Table 1).

Regarding metabolic response, the influence of stocking density was more pronounced in clams reared with substrate. Under both culture conditions (with and without substrate), no significant differences were observed in glycogen and total lipid levels. However, cholesterol, triglycerides, and glucose (also without substrate) levels decreased in clams reared with substrate at high density (HSD). Additionally, lactate concentrations reached their peak in these clams (Table 2). This metabolic profile may reflect increased spatial competition, which likely impairs feeding efficiency and consequently limits growth. The accumulation of lactate can thus be associated with physiological stress, potentially induced by elevated competitive pressure.

These findings, which have direct implications for aquaculture practices, highlight the importance of optimizing rearing conditions for *R. decussatus*. Based on the present results, a maximum recommended stocking density of ≤ 2000 individuals/m² on substrate is proposed to enhance the profitability and sustainability of this species' cultivation.

# THE AQUALEX MULTIMEDIA CONSORTIUM AND THE CONTRIBUTION OF MARGARET ELEFTHERIOU

E. Mente[1*], Eilleen Dillane[2] and Lluis Tort[3]

[1] School of Veterinary Medicine, Laboratory of Aquaculture and Aquatic Animal Diseases, Aristotle University of Thessaloniki, University campus, 54124 Thessaloniki, Greece
emente@vet.auth.gr
[2] School of Biological, Earth & Environmental Sciences, UCC, Cork, Ireland.
[3] Departmemt of Cell Biology, Physiology and Immunology. Universitat Autonoma de Barcelona. Spain

**AQUALEX Multimedia Consortium Ltd. (AMC)** was founded in 1996 in Dublin, Ireland, as a not-for-profit organization aimed at promoting the outcomes of the European Commission **LINGUA** Programme project, **AQUALEX**. The organization is managed by a Board of Directors elected from the original AQUALEX LINGUA project partners and subsequent collaborators. AMC's mission is to provide high-quality multilingual aquatic science resources that facilitate communication within Europe's diverse scientific community, with particular focus on supporting scientists in training.

Since its inception, AMC has made significant contributions to European science, particularly in the development of interactive learning tools for the aquatic sciences. Notably, AMC led to the publication of the **AQUALEX** Glossary in 1997 by John Wiley & Sons, New York. In 1999, AMC expanded its multilingual offerings by launching the **AQUALEX Aquaculture Glossary** online, available in seven key languages for the aquaculture sector (English, French, Spanish, Norwegian, Greek, Italian, and German). Further efforts saw the creation of a **Virtual Learning Environment**, featuring an extensive resource repository that includes open-access teaching and learning tools in various languages, such as English, French, Spanish, Norwegian, Greek, Italian, Portuguese, and Swedish. AMC has consistently supported the development of multilingual aquatic science materials, which are used in both e-learning and academic contexts. These materials include language learning tools tailored to the aquatic science sector, but applicable beyond this field as well.

In 2008, in collaboration with **AquaTT**, AMC established an award in honor of Dr. **Lindsay Laird**, recognizing the most innovative poster submitted by a student in aquaculture and aquatic sciences. This award, supported by publishers Wiley/Blackwell, includes a selection of aquaculture publications donated annually to the winner. Additionally, in 2023, the **Richard Fitzgerald Award** was presented at the Environ Conference held in ATU Letterkenny, in association with the **Environmental Science Association of Ireland (ESAI)**. Later that year, at **HCMR Crete**, **Professor Magoulas** presented **Professor Athanasious Eleftheriou** with a plaque commemorating his significant contributions to the institute.

It was with profound sadness that AMC Ltd. learned of the sudden passing of **Margaret Eleftheriou** in October 2024. Margaret, the founding director of AMC, had an extensive educational career in both the UK and Greece, spanning secondary and tertiary levels. From 1979 to 1992, she played a pivotal role in curriculum development in Scotland. From 1987 to 2001, she taught English for Specific Purposes (ESP) in the Biology Department at the University of Crete. Margaret was a key partner in the LINGUA AQUALEX project, and her dedication to developing an accurate, up-to-date, and multilingual aquaculture glossary was instrumental in its early success. As a founder and chairperson of AMC from its establishment in 1996 until her passing, Margaret tirelessly promoted the organization's mission. She was instrumental in launching the **E-Aqualex Aquatic Sciences e-Learning Toolset**, demonstrating her boundless energy, dynamism, and enthusiasm.

Margaret was a cherished colleague, always generous with her time, knowledge, and expertise. She was deeply committed to research and education, contributing to several EU projects related to her scientific interests. Through her work as a special consultant at the **Institute of Marine Biology of Crete**, she contributed to a series of educational videos and CD-ROMs, including the **AQUALEX** aquaculture glossary (now in 8 languages), **Basic Techniques in Fish Haematology**, and **Spotlight on Greek Marine Science** (available in both English and Greek).

*(Continued on next page)*

Her involvement in the **SOCRATES Thematic Network AQUATNET** from 1996 to 2015, as well as her contributions to numerous EU educational projects (such as AQUALEX, ONEDIN, ORION, BIODAQUA, and PESCALEX), were critical in expanding the **AQUALEX** glossary into areas like **Fish Diseases** and **Marine Pollution**. She played a key role in the **WAVE** initiative and the **VALLA** project and contributed to the **AQUATT** submission on **ECVET** (European Credit Transfer for Vocational Education and Training). Her work also led to her nomination as the aquaculture representative in the **EU 2020 ESCO (European Skills/Competences Qualifications and Occupations) Initiative**, which she actively participated in until 2016.

Margaret's expertise in **Vocational Education and Training** (VET) Learning Outcomes made her an invaluable contributor to the **MATES project** (2018–2022), which aimed to foster the European Blue Economy through a Marine Technology Skilling Strategy. She also developed four AMC language courses for the **Marine Training** website and participated in the **EU-funded FLORES project** (2023-2024), where she developed a pilot course, **Introduction to Offshore Renewable Energy**, available in both Spanish and English. Her final focus was on **Ocean Literacy**, and she worked on initiatives to support the **Network of European Blue Schools**. Margaret's dedication to the future of our planet and her vision for the advancement of aquatic sciences were evident in her ongoing work with AMC.

The AMC Board of Directors is deeply honoured to have collaborated with Margaret. She embodied friendship, generosity, and dedication to making a difference in the lives of young students and professionals. Margaret's legacy will continue to inspire all who knew her and worked alongside her. Thank you, Margaret, for the privilege of knowing you and for all your remarkable contributions to the aquaculture and aquatic science fields.

# PRELIMINARY GROWTH DATA ON THE SPIDER CRAB *Maja brachydactyla* JUVENILES OBTAINED IN HATCHERY

N. Tourón* and M. Urcera

Unit of Biological Resources and Marine Resources (UCM), Toralla Marine Sciences Station (ECIMAT), *University of Vigo*, Illa de Toralla s/n, 36331, Vigo, *Pontevedra*, *Spain*.
Email: noelia.touron.besada@uvigo.gal

## Introduction

The spider crab species, *Maja brachydactyla* (Herbst, 1788), is the most commercially valued in Spain, with Galicia being the producing region par excellence, with catches of 485,604 kg (€6,037,005) during 2024 (pescadegalicia.gal). Overexploitation of the species was detected since 2002, since more than 90% of the market stocks come from fishing (Freire et al., 2002). As it is not a species produced through aquaculture, the culture of this species in hatcheries could alleviate its scarcity on the market and, in turn, serve to repopulate natural populations that are unstructured. The objective of this work is to determine the optimal cultivation protocol for this species in a hatchery, which would be applicable to the other species of spider crab found on the Mediterranean coast of Spain, *Maja squinado*, whose populations are at risk of extinction (UNEP, 1996).

## Materials and methods

Se compró una hembra ovada de *M. brachydactyla* en la lonja de Canido, se transportó hasta la ECIMAT de Toralla en un contenedor con agua de mar y were placed in square 1000 L fibre glass tanks in a flow-through system. Larval culture was done in duplicate, in 1,000 L square tanks. After a volumetric counting, a total of 50,000 zoeas were placed in each tank. Zoeas and megalopas were fed enriched Artemia on a daily basis at concentrations of 1-3 ind/ml. A continuous small flow of microalgae (T-Iso) was used to enrich water in the culture systems. Water temperature varied between 14 and 17°C. Photoperiod was 12:12 light/darkness. At the end of the pelagic phase, larval survival and the total of the benthic juveniles were determined by individually counting all remaining animals in the tanks. Growth of juvenile individuals was determined by measuring the total carapace length (mm), measured from the frontal peak and the telson (n = 20 each) at 17,31,48,54,71,101,118 and 134 DAH. Individual sizes in the two replicates at the end of the measurement period were compared using an ANOVA to determine significant differences ($p < 05$).

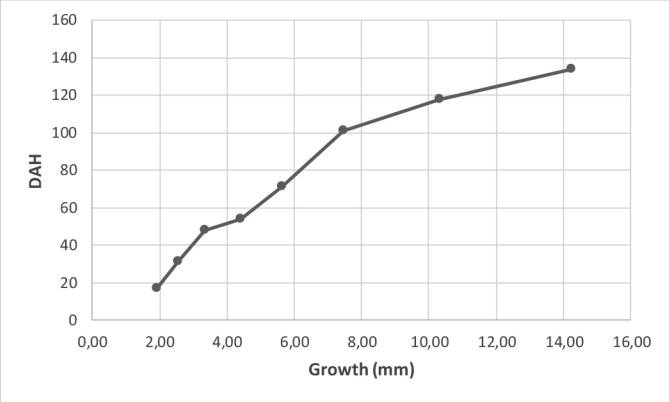

**Figure 1. Growth data of juveniles from 17 DAH**

*(Continued on next page)*

An ovate female of *M. brachydactyla* was purchased at the Canido fish market, transported to the ECIMAT in the Toralla Island (Vigo) in a container with seawater and placed in square 1000 L fiber glass tanks in a flow-through system. Larval culture was done in duplicate, in 1,000 L square tanks. After a volumetric counting, a total of 50,000 zoeas were placed in each tank. Zoeas and megalopas were fed enriched Artemia on a daily basis at concentrations of 1-3 ind/ml. A continuous small flow of microalgae (T-Iso) was used to enrich water in the culture systems. Water temperature varied between 14 and 17°C. Photoperiod was 12:12 light/darkness, $O_2$= 7,22 mg/L, salinity= 35,1 pps. At the end of the pelagic phase, larval survival and the total of the benthic juveniles were determined by individually counting all remaining animals in the tanks. Growth of juvenile individuals was determined by measuring the total carapace length (mm), measured from the frontal peak and the telson (n = 20 each) at 17,31,48,54,71,101,118 and 134 DAH. Individual sizes in the two replicates at the end of the measurement period were compared using an ANOVA to determine significant differences ($p < 05$).

**Results**

On average, zoeas I turned to zoea II megalopa in 5 DAH and from zoea II to megalopa in 10 DAH; from megalopa to juveniles lasted 11-13 days. Average survival was 51%, a very high data compared with survival obtained in the bibliography, for example Pazos et al., (2018) obtained an average survival of 13% from megalopa to juvenile. Figure 1 shows the growth data of obtained juveniles from 17 days after hatching.

As you can see in the figure 1, spider crab juveniles obtained in hatchery, reach a size of 14,22 mm at 134 days after hatching.

**Conclusion**

The cultivation of the spider crab *Maja brachydactyla* in hatcheries is a viable alternative for supplying the national market throughout the year, as well as for obtaining juvenile individuals that allow repopulating natural banks that are diminished or unstructured. The cultivation methodology can be extrapolated to the species *Maja squinado*, which is in danger of extinction on the Mediterranean coast of Spain.

# AQUACULTURE UNDER CLIMATE CHANGE: HOW SKIN MICROBIOME DISRUPTION INFLUENCES WINTER ULCER INFECTION IN ATLANTIC SALMON

S. Toxqui-Rodríguez[1]*, E. Ytteborg[2], L.H. Johansen[2], A. Sitjà-Bobadilla[1], J. Pérez-Sánchez[1], M.C. Piazzon[1], C.C. Lazado[2]

[2]Nofima, The Norwegian Institute of Food, Fisheries and Aquaculture Research, 9019, Tromsø, Norway
E-mail: Socorro.toxqui@csic.es

**Introduction**

The aquaculture sector's long-term sustainability is threatened by the effects of climate change, which are not just a future, but a present reality. Changing environmental factors increase the vulnerability of Atlantic salmon to infections such as winter ulcer disease (WUD), which represents a significant challenge in salmon farming, particularly during the sea phase of production. WUD refers to the infection by the bacterium *Moritella viscosa*. However, other species, such as *Aliivibrio wodanis* and *Tenacibaculum spp*., have been isolated from winter ulcer outbreaks. The skin mucosal microbiome constitutes the first barrier of defence against infections by environmental opportunistic pathogens. Research concerning this field has implications for aquaculture sustainability, as shifts in microbial composition (i.e., dysbiosis) are linked to disease outbreaks. Thus, this study aimed to characterize the changes in Atlantic salmon (*Salmo salar*) skin microbiota when subjected to multiple climate change-related environmental stressors and infection by *Moritella viscosa*.

**Materials and Methods**

Smolts were reared under three environmental conditions for 92 days. In the first condition, fish were maintained at 12°C during the whole trial (Control "C" group). The second condition simulated a period of elevated temperatures and was repeated throughout the trial. Here, fish were maintained for five days at 12°C with a gradual increase of temperature during five days up to 17°C, then this temperature was maintained for 10 days, and after this period, it progressively declined to 12°C within 5 days. This temperature fluctuation was repeated three times (Increased temperature (heat) "H" group). In the third condition, temperature changes were maintained as in the H group, with an additional decrease in the percentage of available oxygen to 70% when water temperature reached 17°C (Increased temperature + limited oxygen "HO" group). Subsequently, all fish were transferred to two tanks in a common garden trial, and after 6 days of acclimatization, fish from one of the tanks were infected with *Moritella viscosa* through bath challenge ("I"). Skin mucus samples were collected after 4 and 14 days post-exposure and were analysed through ONT MinION V1-V3 16S rRNA amplicon sequencing and standard analytical pipelines.

**Results**

Bacteroidota was the most abundant phylum among all groups, constituting more than 29.4% of the total bacterial abundance in salmon skin, followed by Pseudomonadota (21.9%), Actinomycetota (18.7%), and Bacillota (6.9%). Interestingly, no significant differences were found in the alpha and beta diversity between the different tested conditions (C, H, HO). However, the genera *Staphylococcus*, *Enhydrobacter,* and *Chryseobacterium* were significantly higher when comparing the H and HO groups with the C group. On the other hand, the bacterial challenge drove significant differences in beta diversity, where several genera, including *Moritella,* significantly changed their abundance between the two sampling points (Fig.1). Interestingly, the abundance of this genus shifted over time, dramatically decreasing in the 14-day sampling, leading to the overgrowth of other taxa such as the genus *Nonlabens* from the family Flavobacteriaceae.

*(Continued on next page)*

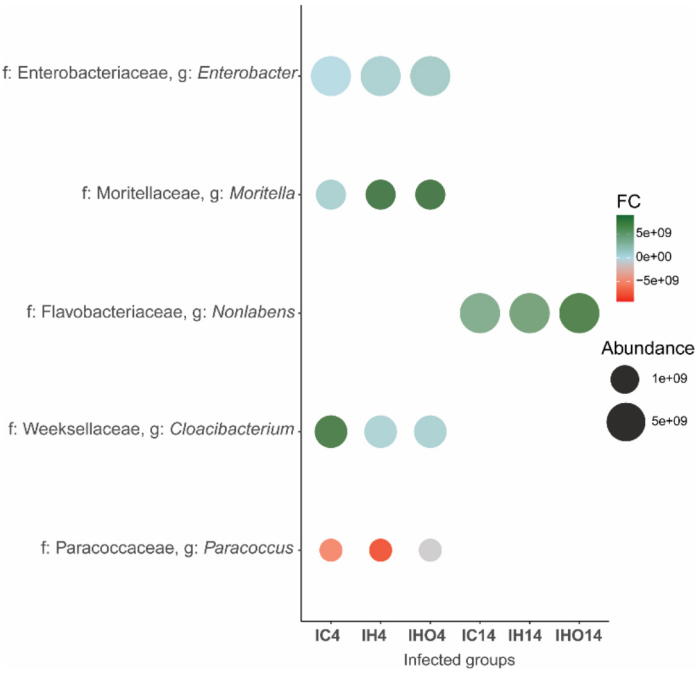

**Fig.1:** Dot plot representing differentially abundant taxa upon *M. viscosa* challenge. Only taxa significantly changing in the three conditions are shown. The colour scale represents the log 2-fold change in abundance relative to the control group. The size of the dots represents normalized counts in each group.

## Conclusions

So far, the experimental infection with *Moritella viscosa* has provided insights into the microbial dynamics associated with WUD through time and while facing different climate change environmental stressors. Increased temperature, in combination with or without decreased oxygen levels, did not dramatically affect skin microbiota or worsen the outcome of the disease. However, these conditions facilitated the increased abundance of opportunistic bacterial taxa like *Staphylococcus* or *Chryseobacterium*. Upon infection, the microbiota in the ulcers changed from colonization by the initial pathogen, *M. viscosa*, to a significant overgrowth of a member of the Flavobacteriaceae family. This effect was probably due to the temperature being too high for *M. viscosa* to prevail, and the ulcer environment favouring the overgrowth of other more adapted genera. A deeper analysis of the microbial composition of the ulcers, their progression with time and temperature, and their functions is needed to determine the roles of key microbial players, with special focus on this microbial shift concerning *Moritella* and the genus *Nonlabens*, which has not been well described as a fish pathogen. Of note, several studies have linked a previously uncharacterized Flavobacteriaceae to infections in fish, indicating that there may be unknown pathogenic genera or species within this family that require further investigation.

## Introduction

Methanotroph (*Methylococcus capsulatus*) bacteria protein (MCP) has been proposed as a sustainable and affordable protein source for aquaculture fish species. Studies on Japanese yellowtail (*Seriola quinqueradiata*) (Biswas et al., 2020), white shrimp (*Litopenaeus vannamei)* (Chen et al., 2021), seabass (*Lateolabrax maculatus*) (Yu at ela., 2023), among others, have showed positive effects in terms of growth performance, immunity, and other physiological indices. Siberian sturgeons is an economically important aquaculture fish across global, but the effects of dietary MCP on physiological indcies and gut microbiota have not been tested. This study aimed to to use amplicon sequencing technology to characterrise the gut microbiota of Siberian sturgeons fed on four different diets with increasing MCP inclusion levels, in a recirculating aquaculture system.

## Materials and methods

Four isoproteic (52 %), isolipidic (10%), and isoenergic (18.4 Mj/kg) diets, where MCM replaced fishmeal at 0, 25, 50, and 75% (Abbreviated diets: UNI0; UNI25; UNI50 and UNI75) were formulated and extruded in a 3 mm diameter. Five hundred and forty Siberian sturgeon (23.15±0.35g) were randomly assigned to 300 L tanks (45 fish/tank) and fed four diets (three replicates per diet) for 70 days. The posterior intestine (n = 6 fish and 9 fish/diet, respectively) was dissected and sampled for digesta at the start and end of the feeding trial. Nucleic acid extraction, amplicon library preparation, sequencing, and bioinformatics were performed according to previous publications (Nweze et al., 2024).

## Results

### *Microbial composition*

Fusobacteriota, Firmicutes, and Proteobacteria were the predominant phyla in the intestinal microbiota of Siberian sturgeon, irrespective of dietary treatment (Fig. 1A). The Kruskal–Wallis one-way analysis revealed no significant differences in the relative abundance of phyla among the dietary groups ($P > 0.05$).

At the genus level, *Cetobacterium*, *Clostridium*, *Plesiomonas*, and *Aeromonas* were the most dominant across all experimental groups. Similarly, no significant differences were observed in the relative abundance of genera among the diets ($P > 0.05$). However, a comparison of genus-level abundance between the initial samples and those collected after the 70-day feeding trial revealed a significant shift in bacterial composition, as determined by the Wilcoxon signed-rank test ($P < 0.05$).

### *Alpha diversity*

There were no significant differences in the alpha diversity of the microbial communities in the experimental diets, as measured by the Shannon (Kruskal-Wallis test followed by Dunn's post-hoc test, $P = 0.073$), and Simpson index ($P = 0.064$).

### *Beta diversity*

Principal Coordinate Analysis (PCoA) based on Bray–Curtis dissimilarity was conducted using the relative abundance of ASVs with (Fig. 3A) and without (Fig. 3B) initial intestinal samples. PERMANOVA analysis revealed no significant difference in bacterial community structure among dietary treatments ($P = 0.300$).

*(Continued on next page)*

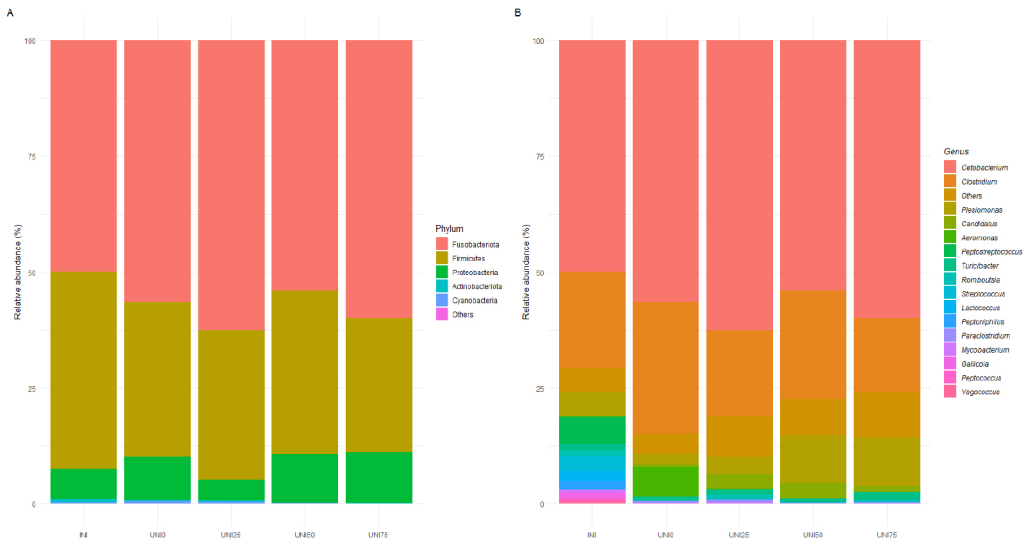

**Fig. 1.** Stacked bar plot showing the bacteria's relative abundance at the phylum (A) and genus (B) level in sturgeon. INI indicates a digesta sample of Siberian sturgeon at the start of the trial (n = 6); CON, UNI25, UNI50, and UNI75 represent experimental diets.

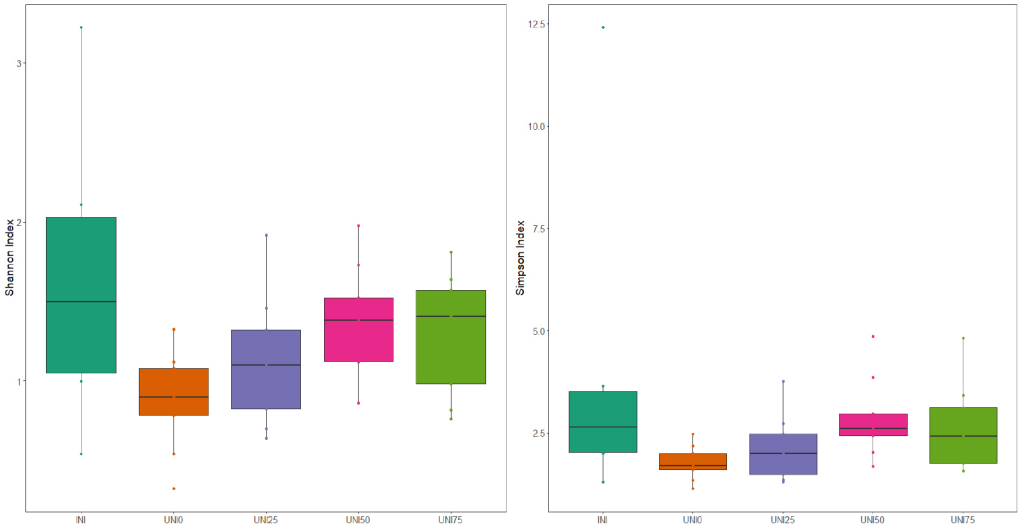

**Fig. 2.** Alpha diversity measured by Shannon and Simpson indexes. Data are shown as box plots (n = 9). The horizontal line indicates the median, and the whiskers indicate the lowest and highest points within the lower or upper quartile interquartile ranges.

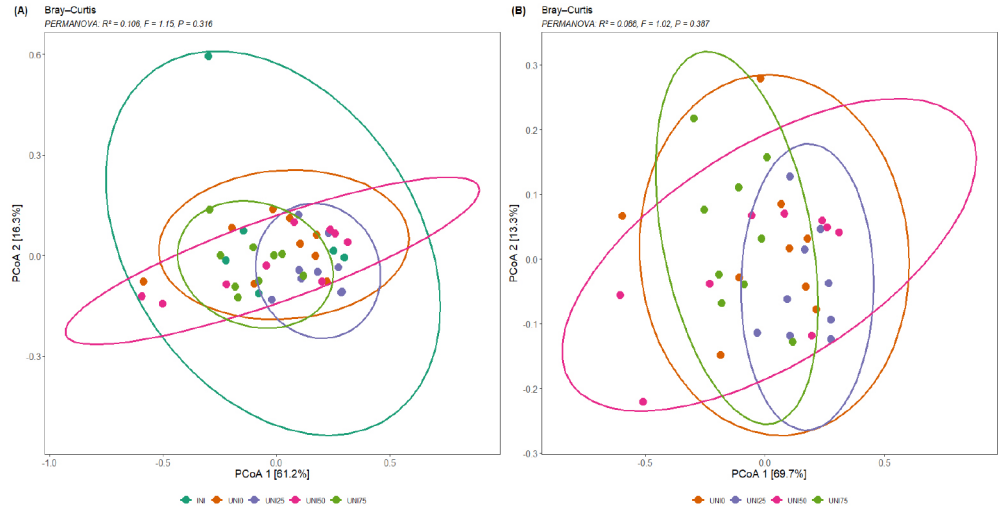

**Fig. 3.** Principal coordinates analysis of intestine microbiota, with (A) and without (B) initial digesta samples (n = 9) based on the Bray-Curtis metric. INI indicates digesta sample of Siberian sturgeon at the start of the trial (n = 6); UNI0, UNI25, UNI50, and UNI75 represent experimental diets.

*(Continued on next page)*

Conclusions

- The microbial composition, at phyla and genus levels, in Siberian sturgeon intestine exhibited a significant shift following the 70-day feeding trial, irrespective of diet.
- Dietary MCM had no significant effect on the intestinal bacterial community of Siberian sturgeon.

# LAND-BASED PILOT IMTA: USING SEABASS HATCHERY EFFLUENT TO GROW SEAWEEDS IN A MEDITERRANEAN AQUAFARM

E. Troianou[1*], E. Abatzidou[1] and I. Tzovenis[1,2]

[1]Kefalonia Fisheries SA, Samoli Livadi, Lixouri 28200, Greece
[2]Microphykos, Halandri, Athens 15238, Greece
E-mail: e.troianou@kefish.gr

## Introduction

Effluent from marine hatcheries, such as those rearing Mediterranean seabass (*Dicentrarchus labrax*), still after treatment. contains considerable levels of inorganic nutrients which could contribute to coastal eutrophication. Integrated multitrophic aquaculture (IMTA) offers a sustainable solution by incorporating extractive species to recover nutrients. The green macroalga *Ulva* spp., with its high nutrient uptake efficiency and rapid growth under variable Mediterranean conditions, is an ideal candidate for such systems (Shpigel et al, 1993).

This work evaluates the cultivation of *Ulva* using seabass hatchery effluent to remove inorganic nutrients while producing biomass for biomaterial applications. We quantify nutrient removal performance, assess biomass yields, and discuss the potential of integrating *Ulva* production into IMTA frameworks to enhance environmental sustainability and circular bioeconomy outcomes in Mediterranean aquaculture.

## Materials & Methods

A land-based pilot IMTA unit was set up at the Kefalonia Fisheries SA finfish hatchery on Cephalonia Island, Greece, to cultivate green seaweed (*Ulva* sp.) using hatchery effluent from sea bass (*Dicentrarchus labrax*) broodstock and juvenile tanks. *Ulva* sp. seedlings sourced locally were loaded at 1 kg/m$^3$ into translucent HDPE tanks (1 m$^2$ each) supplied with sedimentation tank water (the final stage of the hatchery's biological water treatment process), rich in inorganic nutrients, at a 20-minute residence time. Each two-week cultivation cycle included monitoring light, pH, DO, and nutrient levels. All biomass was harvested by net, sun-dried in a greenhouse, weighed, and stored at the end of each cycle.

Light (lux), pH, DO (mg/L) and salinity data were averages of daily measurements (2points, morning-noon). Analyses for nutrients were carried out twice per week. Yield represents the final biomass harvested after two weeks minus the initial loading. Daily growth was calculated from the formula % per day $=100*LN(X_t/X_{t0})/t\text{-}t_0$.

## Results & Discussion

Table 1 shows that cultivating *Ulva* with treated hatchery effluent could be promising if optimised. Biomass output depended on changing ambient factors and nutrient input from the effluent. Nutrient output data were inconsistent, so further experimentation is needed. Generally, dissolved inorganic nitrogen recovery was highest when daily seaweed growth was high (94.43 ± 3 mg/L), medium at moderate growth (65.84 ± 7.08 mg/L), and low at low growth (7.58 ± 1.61 mg/L), though this pattern requires more validation through a different experimental approach (Shpigel personal communication).

Yields and daily growth rates matched the highest values reported in literature (18-20% for land-based *U. lactuca* on fish effluent; Neori et al., 1991; Drawbridge et al., 2024). Optimisation could further improve nutrient recovery and biomass output. Since using animal waste–derived biomass for food or feed is challenging to license, ongoing trials are exploring biomaterial applications such as biofertiliser, biostimulants, and biocomposites, which may be financially viable for the modest output of a typical Mediterranean marine finfish hatchery.

*(Continued on next page)*

# NUMERICAL ANALYSIS OF NOVEL OFFSHORE AQUACULTURE SYSTEMS

A. Tsarau*[1], B. Su[1], Suzy Black[2] and Louise Kregting[2]

[1]SINTEF Ocean, P.O. Box 4762 Torgarden, 7465 Trondheim (Norway)
[2]The New Zealand Institute for Plant and Food Research Ltd, Nelson (New Zealand)
*E-mail: andrei.tsarau@sintef.no

## Introduction

Offshore structures for finfish aquaculture must meet high standards for reliability and animal welfare. Numerical modelling can help assess alternative designs and find solutions that ensure structural reliability in challenging offshore environments. However, this alone is insufficient. For fish welfare, it is also crucial to maintain adequate space, water quality, and dissolved oxygen (DO) levels within the sea cage. Comprehensive analysis tools are needed to evaluate and optimise new aquaculture systems for their ability to withstand offshore environmental loads while promoting fish welfare. Currently, such tools are absent in both offshore engineering and traditional coastal aquaculture technology.

To address this gap, SINTEF Ocean has developed numerical techniques for modelling and integrated analysis of flexible aquaculture structures and mooring systems within the time-domain simulation framework FhSim [1]. This presentation showcases the numerical modelling of a novel membrane enclosure system for open-ocean finfish aquaculture in New Zealand [2, 3]. The focus is on the flexible structure design and mooring optimisation required to withstand offshore loads, as well as the water flow and dissolved oxygen (DO) transport necessary for fish well-being.

## Simulation model

The fish enclosure was modelled as a horizontal fabric cylinder with net-covered ends, stiffened by outer ring structures to maintain its shape (Fig. 1a). The length of the structure ($L$) is 65 m, and the diameter ($D$) is 14 m. A single-point mooring (SPM) system allowed the structure to rotate freely with the flow while submerged below depths strongly affected by waves (Fig. 1b) summarises the main structural parameters used in the present simulations.

## Results and discussions

Time-domain simulations examined the motion of the moored structure in waves and currents, modelling extreme sea states to evaluate structural and mooring reliability under design loads. Fig. 1b shows the structure in an extreme sea state (described by a JONSWAP spectrum): significant wave height $Hs$ = 7.17 m; peak wave period $Tp$ = 11.29 s; current speed $U$ = 0.52 m/s. The predicted vertical displacements of the mooring buoy (2000-L volume) are shown in Fig. 1c, and the corresponding anchor loads are shown in Fig. 1d. Simulations showed that the wave forces acting on the enclosure decrease with increasing submergence, while the anchor loads are also dependent on the buoy size.

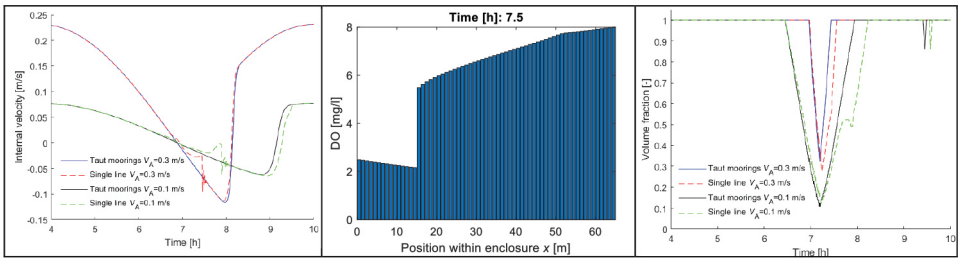

**Fig. 2. Water velocity through the enclosure during the turn of the tide (a), instant DO levels inside the enclosure (b) and time-varying enclosure volume fractions with DO above 60% saturation (c).**

*(Continued on next page)*

The model was also used to predict the structure's motion in a harmonic tidal current (with different velocity amplitudes $V_A$) and their combined effect on the water flow through the enclosure (Fig. 2a). Slack (single-line) and taut mooring configurations were considered here. These simulations provided the basis for predicting the DO dynamics within the enclosure considering different water temperatures and fish respiration rates [3]. Since adequate DO levels are crucial for fish welfare, simulations were used to identify periods of reduced DO levels during tidal transitions (Fig. 2b-c). The internal conditions were characterised by evaluating volume fractions with DO levels above 60% saturation, which is considered a threshold for salmon welfare. Results showed that the motion of the structure connected to an SPM system significantly impacts internal oxygen levels, offering insights for optimising the mooring design.

**Conclusion**

The presented case study highlights the benefits of using numerical simulations to support the development of flexible structures for offshore aquaculture. With modifications, the presented numerical framework could also be useful for modelling other aquaculture systems, including conventional net pens.

## Positive animal welfare as a concept

Positive animal welfare (PAW) is an evolving concept, shifting from minimising suffering to promoting positive experiences. While animal welfare science has traditionally focused on alleviating negative states, there is a growing recognition that the absence of suffering does not automatically equate to good welfare.

The latest effort to clarify meanings and definitions resulted in PAW being described as "the animal flourishing through the experience of predominantly positive mental states and the development of competence and resilience. Positive animal welfare goes beyond ensuring good physical health and the prevention and alleviation of suffering. Positive mental states result from rewarding experiences, including having choices and opportunities to actively pursue goals and achieve desired outcomes, according to species-specific and individual capabilities. Genetic, developmental and experiential factors (e.g. pre-natal, early life, environmental) contribute to individual differences in the ability to achieve positive animal welfare. Positive animal welfare can be assessed using animal-based indicators and can be evaluated over different timescales, thereby contributing to the lifetime picture" [1]. This definition emphasises that PAW goes beyond current established concepts of "good health" or "good welfare" in animals (Fig. 1).

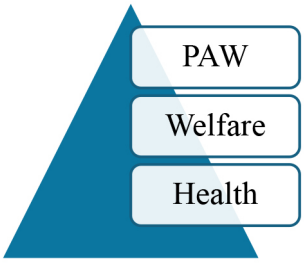

*Fig. 1: A common understanding of clear definitions is important to move concepts from fundamental science theory to applied settings and research*

*Fig. 2: Visit the COST Action LIFT under* www.liftanimalwelfare.eu

## COST Action on PAW in farm animals

Ultimately, PAW aims to improve animal lives by understanding the mechanisms leading to positive experiences [1] and may be a future framework for research, inspiring scientific progress and aligning animal care with societal expectations. This is of particular interest for animal farming, where animal numbers are high, and the purpose of resource production is clear. Therefore, the COST Action "LIFT - Lifting Farm Animal Lives" was initiated in 2022, aiming at laying the foundations for positive animal welfare in research (Fig. 2). This includes creating a clear definition of the concept, identifying valid methods to assess PAW and devising potential indicators of PAW to be used on-farm.

## PAW in farmed fish

Most of the literature around PAW in farmed animals is focused on agriculture and the farming of the most common mammals and birds, while aquaculture and fish are underrepresented, especially given the production volume of global fish farming. This lag can be used as an advantage for aquaculture, as agriculture offers insights into both successful measures and potential failures in including PAW into farming [2]. In order to adapt agricultural practices for measuring, assessing and improving PAW for fish farming, better knowledge of species-specific behaviour and biology is necessary [3]. Therefore, research is needed to identify and monitor species-specific indicators of positive welfare in fish.

*(Continued on next page)*

While applied research in aquaculture has made progress in developing welfare monitoring and assessment schemes [4–7], those have a focus on health indicators and include welfare mainly in the form of proxy behavioural indicators. Here, effort is needed to include more welfare aspects, and while fundamental science will allow insights into affect states in fish in the future, QBA (qualitative behavioural assessment) may be a possibility to already now include proxy indicators for PAW in applied science[8–10]. QBA involves observing and quantifying the expressive qualities of an animal's behaviour, using descriptors like 'relaxed', 'inquisitive', or 'energetic', allowing for the inclusion of how behaviours are performed in addition to which behaviours occur, and therefore providing insights into the animal's subjective experiences. However, including an anthropomorphic evaluation of affect states, for example by using the Arousal-Valence Model, the assessment of welfare in fish is likely to become subject to subjectivity and ambivalence[11] which have to be critically reviewed, prevented and counteracted.

# A COMPREHENSIVE GENETIC STUDY AIMING AT MAPPING QUANTITATIVE TRAIT LOCI AND INITIATING THE FIRST EUROPEAN GENETIC SELECTION PROGRAM FOR THE MEAGRE (*Argyrosomus regius*)

C. S. Tsigenopoulos[1]*, T. Manousaki[1], D. Chatziplis[2], S. Oikonomou[2,3], C. Batargias[3], N. Katribouzas[4], K. Tzokas[4] and L. Papaharisis[4]

[2] Department of Agriculture, International Hellenic University, Thessaloniki, Greece
[3] Department of Biology, University of Patras, Patras, Greece
[4] AVRAMAR S.A., Greece
e-mail: tsigeno@hcmr.gr

In the context of the Greek-funded research project MeagreGen, we genetically analyzed more than 900 samples from eleven meagre broodstocks using microsatellite markers, eight of which were from breeders of AVRAMAR SA, as well as three other stocks and their offspring. Meagre is a fast-growing sciaenid species that has recently gained significant interest in aquaculture diversification and the industry's sustainability. The estimated heterozygosity values were generally low (0.40 to 0.84), as was the number of alleles per site (average 3.58). Structure and DAPC analyses suggested that the populations may be optimally grouped into five groups. We analyzed the relatedness results using two selected methods to demonstrate that there is no strong kinship relationship between the stocks. Conversely, we found parent-offspring and/or full-sibling relationships within the stocks (Nousias *et al*., 2021).

We also initiated the first massive production of genetic data in meagre with genomic and transcriptomic sequences. In total, over 38 million base pairs (bp) were sequenced with the ONT MinION platform (long-read sequences), and more than 3 million sequences with an average length of 12,640 bp, providing 54.5× coverage of the genome. Additionally, over 166 million sequences of 150 bp were sequenced using the Illumina platform (short-length and high-fidelity sequences), providing 30.9× coverage of the genome. Moreover, the transcriptome sequencing generated over 100 million sequences that were used for constructing the transcriptome of the species. At the end, the first high-quality reference genome as well as the first gene predictions were delivered for meagre. The genome has a total length of 696 megabases (Mb) and includes 1,012 highly relevant sequences. More than 93% of the genome is included in the 24 largest scaffolds, which correspond to the 24 chromosomes of the species (Papadogiannis *et al*., 2023).

Subsequently, we conducted the first complete genomic evaluation of the species for body weight, length and growth parameters using more than 800 offspring genotyped with a double-digest RAD sequencing protocol. Parentage assignment was performed using SNP markers and a quantitative trait locus (QTL) associated with growth, and explaining approximately 3.25 % of the phenotypic variance was detected in chromosome 17. Using pedigree and genomic relationship matrix, moderate to high heritability estimates along with high genetic/genomic correlations between all studied traits were detected except for the initial body weight. The predicted performance of the breeding values estimation was higher with the genomic than the pedigree relationship matrix for body weight and growth (Oikonomou *et al*., 2025). Lastly, other significant or minor QTLs for head centroid size and skeletal deformities, such as lordosis and pugheadedness, were identified by integrating data from geometric morphometrics, and their use was evaluated as an improvement target in breeding programs. Finally, we propose the application of genomic selection (GS) over MAS, which has advantages over the classical polygenic effects based on pedigree, because it predicts the breeding value for each phenotype with greater accuracy, reduces the generation interval with positive effects on genetic progress, and helps maintain homozygosity at low levels under breeding conditions.

## Introduction

Significant amounts of fish and seafood are wasted worldwide due to spoilage and degradation during icing, packaging, storage and transportation after landing (ranging from ≈30% of the initial catching in Latin America, Africa and Europe to 50% for North America and Oceania, according to FAO). Waste at the end of the food supply chain is also substantial in all three regions, with 15-30% of purchases by mass discarded by consumers. Packaging plays a crucial role in adequate preservation and storage of sensitive products. Developing novel and efficient packaging solutions to improve product quality and shelf life and reduce waste while not increasing packaging waste is a major challenge to improve sustainability of food supply chains (Athanasopoulou et al., 2024; Basdeki et al., 2024; Spanou et al., 2024).

Marine biomass contains significant quantities of polysaccharides, proteins and minerals. During the past years, there has been significant interest in natural products obtained from marine organisms, which may provide valuable commodities while at the same time promote health and well-being in humans (Vasilakis et al., 2025). Algae is a promising source for deriving monomers used in plastic production. Both macro- and microalgae are rich primary sources of bioactive compounds and could be used as a source of functional ingredients such as carotenoids, fatty acids, polysaccharides, peptides, vitamins and sterols (Hidhayati et al., 2025; Koletti et al., 2025).

The AQUAPACK project aims to develop active and sustainable packaging materials based on the selection of suitable aquatic biomass (micro- and macro-algae, fish processing side streams and by-catch) with the aim of obtaining appropriate raw materials (carbohydrates, proteins, fatty acids etc.) and biopolymers, to produce biodegradable packaging systems specifically tailored for the food and cosmetic industry. The project is at the interface between research and commercial exploitation and will generate knowledge and innovations to promote growth of the sustainable blue bioeconomy, preserving marine resources and ecosystems.

By valorising underutilized marine resources, AQUAPACK is expected to contribute significantly to reducing reliance on fossil-based plastics, closing nutrient loops, and driving innovation through bio-based packaging alternatives.

## Materials and methods

To turn AQUAPACK objectives into practice, trans-regional cooperation is needed to create a strategic partnership between academia and industry, to ensure resource availability, facilitate knowledge exchange and harmonize policies. AQUAPACK project brings together 15 partners (8 academic and 7 commercial) located in 9 EU countries (Greece, Portugal, Italy, France, Cyprus, Spain, Croatia, United Kingdom and Netherlands). The proposed research work plan is organized into 3 complementary and multi-disciplinary workflows, including: (1) Customized packaging technologies based on aquatic biomass, (2) Development and evaluation of novel packaged food and cosmetic prototypes, (3) Evaluation of the sustainability and safety of biodegradable packaging systems.

*(Continued on next page)*

Suitable aquatic bioresources (micro- and macro-algae biomass, fish and seafood production side-streams and by-catch) and algae growth conditions are selected, with the aim to obtain appropriate bulk raw materials (carbohydrates, proteins, fatty acids, biopolymers etc.) for the development and production of novel sustainable and biodegradable systems. The produced aquatic-based bioactive compounds are screened and characterized for application as active components in active packaging systems. Surface functionalization of biopolymers is carried out using cold plasma, to modify biopolymer wettability, mechanical properties and barrier characteristics and for surface disinfection of packaging materials. Biodegradable, safe and high-quality materials are developed and tested for their efficiency as appropriate packaging systems for sensitive products, including fresh fish.

## Results and Discussion

The AQUAPACK project will develop biodegradable, active packaging materials using aquatic biomass and side-streams, targeting both the food and cosmetics sectors. Two representative outputs will be presented: (i) a biodegradable active packaging film designed to preserve the quality and extend the shelf life of fresh fish and (ii) a compostable rigid container tailored for cosmetic products, offering structural integrity and environmental sustainability. These innovations demonstrate strong potential to reduce plastic waste, maintain product safety, and support a circular bioeconomy, while fostering collaboration between academic and industrial partners.

# IMPACT OF COOKING METHODOLOGY ON NUTRITIONAL QUALITY OF SENEGALESE SOLE FARMED IN IMTA-RAS SYSTEM

I. Tucciarone[1]*, L. Bruni[1], G. Parisi[1], J. Pintado[2]

[1]Department of Agriculture, Food, Environment and Forestry, University of Florence, 50144 Firenze, Italy

## Introduction

Recent efforts in aquaculture focus on sustainable systems that maintain productivity while preserving product quality. Recirculating aquaculture systems (RAS) minimize nutrient discharge compared to traditional methods, and when combined with Integrated Multi-Trophic Aquaculture (IMTA), they enhance nutrient efficiency by co-culturing fish with extractive species like macroalgae. *Ulva ohnoi* is a key IMTA species due to its rapid growth and strong nitrogen and phosphorus uptake. Beyond improving water quality, *Ulva* is valued for use in animal feed, ulvans for biomedical applications, and as a carrier for probiotic bacteria such as *Phaeobacter* sp., antagonist of fish pathogens. Integrating *U. ohnoi* and *Phaeobacter* in IMTA-RAS may improve fish resilience and nutritional quality, but little is known about how these benefits persist after cooking. Cooking significantly affects moisture, protein structure, lipid oxidation, and sensory traits such as color and flavor. Steaming and baking (common household methods) differ in their impact on nutrient retention and oxidative stability.

This study examined whether co-culturing Senegalese sole with *U. ohnoi* and *Phaeobacter* in IMTA-RAS improves quality parameter retention during steaming and baking. Key metrics included lipid and fatty acid composition, cholesterol, oxidative status, proximate composition, and fillet color and texture. Potential mechanisms included *Ulva*-derived antioxidants and ulvans acting as natural preservatives, and *Phaeobacter*-mediated microbiome effects slowing down spoilage. By linking sustainable production to post-harvest quality, this research aimed to highlight how IMTA-RAS could deliver fish with enhanced nutritional and sensory attributes while reducing environmental impact.

## Materials and Methods

Three growth experiments were conducted: (1) sole in RAS; (2) integrated sole–*Ulva* in IMTA-RAS; (3) like in experiment 2 with *Phaeobacter* sp. inoculation to water. For each experiment, Senegalese soles (~85 g initial body weight) were reared for 8 weeks each. Water quality was maintained with temperature of 18.5–21 °C, total ammonia < 0.05 mg/L, nitrites < 0.8 mg/L, pH 7.2–8.2, and dissolved oxygen > 65%. *U. ohnoi* was cultivated in three parallel couples of tanks under light/dark conditions alongside three fish tanks. Fish were fed commercial pellets (0.45–0.9% of biomass initially, 250 g/day stabilized) via automatic feeders. After 8 weeks, 54 fish (~120 g final body weight) per experiment were sampled by 2-phenoxyethanol overdose, then divided into 3 treatments: raw, steam (STE), and bake (BAK) (18 samples for each treatment). Fish were measured (length and weight), stored at –80 °C, and thawed at 4 °C before the scheduled analyses. A group of fish was analyzed as raw. the cooking methods were steaming (wrapped in foil over boiling water, at ~100 °C) and baking (180 °C, fan oven). Both continued until 62 °C core temperature was reached. The analyses included biometric measurements, skin and fillet color, cooking loss, texture, moisture, ashes, crude protein total lipids, fatty acids, cholesterol, and oxidative status (conjugated dienes, TBARS). Data were subjected to one-way ANOVA followed by Tukey's multiple comparison test. Significance was set at $p < 0.05$.

## Results and Discussion

Fish provides high-quality protein, long-chain n-3 polyunsaturated fatty acids (PUFAs), and essential micronutrients. High intake of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in human diet is linked to improved lipid profiles and reduced inflammation, underscoring fish's value in a healthy diet for humans. Cooking, however, can alter/modify the fish nutritional quality [1]. Cooking significantly reduced texture ($p<0.0001$) in all samples regardless of the experiment. For instance, in RAS fish, hardness dropped from 10.01 N (RAW) to 4.16 N (STE) and 4.23 N (BAK), while IMTA-RAS (without *Phaeobacter* sp.) samples showed similar trends, falling from 9.72 N (RAW) to 3.54 N (STE) and 3.37 N (BAK).Color also changed after cooking: lightness ($L^*$) increased in all samples, especially in the STE ones, while redness ($a^*$) rose more in BAK than in STE samples, likely due to Maillard reaction. Total lipid content declined after cooking ($p<0.0001$), with the highest losses in BAK, reflecting a greater dehydration. Both methods improved the PUFA/SFA ratio and n-3 PUFA incidence in fatty

*(Continued on next page)*

acid profile compared to RAW, with BAK showing a slightly stronger effect. Palmitic acid (C16:0) was the main saturated fatty acid, while oleic acid (C18:1n-9) dominated the monounsaturated fatty acids group. PUFAs, especially of the n-3 and n-6 series, were preserved; DHA was the predominant n-3 fatty acid (9.66–16.19%), followed by EPA (2.18–2.34%). Cooking increased the EPA+DHA content across all three experiments (with a minimum incidence of 15.60%), with STE reaching 18.53% in the Experiment 3. The n-3/n-6 ratio also improved in fish belonging to Experiment 3, reaching >2.0, a value in agreement with the human recommended dietary values. Cholesterol levels rose after cooking due to water loss associated with the thermal treatment, more in BAK (85.49 mg/100g) than in STE (76.60 mg/100g). Oxidation markers showed minimal changes: conjugated dienes decreased slightly with cooking, whilst TBARS values remained low (<0.2 mg MDA/100g), indicating an excellent lipid stability regardless of the cooking method. As fish might have eaten fragments of *U. ohnoi*'s blades that accidently passed to their tanks, algal antioxidant compounds may have further limited oxidation in IMTA-RAS fish. Moisture content decreased significantly ($p<0.0001$) due to thermal processing, especially in IMTA-RAS with *Phaeobacter* sp. (Exp 3). On the contrary, protein levels rose in cooked samples due to water loss, while ash content showed minor, inconsistent increases. However, baking generally caused more pronounced nutrient concentration than steaming.

Overall, both cooking methods altered texture and composition but improved the nutritional quality of the lipid profile, especially by enhancing n-3 fatty acid incidence and improving the PUFA/SFA ratio. IMTA-RAS systems, particularly with *Phaeobacter* sp. (Exp 3), maintained or improved fatty acid ratios and oxidation stability without compromising nutritional value, representing a sustainable alternative to conventional farming systems. The prevalence of DHA over EPA and high EPA+DHA content confirmed *S. senegalensis* as a valuable source of health-promoting fatty acids. However, further statistical comparisons between systems and cooking methods are recommended to confirm these findings.

# MODELING STAKEHOLDER OPINION DYNAMICS IN GLOBAL AQUACULTURE: AN EMPIRICALLY-GROUNDED AGENT-BASED FRAMEWORK

Sezgin Tunca

sezgin.tunca@gmail.com

The rapid growth of aquaculture has increased conflicts among stakeholders with various assessments of environmental risks, economic returns, and social fairness. Collective analyses do not cover the micro-level processes through which belief revisions and social influences shape governance outcomes. We introduced an empirically parameterised agent-based model that simulates opinion dynamics within the multilayer social–ecological system of aquaculture. A global dataset of media coverage on aquaculture, represented eight stakeholder classes: producers, consumers, government officials, industry leaders, local communities, non-governmental organisations, researchers each holding Bayesian belief states updated by bounded confidence, Bayesian learning, and ideology-conditioned confirmation bias. Stakeholder interactions are designed to occur across various networks, with each layer representing empirical co-occurrence, ideological similarity, and geographical proximity whereas connections among stakeholders evolve through preferential connections moderated by similarity thresholds. Media effects were endogenized with a three-cut ordered probit that maps ideology and topic importance to stochastic sentiment shocks. The model can potentially test policies for interventions such as ideology-targeted outreach, adaptive licencing, and broker-facilitated dialogue with the integration of media sentiment scores, agents, and dynamic networks. This model also aims to demonstrate how data-driven agent-based models can reveal adaptive governance dynamics and inform evidence-based strategies for socially acceptable and environmentally sustainable aquaculture development.

# EMISSION REGULATION – PROPOSED SEA LICE QUOTAS IN NORWEGIAN AQUACULTURE

Ragnar Tveterås*

University of Stavanger School of Business and Law
4036 Stavanger, Norway
Email: ragnar.tveteras@uis.no

In salmon aquaculture sea lice is an externality that contributes to poor welfare of farmed salmon and wild salmon mortality. Sea lice is one of the main factors limiting growth in global salmon production.

In Norway the government has tried to regulate sea lice externalities to wild salmon through a traffic light system (TLS). This system employs several methods to estimate the relationship between sea lice populations in aquaculture farms and sea lice induced mortality of wild salmon smolt migrating from rivers to the open ocean. The Norwegian coastline is divided into 13 production areas. In each production area aquaculture farms are allowed to increase production if the estimated mortality of wild smolt is below 10%, but have to reduce production if mortality is above 30%. The collective reward/punishment system in TLS is assessed to not give salmon firms sufficiently strong incentives to mitigate sea lice externalities.

In April 2025 the Norwegian government proposed a sea lice quota system to replace the collective mechanism in the TLS. The government proposes that the total sea lice quota for a production area is set equal to a level corresponding to 10% sea lice induced mortality. The quota is going to be divided between firms, probably corresponding to their allocated salmon production quota.

The dominant conventional open cage farm technology allows sea lice to migrate in and out of farms. This paper analyzes what levels of investments are necessary in alternative 'low lice' and 'zero lice' production systems to satisfy lice quotas. For each possible sea lice quota level we estimate the production technology combinations of (1) 'low lice' deep sea cages, (2) 'zero lice' sea based closed containment systems and (3) land based closed systems that can satisfy the quota with the highest net present value (NPV). Investment cost per kg of salmon produced increases substantially from deep sea systems via closed containment to land based systems. Furthermore, the production share of each production technology is constrained by nature, government regulations, etc.

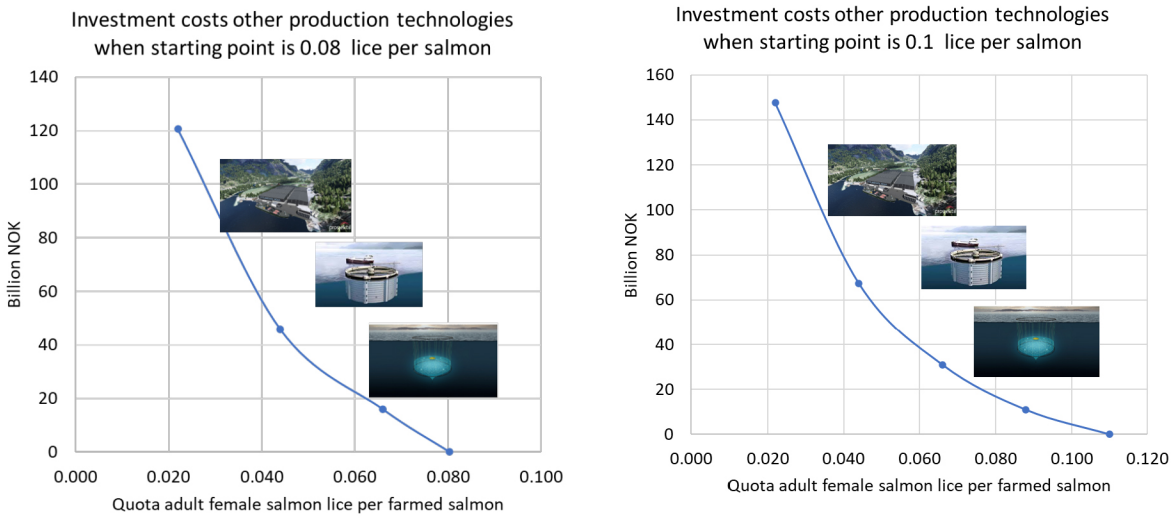

**Figure 1. Estimated investments required to maintain production of 1.6 million metric tonnes (1EUR=12 NOK)**

*(Continued on next page)*

Figure 1 shows the estimated investment curves maximizing NPV for different sea lice quota levels and different starting points for sea lice prevalence. It turns out that investments may be in an order of magnitude that will require a multi-year investment horizon, consuming much of the after-tax cash flow of the industry. Future after-tax cash flows in Norwegian salmon aquaculture may be 1-2 billion EUR each year, while the total investment budget may be in the order of 10 billion EUR. As indicated by Figure 1, total investments are highly sensitive to the quota levels. Required investments increase exponentially with a stricter quota, as an increasing share of production must be allocated to the more capital-intensive closed systems in sea and on land.
The effects of sea lice quota design on investment decisions are also analyzed. This includes the transition from TLS to a quota system. An immediate introduction of strict quotas will not be possible to accommodate in several production areas, due to constraints on financial capital, supplier industry capacities and government regulatory capacities. Hence, it is necessary to have a transition period with a sufficient time horizon allowing for sufficient investments and learning. The sea quota can in principle be changed over time due to changes in sea temperature, model estimates etc. We discuss constraints on quota changes, given challenges in adapting to stricter quotas.

Sea lice is also an externality between farms. We analyze the collective investment problem in a production area, as several firms must jointly invest to satisfy quota levels.

A new social contract may be necessary to enable a sustainable path to sustainable aquaculture, with the following elements:

- A sufficient time horizon for investments and adaptation, probably at least ten years.
- Salmon industry commitments to investments in the order of several billion EUR.
- Salmon companies in each production area commit to each other.
- Government commits to predictability with respect to (a) after-tax cash flow available for investments, and (2) administrative processes that enable investment projects.

It is reasonable to argue that a social contract enabling sufficient investments will require a broad political consensus to be credible.

# EFFECTS OF ONION (*Allium cepa*) IN FEED ON BLOOD PARAMETERS OF CATFISH AND AQUA-FARM WATER QUALITY

Anyaele Uka and Bright C. Uka

Department of Fisheries and Aquatic Resources Management
College of Natural Resources and Environmental Management

*Corresponding author: uka.anyaele@mouau.edu.ng

Feed is an important factor in aquaculture with the individual ingredients being significant to the physiology of fish and to the condition of culture water. This study therefore investigated the effects of including onion at 0%, 1.02%, 2.05% and 3.07% in fish feed on the haematology of *Clarias gariepinus* and on water quality. The haematological parameters evaluated included red blood cell count (RBC), white blood cell count (WBC), packed cell volume (PCV), haemoglobin content, mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), and mean corpuscular haemoglobin concentration (MCHC). Furthermore, cholesterol and protein were determined using spectrophotometric-enzymatic and Bradford methods respectively. Albumin and glucose were determined using kits that detect albumin and glucose-oxidase reaction respectively. Globulin was calculated by subtracting the measured albumin value from the total protein. Water quality parameters evaluated were temperature, dissolved oxygen and pH

There was significant increase ($P<0.05$) in RBC, PCV and Hb but decrease in WBC in the fish fed diet containing onion (Table 1.0). The decrease in WBC became significant ($P<0.05$ when onion was included at 2.05%. However the value of the WBC spiked when the onion concentration was 3.07%. There was no significant difference in the value of MCV at the studied concentrations. The increase in MCH due to onion in feed became significant ($P<0.05$) at 2.05%. Value of MCHC followed the same trend as MCH (Table 2.0). There was decrease in cholesterol and glucose due to onion in feed (Figure 1.0). There was increase in total protein and albumin but decrease in globulin due to onion in the diets (Figure 2. 0). Lowest globulin was observed when onion was included at 2.05%. There was no significant difference ($P>0.05$) in the water quality parameters studied among the treatments (Table 3.0). Results from the study suggest 2.05% as a preferred inclusion level of onion in feed for African catfish.

Table 1.0: Values of some haematology parameters of *Clarias gariepinus* fed diets containing different percentage levels of onion

| Onion in diet | RBC Cells/μL | PCV % | Hb g/L | WBC Cells/μL |
|---|---|---|---|---|
| 0% | $3.67\pm 0.07^{c}$ | $25.8 \pm 0.91^{c}$ | $9.2 \pm 0.2^{b}$ | $9.44 \pm 0.66^{a}$ |

# CONCENTRATED NUTRIENTS RECOVERED FROM EFFLUENT WATER FROM RECIRCULATING AQUACULTURE SYSTEM (RAS) USED AS FERTILIZER IN A HYDROPONIC FARM

D. Ulleberg[1]*, G. Lilleng[2]

[1]SINTEF Nord, Storgata 118, 9008 Tromsø, Norway
E-mail: didrik.ulleberg@sintef.no

## Introduction

The transition to a circular bioeconomy hinges on innovative green technologies able to recycle waste streams into reusable components. This study investigates a pilot-scale system for nutrient recovery from recirculating aquaculture system (RAS) effluent water employing membrane technologies for fertilizer production. The innovation could provide the Norwegian aquaculture sector with an alternative to discarding RAS effluent water, potentially making the industry more sustainable by reducing eutrophication and the need for wastewater treatment. Moreover, the production of a novel recirculated fertilizer product from RAS effluent water might alleviate the dependency on mineral fertilizer across agricultural sectors. For instance, Norwegian agriculture consumed 87,000 tons of nitrogen and 7,000 tons of phosphorus mineral fertilizer in 2023 [1]. This dependency poses significant challenges due to the energy-intensive production of nitrogen fertilizers, which represents 2 % of the global energy consumption and the emission of 450 mT $CO_2$ annually [2].

The primary goals of the study were to evaluate the performance of the water treatment system when producing a concentrate intended as fertilizer from RAS effluent water, to assess the storage stability of the produced fertilizer with and without pasteurization, and to assess the concentrates suitability as a fertilizer. By measuring the input and output streams of the water treatment system over time, the study aimed to determine system performance and compare the composition of the resulting concentrate to plant nutrient requirements. Additionally, the chemical and microbiological storage stability of pasteurized concentrate was monitored for six months and compared to an unpasteurized control. The concentrates suitability as a fertilizer was tested through plant cultivation trials in a hydroponic farm.

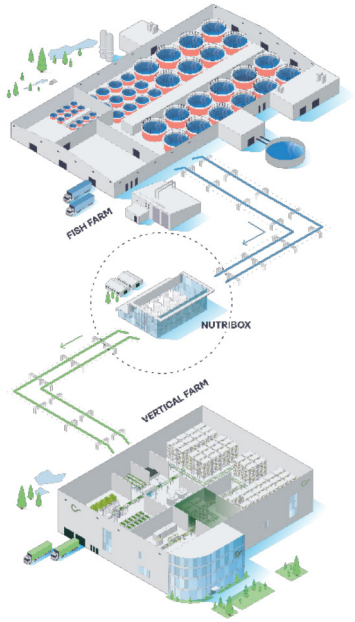

***Figure 1.*** *Effluent water from RAS is processed through a water treatment unit (Nutribox"), to produce clean water that can be recirculated back to the RAS, and a concentrate used as fertilizer for plant cultivation in a vertical farm.*

## Materials and methods

A pilot system consisting of a research scale RAS facility, a water treatment system, and a vertical farm was built and operated for the project duration of three years, located at the research station of NIBIO Landvik, Norway. The RAS system consisted of two 1,000 L fish rearing tanks with *Salmo salar* grown at a density between 70 – 100 kg/m$^3$, a moving bed biofilter, $CO_2$ scrubber, oxygenation, pH regulation and a hydrocyclone and drum filter for sludge removal. All RAS effluent water of 900 – 1,200 L/ week was processed in batches of 300 L through the water treatment system to produce a nutrient rich concentrate and clean permeate. The storage stability of pasteurized and unpasteurized concentrate was assessed through a six-month shelf-life study monitoring chemical and microbiological changes. Meanwhile, the concentrates potential as a fertilizer was assessed through plant cultivation studies in a 6.72 m$^2$ hydroponic vertical farm.

*(Continued on next page)*

**Results and discussion**

The water treatment system used RAS effluent water to produce a concentrate with a high element ratio of the plant macro nutrients nitrate and potassium. However, the extract was low in phosphorous due to the low contents of water soluble phosphate in the RAS effluent water. Preliminary results from the hydroponic cultivation trials indicated that RAS concentrate enriched with mineral fertilizer achieve plant yields comparable to the mineral fertilizer control treatment. In the shelf-life study the RAS concentrate was found to be microbially and chemically stable for at least six months regardless of pasteurization.

The study show that concentrated RAS effluent water can be used as a fertilizer in plant cultivation, which have the potential to alleviate the consumption of mineral fertilizer while simultaneously decreasing the eutrophication potential of commercial RAS systems by collecting and using discharged nutrients. In future studies, efforts should be made to concentrate the fertilizer further to make distribution to a global marked more feasible, asses the economic and environmental feasibility of a scaled-up system and investigating the impact on fish-health when recycling water cleaned by the developed water treatment system back to the RAS.

This research is part of the IPN Nutricycle project, and is funded by the Research Council of Norway (grant number # 336971)

# UPSCALING RESOLUTION IN FISH ACOUSTIC TELEMETRY

J. Urban*, D. Laštovka

**Introduction**

Understanding behavior of fish in aquaculture relies on semi-continuous monitoring, yet obtained data are discrete and often irregular. This study investigates the fish acoustic telemetry RMS acceleration measurements as a stochastic stationary process. Unlike in the wild conditions, where fish behavior is highly variable and nonstationary, captive aquaculture environments should offer stability and predictability. The stability is valid under the assumption of *weak stationarity*, where the mean and variance of the process remain constant over time. Such conditions is justifying the use of probabilistic model which preserves the statistical characteristics during interpolation to reconstruct the continuous behavior from discrete samples.

**Dataset and Methods**

The dataset analyzed in this study comprises root mean square (RMS) acceleration values recorded via acoustic telemetry of Atlantic salmon held in captive. The data covers the period of 148 days, with approximately 92,500 values for a single fish. The measurements were taken in non-equidistant intervals ranging from 220 to 380 seconds. The acceleration values range from 0 to 255, with each unit increment corresponding to 0.014 m/s². The acceleration time series is modeled as a causal stochastic system using discrete Markov transition matrices to estimate conditional probabilities between acceleration states. The data passed the tests for weak stationarity (Augmented Dickey-Fuller test), for Markov property (Chapman-Kolmogorov Equation), and for practical differentiability of the autocorrelation function. A Wiener-Levy process was then applied to perform high-resolution interpolation of transition probabilities while preserving the mean and standard deviation of the original distributions.

**Results and Discussion**

Two levels of continuation tests were performed: one on reduced transitions matrix, and one witht 100× finer resolution. The results demonstrated that the RMS acceleration data from captive Atlantic salmon exhibited weak stationarity and practical differentiability, validating its suitability for modeling as a diffusion system. Transition matrices revealed dominant self-transitions, indicating behavioral stability. The application of the Wiener-Levy process, repeated 1,000 times for each transition, enabled fine-resolution interpolation that preserved statistical properties.

These tests confirmed that the system exhibits the necessary smoothness and continuity properties, validating the use of Wiener-Levy diffusion as a tool to simulate realistic interpolated behavior in fish activity.

# ENVIRONMENTAL INTERACTIONS AND POSSIBLE SOLUTIONS FOR CARP-DOMINANT POND AQUACULTURE IN HUNGARY

Béla Urbányi[1,2*], Mónika Bojtárné Lukácsik[1], Krisztián Szabó[1], Alexandra Ferencz-Havel[1], Ágnes Irma György[1], Katalin Rácz[1], Pál Goda[1], Zoltán Bokor[1]

E-mail: urbanyi.bela@aki.gov.hu

Carp-dominant pond aquaculture is a traditional and significant sector in Hungary's freshwater fish production, with deep-rooted traditions and significant socio-economic value. However, its environmental interactions - such as nutrient loading, eutrophication, sediment accumulation, and biodiversity impacts - raise ecological concerns. Climate change further exacerbates these issues by altering water availability, increasing temperatures, and intensifying weather extremes, all of which affect pond ecology and fish health. In response, sustainable and adaptive management strategies are urgently needed.

Potential solutions include integrated multi-trophic aquaculture (IMTA), optimized feeding strategies, water quality monitoring, and better sludge and effluent management. From a policy perspective, encouraging data-driven decision-making, farmer training, and the adoption of best management practices (BMPs) will be critical. Strengthening research–industry collaboration and revising subsidy schemes to favor environmentally friendly technologies can support this transition. By addressing both ecological impacts and production efficiency, Hungary can lead the way in developing sustainable, climate-resilient carp pond aquaculture systems.

# EFFECT OF LIGHT ON PRODUCTION AND BREEDING PARAMETERS OF POND FISH SPECIES

Béla Urbányi1,2*, Mónika Bojtárné Lukácsik1, Krisztián Szabó1, Alexandra Ferencz-Havel1, Ágnes Irma György1, Katalin Rácz1, Pál Goda1, Zoltán Bokor1

E-mail: urbanyi.bela@aki.gov.hu

Light plays a fundamental role in the behaviour, physiology, and growth performance of freshwater fish species. In aquaculture, manipulating light conditions can significantly influence feeding activity, reproduction, stress response, and overall productivity. This study reviews and compares the effects of light intensity, photoperiod, and spectral composition on the production of key species cultivated in Central and Eastern Europe: common carp (*Cyprinus carpio*), Chinese carps (e.g., *Hypophthalmichthys molitrix*, *Ctenopharyngodon idella*), northern pike (*Esox lucius*), pikeperch (*Sander lucioperca*), and European wels (*Silurus glanis*).

Carp and Chinese carps show adaptive responses to natural light cycles, but extended daylight hours under controlled conditions have been shown to improve feed intake and growth in juvenile stages. Pike and pikeperch, both predatory species with more sensitive visual systems, require carefully managed low-light environments during larviculture to reduce cannibalism and optimize survival. Light colour (e.g., blue or green wavelengths) can further affect their behaviour and feeding success.

European wels, a nocturnal benthic predator, is especially sensitive to light intensity. Dimming light or maintaining dark conditions during rearing improves welfare and reduces stress-induced aggression. Tailoring light regimes in hatchery and grow-out phases is therefore critical to meet species-specific needs.

Understanding the species-specific light preferences and tolerances offers practical benefits for optimizing production protocols, especially in recirculating aquaculture systems (RAS) and hatcheries. Future research should focus on integrating smart lighting technologies with precision aquaculture to improve fish welfare and yield across diverse freshwater species.

The work was supported by MAHOP_PLUSZ-1.2.1-24-2024-00001 project.

# FROM LAB TO WILD: AN INTEGRATED STRATEGY FOR NURSEHOUND CONSERVATION. OPTIMIZING REINTRODUCTION VIA ENVIRONMENTAL ENRICHMENT AND ASSESSING WILD POPULATIONS WITH POPULATION GENOMICS

## Introduction

The Small Sharks project aims to establish a foundation for a successful reproduction and reintroduction program for the endangered nursehound (*Scyliorhinus stellaris*).

A core component of this work is to determine whether nursehounds raised in captivity have innate habitat preferences or if their preferences can be altered by 18 months of environmental enrichment (Arechavala *et al.,* 2022). We will test this by conducting an acoustic tracking experiment in the Balearic Islands. The data collected on residency time, dispersion, movement, and survival will be used to test our hypotheses and improve future reintroduction and conservation efforts.

A second objective of the project involves next-generation sequencing (NGS) of nursehounds. This genetic analysis will establish a baseline for continuous monitoring, allowing us to detect changes in population dynamics. This genetic information will also inform conservation and breeding programs designed to promote greater genetic variability, thereby enhancing the resilience of wild populations (Avise, 2008, Ardura *et al.*, 2011).

## Material and methods

An additional network of Thelma-Biotel TBR 800 receivers was installed in the Palma Marine Protected Area, spaced 300 meters apart. This expanded the existing infrastructure of the Balearic Tracking Network (BTN).

For the reintroduction study, a Thelma-Biotel A-HP9L transmitter was surgically implanted into the visceral cavity of each nursehound. Thirty individuals that had been raised with environmental enrichment (e.g., artificial seaweeds, tiles, and shelters) were released at the bottom in the center of the receiver network. One week later, a second group of 30 individuals, raised without environmental enrichment, was released in the same location.

To assess population connectivity, blood, tissue, or fin samples from nursehounds in the Balearic Islands, the Adriatic Sea (Italy and Croatia), the Ionian Sea (Greece), and the Cantabrian Sea (northern Spain) are being analyzed to obtain a SNP panel.

## Results and discussion

The receivers will be retrieved from the sea at the end of September, at which point the data will be analyzed. We already know that one nursehound from the environmentally enriched group was captured just one week after its release. The animal was found 5 miles away and at a depth of 60 meters.

Based on previous findings, our working hypothesis is that animals raised with environmental enrichment are better conditioned to use the shelters in the release area and are therefore less likely to disperse quickly. This is supported by earlier studies in the Balearic Islands (Vanrell et al., 2024) which show that nursehounds raised without this enrichment disperse rapidly.

*(Continued on next page)*

The NGS sequencing will be performed in specialized centers with proven expertise in these techniques. The resulting raw data will then undergo **bioinformatics analysis** to identify and generate a comprehensive **SNP panel**. This panel will be used to assess the genetic variability, population structure, and connectivity among the different nursehound populations.

The central hypothesis is that the nursehound population of the Balearic Islands is genetically distinct from the other populations being analyzed. This is based on the species' demersal nature, a preferred depth range that does not exceed 400 meters, and their sessile eggs, which do not contribute to dispersal. The deeper waters surrounding the Balearic Islands are therefore hypothesized to act as a physical and genetic barrier. If our genetic analysis confirms this differentiation, it would have significant implications for conservation, suggesting that this population should be managed as a separate and vulnerable unit to ensure its long-term viability.

## Acknowledgments

The authors acknowledge the financial support for this research, provided by the Pla de Recuperació, Transformació i Resiliència of the Spanish Government. The project was managed by the Government of the Balearic Islands (through the Conselleria d'Economia, Hisenda i Innovació and its Servei de Recerca i Desenvolupament) and funded by the European Union's NextGenerationEU instrument. This work was conducted under the framework of project [BIOPRO2024-015].

## Introduction

*Piscirickettsia salmonis* is the etiological agent of the *Salmonid Rickettsial Septicemia (SRS)*, which induces a systemic infection in fish generating millions of dollars in losses to the salmon industry. The bacterium can enter the host through mucosal surfaces, being the gills one of the primary routes of entry. Additionally, *P. salmonis* can modulate the autophagy process, a non-canonic immune mechanism in gill epithelial cells. In this context, gills are multifunctional tissue that combine physical barrier and immune defenses, where epithelial cells interact with immune cells to protect fish against environmental challenges and pathogens. Preliminary studies conducted by our research group have demonstrated that the gill epithelial cell line of rainbow trout RTgill-W1 can respond to *P. salmonis* infection, by upregulating the expression of pro-inflammatory cytokines and pattern recognition receptors. However, the interplay between macrophages and the epithelial gill cells on mounting an effective immune response against *P. salmonis* and the related autophagy modulation is still unknown. In this context, our study hypothesized that the presence of RTS-11 macrophage cell line in co-culture with RTgill-W1 epithelial cells enhances the immune-like response of RTgill-W1 against *P. salmonis,* by increasing pro-inflammatory cytokine expression and activating autophagy. The main objective was to characterize at the transcriptional and protein levels how the interaction between gill epithelial cells and macrophages interact to cope with *P. salmonis* infection.

## Methodology

To address this, an *in vitro* co-culture of RTgill-W1 cells and RTS-11 macrophages/monocytes cell line was established. The co-culture of RTgill-W1 / RTS-11 was challenged with *P. salmonis* for 24 hours, where the bacteria was used only in the RTgill-W1 area. After 24 hours of challenge, mRNA was extracted from RTgill-W1 cells. The expression of immune-related genes (immune receptors, pro-inflammatory cytokines and antimicrobial peptides) and autophagy-related genes was evaluated through real time qPCR, along with the activation of autophagy through changes in the protein content of LC3-II/LC3-I ratio. Additionally, an ELISA assay was performed to evaluate TNFα and IL-1β levels in the RTS11 media.

## Results

The results show that *P. salmonis* infection enhances the immune response of RTgill-W1 cells under co-culture conditions compared to a non-infected co-culture through the up-regulation of pro-inflammatory cytokines TNFα, IL-1β and IL-8 and the modulation of different pattern recognition receptors (PRRs) like NOD1. Additionally, the antimicrobial peptide (AMP) hepcidin was up-regulated in the presence of macrophages. In RTS-11 media, TNFα levels was higher in contrast with non-infected group. Interestingly, autophagy was downregulated under co-culture conditions at protein level, suggesting that the presence of macrophages might inhibit the activation of this process through the release of certain cytokines. However, further experiments are required to analyze and determine how macrophages interfere with autophagy activation. Our preliminary results suggest that the presence of macrophages enhances the immune response of gill epithelial cells, whereas autophagy appears to be reduced. This co-culture model provides a valuable platform for elucidating the cellular communication mechanisms between epithelial and immune cells in fish.

# IN VIVO STUDY OF THE ANTI-INFLAMMATORY AND INMUNOMODULATORY EFFECTS OF *Ulva rigida*-DERIVED POLYSACCHARIDES ON TISSUE REGENERATION IN *Danio rerio*

Email: piedad.vg.10@uma.es

The search for new pro-regenerative drugs focuses on substances of a variety of origins with biological activities that include immunomodulation, pro-angiogenesis, antioxidation, or anti-inflammation [1,2]. In this field, *Danio rerio* has become a well-established experimental model for drug evaluation due to its genetic, reproductive and developmental advantages.

In this communication, we investigate the anti-inflammatory and immunomodulatory effects of polysaccharides extracted from *Ulva rigida* (Ulvans) during *Danio rerio* fin regeneration. Our aim is to assess the regulative potential of these extracts over wound healing, blastema formation and regeneration outgrowth to evaluate potential applications in aquaculture.

These effects were studied over three-month zebrafish adults previously fed for two months with Ulvan-containing diets under a constant feeding regime. At 70dpf, the caudal fins of experimental and control zebrafish were amputated to assess regeneration of this organ over a 30-day period. During this procedure, stocking density, size heterogeneity, and food particle size were controlled. Body length, weight and fin anatomy was measured during this process and morphometrical results adjusted to mathematical growth models. In vivo fluorescence probes for oxidative, mitochondrial or endoplasmic reticulum stress were also studied under confocal and fluorescence microscopies.

Preliminary results suggest a slight amelioration of the morphometrical parameters of fin regenerates of fishes fed with the experimental feeds. This study is part of a global comparison of the biological effects of functional feeds over zebrafish and other fish species of economic interest. This study has been funded by a **N**extGenerationEU grant, European Union (PCM-00035, Marine Sciences).

# ENHANCING TRACEABILITY IN LAND-BASED AQUACULTURE

R. van de Ven*, E. Syropoulou, L. Negrão, J. Rito, C. A. Espinal

Landing Aquaculture B.V.
5281PS Boxtel
The Netherlands
*Email: rob@landingaquaculture.com
info@landingaquaculture.com

## Introduction

To ensure sustainable aquaculture practices and keep end consumers well informed, effective traceability tools are essential. As part of the SEA2SEE project (https://sea2see.eu/), an innovative end-to-end blockchain model has been developed to capture data across the entire seafood value chain. The aquaculture value chain involves multiple stakeholders, including enginnering companies that support farming operations. In this context, Landing Aquaculture, together with SEAentia, has been demonstrating how IoT technology can be applied in indoor recirculating aquaculture systems (RAS) to provide real-time traceability of both the farming environment and the fish production process.

## Materials & Methods

For the demontration case, a state-of-the-art RAS (Fig1), previously designed by Landing Aquaculture, was used to simulate the commercial production of meagre (*Argyrosomus regius*) at SEAentia in Peniche, Portugal. The RAS (~60 $m^3$) consists of eight tanks (2 fingerling, 3 on-growing, 2 grow-out, and 1 purging tank), all connected to a centralized water treatment unit. Designed to operate under a feed load of approximately 20 kg/day with 95% daily water recirculation, the system ensures optimal water quality through mechanical and biological filtration, gas exchange, and temperature control. Solids are removed using a drum filter (CM Aqua F2-1T) and protein skimmer with ozone injection (Clarity CL10); ammonia is reduced in a moving-bed bioreactor (4.5 $m^3$ RK plastic bio media; 750m2/m3); carbon dioxide is stripped via a degasser (0.8 $m^2$); dissolved oxygen is maintained with a low-head oxygen cone (75-100 $m^3$/h); and temperature is regulated using a heat pump (DM-Vario). An OxyGuard monitoring system enables real-time data collection and alerts for deviations, with all water quality data stored in the SmartWater Cloud management software to support bi-weekly analysis and integration into the blockchain traceability model. Each fish batch is eventually linked to a QR code, providing consumers with transparent, easy-to-read information on the fish's life from hatch to harvest.

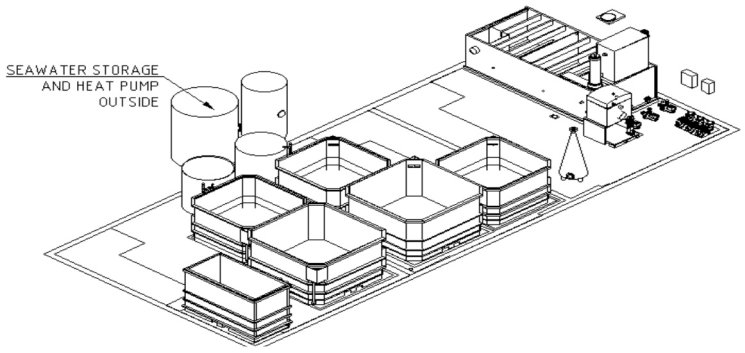

Fig1. RAS layout featuring its key components.

*(Continued on next page)*

## Results & Discussion

With the implemented system design, water quality was consistently maintained at optimal levels for the cultured species, supporting a stable annual production of 5-7 metric tonnes. The real-time monitoring system provided SEAentia with continuous insights into culture conditions, easing farm management by offering full control over the farming environment. Additionally, the continuous digital logging of water quality data created a reliable operational record, supporting SEAentia's qualification for certifications such as the Aquaculture Stewardship Council (ASC) and Best Aquaculture Practices (BAP).

By integrating this data into the blockchain model, stakeholders across the value chain gain access to transparent, verifiable information about production conditions. This apporach not only prevents data loss or miscommunication, but also strengthens consumer trust. This pilot serves as a blueprint for future large-scale applications aimed at increasing transparency in seafood supply chains.

## Introduction

Sharks play a fundamental role in maintaining the ecological balance of marine ecosystems (Motivarash *et al*., 2020). Despite their ecological importance, sharks are increasingly at risk due to the widespread and accelerating global decline in the variety and abundance of biodiversity. One example is large-spotted dogfish (*Scyliorhinus stellaris)*, which is listed as vulnerable species due to ongoing population declines (IUCN SSC Shark Specialist Group, 2010). In the Balearic Islands, a restocking program has been established to raise large-spotted dogfish in captivity with the goal of reintroducing them into their natural habitat. Ensuring the well-being of these sharks during their time in captivity is crucial for the success of this effort. This study investigates the effect of different types of environmental enrichment on the growth of this species. To evaluate growth performance, individuals were maintained under experimental conditions with varying habitat complexities over an eight-month period. Enhancing enclosure complexity through environmental enrichment can create a more natural setting that promotes increased foraging behavior (Näslund & Johnsson, 2014).

## Material and methods

A total of 45 large-spotted dogfish born in captivity were tagged with microchips and randomly divided into three groups of 15 individuals, each kept in a 1000 L tank with oxygen and temperature control maintained at 18ºC. Each tank featured a different type of structural environmental enrichment: artificial seaweed (TL1) to simulate natural vegetation, ceramic tiles (TL2) providing structural complexity, and a control group without any environmental enrichment (TL3). The sharks were fed *ad libitum* three times per week, with the feed amount calculated at 5% of their live body weight (Janse, 2003). The diet included fresh oily fish (anchovies), hake, crustaceans, and squid.

Following standard dosing protocols to ensure minimal stress and rapid recovery, the individuals were anesthetized monthly using MS-222 (tricaine methanesulfonate) in order to measure parameters such as length and weight.

The results were analyzed using R statistical software with ANOVA test.

| | Df | Sum Sq | Mean Sq | F value | Pr (>F) |
|---|---|---|---|---|---|
| Tanc | 2 | 500 | 249.77 | 3.785 | 0.0238* |
| Residuals | 292 | 19627 | 65.98 | | |

Signif. Codes: ns not significant; *** <0.001; ** < 0.01; * <0.05

Table 1: Analysis of variance (ANOVA)

*(Continued on next page)*

## Results and discussion

In TL1, individuals had an average initial weight of 134.9 g (SD = 42.7 g) and an initial length of 31.78 cm (SD = 2.53 cm). At the end of the experiment, TL1 individuals reached a mean weight of 828.82 g (SD = 89.22 g) and a mean length of 56.67 cm (SD = 1.71 cm). In TL2, the initial average weight was 118.24 g (SD = 37.49 g), and the initial length was 30.89 cm (SD = 2.82 cm). Final values in TL2 reached 712.72 g in weight (SD = 84.08 g) and 53.73 cm in length (SD = 2.23 cm). Finally, TL3 individuals started with an average weight of 125.82 g (SD = 35.40 g) and a length of 31.35 cm (SD = 2.81 cm), reaching a final average weight of 707.97 g (SD = 104.27 g) and a length of 54.46 cm (SD = 2.52 cm).

The ANOVA analysis revealed a significant overall effect, with an F-value of 3.78 and a p-value of 0.0238, indicating that there are statistically significant differences among TL1, TL2, and TL3 (Table 1).

Several environmental factors may help explain these growth differences among groups. Observations during the trial suggested that individuals in TL1 and TL3 appeared to have easier access to food compared to those in TL2. Additionally, both TL1 and TL2 had more hiding places than TL3, which may have influenced stress levels and consequently, growth. These differences in environmental complexity and food availability may have contributed to the observed variation in final size among the treatment groups.

Enrichment strategies vary depending on species, age, sex, and reproductive condition, and should ideally be adapted to the specific needs of each individual animal rather than applying a universal approach across populations or species. Furthermore, enrichment has been shown to reduce stress in captive animals and promote natural behaviors (Corcoran, 2015).

In summary, our results suggest that environmental enrichment plays a role in the growth of *Scyliorhinus stellaris*. Artificial seaweed (TL1) appeared to promote the greatest growth in both weight and length, compared to ceramic tiles (TL2), while the control group (TL3) showed intermediate outcomes that were not significantly different from either. Therefore, we conclude that environmental enrichment can positively contribute to the welfare and development of *Scyliorhinus stellaris* in captivity, supporting better growth under enriched conditions.

## Introduction

Insects are a promising alternative protein source for aquafeed since they have an adequate nutritional profile, with a high protein content, that can account for more than half of the weight of the dried larvae (Rumpold and Schlüter, 2013). Insect meals, apart from protein, also contain fat and chitin, which can be separated and further utilized. To obtain these meals, the insect must undergo several processing steps, which may include slaughter, drying, and certain types of fractionations, such as defatting (Ojha et al., 2021). These processing steps affect different parameters in the obtained meals, such as nutritional, sensory, and hygienic-sanitary quality (Varga et al., 2024). Mechanical pressing is a relatively cheap, scalable, and economical technique. The fractionation of insects by mechanical dry pressing is frequently applied to eliminate partially or totally the insect fat, while wet pressing is intended to obtain a protein fraction composed mainly of the insect hemocoele and another fraction composed primarily of the insect exoskeleton, rich in chitin. In this study, we evaluated the possible use of each of these fractions as protein-rich meals in aquafeed.

## Materials and methods

*Tenebrio molitor* (TM) larvae were purchased from Artroposfera (Toledo, Spain). Larvae were sacrificed by immersion in liquid nitrogen and stored at -20 °C until further processing. TM larvae were fractionated in a mechanical press at 135 °C. The larvae were freeze-dried (Telstar Lyoquest -55 °C, Barcelona, Spain) prior to the dry-pressing process; a part of the whole dried TM larvae was ground (COM) and stored at -20 °C. DPD fraction was obtained by hot-pressing the dry TM larvae. Wet fractionation was carried out in similar conditions as the dry-pressing process, obtaining a chitinous fraction (WPE) and a fraction consisting mainly of the larval hemocoele (WPH). WPE and WPH fractions were freeze-dried and stored at -20 °C.

Proximate composition of TM meals was carried out according to the methods described by the Association of Official Analytical Chemists (AOAC, 2005). The amino acid profile composition was analyzed with a Biochrom 30+ amino acid analyzer (Biochrom LTD., Cambridge, UK). *In vitro* protein digestion was performed simulating the gastric and intestine steps of the digestive process, following the modified method described by Varga et al. (2024). The protein digestibility of TM meal was evaluated using the enzyme extracts from the stomach and intestine of *Sparus aurata*, and the degree of hydrolysis of gastric phase (DA) and intestinal phase (DB) was expressed as g of -$NH_2$ released with respect to the total -$NH_2$ in the meal.

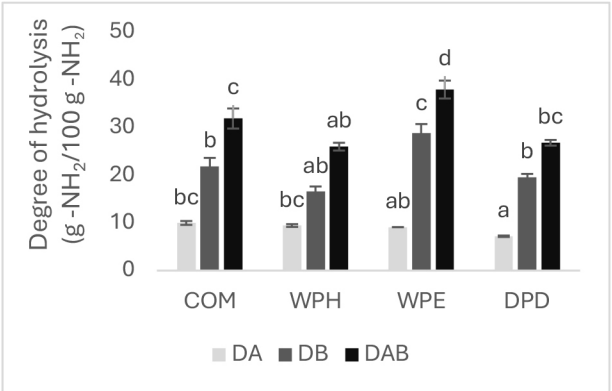

**Figure 1.** Degree of hydrolysis of the obtained fractions. DA: degree of hydrolysis of gastric phase; DB: degree of hydrolysis of intestinal phase; DAB: total degree of hydrolysis. Different letters indicate significant differences (P<0.05).

*(Continued on next page)*

**Results and discussion**

The dry-pressing process yielded 245.2 g of DPD meal and 22.7 g of fat from 1 kg of fresh TM, reaching 845.8 and 78.30 g of DPD and fat, respectively, when calculating with the dry starting material. The wet-pressing process resulted in 124.5 g of WPE (45 % of dry matter) and 150.4 g (55 % of dry matter) of WPH for each kg of fresh TM used. As for the proximal composition, the protein content calculated from the nitrogen content obtained by Kjeldahl analysis results in a significant increase in crude protein for the WPE and DPD meals compared to the unfractionated insect (COM). The crude fat content was significantly decreased for the WPE and DPD meals with respect to COM, while the WPH fraction accumulated most of the fat resulting from wet pressing. Due to the high content of non-protein nitrogen in insect meals, the Kjeldahl analysis and the choice of the nitrogen conversion factor can lead to errors in the calculation of the protein content. The total amino acid content calculated by HPLC showed that the protein content in WPE accounted for more than two-thirds of the dry weight of the meal.

As shown in Figure 1, the hydrolysis degree results showed that the gastric digestion (DA) resulted in similar values except for DPD, which had a significantly reduced degree of hydrolysis. Furthermore, in the intestinal phase (DB), the degree of hydrolysis was clearly seen to be significantly increased and reaches its maximum value for WPE with respect to the rest of the treatments. However, when it comes to the total *in vitro* protein digestibility, this effect lessens.

Results showed that the obtained fractions have high protein levels, satisfactory amino acid profiles, and good *in vitro* amino acid digestibility. Thus, either the complete insect may be directly included in the diet, or DPD may be applied when the separation of fat is crucial. As for WPH, Kang et al. (2023) have previously suggested its use for human consumption as it had excellent properties as 3D printable food. In the same study, WPE was discarded, which, based on the results of the present work, may be destined to aquafeed as it is a more promising protein source than it was previously believed. The remaining chitin content can be either separated for further use; or can remain part of the meal, as several authors confirm its beneficial effects in aquafeed.

# CIRCALGAE: UNLOCKING THE FULL POTENTIAL OF ALGAE THROUGH CIRCULAR BIOREFINERY APPROACHES

Agnes Timea Varga*[1], Kasra Khatami Mashhadi[1], Amparo Jiménez-Quero[1]

Division of Industrial Biotechnology
Department of Life Sciences
Chalmers University of Technology

E-mail: agnesvar@chalmers.se

Algae hold significant promise for driving Europe's transition to a sustainable blue bioeconomy. Yet, current industrial processing discards up to 95% of harvested biomass, leaving valuable compounds underutilized. The CIRCALGAE project addresses this gap by developing a circular biorefinery model to convert these side streams into high-value ingredients for the food, feed, and cosmetic sectors.

The project integrates advanced green extraction technologies, including subcritical water extraction (SWE), ultrasound-assisted extraction (UAE), and high-pressure homogenization (HPH), to enhance resource efficiency and minimize environmental footprint. Three pilot-scale biorefinery schemes (TRL 7) are being implemented to demonstrate the transformation of industrial algae residues into nutrient-rich food additives, bioactive cosmetic components, and sustainable feed formulations.

CIRCALGAE's multidisciplinary consortium of universities, research centers, SMEs, and industry partners works across the entire value chain. Twelve demonstrator products are being developed, with their bioactivity validated and market potential assessed through consumer acceptance studies. By fostering circular business models, stakeholder engagement, and alignment with EU strategies such as the European Green Deal and Farm-to-Fork, CIRCALGAE supports a low-carbon, resource-efficient bioeconomy.

Launched in October 2022, the project has moved from extract characterization to prototyping for food, feed, and cosmetic applications, while actively engaging consumers to ensure market acceptance. These efforts are paving the way for a scalable, sustainable, and competitive algae-based industry in Europe, turning today's waste into tomorrow's opportunity.

# INVESTIGATION ON THE RELATIONSHIP BETWEEN REPRODUCTIVE BIOLOGY AND THE MICROBIAL COMMUNITY IN COMMON CARP (*Cyprinus carpio*)

## Introduction

Common carp (*Cyprinus carpio*) plays an important role in fish production in Hungary. This species accounts for 82% of the annual production of fish (Bojtorné et al., 2023). Successful fish production depends on the overall stable health and favourable reproductive biology of the broodstock. The sector is highly exposed to extreme weather conditions. In addition to this factor, the sorting, transport and handling of individuals may further increase the stress on the fish, which can open the door to infections. An increasingly important area of research today is the study of microbial communities on the surface and in the organism of fish and their impact on health, growth and reproductive parameters. Following research in humans and mammals, it has been described that pathogenic and symbiotic microbes on the surface and within the body of fish influence the internal environment through complex mechanisms (Bernáth et al., 2023). When the balance is disturbed, the overall health of individuals can deteriorate, reducing their growth and thus their reproductive capacity (Amillano-Cisneros et al., 2025). The aim of our study was to investigate the relationship between the reproductive biology of carp and the effects of microbial communities.

## Materials and methods

The experimental propagation and sampling were carried out at a Hungarian fish farm (Szabolcsi Halászati Ltd.). During breeding season, 15 male and female individuals were selected from 2 wintering ponds. On the day of sampling individuals (N=10 male and female) were stripped. During sampling, the following parameters were measured and calculated: total volume of milt (TVM), volume of milt per kg of body weight (VOM), spermatozoa per millilitre (SPZ), total sperm production (TSP), total sperm production per kilogram of body weight (TNS), sperm motility and kinetic parameters, osmolality and pH of the seminal plasma and ovarian fluid. The total weight of eggs/individual (kg), the number of eggs/gram (pcs), and the pseudo-gonadosomatic index were recorded. Milt and roe samples were collected from each individual for further microbiological examination. The stripped fish were euthanized and intestinal samples were collected. A tenfold dilution series was prepared from the gut, sperm and egg samples with PBS solution. The dilution series members were spread on tryptic soy agar (TSA), de Man, Rogosa and Sharpe (MRS) agar and incubated for 96 hours at 22 °C. At the end of the incubation period, colony forming units (CFU) were counted, and morphologically distinct colonies were subcultured. The pure cultures were used for MALDI-TOF MS identification. During statistical analysis, correlation matrix and Pearson's correlation coefficient test were applied ($p<0.05$).

*(Continued on next page)*

**Results**

Negative correlation was observed between the number of CFUs of sperm TSA samples and the total sperm counts (high CFU number - low sperm count, p=0.0226). In addition, a negative correlation was identified between the number of sperm TSA CFU and the amount of semen per body weight (high CFU count, low sperm count; p = 0.0132). Negative correlation was detected between the number of semen CFU on MRSA medium and DSL (straight line distance) kinetic parameter (high CFU count but low DSL, p=0.0481). A negative correlation was identified between semen CFU on MRSA medium and the WOB (wobble coefficient) kinetic parameter (where a high number of CFU was observed, but low WOB kinetic parameter, p=0.0268). Negative correlation was observed between the formation of CFU on the egg MRSA plates and the osmolality of ovarian fluid (high germ count-low osmolality, p=0.0394).

**Discussion and conclusion**

In addition to the qualification of the gamete samples, several representatives of 17 bacterial genera were isolated and identified from the intestinal tract and gametes of the individuals with traditional culturing and molecular methods as well. The results show that several species within a genus can be found in the organs of a single individual. In the gut, members of the genera *Lactococcus* and *Lactobacillus* were abundant, whereas *Aeromonas spp*. and *Pseudomonas spp*. were more abundant in the gametes. The number of CFU was associated with negative changes in some gamete quality parameters. Several identified bacterial species are facultative pathogenic (risk group 2) organisms, therefore they may possess a biological risk on fish health.

**Introduction**

Currently, plastics are the most common pollutant in ocean ecosystems. Once in the environment, plastic waste breaks down into microplastics (MPs, < 5 mm) through a combination of physical, chemical, and biological processes. The presence of MPs in marine environments has profound implications for both wildlife and human health [1; 2]. In recent decades, biodegradable polymers have gained more attention due to their biodegradability and biological origin, emerging as promising alternatives to conventional plastics due to their environmental degradability and biological origin [3]. Among these, polyhydroxy-butyrate-co-valerate (PHBV), a bio-based co-polymer, that belongs to the polyhydroxyalkanoates family, has gained attention. However, its potential impact, particularly in aquatic organisms, remains largely unexplored. To address this gap, this study investigates the effects of PHBV microparticles on survival, growth, feeding rates, and ingestion in the aquatic model species *Artemia franciscana*.

**Materials and Methods**

Short-term tests were done in darkness at 25 ± 0.5 °C, and long-term tests were conducted under controlled conditions (25 ± 0.5 °C; 14:10 h light/dark). Short-term assays: ten instar II-III (**Exp 1**) and 10 juveniles (**Exp 2**) were exposed to PHBV (0 - 500 mg $L^{-1}$) in 24 and 6 well plates in triplicate, respectively. Mortality was recorded at 24 and 48h. Long-term assays: Organisms (0.5 ind $mL^{-1}$) were exposed to 25 - 500 mg $L^{-1}$ PHBV under two conditions: 1) with food (**Exp 3**): Instar II-III nauplii were exposed for 7 days with microalgae *Tetraselmis suecica.* 2) without food: Instar II-III (**Exp 4**) and juvenile (**Exp 5**) were exposed during 7 and 14 days, respectively. Two controls were included, with microalgae (CTRL (+)) and without microalgae (CTRL (-)). Survival was monitored throughout, and growth (body length) measured at start and end. Filtration and ingestion rates were assessed after 14 days at 100 mg $L^{-1}$ PHBV with food. Uptake was confirmed by exposing nauplii and juveniles to Nile Red-labeled PHBV (100 mg $L^{-1}$, 30 min) and observed under bright-field/fluorescence microscopy. Histological intestinal analysis was done after 14-day exposure (100 mg $L^{-1}$). Culture media were filtered (20 µm mesh) to collect *Artemia* fecal pellets. Filters were vacuum-dried and platinum-coated by sputtering (15 s, argon atmosphere; BalTec500). PHBV granules in fecal pellets were analyzed using scanning electron microscopy (SEM; JEOL 7001F, 5 kV). Negative controls included commercial polymers unexposed to *A franciscana*.

**Results**

Short-term exposure showed <20% mortality of both nauplii and juveniles at all concentrations (**Exp 1&2**). In long-term tests, only 500 mg $L^{-1}$ caused significant mortality in nauplii (76% by day 2); other concentrations had >85% survival with food (**Exp 3**). Without food (**Exp 4**), nauplii survival declined with concentration. CTRL (−) had 100% mortality by day 5. CTRL (+) maintained 93% survival. Juveniles (**Exp 5**) showed highest survival at 250 mg $L^{-1}$ (90%) by day 7 and dropped to 17% by day 14. CTRL (+) had 83% survival. Growth was unaffected with food (**Exp 3**); and significantly reduced without food (**Exp 4**) compared to CTRL (+), but not between treatments. In contrast, no growth differences were observed in juveniles. Feeding behavior were not affected. PHBV ingestion was confirmed in both stages, with particles visible in the digestive tract and fecal pellets (**Fig 1**). No major histological damage was observed, but intestinal epithelium appeared disorganized with reduced vacuolation and areas fragmented (**Fig 2**). Granules present in *Artemia* feces showed increased surface roughness and structural deformation relative to control particles (**Fig 3**), supporting the hypothesis that *A. franciscana* can process or partially

*(Continued on next page)*

Figure 1: Images of PHBV fluorescence stained with Nile red in the digestive tract of *A. franciscana* nauplii (A - D) and 14 days organisms (E - H). Images of fecal pellets (I - L).

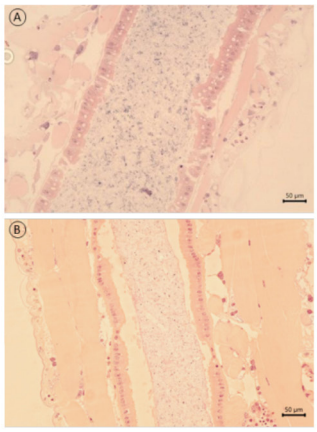

Figure 2: Instestinal tissue of *A. franciscana*. A) control B) PHBV 100 mg $L^{-1}$

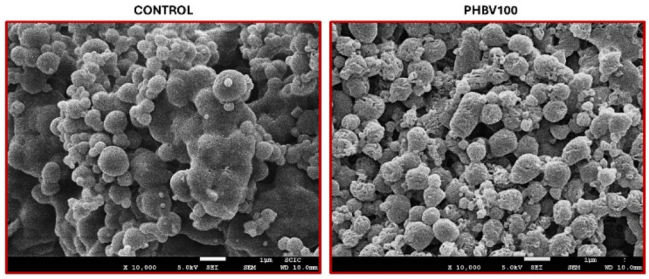

Figure 3. Scanning electron microscopy (SEM) images of PHBV granules before ingestion (left) and after ingestion, as recovered from the feces of *A. franciscana* (right).

assimilate PHBV through digestive activity. The results showed that *A. franciscana* ingests PHBV, which supports survival in the absence of food, especially in juveniles, but does not promote growth. PHBV is less harmful short-term exposures than some conventional plastics, however in long-term exposure under food-limited conditions require further study. These findings contribute to the environmental risk assessments of biodegradable plastics in marine systems.

## Introduction

Biological rhythms are intrinsic timekeeping mechanisms that regulate physiological processes in living organisms, including daily feeding patterns. Feeding behaviour is a key determinant of an organism's nutritional status, and the timing of food intake plays a critical role in overall health and welfare (Asher and Sassone-Corsi, 2015). Although subadult and adult *Octopus vulgaris* are known to be mostly nocturnal predators, nothing is known about the activity rhythms of juveniles in the wild, active predators mostly on amphipods (Escolar et al. 2024). Understanding the molecular rhythms of its digestive system is essential for developing optimized feeding strategies that promote growth, enhance physiological efficiency, and ensure animal welfare under culture conditions. In this study, we investigate the gene expression patterns in the digestive gland (DG) of recently settled, juvenile *O. vulgaris* over a 24-hour cycle using RNA-sequencing analysis.

## Materials and Methods

***Collection of material:*** *O. vulgaris* individuals were collected on November 11, 2023, using experimental juvenile octopus' collectors (Escolar et al. 2021) placed at 5–15 m depth on sandy bottoms off Vilanova i la Geltrú (NW Mediterranean). A total of 35 individuals were collected between 06:30 and 11:00 h. Specimens (mean weight: 427 ± 622 mg; range: 183–3428 mg) were kept in small containers onboard, transported to aquarium facilities of the ICM-CSIC located at 50 km and provided by an open seawater system, and placed in rearing tanks by 13:00 h. They were housed in six 5 L polyethylene tanks (8 individuals/tank) with refuges, under natural photoperiod and ambient seawater temperature of 17.2 °C. Light intensity at tank bottom was 15 lux. Natural sunrise and sunset during the experiment were at 07:45 and 17:45 local time, respectively. No food was provided.

***Sampling for endogenous rhythms analysis:*** Five individuals were sampled every 4 hours across seven time points starting at 12:00 h (t0 (midday)), 16:00 h, 20:00 h (t4, t8 (afternoon, evening)), 24:00 h (t12, (midnight)), 04:00 h, 08:00 h (t16, t20, (early morning, sunrise)) and 12:00 h (t24 (midday, after 24h)). Digestive glands (DG) were dissected after the death of the individuals, preserved in RNAlater at 4ºC during 24h, and stored at -80 °C for transcriptomic analysis. Animal welfare procedures followed EU guidelines (Directive 2010/63/EU) and cephalopod-specific recommendations (Fiorito et al., 2015).

***RNA extraction and sequencing:*** Total RNA from pooled DG samples of each time point was extracted using the RNeasy Mini Kit (Qiagen). RNA quality was assessed via NanoDrop 2000. Library preparation and sequencing were performed by Biomarker Technologies (BMK GmbH, Germany) using Illumina NovaSeq X (PE150).

***Bioinformatics and statistical analysis:*** Raw FASTQ reads were cleaned using custom Perl scripts. Quality metrics (Q20, Q30, GC content, duplication rates) were calculated. Clean reads were aligned to the *O. vulgaris* genome (NCBI Accession number: GCA_951406725.2) using HISAT2 v2.2.1 (Kim et al., 2019). Transcript reconstruction and quantification were done with StringTie (v2.2.1; Kokava et al., 2019, FPKM method), and transcriptome quality assessed via GffCompare (v0.12.6; Pertea & Pertea, 2020). Time-course expression data were normalized using edgeR (TMM method, Robinson and Oshlack, 2010), filtering low-expression genes (<0.5 CPM). Differentially expressed genes (DEGs) were identified ($p < 0.05$, $FC \geq 2$). Mfuzz

*(Continued on next page)*

(Kumar and Futschik, 2007) and TMixClust (Martínez-Bueno and Díaz, 2021) were used for soft clustering and time-series visualization, respectively; Heatmap3 for clustered heatmaps (Zhao et al., 2014). DESeq2 was used for pairwise DEG analysis (Love et al., 2014). GO enrichment was performed using topGO (Alexa & Rahnfürer, 2010) and GOseq (Young et al., 2010) adjusting for gene length bias). Pathway analysis was conducted using KEGG (Kanehisa et al., 2008).

**Results**

Time-course analysis of differentially expressed genes in the digestive gland of *O. vulgaris* juveniles identified 3 different clusters with distinct temporal patterns. Clusters 1 and 2 show opposing expression profiles, suggesting opposed regulation between gene sets, while Cluster 3 displays an intermediate pattern. Cluster 1 shows two peaks of maximum expression: one at midday (t0 and t24; 12:00 h) and another early morning at 4:00 h (t16). In Cluster 2, the peaks occur from afternoon to midnight (t4–t12; 16:00–00:00 h) and at sunrise (t20; 8:00 h). Cluster 3 reaches its maximum expression at evening (t8; 20:00 h) and early morning (t16; 04:00 h). Enriched GO terms observed include: metal ion binding (associated with enzymes and metabolic processes), ATP binding and nucleic acid binding (involved in nuclear and enzymatic functions), integral component of membrane (related to transporter proteins or receptors), and response to stimulus (adaptation to external signals, such as the light/dark cycle).

The KEGG pathway enrichment analysis of differentially expressed genes (DEGs) between 8:00 h (t20) and midday (t24 and t0), peak at 12:00 h, suggest the completion of digestive activity, metabolic resetting, and preparation for the next phase. Between midday (12:00 h, t0) and afternoon (16:00 h, t4), with a peak at 16:00 h, enriched pathways suggest metabolic shifts**,** likely reflecting active digestion and nutrient assimilation. In the transition from afternoon (16:00 h, t4) to evening (20:00 h, t8), with a peak at 20:00 h, enriched pathways likely represent the post-absorptive phase, during which nutrients are processed and stored. The organism also appears to prepare for nocturnal activity, consistent with the predatory behaviour typically observed in *O. vulgaris* (Rosa et al., 2024).In summary, the temporal variations observed over a 24-hour cycle, together with the KEGG pathway enrichment analysis of differentially expressed genes (DEGs) in the digestive gland of octopuses, reveal complex rhythmic patterns in digestive system activity. These changes are closely aligned with the light/dark cycle and likely reflect underlying circadian metabolic processes.

# LONG-TERM PERSISTENCE AND PUTATIVE VERTICAL TRANSMISSION OF RGNNV/SJNNV BETANODAVIRUS IN GILTHEAD SEA BREAM (*Sparus aurata*)

C. Varvara, P. Berto, L. Biasini, A. Buratin, A. Marsella, T. Pretto, A. Toffan, F. Pascoli

**Introduction**
The gilthead sea bream (*Sparus aurata*) was historically considered resistant to viral nervous necrosis (VNN), an important disease caused by Betanodavirus. However, recent reports have identified significant larval mortality events associated with a reassortant strain of nervous necrosis virus (NNV), the RGNNV/SJNNV, composed of an RNA1 segment from the RGNNV genotype and an RNA2 segment from the SJNNV. Although some marine species have been confirmed to transmit the NNV vertically, this transmission route remains unverified in *S. aurata*. Moreover, the dynamics of long-term viral persistence in this species are still poorly understood.

**Materials and methods**
Previous experimental infections were conducted via immersion on sea bream larvae at 35 and 75 days post-hatch (dph) using the RGNNV/SJNNV strain. Following these initial trials, the surviving fish were maintained under controlled conditions and monitored for up to 7 years to assess long-term viral persistence in brain, retina and gonadal tissues by molecular and virological methods. Reproductively mature, persistently infected individuals were induced to spawn, and samples of eggs, sperm and resulting larvae were analyzed for the presence of Betanodavirus to evaluate the potential for vertical transmission.

**Result**
Previous results from larvae infection showed the presence of Betanodavirus in all larvae starting from 1 day post-infection, with peak viral loads at 10 dpi and comparable replication profiles across both age groups. Histological and immunohistochemical analyses confirmed early viral localization in the brain and retina. No clinical signs nor mortality were observed.

Asymptomatic fish remained positive for Betanodavirus up to 7 years post-infection, with persistent virus detected in brain, eye, and gonadal tissues by RT-qPCR. However, viral distribution within the gonads was not homogeneous: the presence of viral RNA in ovaries and testis showed intra-organ variability. Similarly, viral RNA was detected in both sperm and eggs, but not consistently across all stripping events from the same positive-testing breeder. Furthermore, within a single spawning event, the presence of the virus was not evenly distributed among gametes. In our experimental trials, all newborn larvae tested negative for Betanodavirus by RT-qPCR up to 28 days post-hatch.

**Conclusions**
This study demonstrates that *S. aurata* can harbor long-term persistent RGNNV/SJNNV Betanodavirus infections in both neural and reproductive tissues, without any clinical manifestations. The detection of viral RNA in gametes, along with uneven distribution patterns, suggests a potential—though not yet confirmed—route for vertical transmission. These findings highlight the critical role of broodstock in the maintenance and possible spread of Betanodavirus in aquaculture settings, and stress the importance of implementing sensitive diagnostic protocols and rigorous screening strategies for broodstock management in marine hatcheries.

## Introduction

The pikeperch *(Sander lucioperca)* is a commercially important species in Europe, with well-established protocols of artificial reproduction. However, these protocols are labor-intensive and often require repeated handling of broodstock females, which can induce acute stress and increase broodstock mortality (Rónyai, 2007,) what can even potentially negatively affect offspring quality (Rasal et al., 2024). The largemouth bass (*Micropterus salmoides*) is primarily significant in Europe for recreational angling. However, its low-fat flesh and high-quality fillet have made it globally popular among health-conscious consumers (Parmar et al., 2022). At the same time, rising expectations regarding product quality have led to a decline in demand for common carp (*Cyprinus carpio*) (Hu et al., 2023), resulting in China's annual production of largemouth bass for human consumption approaching one million tons (Liu et al., 2022). However, most of the production is seasonal and/or based on nest spawning technology, which may involve limited controllability and low biological diversity. Despite the high production volume, no well-developed artificial reproduction protocol has been published to date, while the precise spawning ethology of the species remains undescribed. Given these challenges, the objective of the present study was to describe the spawning indicators in both species through camera observation and recording.

## Materials and methods

In January 2025, during preseason pikeperch reproduction, six pairs of breeders were hormonally stimulated with salmon gonadoliberin analog using the warming thermal regime (Ljubobratović et al., 2021). The 6 pairs of breeders were placed in two 4m$^3$ tanks, divided into three spawning chambers, creating a total of six breeding units. In each unit, an artificial nest was placed, made of artificial grass, and an underwater lighting system, programmed to a 12:12 LD photoperiod, with a camera above each compartment. After spawning, nests containing fertilized eggs were placed individually into conical incubators for incubation, and the hatched larvae were subsequently counted. In April 2025, six pairs of largemouth bass breeders were placed into three spawning tanks, each tank with two pairs, with three different setups: D - divided tank: the tank separated in the middle by a partition net, one nest per pair of breeder; CH - chambered nest tank: first and last third the tank each with a nest at in the cover with an empty third in the middle and securing free movement throughout the tank and hiding are for females; F – free tank: one nest at each end of the tank, securing free movement throughout the tank without any chambers included. Fish were hormonally stimulated with human chorionic gonadotropin three days upon stocking, and the behavior of the fish was further camera-monitored. After spawning, eggs were collected from the nests, their number and embryo survival were evaluated, and stocked in Zug jars for incubation.

## Results

During the pike-perch spawning experiment, spawning was observed in all six pairs on the 8th and 9th days after hormonal stimulation. After placing the artificial nests into the incubators, the number of hatched larvae was assessed and ranged from 15.200 to 28.899.. In the case of the largemouth bass experiment, among three setups, the tank equipped with half partitions proved to be the most effective. Two nests contained eggs, and CH treatment yielded ~80 thousand live eggs while the F nest contained close to 40 thousand live eggs. The hatching rate was 100% for both nests. Both at the beginning and the end of the experiment, the males were spermiating.

*(Continued on next page)*

**Discussion**

Artificial intelligence is increasingly gaining ground in various areas of aquaculture and has already been successfully applied in several production processes, such as feeding management and health monitoring (Mandal & Ghosh, 2024). Animal welfare is also receiving growing attention, particularly in relation to behavior-based indicators, which have recently come into focus (Barreto et al., 2022). By utilizing spawning indicators based on video monitoring, new protocols can be developed that not only improve the survival rate of broodstock but may also positively affect the quality of eggs and larvae. Previous research has shown that problems affecting the parents can have molecular-level effects on their offspring, influencing their later performance (Rasal et al., 2024). The present research led to the description of the ovulation indicators that will be further utilized to set the new spawning protocol, reducing the fish handling and labor requirements.

E-mail: harri.vehvilainen@luke.fi

## Introduction

Due to new operation models (e.g. offshore farming) demand for larger fish for sea grow-out is increasing (Bergheim et al., 2009, Ytrestøyl et al., 2022). RAS offers possible way of producing larger fish with control on nutrient output and stable environmental conditions for fish. Sea cage grow-out producers in seasonal environment would preferably have all the fish at the same time in spring after the ice cover has left, while RAS is most cost-effective when it does not have to produce fish with all-in-all-out -fashion. However, it is uncertain how the fish grown to larger sizes in stable RAS conditions will adapt to seasonal sea grow-out environment (Lai et al. 2024, Ytrestøyl et al., 2022). In this study we tested how RAS grown 500 g rainbow trout perform in sea cages when they arrive to sea in different times of the year.

## Materials and methods

At early summer of first grow-out period < 50 g fish from early hatched egg batches were transported from both freshwater flow-through (Control) and RAS (RAS1) farm to sea cages.

Fish from RAS1-group were also kept in RAS and grown to size > 500 g after which they transferred to sea cages at late autumn of first grow-out period (RAS2). Fish from late hatch egg batch were grown in RAS until size > 500 g, and then transported to sea cages in late winter/early spring of second grow-out period (RAS3). From RAS3-group 5 g fish were also taken to colder flow-through water for the summer of first grow-out period. These fish were returned to RAS at size of approx. 50 g at autumn and subsequently raised in RAS until > 500 g when they were transferred to sea cage at late spring at the onset of the second grow-out period (RAS4).

All the fish groups were grown with automated feeders according to feed manufacturer's table adjusted to correspond optimal feeding by visual inspection of appetite (Optimised). In addition, Control and RAS4 -groups were fed with feeders that are adapt (Adaptive) to the feeding amount based on fish appetite.

## Results

Control and RAS1 -groups had a good growth in optimised feeding. However, fish transferred as > 500g from RAS showed difficulties to adapt for the grow-out in sea cages (Fig.1)

## Discussion

Dramatic reluctance of RAS-raised larger rainbow trouts to feed and grow in sea cages makes combination of RAS and sea cage farming challenging, and more causal and physiological investigations to solve this puzzle are needed (Hänninen et al. in prep.).

c Department of Biology, University of Turku, 20014 Turku, Finland
E-mail: harri.vehvilainen@luke.fi

**Introduction**
The start-up and activation of RAS systems is complex technological and biological research subject (Pulkkinen et al. 2018). Parainen brackish water RAS comprises of two separate systems. The RAS has been working as all-in-all-out -principle for two decades, where the system is emptied from water for the summer every year, and activated again in autumn. In addition, due to logistic and technical reasons for almost two decades only one of the systems has been used in experiments, and the other system's biofilters have been dry. As a part of joining Finnish Marine Research Infrastructure (https://www.finmari-infrastructure.fi/) Parainen RAS was upgraded to maintain temperature separately in two systems. This also provided us with an unique opportunity to test how fast will the biofilter with extended period of unuse start to work. Study questions: 1) how fast will the biofilters in two systems start to work, 2) how comparable results of fish trials are in two different systems, 3) how much fish we can we can raise within the system.

**Materials and methods**
The RAS systems were started similarly with chemicals before fish arrived to facility. The temperature of the systems were set to 14,5 C. The fish arrived 9.1.2025 (mean weight 568 g, n=180) and were divided to two systems. Fish were grown with automated feeders according to feed manufacturer's table adjusted to correspond optimal feeding by visual inspection of appetite. The fish growth and water quality parameters were monitored through the experiments. The fish were first grown in two separate systems, and at the end all the fish were transferred to system 1 to see whether we can reach the upper limit of the system capacity.

**Results**
Comparison of the two systems.

**Discussion**
The start-up of System 2 after nearly two decades of dry biofilters was astonishingly fast, after initial peak of nitrite, the water quality parameters came to same level with System 1, and the fish growth was similar in both systems Upper limits for System 1 could not be reached within experimental period, but it is evident that the system is capable to function as full RAS (<20 % of water renewal, 800 l / kg feed, > 70 kg /$m^3$). Besides interesting experimental system for fish trials, the biofilters themselves provide subject of further studies.

## Introduction

Aquaculture is the fastest-growing food production sector worldwide. Despite this positive trend, the industry faces several challenges that keep it from reaching its full potential. A major limitation is the lack of understanding of the molecular pathways involved in regulating reproduction, growth, and disease resistance of the farmed species.

In this context, fish cell lines are gaining relevance as valuable models for exploring these complex traits. Especially in combination with molecular tools such as RNA interference and CRISPR/Cas9 genome editing, which can dissect the genetic basis of traits of interest using the appropriate cellular models for aquaculture species. However, the application of these technologies remains limited due to technical constraints.

Here, we present optimized methods for the delivery of RNA and CRISPR/Cas9 ribonucleoproteins (RNPs) into cell lines derived from two major aquaculture species: *Sparus aurata* and *Dicentrarchus labrax*.

As proof of concept, we used the CRISPR/Cas9 system to edit genes located in a major quantitative trait locus (QTL) associated with resistance to Viral Nervous Necrosis (VNN) in *D. labrax* (Mukiibi et al., 2025). VNN is caused by the Nervous Necrosis Virus (NNV) and affects the survival and growth of multiple species, including both *D. labrax* and *S. aurata*. Despite its impact on aquaculture production, no prevention or treatment is currently available for this disease. Using our optimized protocol, we edited the previously mentioned QTL in cell lines from *S. aurata* and *D. labrax* (Arana et al., 2025), which will be used to investigate the genetic basis of the resistance phenotype, thus making a first step towards the generation of VNN-resistant fish.

## Materials and methods

We selected two cell lines from the species of interest: SaB-1 from *S. aurata* and DLB-1 from *D. labrax*. In these models, we optimized delivery conditions with two different approaches: electroporation and chemical transfection. To this end, we transfected a tracrRNA-ATTO™ 488 and evaluated transfection efficiency 48 hours later with flow cytometry (CytoFLEX flow cytometer, Beckman Coulter Life Sciences). We also assessed cell viability after transfection using an MTT assay.

*(Continued on next page)*

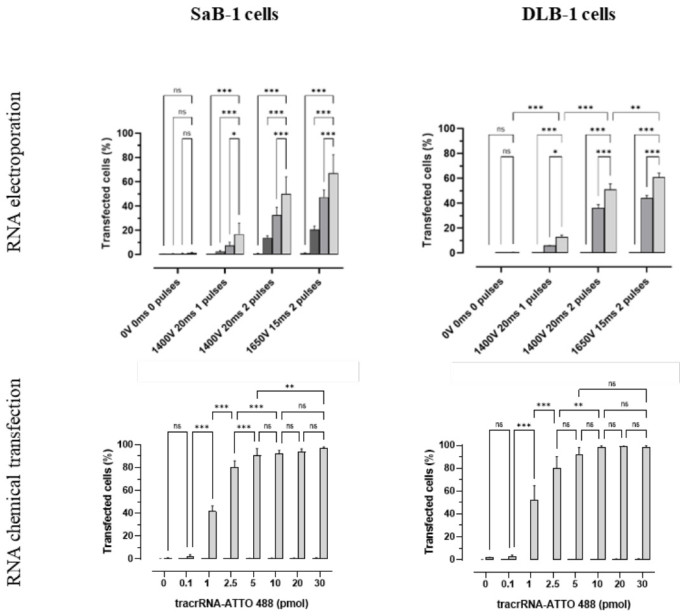

Figure 1. Transfection efficiencies in SaB-1 and DLB-1 cells using electroporation and chemical transfection with a tracrRNA-ATTO 488.

## Results

We optimized RNA delivery using a fluorescent tracer and achieved good transfection efficiencies in both cell lines with electroporation and chemical transfection (Figure 1). Subsequently, we applied the optimized electroporation parameters to edit a QTL associated with VNN resistance using the CRISPR/Cas9 system. The results revealed major differences between the two cell lines: while over 90% of SaB-1 cells were successfully edited, only 30% of DLB-1 cells showed signs of genome modification.

## Introduction

The aquaculture sector plays a key role in meeting the increasing global demand for seafood, experiencing substantial growth and making a significant economic contribution worldwide (1). In Europe alone, aquaculture production has reached record levels in recent years, emphasising the need for sustainable growth strategies. A critical challenge for the industry is developing sustainable, nutritionally adequate aquafeeds, given the environmental, economic and resource constraints that are increasingly limiting the use of traditional marine-derived ingredients such as fishmeal (2). The shift towards more sustainable aquafeeds has led to an increased reliance on plant-based ingredients in salmonid diets. However, replacing marine-derived components entirely can negatively impact the growth and metabolic balance of carnivorous species such as rainbow trout (*Oncorhynchus mykiss*). In this context, functional ingredients are being explored to improve the nutritional value of plant-based formulations (3). Among these, CEAMSEA, a marine algae-derived ingredient currently used in the agri-food industry for its functional properties, emerges as a promising additive for aquafeeds. Including it in plant-based diets may help to counteract the nutritional limitations commonly associated with high levels of plant proteins in carnivorous fish. Therefore, we hypothesise that supplementing a plant-based diet of rainbow trout with 2.5% or 5% CEAMSEA will improve growth performance, physiological indices and plasma metabolite profiles, thereby enhancing the overall health and growth efficiency of fish fed a plant-based diet.

## Materials and methods

Four experimental diets were formulated to evaluate the impact of CEAMSEA supplementation on rainbow trout. A fishmeal-based diet (CTRL) was used as the positive control diet, while a plant-based diet (V0) served as the negative control. Two additional diets were derived from V0 by supplementing it with 2.5% or 5% CEAMSEA obtained from CEAMSA (Porriño, Spain), resulting in four isoproteic, isoenergetic and isolipidic formulations: CTRL, V0, V2, and V5. Diets were randomly assigned to triplicate groups of 30 rainbow trout juveniles (initial weight 18.3 ± 3 g), which were distributed into twelve tanks of an open rearing system in 100 L-fiberglass within an open rearing system at INRAE's experimental facilities in Donzacq (France). Fish were exposed to natural photoperiod conditions and a constant water temperature of 17 ± 2 ºC; and fed their respective diets to apparent satiation once daily. After 84 days, all fish were individually weighed and measured. Hepatosomatic (HSI) and viscerosomatic (VSI) indices were calculated, and blood samples were collected for plasma metabolite analysis, using 15 fish per treatment (5 fish per tank). Growth performance, feed efficiency and physiological parameters were then compared across the different dietary treatments to evaluate the effect of including CEAMSEA in plant-based diets. Statistical analysis was performed using GraphPad software. A one-way ANOVA was conducted and, when significant effects were detected ($p < 0.05$), a Tukey's post hoc test was performed.

## Results and discussion

All experimental diets promoted substantial growth, with fish increasing their initial body weight by five to seven times over the 84-day feeding trial, indicating good overall acceptance. As expected, the control diet containing 25% fishmeal (CTRL) produced the best growth results, with the highest final body weight (128.2 g ± 3 g) and weight gain (110 g ± 6 g). Growth was significantly impaired by the plant-based diet without supplementation (V0), resulting in a 24% lower final weight (97 g ± 14 g), and a significantly reduced weight gain compared to the CTRL group. However, the inclusion of CEAMSEA at 2.5% (V2) and 5% (V5) effectively restored growth performance to levels comparable to CTRL, eliminating the significant differences observed with V0. Furthermore, although V5 was superior to V2 in both final weight and weight gain, apparently in a dose-dependent manner, no statistically significant differences were detected between the two supplemented groups.

*(Continued on next page)*

Interestingly, the condition factor (K) was significantly higher in the V5 group (1.35) than in the CTRL group (1.12), with no significant differences observed among the other groups. Despite having slightly lower final weights, fish fed the V5 diet exhibited better body conformation, suggesting that supplementing with 5% CEAMSEA may enhance somatic growth or promote more compact body development in rainbow trout under plant-based feeding conditions. The specific growth rate (SGR) followed a similar trend, with the CTRL group showing the highest value (2.32), which was significantly higher than those of the V0 (1.99) and V2 (2.05) groups. However, no significant difference was found between the CTRL group and the V5 group (2.13), which reinforces the potential of 5% CEAMSEA inclusion to restore growth performance in plant-based diets. In terms of physiological indices, no significant differences were observed in VSI between the groups. However, HSI was significantly lower in fish fed the V2 diet than in those on the CTRL group. Further metabolic analysis is required to clarify the underlying mechanisms and implications.

In terms of plasmatic metabolites, no significant differences were observed in glucose, lactate or triglyceride levels between groups. Interestingly, vegetable-based diets (V0, V2 and V5) exhibited higher levels of non-esterifies fatty acids in plasma compared to CTRL group.

Overall, these findings suggest that growth performance and body condition of rainbow trout were improved by supplementing a plant-based diets with CEAMSEA at 2.5% and 5%. The 5% inclusion level was particularly effective in partially bridging the performance gap with a fishmeal-based diet. These results demonstrate CEAMSEA's potential to improve the nutritional quality of sustainable aquafeeds. Further research is needed to explore the effects of higher inclusion levels and to elucidate the underlying metabolic and histological mechanisms.

## Introduction

The need to seek new high-quality protein alternatives to feed salmon has motivated the emergence of innovative alternatives for this purpose. Fish depend externally on essential amino acids to meet their requirements, so if these are not provided in the diet in adequate amounts, fish may suffer detrimental consequences in their physiology, metabolism, and overall health (Jones et al., 2020). On the other hand, microbial proteins of ruminal origin have a high biological value, highlighting their high content of essential amino acids, making them a potential alternative to generate a protein extract for nutritional purposes (Johansen et al., 2018). To obtain these protein extracts from the ruminal microbiota, it will be necessary to cultivate the inocula in bioreactors, which means that the technique used to generate these extracts could affect the amino acid composition. Consequently, the objective of this research was to evaluate the amino acid composition of two protein extracts of microbial origin obtained through two protein purification techniques.

## Materials and methods

The ruminal fluid (RF) was collected from six Suffolk Down sheep using the oro-ruminal technique. The donor sheep were fed with timothy hay under maintenance requirements. The ruminal protein extracts were obtained under two purification alternatives: 1. Centrifugation of the RF at 4000 rpm at 4°C, generating a pellet rich in microorganisms; subsequently, this pellet was freeze-dried and stored under refrigeration until its amino acid analysis. This extract was designated Raw Extract of Rumen Microorganisms (EBMR). 2. After obtaining the pellet of microorganisms, it was resuspended in potassium phosphate buffer pH 7.0 ($KH_2 PO_4$), and then subjected to disruption by sonication (ultrasound), followed by centrifugation at 12,500 rpm at 4°C. To isolate the proteins, they were precipitated with ammonium sulfate (550 g/l) using the *salting out* technique. Then, a second type of protein extract was obtained, termed Pure Extract of Microbial Proteins (EPPM). After generating the two types of extracts, the crude protein (Kjeldahl) and its amino acid profile were determined through HPLC (high-performance liquid chromatography). The experimental design was completely randomized with a factor with two levels (type of extract). Three replicates per treatment were performed. To evaluate the differences in means, the Mann-Whitney Non-Parametric Ordinal Test was used. It was inferred that the differences were significant when $P<0.01$. The statistical analysis was conducted using the IBM SPSS Statistics 19 software.

## Results

The Crude Protein (CP) content was 48.28% and 66.61% for the EBMR and EPPM treatments, respectively, clearly evidencing the difference in the level of protein purification that implies generating cell disruption and subsequently precipitating the released cellular proteins with ammonium sulfate. Regarding the amino acid analysis, a high biological value of the analyzed proteins was observed, along with differences between treatments in most of the compared amino acids (Table 1). The values found, both in CP content and amino acid quality, position these types of extracts as an alternative to be considered as supplements in salmon feeding. The Relationship of Essential Amino Acids (EA)/Total Amino Acids (AA) for each type of extract generated was: EBMR: EA/AA=38.7% and for EPPM: EA/AA=51.2%.

## Discussion and conclusión

Nutritional differences were observed between the EBMR and EPPM treatments, mainly in protein content and its amino acid composition. The observed CP content for EBMR and EPPM extract, positions it favorably to be used as an ingredient in formulation for salmon feed, considering that soybean meal contains 45% and fish meal around 60% CP. An adequate biological value was found in both protein extracts for the feeding of salmon, with a higher content of essential amino acids,

*(Continued on next page)*

especially the extract EPPM. Regarding the lysine content, a 4.07% was observed for the EBMR extract and 4.83% for EPPM. These values are promising; between a 4.8 y 8.4% has been reported for soybean meal (Anyiam et al., 2025) and an 5.16% for fish meal (Zhang, 2024). In the case of methionine, this value was 3.61% for EPPM, compared whit 1 and 1,3% to soybean, reported by Anyiam et al. (2025), and 1.77% for fish meal (Zhang, 2024). On the other hand, the detected difference between the types of extracts may have been due to the fact that different proteins were released at different concentrations (intracellular origin), resulting in amino acidically different extracts. The foundation of this phenomenon is based in the fact that sonication (cell rupture) may have released different proteins, or peptides, that were trapped in more refractory cell compartments, or proteins located in the bacterial walls strongly bound to nitrogen compounds or other structural molecules of these walls. Apparently, the EPPM extract, through its purification technique, managed to concentrate proteins of better biological quality. For any of the extracts, the amino acid profile found positions these types of microbial-origin extracts favorably as potential alternatives to be used as additives in the formulation for salmon feed.

Murcia, Spain
manuel.velazquez2@carm.es

## Introduction

Current aquaculture focuses on carnivorous species that require large amounts of protein and lipids derived from fish meal and oils, as well as by-products from the meat industry. The introduction of omnivorous species in Mediterranean aquaculture makes it possible to use exclusively plant-based raw materials for their production (Gisbert et al. 2016). This research explores the use of different raw materials for the whole replacement of animal-based ingredients in the diet of golden grey mullet (*Chelon auratus*).

## Materials and Methods

A total of 180 fish weighing between 3 and 9 grams (5.27±1.32 g) were used. They were distributed into 12 tanks of 216 liters (15 fish per tank) and kept in a semi-closed seawater system with temperature controlled (25.5±0.69°C). Four diets were tested by triplicate: one commercial gilthead seabream diet as control, and three vegan diets based on a mixture of cereals, legumes, vegetables and seeds. The vegan diet contained 20% rice, 20% wheat semolina, 20% lentils, 10% quinoa, and 30% broccoli (Vegan). In the seed diets, 5% of the rice was replaced by sunflower seeds in one diet (VeganGi) and chia seeds in the other (VeganCH). The ingredients were cooked, except for the seeds, which were previously ground and sieved to a particle size of 1–2 mm, suitable for the fish. The fish were fed to satiety three times a day until day 40, when they were weighed to calculate growth and feed utilization indices: initial weight (Wi), final weight (Wf), mean weight (Wm), weight gain (WG), absolute feeding rate (AFR), specific feeding rate (SFR), both also calculated on a dry weight basis (AFRd and SFRd), absolute growth rate (AGR) and specific growth rate (SGR), as well as feed efficiency ratio (FE) and feed conversion ratio (FCR), with their respective dry weight values (FEd and FCRd).

## Results

The composition of the plant-based diets differed greatly in macronutrients compared with the commercial diet, with the latter containing higher protein and lipid content and much lower carbohydrate content (Table 1, $P < 0.05$).

Fish fed commercial diet achieved significantly higher growth and feed utilization indices than those fed plant-based diets ($P<0.05$), despite feed intake being much higher in the plant-based diets ($P < 0.05$). There were no significant differences between vegan diets for any of the calculated indices ($P>0.05$).

## Discussion and Conclusions

Differences in growth and feed utilization may be attributed to the nutritional composition of the plant-based diets, which, although rich in carbohydrates, were low in protein and lipids. Furthermore, despite the high feed intake observed in the fish fed vegan diets, the final protein intake was lower (0.046-0.060 g protein/day/fish) compared with the control diet (0.079 g protein/day/fish). An imbalance in the amino acid profile or any other nutritional deficiency may also have affected fish growth. On the other hand, selective feeding on certain ingredients in the vegan diets cannot be ruled out.

Protein and lipid levels were considerably lower in the vegan diets compared with the commercial diet, but not very different from those used by Luzzanna et al. (2005) and De Basis et al. (2012), where protein levels were similarto seed-based diets supplied in the present study. In their case, better growth results were obtained suggesting nutritional deficiencies in the vegan diets.

## Introduction

During commercial shrimp farming, common practices often induce acute stress, triggering a range of behavioural and physiological responses. Decapod species respond to these stressors through changes at various biological levels, affecting their physiology, behaviour, and welfare in farming systems (Martins et al., 2012). Additionally, previous research has provided evidence of circadian variation in crustacean physiology(Louis & Emery, 2025). Palaemon elegans is an interesting experimental model in animal welfare research due to its wide distribution, commercial interest and ability to tolerate various environmental stressors. This crustacean species serves as a food source for other commercial species (Moronidae, Sparidae), is consumed directly, and consequently is being investigated as a new species in aquaculture. This study aims to characterize the daily rhythm in locomotor activity of the rockpool shrimp and investigate its behavioural stress responses, assessing the influence of the time of day. It provides a reference model for other commercially important shrimp species, facilitating the optimisation of management strategies in aquaculture and promoting sustainable practices in the shrimp industry.

## Methodology

A total of 32 shrimp with an average total length of 4.25 ± 0.14 cm were acclimated for 38 days and maintained in a 40 L aquarium under a 12:12 h light:dark (LD) cycle, fed once a day during the night. The aquarium was equipped with an infrared photocell to record the locomotor activity of the experimental subjects prior to the stress challenge and behavioural testing. After acclimation, 16 individuals were exposed to air for 60 seconds (stress group), either at ML (mid-light; n=8) or MD (mid-darkness; n=8). A bifactorial design was implemented with 4 subgroups: Control-ML, Control-MD, Stress-ML, and Stress-MD (n = 8 shrimp per subgroup). Following the stress challenge, two behavioural tests (open field and novel environment) were conducted. Control shrimp were also tested at the same time-points (ML and MD). Anxiety-related behaviours (i.e., immobilization, thigmotaxis, bottom-dwelling, erratic movement) and activity parameters (i.e., distance travelled) were evaluated using EthoVision XT® software. Locomotor activity recorded in the housing tank was analysed using the chronobiology software El Temps. For statistical analyses, when data met the assumptions of normality and homogeneity of variances, two-way ANOVA (ANOVA II $p < 0.05$) was used. When these assumptions were not met, the nonparametric Scheirer-Ray-Hare test was applied.

## Results

During acclimation, shrimp displayed a mostly nocturnal activity pattern, with 65% of their daily activity being recorded during the dark phase. In the open field test, two behavioural parameters showed significant differences between day and night. Thus, the thigmotaxis response was higher at MD (Fig. 1A; Scheirer-Ray-Hare, $p<0.04$), indicating that shrimp spent significantly more time at the periphery of the aquarium during the night. Similarly, angular velocity analysis revealed significantly more erratic behaviour at night (Fig. 1B; Scheirer-Ray-Hare, $p<0.001$). In the novel environment test, freezing behaviour was also significantly greater at night. In contrast, walking distance (Scheirer-Ray-Hare, $p<0.01$) and erratic movements (ANOVA II, $p<0.01$) were higher during the day.

*(Continued on next page)*

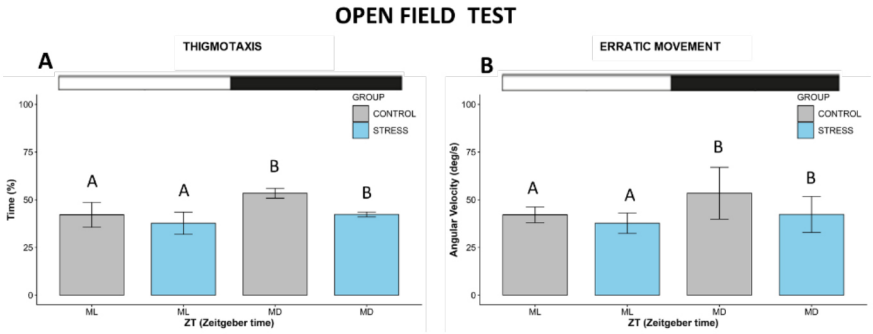

**Figure 1**. Thigmotaxis (A) and Erratic Movement behaviours during the Open Field Test at ML and MD in control (grey bars) and stressed (blue bars) shrimp. Data are presented as mean ± standard error, and superscript letters (A, B) indicate significant differences between time periods (ML and MD) ($p<0.05$).

## Discussion and conclusion

Our findings reveal that *Palaemon elegans* displays clear day/night differences in both locomotor activity and behavioural responses to acute stress. Shrimp were more active at night, and some anxiety-related behaviours such as thigmotaxis and freezing were more pronounced during the dark phase, suggesting higher stress sensitivity during their active period. However, in the novel environment paradigm, walking distance and erratic movements were higher following the stress challenge at ML, suggesting a shift in behavioural strategy depending on the time of day. While these results suggest a circadian modulation of stress-related behaviours, they remain preliminary and rather inconclusive due to the limited sample size and scope. Further research is needed to confirm these patterns across different environmental conditions and developmental stages. Even so, this study supports the potential of *P. elegans* as a chronobiological model and highlights the value of considering time-of-day effects in welfare assessments and aquaculture practices.

## Introduction

Animal welfare represents a fundamental pillar in modern aquaculture, which aims to develop sustainable, ethical, and scientifically supported practices. In current farming practices, the slaughter phase is critical, as inadequate measures to minimise suffering during this process can compromise animal welfare. Current guidelines, therefore, underscore the need to use an appropriate stunning method that renders fish unconscious immediately prior to slaughter (OIE, 2019). In the case of sole, slaughter is typically carried out using traditional methods involving live chilling. However, compliance with welfare standards during this method remains uncertain. Consequently, sole farmers have expressed interest in identifying the most appropriate sole´s slaughter method from a welfare perspective. To determine a solid methodology, it is essential to conduct a rigorous evaluation of existing stunning methods. Traditional studies have evaluated stunning by assessing operational indicators based on clinical and behavioural responses (Morzel et al., 2003). However, these approaches have been demonstrated to be inconclusive as these indicators exhibit poor correlation with neurological activity (Bowman et al., 2019). Consequently, the recommended technique for assessing the efficacy of the stunning methods is electroencephalography, as it displays the effects of stunning at the brain level (OIE, 2019). This study aims to adapt existing electroencephalographic procedures to assess the effectiveness of stunning in sole.

## Materials and methods

The present study used commercial-sized sole (*Solea senegalensis*), weighing between 500 to 800 g, to develop a methodological protocol for electroencephalogram (EEG) recording. An anatomical comparison with turbot was performed using a computed tomography (CT) scan to identify the position of the electrodes and adapt the EEG methodology developed for turbot (Ramirez-Rodriguez et al, 2024). To record the EEG signal, each fish was anaesthetised with MS-222 (80 mg/L) to facilitate the surgical placement of stainless-steel electrodes. After anaesthetising the fish, baseline EEG activity and visual evoked responses (VERs) were recorded using a strobe light stimulus. Spectral EEG parameters, including total power (Ptot), alpha-beta power (Pαβ), median frequency (F50), and spectral edge frequency (SEF), were obtained by power spectrum analysis using Spike2 software. VERs were analysed by averaging light-induced responses over one-second windows.

## Results

Our study adapted the EEG protocol from turbot to record brain activity in the sole. The use of an anatomical comparison via a CT scan facilitated the identification of analogous skull regions to those identified by our group for EEG recording in turbot. This allowed us to apply previously developed methodologies with only minor anatomical adjustments. Spectral analysis of the EEG baseline signal demonstrated the feasibility of analyzing brain activity. The spectral parameters were sensitive to alterations in brain activity associated with stunning procedures. Furthermore, this study demonstrated the feasibility of detecting VERs in the sole using strobe light stimulation, thereby enabling the evaluation of its visual sensory perception capabilities.

*(Continued on next page)*

## Discussion

Our study represents a significant advance in developing tools to support more conclusive decision-making when assessing the effectiveness of existing stunning methods for slaughtering sole. This study demonstrated the technical feasibility of adapting the EEG recording protocol originally developed for turbot to sole. This adaptation enabled the successful acquisition and analysis of brain activity in sole, thereby expanding the applicability of neurophysiological tools within the field of fish welfare research. Anatomical comparison via CT scan is crucial for identifying homologous cranial regions and adapting electrode placement, thereby facilitating the accurate and consistent acquisition of EEG signals. The ability to record a reliable EEG signal facilitates the estimation of classical spectral parameters, including total power (Ptot), alpha-beta power (Pαβ), median frequency (F50), and spectral edge frequency (SEF) parameters (Tonner & Bein, 2006). This methodology demonstrates its efficacy in monitoring brain activity in the sole, thereby substantiating its potential to provide objective indicators of sentience. Notably, the present study confirmed the feasibility of detecting VERs in sole. The ability to identify the presence of VER strengthens the robustness of the EEG recording methodology for use in assessments of stunning efficiency. This is because it can provide an indicator that has been described as reliable for this type of evaluation in other fish species (Hjelmstedt et al., 2024). In summary, our findings demonstrate that the adapted EEG methodology provides direct insight into brain activity and enables objective indicators of sensitivity in the sole to be identified. This methodological advancement provides the basis for a decision-making support tool designed to promote animal welfare during the industrial sole slaughter. Implementing EEG-based assessments offers a scientifically robust approach for evaluating the effectiveness of stunning methods. This supports the development of more ethical, evidence-based protocols in modern aquaculture.

**Introduction**

The transition from endogenous to exogenous feeding characterizes early developmental stages of farmed fish and it is often associated with high mortality rates, resulting in economic loss and reduced animal welfare[1,2]. The gut and its stem cell niche, as major actors in nutrient absorption and drivers of epithelial development respectively, play a key role in this delicate event[3]. Therefore, expanding the current understanding of intestinal ontogenesis could improve farming efficiency. In this study, we investigated the intestinal morphological and cellular changes across three early developmental stages of rainbow trout (*Oncorhynchus mykiss*) - larval, parr, and juvenile – particularly focusing on the cellular populations of the intestinal stem cell niche.

**Materials and methods**

Whole larvae (20 dph) and intestinal samples from parr (50 dph) and juvenile (12 months) rainbow trout were collected and processed for histological purposes. Briefly, we used: (i) hematoxylin and eosin to assess the general tissue morphology; (ii) Masson's trichome to highlight the compactum layer of the *submucosa*; (iii) Alcian blue (pH 2,5) and Periodic Acid Schiff, used in combination, to detect mucins-secreting cells. Proliferating intestinal cells were identified through immunofluorescence of proliferating cell nuclear antigen (PCNA); in situ-hybridization was used to detect the expression of *sox9* and *pdgfrα* as specific markers of intestinal stem cells and telocytes - a stromal cell population regulating stem cell differentiation [4,5]according to the frequency and distribution of specific cell types, the rainbow trout (RT.

The transition to the parr stage was marked by a more structured morphology with intestinal folds acquiring a finger-like phenotype and an increased complexity of the *submucosa*. At this stage, a fully developed epithelial stem cells niche restricted to the fold's base became evident (Fig 2). Moreover, at this stage, enteroendocrine cells appeared scattered along the epithelium.

At the juvenile stage, the *mucosa* acquired its definitive configuration with long finger-like folds and a fully developed *submucosa* consisting of the three distinctive layers: the two granulosum and the thick collagen compactum layer located in between.

**Conclusion**

The timing of these events suggests that telocytes play a key role in triggering and guiding the formation of a well-defined stem cell niche and that its differentiation is largely completed by the parr stage.

These results expand and integrate the current understanding of the ontogeny of the rainbow trout intestine, providing novel insights into this delicate phase. The definition of the accurate timing of the detailed intestine development may help in optimizing feeding strategies and improving animal welfare, limiting possible economic losses.

**Introduction**

The creatine system in vertebrates is an important cellular energy buffer, maintaining high-energy phosphate bonds that quickly replenish adenosine triphosphate (ATP) when needed. This is especially important in tissues with a high energy demand like the brain, heart or muscle. Creatine can be gained via nutrition or it can be synthesized intrinsically through a two-step mechanism catalyzed by the enzymes glycine amidinotransferase (GATM), guanidinoacetate N-methyltransferase (GAMT) and creatine kinases (CKs). The uptake of creatine from the bloodstream into cells is mediated by the sodium- and chloride dependent creatine transporter 1 (CT1), which belongs to the solute carrier 6 (SLC6) transport family of secondary active $Na^+/Cl^-$ co-transporter (Kristensen et al., 2011).

Due to their different habitats, fishes have developed different metabolic strategies compared to other vertebrates. We have recently shown that teleost fish and mammals differ in regard to their creatine systems. The findings indicate the presence of a muscle-specific creatine synthesis in fish (Borchel et al., 2019). Based on these differences, the present study was aimed to further enhance the knowledge on the transportation of creatine in a teleost model species. Hence, we characterized the *SLC6A8* genes encoding the creatine transporter CT1 in rainbow trout *Oncorhynchus mykiss*. Structural and functional properties in terms of evolutionary conservation, as well as their role as creatine transporter in a salmonid cell model were investigated by complementary molecular techniques.

**Material & Methods**

Database searches identified two entries in the NCBI (National Center for Biotechnology Information; http://blast.ncbi.nlm.nih.gov/) database: rainbow trout *SLC6A8* gene variants *SLC6A8a* (XM_021566996) and *SLC6A8b* (XM_036947549). Structural analysis of functional domains and the prediction of the transmembrane topology of the encoded protein sequences were conducted using the InterProScan (https://www.ebi.ac.uk/interpro/search/sequence/) and the Protter (https://wlab.ethz.ch/protter/start/) tools. 3D-modelling and visualization was performed by SWISS-MODEL (https://swissmodel.expasy.org/) and UCSF Chimera (http://www.rbvi.ucsf.edu/chimera). The evolutionary relationship of the gene variants and the corresponding orthologous genes from other teleosts and higher vertebrates was investigated by synteny analysis using the Genomicus database (v98.01 http://genomicus.biologie.ens.fr/genomicus) and the construction of a phylogenetic tree for the SLC6 family in MEGA 11 software by using the Neighbour-Joining method including 1000 bootstrap replicates and the Poisson correction method.
Expression of creatin system genes *SLC6A8a*, *-b*, *GATM*, *GAMT*, and *CKM* in rainbow trout was quantified in different tissues and the salmonid cell line CHSE-14 (Sigma-Aldrich) by quantitative PCR on the LightCycler96 system (Roche Diagnostics) and in publicly available RNA-Seq data from BioProject PRJNA638521.

Live-cell imaging was performed using the confocal microscopy LSM 780 (Carl Zeiss Microscopy) to determine the subcellular localisation of constructed GFP-SLC6A8a - and Plum-SLC6A8b or GFP-SLC6A8a and Plum-SLC6A6 fusion genes. Creatine uptake in pre-incubated CHSE-214 cells was determination in extracts of white-muscle tissue.

*(Continued on next page)*

**Results and Discussion**

The *SLC6A8a* and *SLC6A8b* gene variants show variant-specific expression patterns (Figure a). Both exhibit the highest transcript level in the heart. Despite this similarity, *SLC6A8a* significantly exceeds the expression of *SLC6A8b* in the heart, brain, spleen, head kidney and gill tissue, while *SLC6A8b* is predominantly expressed in the muscle and liver. Moreover, we detected clear differences in the expression of the central creatine system genes *GATM*, *GAMT* and *CKM* in the heart and skeletal muscle (Figure b) suggesting an overall different creatine metabolism between both tissues in rainbow trout.

The pre-incubation of the CHSE cells with creatine resulted in its significant increase in concentration in the cells from 0.52 mM to 0.83 mM (Figure c), indicating its carrier-dependent transport of creatine across the cell membrane. In line with this, we verified the cellular localisation of rainbow trout proteins SLC6A8a and SLC6A8b in the cell membrane (Figure d-f).

The present study extends the knowledge of the creatine transporter SLC6A8 in rainbow trout and supports the previously reported differences in the creatine system of mammals and teleost fishes. However, further functional analyses are required to deepen the knowledge on the variant-specific membrane transport of creatine by SLC6A8a and SLC6A8b in fish.

# IMPROVING STRESS RECOVERY IN ATLANTIC SALMON (*Salmo salar*) WITH FUNCTIONAL FEED

R.I. Vestrum*, T. Forberg, E. Aasum, S.L. Wadsworth

BioMar AS
Havnegata 9
7010 Trondheim
Email: ragve@biomar.com

## Introduction

In intensive production of Atlantic salmon, the fish are subjected to various handling procedures such as transport, vaccination, and mechanical treatments for sea lice. These events induce acute stress in the fish. Additional stressors include sudden changes in water quality or environmental changes during the transition from freshwater to seawater. Stressed fish exhibit reduced disease resistance and diminished appetite [1, 2], leading to decreased growth and economic losses for fish farmers. A recent study estimated that a single mechanical treatment against sea lice could result in a 200-gram growth loss per fish [2]. Feed that enhances appetite following a stressful treatment can improve growth and robustness, ultimately reducing the time required to reach the desired market weight. To accurately access feed efficacy, it is essential to move beyond controlled lab-scale trials and consider real-world challenging environments.

## Materials and methods

A challenge model was developed to emulate the handling of Atlantic salmon prior to mechanical delousing in well boats. The handling procedure consisted of mild crowding for 1.5 hours, followed by netting, sedation, individual weighing, and manual delousing. This model was validated through a nine-month feeding trial conducted at LetSea (Dønna, Norway), which compared stressed and non-stressed treatments among the salmon. Throughout the trial, the handling procedure was performed four times. This challenge model has been used in assessing functional feeds at LetSea. The test feed in this trial contains additional magnesium and specific plant raw materials, which are hypothesized to enhance appetite. The primary objective was to mitigate stress-related growth loss in Atlantic salmon post-handling. The experimental feed was administered two weeks preceding, and during the week of handling.

## Results

The challenge model was verified by a significant stress response shown as increased levels of cortisol in fish scales, serum biomarkers such as the secondary stress response parameters lactate, glucose, magnesium, calcium and potassium, and altered expression of stress-related genes in the liver of stressed fish compared to the non-stressed control treatment. In addition, the cardio somatic index (CSI) and heart length and roundness were significantly affected by the stress treatment, with unstressed fish having lower CSI and wider and rounder hearts, and stressed fish had increased skin hemorrhages and snout wounds.

During the feeding trial the fish grew from approximately 1.5 kg to 4.3 kg. Comparing stressed control treatments with stressed functional feed treatments, we have seen no significant differences in cortisol levels in scales or stress response serum markers. This indicates that the fish fed the functional feed had a normal adaptive stress response. Additionally, we have seen an increase in appetite (increased feed intake) and growth after the handling events for fish fed the functional feed, as evidenced by higher TGC (thermal growth coefficient). Despite the stress induced by the challenge model, the fillet color (pigmentation) was improved reflecting the increased feed intake.

## Conclusion

The findings of the current study underline the importance of addressing stress and growth in fish through scientific interventions. The challenge model tested effectively simulates the handling of Atlantic salmon prior to mechanical delousing operations and has been verified through extensive feeding trials. The new functional feed significantly improves appetite and growth in salon following stress-induced handling procedures.

# OMEGA-3 FATTY ACID LIPOGENIC FLUX IN MICROALGAE – USING DEUTERATED WATER TO GROW *Munda aquilonaris*

Gaspar, R.[1], Assunção, M.F.G.[1], Aksoy, B.[1], Duarte, P.[2], Viegas, I.[2*]

[1] Coimbra Collection of Algae (ACOI), Department of Life Sciences, University of Coimbra, Calçada Martim de Freitas, 3000-456, Coimbra, Portugal

Email: iviegas@uc.pt

The consumption of essential fatty acids, namely omega-3, has been increasingly linked to major health benefits. Currently the main dietary source of these highly valuable fatty acids are small oily fish and their derivatives. Their metabolic capabilities to synthesize these compounds is limited, as is in most vertebrates, and their rich composition derives from biomagnification processes along the marine trophic chains. These originate in microalgae, the primary producers of such high-value polyunsaturated fatty acids (PUFA). As such, understanding the metabolic pathways and lipogenic fluxes of these organisms is extremely relevant particularly if the goal is to optimize and maximize their yields.

Deuterated water ($^2H_2O$) has systematically provided reliable lipid biosynthetic flux estimates, validated in several different animal models. The incorporation of deuterium ($^2H$) into cells follows well-defined metabolic steps and positional $^2H$-enrichments can be traced by deuterium Nuclear Magnetic Resonance ($^2H$-NMR). In order to validate its utilization, this study aimed to determine if $^2H$-enrichment of the medium interferes with microalgae growth, while assessing the effectiveness of fatty acid $^2H$-labelling in microalgae. To achieve this, *Munda aquilonaris* ACOI 2424 was cultivated in three distinct $^2H$ concentrations, while growth was monitored through cell counting. Lipids extracted from the resulting biomass were analyzed using NMR, acquiring both $^1H$ and $^2H$ spectra. The results showed that $^2H$ was successfully incorporated into the metabolic pathways enabling the distinction of the *de novo* omega-3 fatty acid synthesis.

These findings pave the way for innovative metabolic studies using this stable isotope to trace omega-3 lipogenic fluxes in microalgae. This could enhance the production of essential fatty acids and uncover new possibilities for applications in human and animal nutrition.

## Introduction

The increasing global population poses a major challenge to the sustainable production of seafood. Although plant-based protein sources are commonly used in aquafeeds, their sustainability is limited by competition with the human food supply and the high carbon footprint associated with their production and transport. In this context, the circular economy concept, particularly emphasized by the European Union's Farm to Fork strategy, promotes the valorization of agro-industrial by-products. These by-products are generated in large quantities and are often discarded, thereby contributing to environmental impact. Europe imports around 800.000 tons yearly, which corresponds to 32.000 tons of peanut peel generated by-products (FAOSTAT, 2022; Manrich et al., 2022). Due to their composition, these by-products may be used as feed additives or alternative ingredients for aquafeeds. Among these, peanut peel as a major by-product of the peanut butter industry, typically discarded, representing an additional cost to the industry. Despite being undervalued as a feed ingredient, peanut peel contains moderate protein and lipid levels and a high concentration of bioactive antioxidant compounds that may promote fish wellbeing. To the best of our knowledge, this is the first study to evaluate the use of peanut peel in aquaculture. Therefore, this study aims to evaluate the apparent digestibility coefficients (ADCs) of the peanut peel by-products and to assess the effects of its dietary inclusion at increasing levels on the zootechnical performance of juvenile gilthead seabream (Sparus aurata).

## Materials and methods

The apparent digestibility of peanut peel by-products (PP) ingredient was evaluated. Two diets were formulated to determine ADCs; a control diet similar to a current commercial diet, and a test diet, containing 30% PP and 70% of the control diet. Apparent digestibility coefficients (ADCs) of dry matter, protein, lipid, and energy for both diets and the PP ingredient were determined according to Bureau et al. (1999). The digestibility trial was performed in a RAS system with 6 fiberglass tanks (60 L) equipped with fecal sedimentation columns. Triplicate groups of 15 gilthead seabream juveniles (IBW: 50g) were fed twice a day, and feces were collected daily, before the morning meal, for 30 days.

A growth trial was also conducted to evaluate the zootechnical effects of dietary inclusion of PP. Five isoproteic (44%) and isolipidic (18%) diets: a control diet similar to a current commercial diet, and 4 diet including an increased level of PP. Two diets included 0.5% and 1% (0.5PP and 1PP), to evaluate PP as functional ingredients, and 2 other diets including 5% and 10% peanut peel (5PP and 10PP), replacing up to 56% of soybean meal to evaluate PP's potential as an alternative ingredient. The growth trial was conducted for 12 weeks in a RAS system maintained at 24 ºC. Triplicate groups of 15 gilthead seabream juveniles (initial body weight: 36g) were fed until apparent satiation, six times per week. At the end of the trial, fish's growth performance, feed intake, feed efficiency, protein efficiency ratio, nitrogen, and lipid retention were evaluated. At the end of the trial, 3 fish per tank were sampled, and liver and intestine were collected for oxidative stress analysis and lipid peroxidation, and muscle for lipid peroxidation analysis.

Digestibility data were analyzed using one-way ANOVA. Growth performance data were evaluated by polynomial contrast analysis and one-way ANOVA, followed by Tukey's post hoc test. A significance level of $p < 0.05$ was used for all statistical analyses.

## Results

Apparent digestibility coefficients (ADCs) for dry matter, protein, lipid, and energy were statistically similar between the control and peanut peel diets, indicating that the inclusion of up to 30% peanut peel in aquafeeds does not compromise overall nutrient digestibility. The apparent digestibility coefficient for protein in peanut peel was approximately 38.5% ± 20.1, whereas lipid digestibility reached 73.5% ± 6.8.

*(Continued on next page)*

During the growth trial, mortality was low and not affected by the dietary inclusion of PP. Weight gain, daily growth index, feed intake, feed efficiency, protein efficiency ratio, and lipid retention were not influenced by increasing levels of PP. Nitrogen retention was also unaffected by PP inclusion; however, a quadratic tendency was observed, with increased retention in diets containing 0.5%, 1%, and 5% PP compared to the control diet, and a decrease at the 10% inclusion level. Whole body dry matter, lipid, and ash contents were not influenced by PP inclusion. However, whole-body protein content showed a quadratic trend to increase in the PP included diets compared to the control. Visceral and hepatosomatic indexes were not affected by the inclusion of PP.

**Conclusion**

Peanut peel showed moderate digestibility as an ingredient, but when included at 30% in the diet, its digestibility was comparable to that of the control diet. The dietary replacement of soybean meal by PP up to 10% (representing a replacement level of 56%) did not affect growth performance, feed utilization or whole-body composition. Oxidative stress and lipid peroxidation results are being analysed and will be presented.

These findings highlight the potential of peanut peel as a sustainable alternative ingredient in aquafeeds and open new avenues for future research on its functional and nutritional applications in aquaculture.

## Introduction

Fish used in aquaculture often need to be moved between tanks or sites, especially during the pre-slaughter period. However, the effects of screw pumps *vs.* suction pumps on welfare and flesh quality are not well understood. Research has indicated that vacuum pumps can cause damage to pelvic fins and increase stress responses in salmonids, potentially leading to higher mortality rates (Espmark *et al*., 2016). In contrast, the Archimedes screw is considered "fish-friendly" due to the absence of sudden pressure changes and hydraulic shear forces (Þórðarson *et al.*, 2022). An additional factor that has yet to be explored is the interaction between water temperature and the fish's response to catching methods. This study compared the impacts of two mechanized methods on stress indicators and quality parameters in rainbow trout (*Oncorhynchus mykiss*) in winter (WI) and summer (SU).

## Materials and methods

A total of 240 trout with an average weight of 248.9 ± 46.2 g were captured using nets (N), a screw (A), or a vacuum pump (V), in WI (10°C) and SU (17ºC), ensuring the quickest yet gentlest movements. Less than a minute later, they were stunned using a dry stunning method. In order to assess animal welfare and flesh quality, several plasma parameters were measured (cortisol, lactate, non-esterified fatty acids, and creatine phosphokinase), as well as skin colour, and muscle pH.

## Results & Discussion

At 0 hours *post-mortem*, pH values for A-WI were higher than in all other cases, with values for N and V in WI also higher than those observed in SU, where the metabolic effort appeared to be lower. Increased effort can lead to increased lactate levels and subsequent pH drops (Milligan, 1996). At 24 hours post-mortem, pH levels showed treatment interaction, which was highest for N-SU, while N-WI had the lowest pH. Additionally, A-WI had lower pH than V. This could be due to the higher energy demand of method V, which may result in greater stress. Cortisol levels varied by catching method, with the highest levels observed in V, suggesting that the suction pump may impose higher stress (Þórðarson *et al*., 2022), followed by A and N. Lactate was influenced by the interaction of catching method and seasonality, with N in WI showing lower levels compared to other groups, reflecting reduced movement due to colder temperatures; while A-SU exhibited higher levels than N and V in SU, suggesting acute effort in A and the hypothesis that method V may impose greater stress, as indicated by its lower lactate levels. NEFA was higher in fish caught with V-SU relative to A and V in WI, however, its levels were lowest for V-WI compared to A-SU and N at both seasons. The consistency in NEFA levels across seasons for N and A suggests a reduced stress response compared to V. The CPK-WI levels were consistently higher than SU across all catching methods due to the slower metabolism, with A-WI showing significantly elevated levels compared to the other cases, highlighting the increased energy demand associated with physical exertion (Liquin *et al*., 2016) as in lactate. Skin lightness (L*) was higher for N-WI compared to the other cases, and with lower values observed for V-SU than in WI, which could be attributed to higher temperatures during SU or the physical effort required by the catching method during WI (Iger *et al*., 2001). Higher yellowness (b*) and chroma (C*) values were observed in N-SU and in V-WI, while lower values were found in A in WI and SU and in V-SU. N-WI also had lower b* and C* values compared to SU. These findings suggest that method V may be more stressful than method A, similarly to Erikson & Misimi (2008). Hue (h*) was affected by the interaction, with A in WI showing lower values than N-SU and V-WI, possibly linked to the higher activity associated with this method, suggesting h* as an indicator of trout exertion.

*(Continued on next page)*

## Conclusions

Based on our trial, the Archimedes screw appeared to be more product and welfare friendly than the suction pump for trout harvesting, despite being more demanding a higher metabolic effort. However, it is essential to ensure that water temperatures remain within the optimal range for trout during pumping/movement.

# FROM ISOLATION TO APPLICATION: THE ROLE OF *Cetobacterium* sp. C33 IN NILE TILAPIA

Luisa M. Villamil*, Mario Colorado, Javier Melo-Bolívar, Ruth Y. Ruiz, Jorge Rodríguez, Howard Junca y Juan Alzate

PhD In Biosciences
Engineering School
Universidad de La Sabana
Colombia
Luisa.villamil@unisabana.edu.co*

Intestinal microbiota plays a crucial role in fish health, with anaerobic bacteria such as *Cetobacterium,* emerging as key contributors to gut homeostasis. In this study, we report the isolation, genomic characterization, and probiotic potential of *Cetobacterium* sp. C33, a strain obtained from the intestinal tract of Nile tilapia (Oreochromis niloticus) under anaerobic conditions.

In vitro analyses demonstrated C33's adaptability to gastrointestinal conditions, including survival in bile salts (0.3%) and low pH. Whole-genome sequencing and annotation revealed a unique genetic profile distinct from closely related species, such as *Cetobacterium somerae* and *Cetobacterium ceti*. The genome harbors genes linked to antibacterial activity, intestinal adhesion, and immune modulation, reinforcing its potential as a probiotic. Further comparative genomics confirmed its phylogenetic divergence from previously characterized *Cetobacterium* species. Also, the absence of toxin-related genes and antibiotic resistance further supports its safety as a probiotic candidate.

To validate its functional application, an in vivo trial was conducted by feed administration of *Cetobacterium* sp. C33 at 1 × 10□ CFU/g to tilapia fingerlings for five days. Results revealed 100% survival, successful intestinal colonization, modulation of the gut microbiota, and immune response regulation, as evidenced by transcriptomic analysis of the head kidney that revealed upregulation of immune genes such as claudin-8-like Perforin 1, E3 ubiquitin among others.

# PRODUCTION OF ALTERNATIVE PROTEINS FROM AGRI-FOOD BY-PRODUCTS THROUGH MICROALGAE CULTIVATION (PROALGAE)

Belén Villarreal Toribio[(1)], Ander Letamendi[(2)], Ruben Díez Montero[(2)], Etiele Greque de Morais[(1)], Enrica Uggetti[(1)]

**Introduction**

The PROALGAE project will explore the feasibility of producing alternative protein through microalgal biomass grown on agri-food industry byproducts (i.e. process effluents), within a circular economy context. Thus, it is built on the following hypotheses: i) specific agri-food by-products can be valorized by recovering their nutrients through the growth of a high-value microalgal biomass, and ii) microalgal biomass production using agri-food industry by-products is a sustainable and climate change resilient alternative for protein production that can be used for food and feed.

**Materials and Methods**

The research will focus on specific agri-food by-products, i.e. cheese whey, aquaculture, fish canning, beverage production and hydroponic culture effluents. Firstly, the feasibility of growing target microalgae species in those effluents will be tested, aimed at obtaining the maximum productivity of specific species feasible to be used as feed or food, as well as achieving the desired treated effluent quality. Then, the microalgal biomass will be characterized, for monitoring the production of compounds of nutritional interest and food-and-feed safety issues. Finally, the microalgal biomass will be used for the production of food and feed products. The characteristics of the food products will be analysed in order to assess the acceptability of these bioproducts as alternative protein source, while the feed products will be tested as alternative feed ingredients. In addition, the economic, environmental and social sustainability of the proteins production from microalgae grown in agri-food by-products will be assessed, and the potential production will be evaluated through model simulations and market strategy surveys, with the objective of assessing their potential industrial application prior to the industrial scale production.

**Current Status**

Currently different microalgae strains have been grown in different agri-food effluents. These screenings showed potential of growing *Nannochloropsis gaditana* in dairy by-products in particular in diluted whey and digestated whey. The optimal combination have been scalated to 50 L to prove the continous production of microalgae biomass while achieving wastewater treatment of the effluent. On the other side, *Scenedesmus* sp. cultivated in brewery effluents has shown to outperfom *Chlorella* sp. and *Spirulina* sp. The strain has been scalated to 4.5 L photobioreacors and grown in semicontinous operation during six weeks.

**Future directions**

The microalgae biomass will be characterized for protein and pigments content, nutritional properties, biomass composition and physical characteristics. Once characterized it will be used as ingredients in aquafeed for turbot (*Scophthalmus maximus*) culture: a control diet (CT) without microalgae, and three diets (M5, M10 and M20) with 5%, 10% and 20% microalgae, respectively. Samples of size and weight of all the fish will be carried out monthly after fasting 24 hours, to obtain the growth data. Fish growth performance will be analysed in terms of survival (S, %), weight gain (WG, g), percentage weight gain (WG, %), specific growth rate (SGR, % day -1), Fulton's condition factor (k) and hepatosomatic index (HI). After culture, the samples of the intestine for microbiota analysis will be collected, namely muscle and liver for the study of metabolites, and carcasses for proximal composition analysis. For the intestinal microbiome study16S rRNA sequencing analysis of bacterial DNA will be used.

# LC-PUFA BIOSYNTHETIC CAPACITY OF THE POLYCHAETE *Heduste diversicolor:* CULTIVATION ON SIDE STREAMS FOR CIRCULAR AQUEFEED APPLICATION

## Introduction

The rapid growth of aquaculture has prompted the exploration of sustainably sourced ingredients that, like traditional marine ingredients as fishmeal and fish oil, are rich in the essential long-chain ($\geq C_{20}$) polyunsaturated fatty acids (LC-PUFAs) eicosapentaenoic acid (EPA, 20:5n-3), arachidonic acid (ARA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3). Biomasses derived from aquatic invertebrates, particularly polychaetes, have emerged as promising LC-PUFA-rich ingredients for aquafeeds [1]. Many aquatic invertebrates have the capacity for endogenous production (biosynthesis) of LC-PUFAs, with complete sets of key enzymes termed methyl-end (or "omega") desaturases (ωx), front-end desaturases (Fed), and elongases (Elovl) [2]. A unique trait of the LC-PUFA biosynthetic pathways from invertebrates including polychaetes, is the occurrence of ωx, enzymes that enable the *de novo* biosynthesis of PUFAs and, from them, n-3 LC-PUFAs [3]. This metabolic capacity, combined with their detritivorous feeding habits, makes polychaetes ideal candidates for Circular Economy approaches, where low-value, n-3 LC-PUFA-poor side streams from bioindustries can be recycled into high-value, n-3 LC-PUFA-rich biomass. The aim of the present study was to report on results collected from the molecular and functional characterisation of the LC-PUFA biosynthesising desaturases and elongases from the nereid polychaete *Hediste diversicolor*. Furthermore, due to the capacity of polychaetes to modulate the LC-PUFA biosynthesis in response to environmental factors, we carried out an *in vivo* feeding trial aiming to assess the effects of temperature and salinity on LC-PUFA biosynthesis in *H. diversicolor* juveniles fed on diets composed of side streams from the aquaculture and biogas industries.

## Materials and Methods

The molecular characterisation of desaturases and elongases involved in the *H. diversicolor* LC-PUFA was conducted by determining the phylogeny of the encoded enzymes. Searches for relevant sequences were performed in both public and non-public genomic/transcriptomic databases. Functional characterisation of the *H. diversicolor* desaturases and elongases was done by heterologous expression of their coding regions in brewer's yeast (*Saccharomyces cerevisiae*). Conversion of the enzymes was determined by analysing the proportion of the fatty acid substrate converted to the corresponding product(s). To evaluate the influence of temperature and salinity on LC-PUFA biosynthesis, an *in vivo* feeding trial was conducted using *H. diversicolor* reared on side stream-based diets. Polychaetes were cultured for 28 days along a 5-step temperature and salinity gradient ranging from 7.7 to 17.9 °C and 5 to 40 psu, respectively. Growth, survival and fatty acid (FA) profiles of the worms were analysed.

## Results and Discussion

Molecular and functional analyses revealed that *H. diversicolor* possess three elongases (Elovl2/5, Elovl4 and Elovl1/7) capable of elongating $C_{18}$ $C_{20}$ and $C_{22}$ PUFA substrates, and two front-end desaturases (Fed1 and Fed2), with Δ5 and Δ6/Δ8 desaturase activity, respectively. This enzymatic capacity is shared with other invertebrates such as molluscs, echinoderms and annelids [2]. Collectively, these enzymes, along with the two methyl-end desaturases reported by [4], confirm that *H. diversicolor* has complete pathways to biosynthesise LC-PUFAs, including ARA and EPA (Fig. 1). However, the data collected suggest that *H. diversicolor* is unable to biosynthesise DHA. Regarding the regulation of LC-PUFA biosynthesis by temperature and salinity, our findings showed that the FA composition of *H. diversicolor* remains relatively stable, regardless of the temperature conditions. Nevertheless, low salinity (5 and 15 psu) was associated with increased levels of n-3 LC-PUFAs primarily driven by EPA, in the lipids of the polychaetes. These results support that the activities of the LC-PUFA biosynthetic enzymes (desaturases and elongases) characterised in yeast, appear to be operative *in vivo* according to the high levels of LC-PUFAs found in the lipids of *H. diversicolor* fed on diets with very limited LC-PUFAs. Overall, our findings underscore the biotechnological potential of *H. diversicolor* for generating high nutritional value biomass for aquaculture, following Circular Economy principles.

# REPLACEMENT OF DIETARY FISHMEAL ON THE GROWTH OF JUVENILE YELLOWTAIL, *Seriola lalandi* IN A RECIRCULATING AQUACULTURE SYSTEM

NG Vine and A Manjingolo

Department of Biotechnology & Biological Sciences
University of Fort Hare
Alice, South Africa
nvine@ufh.ac.za

Fishmeal is typically the main protein ingredient when formulating a diet for carnivorous fish due to its high protein content, good digestibility and balanced essential amino acid profile. Issues around the sustainability and high cost of fishmeal have driven research to reduce its inclusion and replacement using alternative animal protein sources. Two feeding trials were conducted to determine the effect of dietary protein and fishmeal replacement on survival, growth and feed conversion ratio (FCR) of juvenile yellowtail, *Seriola lalandi* in a RAS. The first experiment investigated four formulated iso-calorific diets containing different dietary protein levels (38%, 44%, 50% and 56%) for 49 days. Dietary protein level did not have an effect on survival of juvenile yellowtail. In terms of growth performance, specific growth rate (SGR) (ANOVA: $F(3,8) = 10$, $p = 0.003$) and weight gain ($F(3,8) = 10$, $p = 0.003$) was greater in fish fed 56% protein compared to fish fed 38% protein but there were no differences between the 56%, 50% and 44% protein diets. There were no differences in protein efficiency ratio (PER) (1.28±0.32- 1.6±0.5) between the four diets. FCR decreased with increasing protein level with fish being fed the 56% protein yielding the lowest FCR (1.26±0.09) compared to fish fed 38% protein (1.76±0.2) ($F(3,6) = 13$, $p = 0.003$) however there was no difference between the 44%, 50% and 56% protein levels.

A second experiment investigated alternative animal protein sources using the 44% protein diet from Experiment 1. Four experimental diets were formulated to be iso-nitrogenous (44% protein) and iso-calorific (19.50 Mg/Kg). Diets included (i) a control diet with 100% fishmeal as the only protein source (the same formulation as used in Experiment 1), (ii) 67% fishmeal, (iii) 33% fishmeal and (iv) 0% fishmeal with the balance of protein being made up in diets 2-4 of chicken meal, blood meal and soyabean meal in similar proportions. Different fishmeal levels in the diets did not have an effect on the survival on juvenile yellowtail. Specific growth rate was however greater (0.50 ±0.05-0.54±0.10) for fish fed the 67% and 100% fishmeal diets (One-Way ANOVA, $F = 6.27$ $df=3$, $p = 0.017$) compared to fish fed 0% fishmeal (0.16±0.16). There were however no differences in SGR between fish fed 33%, 67% and 100% fishmeal (0.46±0.17-0.54 ±0.10). Diets containing fishmeal had FCR's which were significantly lower than the diet with no fishmeal at all ($p = 0.001$). Fish fed diets having 67% and 100% fishmeal had low PER (0.44±0.11-0.45±0.11) ($p = 0.026$) compared to fish fed 0% fishmeal (0.11±0.10). The results suggest that a 44% protein diet is optimal and that full replacement of fishmeal (0% fishmeal diet) is not recommended as it produced the worst SGR, FCR and PER. The remaining diets were statistically similar suggesting that 33% fishmeal diet produces equivalent growth, FCR and PER as the 67% and 100% fishmeal diets. However, as there were similarities in SGR and PER for 0% and 33% fishmeal diets it is recommended that future experiments possibly focus on the 10% - 50% fishmeal component to find the optimal breakpoint for the various growth and feeding indicators while reducing diet cost and the reliance on fishmeal.

# A NOVEL EX VIVO MODEL TO STUDY WOUND HEALING IN FISH SKIN

Visaliyil, H. *, Warwas, N., Lukásiková, R., Khansari, A.R., Sundell, K., Zurcher, J., Sundh, H., Doyle, D.

* Department of Biological and Environmental Sciences
University of Gothenburg
Gothenburg, Sweden

Email: gusvisahi@student.gu.se

## Introduction

Skin wounds are a leading welfare concern and driver of mortality in salmonid aquaculture. However, the earliest stages of repair are difficult to track *in vivo*. Most existing wound-healing studies in fish rely on *in vivo* sampling at discrete time points, which limits resolution of the earliest repair processes. Our approach addresses this gap by providing a continuous, real-time measure of epithelial barrier restoration under controlled *ex vivo* conditions, using the Ussing chamber method.

Ussing chamber technique help to measure the electrophysiological properties from an epithelium *ex vivo*. The epithelium is placed between two chamber halves and covers a small aperture, through which solute and water transport and diffusion take place. Transepithelial electrical resistance (TER) is calculated from the slope of alternating adaptive DC voltages (U) and from its corresponding currents(I). The transepithelial potential difference (TEP) was measured using KCl electrodes. The short circuit current (SCC) was calculated as SCC = TEP/TER. The TER mainly reflects the ion permeability of the tissue and it is a proxy for barrier integrity. Whereas, the TEP measures the net ion distribution across the epithelium and SCC shows the net active ion transport.

## Methods

Rainbow trout skin explants were mounted in Ussing chambers at 10 °C. Explants acclimated for 3-4 h before standardized superficial wounding, which was performed directly in-chamber by scraping a section of the epidermis. The epidermal (apical) side was exposed to freshwater and the dermal (basolateral) side to physiological saline solution. TER, SCC and TEP were recorded repeatedly (5-min intervals; analyzed in 30-min bins). Repeated-measures one-way ANOVA with Dunnett adjustments compared post-wound values to pre-wound baseline (paired design; N = 24). To validate this approach, histological analysis was carried out.

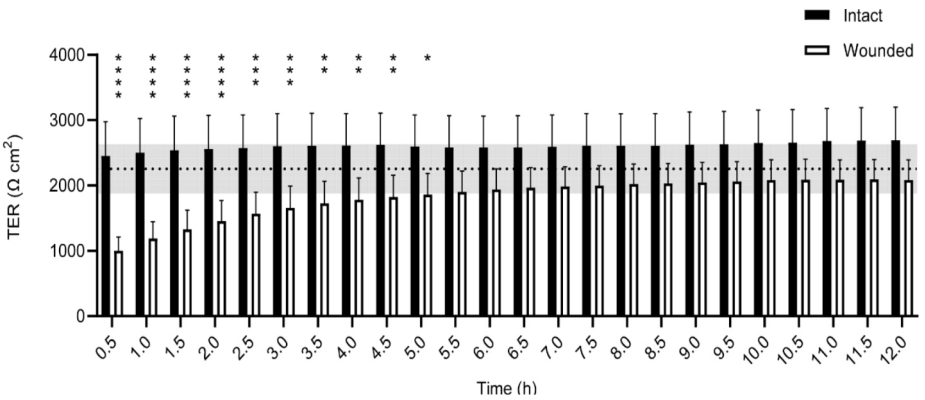

Fig 1 Transepithelial resistance (TER) remains stable for the intact skin and increases for the wounded skin. At 5.5h, there is no significant difference between the wounded and baseline TER.

*(Continued on next page)*

**Results & Discussion**

TER remains stable for the intact skin and increases for the wounded skin (Fig 1). At 5.5h, there is no significant difference between the wounded and baseline (dotted line and grey band) TER. This indicate that wounding caused an immediate TER drop followed by rapid recovery. TEP remains relatively stable for the intact skin but slightly trends towards zero over the course of the experiment. But, the wounded skin trends towards a higher, more negative TEP, closer to its baseline. SCC of the intact skin decreases slightly over the experiment but remains stable from around 4h. The wounded skin shows a high SCC immediately after wounding, but becomes consistent with the intact skin over the course of the experiment.

The TER increase in wounded skin relative to the control skin indicate that a wound healing response was occurring like cell migration. The histological assessment confirmed the presence of a neoepidermis and found that a neoepidermis was present within the first 12 h pw.

**Conclusions**

This study is a positive step towards a functioning *ex vivo* wound healing model. It provides high-resolution, real-time observations of the earliest phases of wound healing in fish and is well-suited for testing environmental or husbandry modifiers relevant to aquaculture. It offers a tissue-complex alternative to cell-only assays while supporting reduction and refinement principles.

# SECONDARY TREATMENT OF RAS WATER AND NUTRIENT REVALORIZATION BY SITE-SPECIFIC MICROBIAL BIOFILM

Charlotte Volpe#[1], Deni Ribičić[2], Lise[3*], Johan[3*], Hubert Bonnefont[4], Vanessa Magana[5], Kjell Inge Reitan[3], Kari Attramadal[5,6]

[6]Department of Biotechnology, Norwegian University of Science and Technology, N-7491, Trondheim, Norway

**Introduction**

Land based aquaculture systems, such as Recirculating Aquaculture Systems (RAS), produce excess water highly rich in Nitrogen (N) which must be treated. The release of N-rich water in the environment can lead to undesirable eutrophication, and regulations, to avoid and control this, are increasing. In this context, the existing solution, besides releasing to close water bodies, is fixating the N back to air. These solutions are not ideal in terms of sustainable use of the nutrients and do not promote resource revalorization. At the same time the feed industry is looking for new and more sustainable ingredients to supplement their feed. Several systems focusing on the uptake and valorization of nutrient rich side stream have been proposed, including coupling land-based fish farms with plant growth in aquaponic systems or with bioreactors growing a microalgae monoculture.

**Materials and methods**

The water used for the experiments was collected in a representative Norwegian RAS installation during four separate samplings throughout a time period of 10 months. The experiments were performed either in culture flasks or reactors at 13°C with a constant light intensity of 203-333 μmol $m^{-2}$ $s^{-1}$. We tested how conditions such as harvesting rates, nutrient concentration and light affected the growth of the biofilm. We evaluated the bioremediation capacity and performed eurokaryotic and prokaryotic community analysis.

**Results**

We found that in this reactor, organisms naturally present in the RAS form a biofilm and can efficiently bio-remediate the water by reducing the $N\text{-}NH_3$ up to 76.6%, $N\text{-}NO_3^-$ up to 84.9% and the $P\text{-}PO_4^{3-}$ up to 95.7%. Sequencing results indicate that the eukaryotic community was, in all conditions, strongly dominated by the diatom *Phaeodactylum tricornutum,* almost resembling a monoculture.

# EVENT BASED FISH DETECTION IN A CYBER-ENHANCED TANK. TWO NOVEL CONCEPTS FOR PRECISION FISH FARMING

## Introduction

Aquaculture has seen significant changes the recent years, since aquatic resources are considered a primary protein supplement for daily lives in many communities. The aquaculture industry is experiencing a steady increasing production, with an approximate average annual growth rate to 1.72 % since 2010 [1]. Common practices for fish farming require standard procedures that are considered expensive and time-consuming. In recent years, science has presented outstanding novelties, featuring a wide pallette of technological advancements. Frame- and event-based cameras, scanning sonars and light enrichment are some of this wide variety that can create novel methodologies for fish farming.

In our project, two new concepts are introduced: a cyber-enhanced tank and an innovative fish behavior detection via neuromorphic vision [2]. The event camera, which is the basis for the neuromorphic vision, can detect alterations in fish movements by analyzing the generated changes in pixel light intensities. We propose an experimental tank setup with these technological deployments which we believe will provide a more realistic environment for the fish and a multi-modal way of observing fish behavior via a set of (frame and event) cameras and a scanning sonar.

## Materials and Methods

### Cyber-enhanced tank

The enhanced tank was built upon an existing conventional tank environment of four cubic meters. A waterproof LED line, illuminating the volume homogeneously with a spectrum close to sunlight (5600K to 6500K), was placed a few centimeters below the surface on a specially designed support frame, providing light conditions that mimic those in a commercial cage-mimicking light conditions. As displayed in Figure 1, the lights (operated by a signal frequency driver) follow the inner perimeter of the tank. A surveillance camera (I), a stereo camera (II), an event camera (III) and a sonar (IV), consist a multi-observatory sensor suite.

### Neuromorphic vision

A novel event-based fish monitoring procedure is presented via neuromorphic vision, by detecting alterations in pixel brightness (known as events). This differs from the operation of commercial frame-based cameras. Figure 1-III shows an example of outputs from this device, where two highly mobile fish are detected.

The black and blue dots represent the variations in the light intensities of the pixels. The main goal of this procedure was to count the events generated by the fish during different stimuli presentation. As an example, Figure 2 shows feeding operations recorded by the same event camera from two different perspectives, bottom (left) and top (right) placement, respectively. The red dotted lines denote the feeding time while blue lines depict the event time series.

## Conclusions

This study introduces two new concepts for aquaculture research: a cyber-enhanced tank that provides a realistic tank environment and a sensor suite for fish monitoring, and a new method for behavioral monitoring based on neuromorphic cameras. The cage-like tank provides light conditions similar to real aquaculture settings, aiming to promote fish welfare during experiments. Neuromorphic vision represents an innovative technology for fish detection, a concept that can provide more information for industrial use.

# PRESENT STATUS OF BIOFLOC TECHNOLOGY SHRIMP CULTURE SYSTEM IN SOUTHERN BRAZIL

W. Wasielesky*, D. Krummenauer, G. Fóes, A. Cardozo; P. L. Oliveira, M. F. Gomes, M. Santos, E. Prates and Luis Poersch

Marine Shrimp Culture Laboratory
Institute of Oceanography
Federal University of Rio Grande
Rio Grande, RS, Brazil
E-mail: manow@mikrus.com.br

## Introduction

The shrimp culture in biofloc technology systems (BFT) is characterized by zero water exchange and super-intensive culture of shrimp in enclosed raceway type. This type of system is considered environmentally friendly and avoids nutrient rich waste from polluting coastal waters. However, as a new strategy for shrimp production, there is much still to be learned about the benefits of producing shrimp BFT systems to enhance the commercial potential of the system. For that reason, several experiments have been carried out trying to find some of the keys for technical and economic feasibility of BFT shrimp superintensive culture systems.

## Materials and methods

Over the past 20 years, numerous studies have been conducted at various experimental scales. Sets of 300-, 500-, and 1,000-L tanks were used to conduct more precise tests. For pilot and commercial-scale tests, 40-$m^3$ and 250-$m^3$ raceways were used in super-intensive systems located in greenhouses. For experiments in intensive systems, 600-$m^3$ lined ponds were used.

## Results and discussion

Technological innovation permits increases in shrimp production capacity per unit area. The addition of new management tools such as air injectors (nozzles), nitrification and denitrification process, use of clarifiers and some new procedures may allow increases in the load capacity of these systems.

For example, the demand for dissolved oxygen (DO) by shrimp is one of the main concerns as culture systems intensify. In intensive or super-intensive culture of shrimp can be possible if the system's aeration devices can meet the organism's oxygen demand. The number of devices to be used will depend on the water's salinity and temperature, stocking density, shrimp size, and the amount of suspended solids in the BFT systems. For this reason, studies and evaluations of the support capacity of each new aeration technology is important to maximize its effect.

Therefore, several researchers have evaluated the influence of the limitation of different parameters and procedures. These are important challenges to overcome production when working in BFT with high densities, and different devices and other procedures (Table 1), that can have significant impacts on shrimp development in super-intensive system.

## Conclusion

In the present study we will present evaluations of some of these important generated technologies for BFT systems, and we will discuss the influence of high stocking densities on water quality and on the growth performance of *P. vannamei* in a BFT system.

*(Continued on next page)*

Table 1: Recent developed technologies for Biofloc Technology super-intensive shrimp culture systems in Southern Brazil

| BASIC CARACTERISTICS OF BFT SYSTEMS |

Email: jweitzman@perennia.ca

## Introduction

Implementing proactive and effective spatial planning in aquaculture requires users and stakeholders to access decision support tools (DSTs) that centralize information to support site planning (Falconer et al., 2020). Spatial DSTs in the forms of models (e.g. carrying capacity) and mapping tools, are increasingly recognized for their role in enhancing aquaculture planning and management (Stelzenmüller et al., 2017; Gangnery et al., 2021). This paper presents the Coastal Classification System (CCS), a new publicly accessible web-based decision-support tool developed to support aquaculture planning and siting in Nova Scotia, Canada. The tool presents the results of province-wide suitability assessments and provides users access to various GIS map layers relevant to four cultured species: Atlantic salmon (*Salmo salar*), Rainbow trout (*Oncorhynchus mykiss*), Blue mussels (*Mytilus edulis*), and American oyster (*Crassostrea virginica*).

## Methods

The Coastal Classification System was developed through collaboration between the Government of Nova Scotia and the Centre for Marine Applied Research. The goal of this project was to create an online mapping platform to support regional-level planning about aquaculture in Nova Scotia (**Fig. 1**). The DST was built through a stakeholder-engaged process involving government, scientists, and industry, who provided input both on inclusion of relevant data, and on the useability of the outputs. It was built with accessibility and transparency in mind, aiming to provide information about aquaculture to a range of users.

## Results

The CCS operates as an online platform using ArcGIS products. A web-based mapping tool (Fig.2) provides users access to over 20 spatial layers of information, including generated suitability maps and data layers relevant to assessing aquaculture suitability. Users can also overlay various informational data layers alongside the suitability maps. To enable area-specific investigations, users can zoom in to any area within the area of assessment and click on each 'cell' (100 m resolution) to view more information about how the area was assessed.

To support the mapping tool, an ArcGIS Story Map was also developed, providing additional information about the suitability assessment, each data layer, as well as guides on how to use the tool. The CCS is publicly available for anyone to access, view, and explore.

## Discussion

The developed online mapping platform not only increases transparency, provides information related to datasets and opportunities, but also supports future planning. With this tool, planners, decision-makers, and prospective producers can understand not only where it is potentially suitable for development, but also the types of information and datasets to consider in their site applications. The tool centralizes information and provides easy to understand language to evaluate where and why an area may have greater or fewer opportunities for development. Furthermore, this tool can help support future decisions around locations for subsequent strategic assessments, and also where there may be data gaps. This transparent, accessible platform was built as a living tool to allow further improvement and can be readily adapted to incorporate new data and meet the needs of the evolving industry.

*(Continued on next page)*

# WHERE TO LOOK? A PROVINCE-WIDE SUITABILITY ASSESSMENT OF MARINE FINFISH AND SHELLFISH AQUACULTURE IN NOVA SCOTIA, CANADA

J. Weitzman*, J. Cunningham, L. Nargis, T. Wilson, L. Lewis-McCrea, G. Reid

Centre for Marine Applied Research
27 Parker St
Dartmouth, NS B2Y 4T5 (Canada)
Email: jweitzman@perennia.ca

## Introduction

As aquaculture seeks to expand into new areas, responsible planning for favourable areas is needed to avoid conflict and promote sustainable development (Aguilar-Manjarrez et al., 2017). Identifying suitable areas for aquaculture requires comprehensive evaluations of multiple biophysical and ocean use factors. Many of these factors are inherently spatial, varying across areas and locations. As such, spatial modelling has become increasingly applied to inform site selection and broader area-based planning globally (Chentouf et al., 2023; Silverthorn et al., 2025). Here, we present the findings from a comprehensive suitability assessment for potential coastal aquaculture development in Nova Scotia, Canada. A province-wide decision-support tool was developed, called the Coastal Classification System (CCS).

## Methods

Through evidence-based and collaborative approaches, this project identified and assessed the various criteria that influence aquaculture suitability. Four marine aquaculture species were assessed: Atlantic salmon (*Salmo salar*), Rainbow trout (*Oncorhynchus mykiss*), Blue mussels (*Mytilus edulis*), and American oyster (*Crassostrea virginica*). Drawing on methods from Geographic Information Systems (GIS) and Multi-Criteria Decision Analysis (GIS-MCDA), suitability classifications were mapped within Nova Scotia's coastal waters (just over 13,000 km$^2$). A total of 15 criteria and constraints were selected to consider critical needs for species health and welfare, potential overlap with other marine users, and proximity to important coastal habitats. Criteria layers were scored based on parameter-specific suitability functions and aggregated using weighted linear combination, rule-based overlay, and constraint overlay.

## Results

Final suitability maps classify each area at a 100 m$^2$ resolution, as one of four ratings: Restricted, Limited, Moderate, or Good for potential aquaculture development. Across all assessed species, restricted areas accounted for only 2% of the area of assessment, predominantly in major traffic separation zones adjacent to high-use ports. For finfish species, roughly 3,500 km$^2$ (25-26%) of the area of assessment was classed as well-suited for potential aquaculture development, while this decreased to ~13.5% for shellfish species.

## Discussion

For different types of species, suitability mapping identifies unique areas for greatest sustainable aquaculture development potential.

The use of GIS-MCDA techniques to assess evaluation criteria and integrate data has allowed for the creation of practical outputs and maps for industry and decision-makers. This information supports early-stage planning to identify where opportunities for aquaculture development may occur and areas that may have limitations. This tool enhances proactive aquaculture planning and can be used to identify further areas for more local-scale investigations.

# FROM SEA TO PLATE: ADVANCING SELECTIVE BREEDING FOR NON-SALMONID SPECIES TO DRIVE AQUACULTURE DIVERSIFICATION

Maren Wellenreuther[1,2]

[1] The New Zealand Institute for Plant and Food Research Ltd, Nelson, New Zealand
[2] School of Biological Sciences, The University of Auckland, Auckland, New Zealand

Email: maren.wellenreuther@plantandfood.co.nz

Diversifying aquaculture species is critical not only for building climate-resilient food systems but also for making more effective use of available water space for food production. In Aotearoa New Zealand, the Australasian snapper (Sparidae: *Chrysophrys auratus*) is emerging as a strong candidate for both coastal and open ocean aquaculture systems [1]. This promising warm-water species has close relatives—such as the red sea bream in Japan and the gilthead sea bream in the Mediterranean region—that are already well established in international aquaculture markets, underscoring its commercial potential. This talk presents recent genomic and phenotypic innovations underpinning the development of a selective breeding programme for this non-salmonid species

Over the past 20 years, snapper have been bred and trialled in both land-based and ocean-based systems, with selectively bred fifth-generation ($F_5$) fish showing marked improvements in growth, feed conversion ratio (FCR), and survival [2, 3]. Domestication selection [4], high-throughput phenotyping [5]—leveraging computer vision and machine learning—and genomics-based selection [6, 7, 8, 9, 10] have driven these production related gains in performance .

While early breeding efforts prioritised growth performance, the escalating effects of climate change have recently shifted the focus toward enhancing temperature resilience. Snapper are highly thermally sensitive [11]: growth is stimulated at temperatures above 15 °C, stalls below this threshold, and fish begin to lose condition as temperatures approach 10 °C. Optimal growth occurs near 21 °C, underscoring the influence of environmental temperature on aquaculture viability. In the wild, snapper populations in New Zealand are expanding southward into regions that were previously unsuitably cold, likely facilitated by ocean warming [12, 13, 14]. However, the persistence of low winter temperatures in these areas continues to limit further range expansion and poses significant challenges for survival and growth. In response, we have initiated New Zealand's largest temperature resilience trial (four temperature treatments, each with 4 replicated tanks, starting snapper numbers per tank 200), involving over 3,000 GBS-genotyped snapper reared under four distinct thermal regimes for 12 months. In addition to high-frequency (8-weekly) phenotyping, the trial integrates whole genome SNP data with transcriptomic and epigenomic profiling to uncover the molecular basis of thermal resilience and growth.

Launched in April 2025, this comprehensive study is producing critical data on genotype-by-environment interactions and physiological responses to thermal stress, with the goal of informing selective breeding strategies for climate-adapted aquaculture. I will present first results from this trial alongside data from recent grow-out comparisons between selectively bred and wild-type fish. Together, these findings highlight the potential of snapper as a climate-resilient aquaculture species and underscore the importance of integrating environmental robustness into breeding strategies for future-ready aquaculture systems.

# RE-IMAGINING OPEN OCEAN AQUAQUACULTURE: DESIGNING WITH THE FISH IN MIND

M. Wellenreuther*, L. Kregting and S.E. Black

New Zealand Institute for Bioeconomy Science
(formerly New Zealand Institute for Plant and Food Research)
P.O. Box 5114
Port Nelson, Nelson, New Zealand.
Email: Maren.Wellenreuther@plantandfood.co.nz

## Introduction

Global seafood demand is anticipated to increase over the long term, with finfish mariculture poised to become a major contributor to future supply [1]. As sheltered, nearshore marine environments are highly valued and regulated and are already occupied in many areas of the world, open ocean aquaculture (OOA) is the most likely way to meet global demand for finfish.

A typical approach to design OOA fish enclosures is to enlarge and fortify existing technologies with the aim to both increase production biomass and to withstand extreme oceanographic forces [2,3]. The New Zealand-based Whakapōhewa ki ahumoana Reimagining Aquaculture project (funded by the Ministry for Business, Innovation and Employment Endeavour Fund) lead by Plant & Food Research, has taken a different approach. Focussing firmly on the needs of the fish, they have designed a system to support healthy fish growth, limit adverse impacts on the marine environment and withstand the physical impacts of sometimes harsh and unpredictable offshore conditions [4].

This presentation describes the very first biological trials of this soft-engineered, semi-mobile aquaculture production system with two exemplar species: Australasian snapper/tāmure/silver sea bream (*Chrysophrys auratus*) and Chinook/King salmon/hāmana (*Oncorhynchus tshawytscha*).

## The innovation: a semi-mobile aquaculture production system

A 500m$^3$ soft-engineered fish enclosure (20m x 5m x 5m) was constructed utilising a laminated ultra-high molecular weight polyurethane fabric with nets placed at the front and back of the enclosure (Figure 1).

The fish enclosure is tethered to a mooring setup allowing the system to swing about the mooring as the tide changed. A support and monitoring buoy (Figure 1b and 2) delivers feed as well as providing a conduit for sensors and underwater camera cabling for monitoring fish inside the enclosure via a flexible umbilical tube to a depth of 15 m.

In early April 2025, approx. 2000 snapper were transported to the trial site and introduced to the system (Figure 2) where they resided in the system for 6 weeks, with approx. 3000 salmon transferred in July. Both species were fed an appropriate commercial pellet diet. Remote monitoring of fish was possible through a continual live underwater video feed.

## Results

Fish were successfully cultured in the semi-mobile system, gaining weight and maintaining health and condition during the trials. The system and fish were subject to a number of substantial weather events during the trial period. Being submerged to a depth of 15 m meant that significant wave motion was avoided compared with surface waters. Feed, monitoring and remote communications were maintained throughout the trial.

## Discussion

To our knowledge, this is the first large-scale demonstration of finfish successfully reared in a submerged, soft-engineered, and semi-mobile aquaculture system. The integration of underwater feeding and continuous video monitoring enabled deployment at a high-energy offshore site and facilitated trials across two biologically distinct species. Engineered around fish welfare, the system can be fully mobile—capable of being towed to track favourable thermal and water quality conditions. This novel, fish-centred approach represents a step-change in offshore aquaculture, offering a low-impact, scalable solution with the potential to reduce capital and operational costs while unlocking under-utilised open ocean areas for sustainable finfish production.

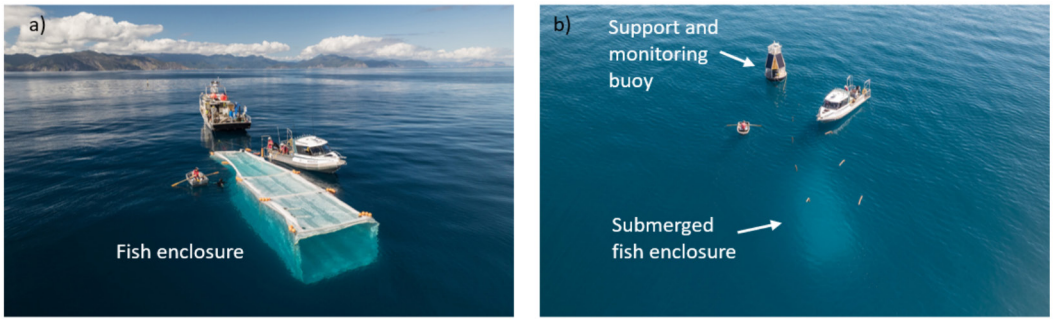

Figure 1. Fish enclosure at the surface (a), and submerged to an operational depth of 15 m (b).

Figure 2. Snapper inside the fish enclosure.

**Introduction**

Mussel aquaculture across Europe is dominated by blue mussels *Mytilus edulis* in the north and Mediterranean mussels *Mytilus galloprovincialis* in the south, with hybridization occurring where ranges overlap. *M. galloprovincialis* expanded into Ireland in the 1970s (Gosling & Wilkins, 1977), and hybrid zones are now common on exposed Irish coasts (Lynch et al., 2020). In Norway, *M. edulis* has been the predominant species, but recent studies report patchy distributions including *M. trossulus* and *M. galloprovincialis* (Simon et al., 2020). Wild and commercial *Mytilus* populations have declined across parts of the North Atlantic due to warming seas, predation, disease, and habitat disturbance (Baden et al., 2021). Ireland produces >10,000 t of rope-grown mussels annually (MSC-certified, ~€14M value), whereas Norway's production remains relatively small (~2,600 t in 2022) (BIM, 2024; Bruvold et al., 2024). Challenges common to both industries include inconsistent growth, poor spawning synchrony, and unreliable spat settlement (Baden et al., 2021; Mortensen et al., 2023). Growth performance directly affects mussel aquaculture profitability and harvest timing, with market size typically 20–25 g per mussel (FAO, 2023) while pathogens/parasites (e.g., *Vibrio* spp.) remain a monitoring concern, with variable prevalence by site and season (Díaz et al., 2022).

This study aimed to characterise and compare age performance, whole wet weight (WWW), species composition, sex ratio, spawning, and *Vibrio* spp. prevalence of rope-cultured mussels in a temperate system Roaringwater Bay (Ireland) and a subarctic system Rundhaugen (Norway). This comparison provided a unique opportunity to investigate how contrasting climatic regimes influence mussel growth, reproduction, and disease dynamics. While both regions employ longline aquaculture, they differ substantially in thermal regime, photoperiod, and primary productivity cycles. Key environmental drivers (sea surface temperature (SST) and chlorophyll-*a* concentration) were evaluated. The findings of this study provide an evidence base for optimising rope deployment timing and improving site-specific grow-out management strategies.

**Methodology**

Seasonal quarterly sampling (April 2023–June 2024 (preharvest)) resulted in the collection of 600 mussels per site (1+ and 2+ year cohorts) at Roaringwater Bay, Ireland (51.526° N, 9.436° W) and Rundhaugen, Norway (65.13428° N, 12.32661° E), providing a latitudinal difference of 17.5° (Figure 1). Whole wet weight (WWW) and shell length were recorded. Gill tissue was sampled for DNA extraction (Chelex-100 method) and species identification via PCR (Me15/Me16 markers, Inoue et al., 1995): *M. edulis* 180 bp, *M. trossulus* 168 bp, *M. galloprovincialis* 126 bp, hybrids = dual amplicons). Gonadal histology determined sex and gametogenic stage. Sea surface temperature (SST) and chlorophyll-a were obtained from Copernicus and BIM datasets. A multiplex PCR was conducted to identify four specific *Vibrio* spp., as well as the general presence of *Vibrio* spp. (O' Leary et al., *In Revision*). Detection of the generic *Vibrio* spp. (419 bp), *V. aestuarianus* (259 bp), *V. spendidus* (182 bp) and *V. anguillarum* (519 bp) were recorded using gel electrophoresis. Regression Analysis was run to examine relationships between independent variables and a dependent variable. Pearson correlation coefficients were used to measure the strength and direction of a linear relationship between two continuous variables. Fisher's Exact Test was used to investigate significant relationships between categorical variables.

*(Continued on next page)*

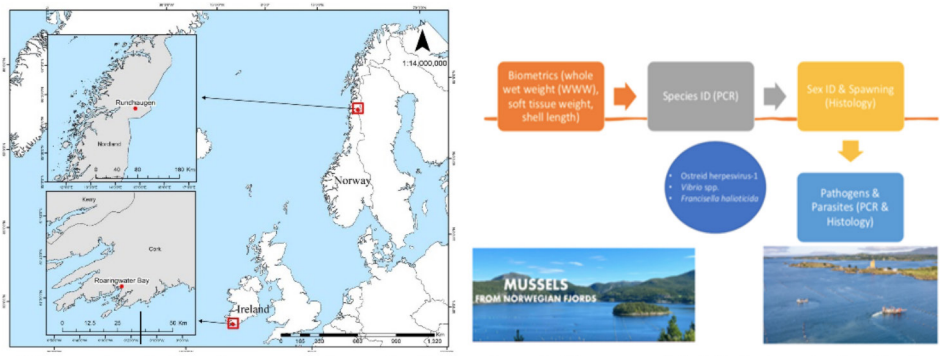

Figure 1 : Mussel rope fishery in Ireland and Norway, highlighting latitudinal difference and an overview of the methodology used.

**Results**

*M. edulis* dominated at both sites (77.7% in Ireland; >70% in Norway). *M. galloprovincialis* occurred at lower levels (≈10% Ireland, 23.8% Norway), and hybrids were only detected in Ireland. No *M. trossulus* were detected in both fisheries. Growth patterns differed significantly ($p<0.05$): Overall Irish mussels exhibited rapid weight gain to the end of the trial (June'24) in the Year1+ cohort (mean WWW 6.19 ±3 g) that slowed in the Year2+ cohort (mean WWW 10 ±4g). Norwegian mussels displayed steadier growth to the end of the trial in the Year 1+ cohort (mean WWW 5.5 ±2.5g) and Year 2+ cohort (mean WWW 11 ±3.5g). Size variability increased with age, particularly in Irish 2+ year mussels (spread ≈13.1 g in July'23).

Sex ratios were female biased and similar at both sites (Roaringwater Bay: 0.59:1-0.88:1; Rundhaugen: 0.53:1-0.88:1). Spawning occurred in both fisheries in the smaller sized/lighter (<14.9g) cohort in all sample months (all seasons) and in heavier mussels (>15g) in April'23 and July'23 in the Irish fishery and in April'23, October'23 and January'24 in the Norwegian fishery. Overall in Roaringwater Bay, males averaged a weight of 6.3 g (4.4 - 10.5 g), while females were lighter at 5.8 g ( 5.1 – 9 g); *M. edulis*, *M. galloprovincialis*, and hybrids showed distinct mean sizes, with hybrids intermediate, and spawning mussels were smaller than non-spawning.*M. edulis* was the heaviest species in both fisheries, consistently exceeding the weights of *M. galloprovincialis* and hybrids. Overall in Rundhaugen, males had a mean weight of 6.5 g (5.3 - 12.2g) compared to females at 7.2 g ( 4.9-13 g), with similar species-specific patterns and reduced size in spawning individuals.

Overall, minimal detection of *Vibrio* spp. was observed in Roaringwater Bay mussels (4.5%) and Rundhaugen mussels (2.8%). At Roaringwater Bay, moderate SST and reduced salinity in April'23 favoured a phytoplankton bloom, followed by a decline in chlorophyll-*a* from July'23 onwards. At Rundhaugen, rising SSTs and increasing chlorophyll-*a* from spring to summer supported gametogenesis, spawning, and growth, while moderate autumn conditions facilitated a second spawning event in the mussels in January'24.

**Discussion**

Hybrids were present in Ireland but absent in Norway suggesting reduced sympatry and potential selection against hybrids under colder conditions. Growth trajectories suggested different energy allocation strategies: Irish mussels grew rapidly in Year 1, then plateaued but this may also have been due to the relocation of the mussels in Year 2 higher up in the bay. Norwegian mussels grew more consistently, reaching higher final weights in the older cohort. Seasonal weight peaked in Norway during winter suggesting that growth is influenced not only by SST but also by reproduction-related energy trade-offs. Females dominated both fisheries and synchronised spawning occurred between the sexes in both fisheries. Spawning occurred in all sample months for the smaller/lighter mussels, while heavier individuals spawned in more defined energetically favourable time periods (spring/summer). These results would indicate that lighter mussels may lack energy reserves and spawn opportunistically whenever energy is available. It may also indicate that smaller mussels are more sensitive to environmental triggers (SST fluctuations, food pulses) and spawn irregularly. Irish mussels displayed one major spawning event (July'23), tightly coupled to peak SST (15 ºC) and the post-spring phytoplankton bloom, suggesting a build-up of energy reserves before releasing gametes. Spawning peaked twice in the Norwegian system, in July'23 which coincided with peak SST and chlorophyll-a and in January'24 after a secondary autumn bloom, when the SST was at its lowest but still within tolerance for spawning in cold-adapted *Mytilus* spp. Although a high energy trade-off is required by female mussels to produce larger and more nutrient rich eggs compared to the male sperm, females may benefit from spreading reproductive effort over time in both systems by avoiding the risk of "putting all eggs in one basket" if a spawning season fails.

*(Continued on next page)*

**Conclusion**

This first comparative analysis of rope-cultured mussels from Ireland and Norway highlights that both biotic (species composition, age, reproduction) and abiotic (SST, chlorophyll-a) factors jointly shape growth and reproduction. Monitoring SST trends and spring chlorophyll-a blooms can help predict the optimal deployment window in a given year. Findings support site-specific optimisation of rope deployment and harvest schedules to maximise settlement success and production yields, as well as informing that the movement of ropes mid grow out cycle to a new location may not always be beneficial.

# ENHANCING SHRIMP COLOUR AND YIELD: EVALUATING THE IMPACT OF NATURAL ASTAXANTHIN IN PLANKTON SYSTEMS FOR COMPETITIVE FARMING IN THE EU MARKET

N. Widjaja

Kasetsart University
Bangkok, Thailand.
Email: ningshinny.w@ku.th

## Introduction

The European shrimp market is renowned for its stringent standards regarding product quality, safety, and sustainability within the aquaculture industry. In this context, our study explores how the incorporation of astaxanthin into feed formulations—specifically through a mixed application at the feed mill—can enhance these critical attributes. Shrimp colour serves as a key sensory factor that signals product quality, playing a pivotal role in gaining access to the EU market. However, beyond aesthetic appeal, it is imperative for farmers to understand the overall impact and return on investment (ROI) of this nutritional enhancement to remain competitive against existing suppliers. Conducted on a commercial farm in Bangka Island, Indonesia, this study evaluates 13 out of 57 ponds and assesses various parameters, including coloration, meat quality, yield performance, and overall shrimp health—each of which directly influences profitability. Ultimately, the goal of this research is to translate scientific insights into commercially viable practices that meet the rigorous standards of the European market.

## Material and Method

All experimental ponds adhered to standardized procedures for pond and water preparation to ensure uniform conditions throughout the study. Each pond utilized the same high-quality commercial feed brand and specifications.

From Day of Culture (DOC) 30 to DOC 101, the experimental design involved administering astaxanthin-enriched feed exclusively to Treatment 2 and Treatment 3 ponds, while the control ponds continued to receive standard feed. Comprehensive data collection was implemented as follows:

1. Growth Performance Metrics: Weekly sampling incorporated parameters such as Mean Body Weight (MBW), Average Daily Gain (ADG), Survival Rate (SR), and Feed Conversion Ratio (FCR). Partial harvest assessments were conducted to gather these metrics systematically.

2. Coloration Assessment: At DOC 101, shrimp coloration was evaluated using a salmon fan and shrimp ruler from DSM. The assessment included samples of raw Highly Unsaturated Fatty Acids Oil (HOSO), cooked HOSO, and peeled and cooked thawed HOSO to determine the impact on pigmentation.

3. Post-Harvest Meat Quality: Meat quality analysis was performed by measuring drip loss and thawed loss. Shrimp specimens were frozen for a period of 24 hours at a temperature range of -1 to 0 °C. Drip loss was quantified after a 15-minute exposure to ambient conditions, followed by thawed loss measurements after an additional 2-hour period.

Experimental Setup

| No | Pond Name | | | Post Larvae | | Treatments | Antioxidant Feed Additives | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | No | Size | Density | Hatchery | Genetic | | Remarks | Type | Sources | Inclusion Rate |
| 1 | D2 | 2.086,13 | 180 pcs/m2 | CPP/BLK | Balance | T1 | No Astaxanthin | | | |
| 2 | D7 | 2.086,13 | | | | | | | | |
| 3 | D8 | 2.086,13 | | | | | | | | |
| 4 | D10 | 2.086,13 | | | | | | | | |
| 5 | D12 | 2.086,13 | | | | | | | | |
| 6 | E1 | 2.202,38 | | | | T2 | Aquacel | Natural | Bacteria | 3kg/MT Feed |
| 7 | E2 | 2.202,38 | | | | | | | | |
| 8 | E3 | 2.202,38 | | | | | | | | |
| 9 | E4 | 2.191,00 | | | | T3 | Yeast CP | Natural | Yeast / Basiomycetous | 1kg/Mt Feed |
| 10 | E5 | 2.191,00 | | | | | | | | |
| 11 | E6 | 2.896,13 | | | | | | | | |

*(Continued on next page)*

4. Biweekly Shrimp Health Parameters: Health evaluations included assessing aggregate total microvilli (ATM), tubular shape and content, health shrimp index, porous shrimp shell condition, chromatophore integrity, white muscle quality, melanisation, gill coloration, soft shell prevalence, hepatopancreas coloration, the occurrence of white spots, and measurements of body colour and shape, lipid size, and bacterial counts.

5. Biweekly Immunological Assessments:Immunological parameters were quantitatively analysed, focusing on lysozyme activity, peroxidase and superoxide dismutase activity, glutathione levels, glycogen content, and total haemocyte count to evaluate the immune responses of the shrimp.

6. Daily Water Quality Monitoring: Water quality metrics were meticulously recorded, including temperature, salinity, pH, dissolved oxygen (DO) levels, plankton species composition, and quantifications of ammonia, nitrate, and nitrite concentrations to ensure optimal culture conditions.

7. Yield Performance Evaluation: The yield performance was assessed at the final harvest to determine the overall efficacy of the treatment conditions.

8. Statistical Analysis: Data were subjected to descriptive statistical analysis, followed by Analysis of Variance (ANOVA), post hoc testing, and regression analysis, with significance established at $p < 0.05$.

This multifaceted approach provides critical insights into the impact of astaxanthin-enriched feed on growth performance, health status, immune function, and overall yield in shrimp aquaculture. Such findings contribute to a comprehensive understanding of the potential benefits of astaxanthin supplementation within aquaculture systems, paving the way for improved practices and enhanced product quality.

**Expected Outcome**

In this study, we present comprehensive data on optimal management practices aimed at enhancing shrimp coloration, meat quality, health, and yield performance. Our findings provide valuable insights into the effects of various feed additives on shrimp health and overall performance, offering actionable knowledge specifically tailored for local farmers seeking to optimize their aquaculture operations. Additionally, we shed light on the interplay between plankton management and feed additives, elucidating their collective influence on shrimp microbiomes and quality traits, which is critical for developing improved farming methodologies. Furthermore, we propose recommendations for optimal inclusion rates of feed additives, balancing financial performance with key shrimp quality metrics, thereby fostering sustainable practices within the industry. Collectively, these insights contribute to a holistic understanding of shrimp aquaculture, promoting enhanced productivity and sustainability.

# NAKED CLAMS: A COMPREHENSIVE ANALYSIS OF THEIR GLOBAL POTENTIAL FOR COMMERCIAL AQUACULTURE

David F. Willer *, Jia Rong Joan Poon, J Reuben Shipway

Department of Zoology
University of Cambridge
The David Attenborough Building
Pembroke Street
Cambridge, CB2 3QZ, United Kingdom

dw460@cam.ac.uk

## Introduction

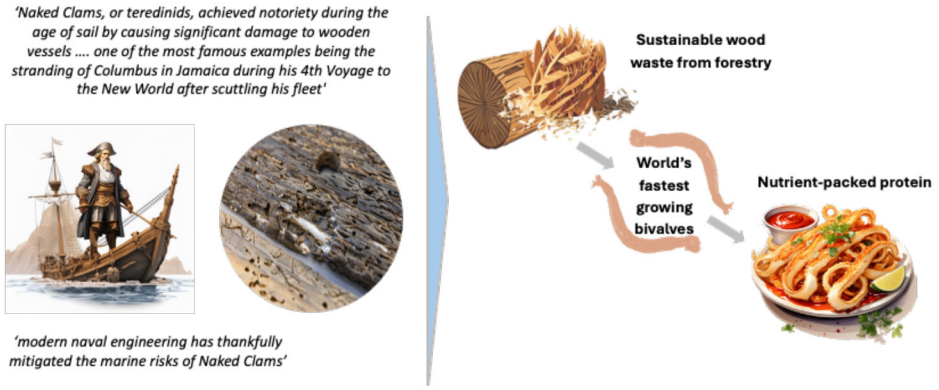
Naked clam aquaculture presents a game-changing solution for sustainable seafood production, capable of transforming waste wood into highly nutritious, low-environmental-impact protein for global consumption. Our previous articles in *npj Sustainable Agriculture* and *Food Frontiers* set the stage for naked clams. We demonstrated the world's first naked clam aquaculture system, nutritional analysis and global social media survey on their perception worldwide. This research showcased the groundbreaking potential of naked clams to turn waste wood into highly nutritious, low environmental impact protein that could feed millions of people worldwide, and captured international media attention, including coverage in the BBC, Financial Times, ITV, Sky News, and The Times, in addition to several aquaculture specific media outlets.

## Approach and Results

Our work presented today is the first comprehensive global analysis of naked clam aquaculture. By synthesising distribution, growth rate and size data across 24 species, we demonstrate that naked clams grow up to 3× faster than commercially farmed blue mussels, with some species exceeding 1.5 meters in length—despite the fact that their aquaculture has yet to be scientifically optimised. Large and fast-growing species are distributed globally, offering a readily available, scalable solution to sustainable seafood production. We further consolidate existing reports on their nutritional attributes, including their high protein content, vitamin B12 levels, and potential health benefits, while identifying critical knowledge gaps requiring further research.

To support the development of a scalable, low-impact aquaculture sector, we outline a strategic roadmap addressing species selection, growth optimisation, and disease prevention, offering a clear framework for future research and commercialisation. This work not only delivers new biological insights but also positions naked clams as a high-yield, low-carbon alternative to conventional aquaculture species, offering a transformative opportunity for sustainable seafood production while fully integrating into circular economies by converting waste wood into nutrient-dense protein, thereby closing resource loops and valorizing forestry byproducts.

The team our currently working on scale-up of naked clams within an IMTA system.



# USE OF CORN FERMENTED PROTEIN AS AN ALTERNATIVE SUPER PROTEIN IN DIETS FOR A RANGE OF COMMERCIAL AQUCULTURE SPECIES

P. E. V. Williams*, Paula, A. T. Velasquez**

*Fluid Quip Technologies 6105 Rockwell Drive NE, Suite C Cedar Rapids, Iowa52402
p.williams@fluidquiptechnologies.com
**Vertex Avda. de Europa 19. Ática XIX. Edf. 3. Módulo Bajo D. 28224 Pozuelo de Alarcón (Madrid)

**Introduction**

Feed represents approximately 80% of the environmental footprint of aquaculture farming. Europe relies heavily on imported proteins to supply over 70% of the protein required for feed formulation for livestock and aquaculture (the Protein Gap). Soybean meal forms the major proportion of this imported protein meal and the challenge for the European feed industry is to source a locally produced protein meal that can replace soybean meal in ration formulation. Corn Fermented Protein (CFP) is a Super (>50% crude protein content) corn protein product which is produced by mechanical separation of the whole stillage fraction from the dry grind production process used to produce bioethanol a renewable transport fuel that reduces GHG emissions by 72% and fosters rural development. Produced as a co-product in the production of a renewable fuel, the carbon index of CFP is approximately one tenth of the production of an equivalent soybean meal protein product. During the 50-60h fermentation of starch to produce ethanol a large quantity of yeast is generated, approximately 8% of the grain starch is used in the generation of yeast. The yeast generated in the process passes through distillation and in the whole stillage remains as yeast cell wall material. Corn fermented protein contains 25% yeast cell wall material of which 44% is protein in the dry matter, derived from a fermentation process. The yeast cell mannans and glucans when used in the rearing period help improve innate and adaptive immunity. CFP is an alternative protein with bioactive components. There are many claims for the benefits of fermentation in terms of improved digestibility and mineral availability of plant material. The feed industry requires concrete evidence of efficacy before it adopts a new product. Over 50 published trials have been completed to demonstrate how to formulate feeds using CFP as a replacement of a wide range of currently used protein supplements in diets for all classes of livestock and companion animals. A major part of this program has been to evaluate the use of CFP in aquaculture species and this presentation summarises the data generated in these trials.

**Results**

Digestibility trials (stripping collection methodology) were carried out with Rainbow Trout (*Oncorhynchus mykiss*), average weight 250g. Average of 5 separate trials. Ingredient apparent digestibility coefficients of each nutrient in the test diet and ingredients were calculated using the traditional formulas presented in Kleiber (1961) and Forster (1999) (Table1).

The digestibility of the protein is approximately 88% measured in salmon and trout. Growth trials have been completed with salmon, trout, tilapia, shrimp and juvenile channel catfish summarised in Table 2.

**Discussion and Conclusions**

The data indicates that CFP is an excellent alternative protein and can replace a range of currently employed protein materials for use in diets for a range of commercially important aquaculture species. There are three unique characteristics of the product that merit note. Corn fermented protein is the product of a 50-60h fermentation process which increases the digestibility of protein and availability of phosphorus. The yeast component of CFP provides additional health benefits and since the product is a co-product of the generation of renewable fuel, CFP has a uniquely low Carbon Index valuable in European formulations.

*(Continued on next page)*

# EDU-FISH - FISHERY EDUCATION AND PROMOTION PROGRAM IN POLAND

Dorota Fopp-Bayat, Anna Wiśniewska*

Department of Ichthyology and Aquaculture
Faculty of Animal Bioengineering
University of Warmia and Mazury in Olsztyn
Oczapowskiego 5
10-719 Olsztyn, Poland
E-mail: dariama@uwm.edu.pl

**Introduction**

A project called "Edu-fish fishery education and promotion program" acronym EDU-FISH has been implemented in Poland since October 2024 under Priority II of the European Maritime, Fisheries and Aquaculture Fund (FEDR) for 2021-2027. Project value: 23,910,692.96 PLN, including EU funding 16,661,036.05 PLN. The program was established through close cooperation of people concerned about the shortage of human resources in the fishing industry and the low number of candidates for fishery studies. A consortium of 3 fishery education institutions in Poland was formed in 2024: West Pomeranian University of Technology in Szczecin (ZUT) - Leader, the University of Warmia and Mazury in Olsztyn (UWM) and the School Complex in Sieraków (ZS), which prepared the EDU-FISH project.

**Material and Methods**

The main purpose of the EDU-FISH Program is to increase human resources potential in fisheries by preparing qualified specialists in fisheries, ichthyology and aquaculture. The stated goal will be achieved as a result of a large-scale promotional campaign to disseminate information on educational opportunities in the ichthyology profession and on professional qualifications obtained at the secondary level, enabling one to obtain the professional title of inland fisheries technician, and at the academic level, enabling one to obtain the professional degree of engineer or master. The proposed EDU-FISH program includes also material assistance in the form of funding for scholarships and wages for apprenticeships, purchase of computers and field clothes for students, the renovation of laboratory and teaching rooms, and the purchase of teaching apparatus and equipment.

**Results**

As part of the implementation of the program, more than 60 promotional activities were carried out, e.g.: participation in educational and industry events, for example: the Fishing and Survival Fair in Kielce 2024, the Fishing Fair Rybomania 2025 in Poznan, the Educational Fair Perspectives 2025 in Warsaw. As part of the promotional campaigns, many workshops and promotional demonstrations at the UWM Center for Aquaculture and Ecological Engineering in Olsztyn were also held for high school and elementary school students. The ichthyological education was also promoted during visits to high schools, including, the Forestry Technical School in Tuchola, the Complex of Schools of Environmental Formation and Agribusiness in Giżycko, the Complex of Schools of the Agricultural Training Center in Radom, and others. The promotion of the ichthyologist profession and education in the field of ichthyology and aquaculture consisted of sharing advertising leaflets and promotional gadgets, giving interviews and sharing educational and industry experiences. Another promotional elements are the promotional campaigns using social media, such as: Facebook, Instagram, Tik-tok, YouTube. Our activities enjoyed great interest, especially among people passionate about fish, angling or aquatics. The activities planned in the EDU-FISH program will make it possible to prepare a qualified workforce ready to achieve economic and social goals tailored to changing administrative and climatic conditions.

Funded by the European Maritime, Fisheries and Aquaculture Fund (FEDR) for 2021-2027" No: FEDR.02.01-IP.01-0001/24.

# OPTIMIZING GROWTH PERFORMANCE AND GUT MICROBIOME DIVERSITY IN JUVENILE ASIAN SEA BASS (*Lates calcarifer*) WITH DIETARY SUPPLEMENTATION OF MANNAN OLIGOSACCHARIDES, *Yucca schidigera* EXTRACT, AND SOLID-STATE FERMENTED *Aspergillus niger*

Li Lian Wong[1*], Gary Petol Felix[1], Philip Lyons[2], Henry Wong[3], Gang Lin[4], Noordiyana Mat Noordin[5], Yeong Yik Sung[1] and Muhd Danish-Daniel[1]

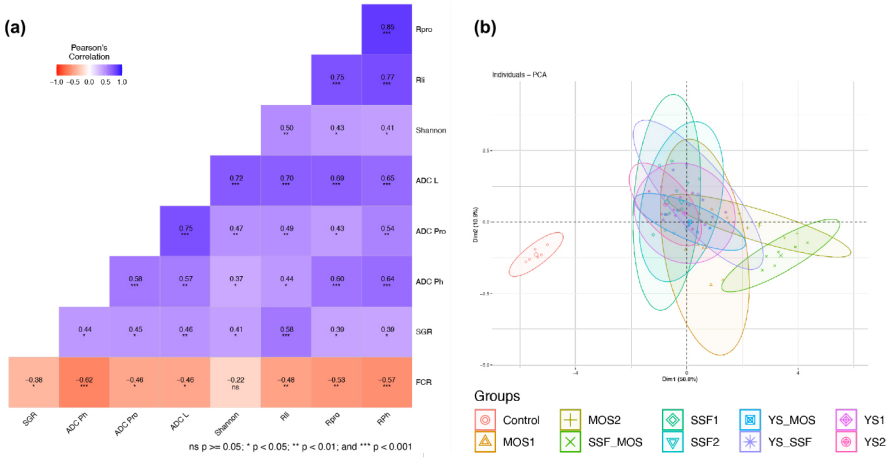
Email: lilian@umt.edu.my

Asian seabass (*Lates calcarifer*), a commercial marine species in Southeast Asia, is prized for its quick development and adaptability, but it is susceptible to various diseases, particularly in dense environments. This study investigated growth performance and gut microbiome diversity using 16S rRNA metagenomic analysis in juvenile Asian seabass supplemented with Mannan Oligosaccharides (MOS), *Yucca Schidigera* extract (YS), and Solid-State Fermented Aspergillus niger (SSF) to optimize aquaculture practices. Fish were fed commercial diets supplemented with ten additive compositions for 70 days, assessing growth performance, feed utilization, and survival. The YS_SSF group showed superior weight gain (WG = 36.05 ± 1.10) and specific growth rate (SGR = 1.36 ± 0.03), significantly outperforming the control group (WG = 24.79 ± 0.26, SGR = 1.07 ± 0.02, $P < 0.05$). Key genera linked to each diet were Burkholderiaceae and Weizmannia (YS_MOS), Enterobacterales and Pseudoalteromonas (SSF2), and Escherichia and Cytophagales (control). PICRUSt functional analysis revealed predominant pathways linked to amino acid and fatty acid biosynthesis as well as organic compound degradation. The Shannon index positively correlated with the Apparent Digestibility Coefficient (ADC) for phosphorus, protein, and lipids, as well as nutrient retention and growth rate. These results indicate MOS enhanced gut bacteria growth and nutrient digestibility; SSF enhanced feed efficiency from the breakdown of antinutrients; and YS promoted gut health and nutrient absorption. Combined feed additives, particularly SSF_MOS, showed great potential for promoting growth and feed efficiency in cultured fish.



# CONTROL OF PARASITIC SALMON LICE (*Lepeophtheirus salmonis*) THROUGH OPTICAL LASER-DELOUSING IN NORWEGIAN SALMONID AQUACULTURE

Martin Worm[1*], Jan Bulla[2,3], John Harald Pettersen[1] and Benedikt Frenzl[1]

## Introduction

Parasitic salmon lice (*Lepeophtheirus salmonis*) present a significant challenge for salmonid aquaculture in Norway. Allowable lice abundance in commercial farms is strictly regulated, and farmers must engage in extensive delousing operations to adhere to regulatory thresholds. The widespread development of resistance to most available treatment chemicals has driven the adoption of mechanical treatment alternatives, many of which negatively impact growth, health, and welfare of farmed fish. Controlling measures that effectively reduce salmon lice without negatively affecting health and quality of farmed fish may therefore increase profitability and reduce the environmental footprint of current farming practices. Optical delousing is an alternative method of lice control that does not require handling of the fish. The system utilizes machine vision and object detection algorithms to identify and remove mobile and adult sea lice stages with targeted laser pulses on freely swimming fish. It relies on mobile hardware components that are continuously deployed in commercial sea cages, where they are actively positioned close to the fish. Here, we empirically evaluate the need for lice treatments at sites with and without optical delousing.

## Materials and Methods

Operational data on lice treatments and lice abundance are publicly available for all aquaculture sites in Norway. We grouped public data from all reportable sites along the Norwegian coast in 2023 into production weeks and added whether optical delousing was used during each production week. To capture possible effects of optical delousing on treatment frequency, we selected generalized linear mixed effects models (GLMEs) and estimated the weekly probability of a treatment taking place, considering sea temperature and the presence of optical delousing as predictors.

## Results

Results showed that sites relying on optical delousing represented 10.9% of production weeks, but only 5.9% of treatment weeks. Adjusted for a sea temperature of 10°C, sites without optical delousing had a 10.1% weekly probability to require treatment. For sites with optical delousing, the weekly probability to require other forms of sea louse treatment was significantly reduced by 50% to 5.06%. These differences persisted despite a lower reliance on cleaner fish at sites with optical delousing and in the absence of any indication of an accompanying increase in lice abundance at these sites.

## Conclusion

In conclusion, we show that optical delousing can be an effective tool to control lice abundance in salmonid aquaculture along the Norwegian coast without stressful handling of the fish. This may both benefit the health of farmed fish and reduce lice infection pressure on wild salmonid populations.

# REARING STRESS IMPACTS THE ENDOCRINE REGULATION OF GROWTH AND MOLTING IN LITOPENAEUS VANNAMEI (BOONE, 1931)

S. Wuertz[*a], P. Gamberoni[a,b,c], M. Boegner[c], D. Bierbach[a,b,d], M. J. Slater[c], H. Kuhl[a]

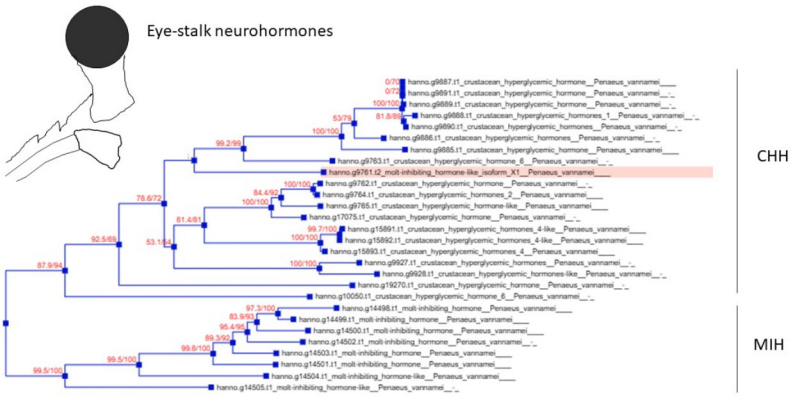
Email: wuertz@igb-berlin.de

Introduction:
Shrimp farming rapidly increased over the past decade, currently comprising 6.8 billion t in Whiteleg shrimps Litopenaeus vannamei alone [1]. At the same time, concerns about the animal welfare have been raised and legislation on farming has been constantly adapted in several countries. Indeed, suboptimal rearing conditions are often not noticed due to lacking criteria and methods [2, 3]. In the interdisciplinary project CrustaWohl we studied stress-related behaviors, easy-to-monitor morphological abnormalities and injuries as well as the molecular basis of chronic stress, focusing on the eye-stalk as endocrine center regulating growth and molting in crustaceans.

Material and Methods:
After three weeks of acclimatization, juvenile Whiteleg tiger shrimps (14.73 ± 0.36 g) were transferred to twelve 600L tanks arranged in a RAS (water exchange one V/h; water renewal 2%/d) with a biofilter, UV disinfection, protein skimmer, drum filter and an ozone generator, providing three experimental groups reared at different stocking densities (low density (LD): 1 kg/m$^2$, medium density (MD): 2kg/m$^2$, high density (HD): 4 kg/m$^2$) and assessed in 4 replicates each.

For sampling, shrimps were euthanized in an ice slurry solution, weight and length were recorded and the molting stage was determined according to Robertson et al. (1987) with a binocular. Only shrimps in the intermolt and early premolt (D0-D1-D2) stages were selected. The eye-stalk was dissected and total RNA was extracted as described in Gamberoni et al. (2025). Library construction and RNAseq was performed by Novogene (Germany). RNAseq reads were mapped by hisat2 and expression analysis was done by cuffdiff using 5 biological replicates for each condition.



Neurohormones identified by RNAseq analysis. The CHH/MIH upregulated in response to chronic stress is marked in red.

*(Continued on next page)*

Results and Discussion:

In the eye-stalk as endocrine center for the regulation of growth and molting we identified 28 neurohormones of the crustacean neurohormone family, including 20 crustacean hyperglycemic hormones (CHH), 8 molt inhibiting hormones (MIH). Among all differentially expressed genes in the eye-stalk, a CHH formerly identified as MIH was up-regulated in the HD group. In crustaceans, the CHH controls blood sugar but also plays a role in molting. Interestingly, the resulting inhibition of growth may thereby shift energy to compensate for the persistent stressor and may function similarly to cortisol in vertebrates increasing plasma sugar in response to stress. Also, a significant growth inhibition was observed at progressively increasing density - both in the HD and MD groups - congruent with this hypothesis. As a conclusion, we believe that this CHH/MIH inhibits growth and molt and regulates hemolymph sugar, shifting energy to compensate chronic stress impact.

**Introduction**

This abstract introduces two documents developed to support the European Commission's (EC) "*Strategic guidelines for a more sustainable and competitive EU aquaculture for the period 2021 to 2030*"[1]. The two documents are the result of a desk study and an extensive consultation process with scientific experts and stakeholders including the Aquaculture Advisory Council (AAC).

**Methodology**

The "Good Husbandry Practices for aquaculture" document was developed by the EU Aquaculture Assistance Mechanism (AAM) through extensive data collection. It is a desk study and a literature review on published reports and peer-reviewed papers on EU and international regulations, standards and industry guidelines. In addition, an online survey targeting EU member states and the AAC, yielding 21 responses was conducted. Expert input was gathered through a cluster meeting with relevant EU-funded project representatives and AAM Board of Ambassadors members, leading to a second survey with 4 additional contributions and the identification of criteria for prioritizing information sources. Bilateral meetings were held with the Aquaculture Stewardship Council (ASC), the European Forum of Farm Animal Breeder (EFFAB), experts from the "Comité National de la Conchyliculture" (CNC), and a workshop with member state experts was organized by the European Commission. Furthermore, technical seminars with member state aquaculture experts and feedback from various associations and experts contributed to the document. The final good husbandry practices (GHPs) selection prioritized concrete industry examples, standards, and relevant project results.

The document on "Code of Good Practices on fish welfare and fish welfare indicators" was developed based on the "Document on Good Husbandry Practices" published on the EU aquaculture website in 2024 and the EU AAM's work on fish welfare good practices and indicators based on relevant data collections. This involved desk research and literature reviews published by international organizations on standards, and industry guidelines from EU member states, Norway, and the UK. Furthermore, an online survey targeting these countries and relevant stakeholders yielded 36 responses. The preliminary findings were then discussed and refined through an expert consultation meeting with representatives of relevant EU-funded projects and AAM Board of Ambassadors members, and the final document was reviewed by the Directorate-General for Health and Food Safety (DG SANTE) and experts from the European Union Reference Centre for Welfare of Aquatic Animals (EURCAW-Aqua).

**Document "Good husbandry practices for aquaculture"**

This document systematically outlines a range of critical husbandry practices essential for maintaining and enhancing the health and welfare of farmed aquatic animals throughout their production cycles. This extends beyond the explicitly mentioned "environmental enrichment (EE)," "functional feed (FF)," and "selective breeding (SB)" in the EU's "Strategic Guidelines for Aquaculture 2021-2030", encompassing fundamental aspects such as feeding regimes (optimizing quantity, rate, and distribution), handling procedures (minimizing stress and physical trauma), mortality management (efficient and hygienic removal), fallowing strategies (disease and parasite control), predator mitigation (prioritizing non-lethal methods), biosecurity protocols (minimizing escapes and disease transmission), water quality management (maintaining species-specific parameters), stocking density optimization (balancing welfare and production), disinfection and cleaning protocols (disease prevention), and prophylactic and therapeutic interventions (vaccination and treatments under veterinary supervision). These multifaceted topics are evaluated through the prism of the widely recognized five welfare domains: nutritional adequacy, environmental quality,

*(Continued on next page)*

health status, behavioral expression, and overall mental state, with the overarching aim of ensuring a high standard of life for farmed aquatic organisms. It systematically maps and compiles a non-exhaustive repertoire of general and species-specific good husbandry practices (GHPs) pertinent to the welfare and health of key European aquaculture species across diverse production methodologies. This compilation, encompassing species such as Common Carp (*Cyprinus carpio*), Rainbow trout (*Oncorhynchus mykiss*), Atlantic salmon (*Salmo salar*), European sea bass (*Dicentrarchus labrax*), Gilthead sea bream (*Sparus aurata*), Mussels (*Mytilus* spp)., and cleaner fish (*Labrus bergylta* and *Cyclopterus lumpus*) aims to provide practical support to operators in meeting and potentially exceeding fundamental legal obligations concerning animal health, welfare, and environmental impact, with a commitment to future updates incorporating additional good practices and relevant indicators. Chapter 4 presents 40 general GHPs and Annex II provides species-specific GHPs for the following species: Common Carp: 19, Rainbow trout: 22, Atlantic salmon: 27, European sea bass: 20, Gilthead Sea bream: 24, Mussels: 8, Ballan wrasse: 6, Lumpfish: 10.

**Code of good practices on fish welfare and fish welfare indicators**

This document serves as a complementary resource to the first GHP document. It delineates non-species-specific best practices for the welfare of farmed fish and the indicators employed in its assessment throughout various ontogenetic stages and production techniques. Developed through a collaborative effort between the EU AAM and the EURCAW-Aqua, this Code functions as a practical and accessible guide for aquaculture producers. Its focus is deliberately restricted to explicit welfare considerations, excluding aspects of fish health. The document details specific good practices related to these topics, feeding, handling, grading, water quality (including physicochemical and microbiological parameters), stocking density, mortality removal, and transport (pre-transport, loading/unloading, and during transport), totaling seventy-three distinct practices aimed at improving fish welfare in aquaculture. The document provides detailed expositions of each GHP topic, elucidating its significance for animal well-being. Chapter 4 outlines general, non-species-specific good practices for fish welfare in aquaculture, addressing topics from the preceding chapter. This Code introduces in Chapter 5 thirteen general, non-species-specific indicators relevant to the key husbandry topics. These indicators are crucial for monitoring animal well-being during critical production phases, including rearing, transport, and slaughter, enabling evidence-based evaluation of current practices and the implementation of targeted improvements. The document reviews existing scientific efforts and tools for welfare assessment, emphasizing the ongoing need for standardized, technology-driven, and universally applicable monitoring protocols to enhance the reliability and comparability of welfare evaluations across the EU aquaculture sector.

**Conclusion**

Both documents are fundamentally aligned with the objectives of the EU's "Strategic Guidelines for Aquaculture 2021-2030", sharing a common goal of augmenting the sustainability and competitiveness of the European aquaculture sector through evidence-based guidance derived from broad stakeholder engagement. The "Good Husbandry Practices" paper provides species-specific recommendations for health and welfare management, whereas the "Code of Good Practices" offers overarching, non-species-specific principles and indicators specifically for fish welfare, representing a concerted effort towards elevating animal welfare standards and fostering responsible practices within the European aquaculture industry.

# FUNCTIONAL DIVERSITY OF METHYL-END DESATURASES EN ANNELIDA REVEALS THEIR POTENTIAL FOR SUSTAINABLE LC-PUFA PRODUCTION IN AQUACULTURE

Wenxuan Xu*, Marc Ramos-Llorens, Juan C. Navarro, Óscar Monroig

Instituto de Acuicultura Torre de la Sal (IATS), CSIC
12595 Ribera de Cabanes
Castellón, Spain
E-mail: wxu728@gmail.com

**Introduction**

Long-chain ($\geq C_{20}$) polyunsaturated fatty acids (LC-PUFA) are essential nutrients with critical roles in neural function, immune regulation, and cellular membrane structure (Tocher et al., 2019). With increasing demand for sustainable LC-PUFA sources in aquaculture, especially for formulating nutritionally enriched feeds, exploring new biological systems capable of de novo LC-PUFA synthesis has become a critical research priority (Tocher et al., 2019). While vertebrates predominantly rely on dietary intake for LC-PUFA, certain invertebrates, including aquaculture-relevant annelids such as *Hediste diversicolor* and *Platynereis dumerilii*, possess endogenous biosynthetic pathways involving methyl-end desaturases (ωx), front-end desaturases (Fed), and elongases (Elovl) (Monroig et al., 2022). Among these, the diversity and functionality of ωx desaturases in Annelida remain underexplored (Kabeya et al., 2018). This study investigated the diversity and function of ωx desaturases in annelids across three major classes in Annelida: Polychaeta, Clitellata, and Sipuncula.

**Materials and Methods**

The sequences of ωx desaturase genes were retrieved from available annelids' genomic and transcriptomic databases. Conserved motifs were identified, and phylogenetic relationships were established. The functions of representative genes were heterologously expressed in yeast. The ωx desaturation activity was evaluated through substrate feeding assays and gas chromatography-mass spectrometry (GC-MS) fatty acid profiling.

**Results and Discussion**

A total of 109 sequences of ωx desaturase genes were isolated from annelids. Phylogenetic analyses grouped them into two main desaturase groups (A and B) (Figure 1). Functional characterisation revealed distinct enzymatic activities of five ωx desaturase genes from two representative species, *Eisenia fetida* and *Sipunculus nudus*: *E. fetida* ωx1 and *S. nudus* ωx1 exhibited Δ12 desaturase activity, catalysing the conversion of 18:1ω9 to 18:2ω6, whereas *E. fetida* ωx2, *S. nudus* ωx2, and *S. nudus* ωx3 demonstrated ω3 activities (Δ15, Δ17, and Δ19 activities), transforming ω6 substrates into their corresponding ω3 fatty acids, including eicosapentaenoic acid (EPA, 20:5ω3) and docosahexaenoic acid (DHA, 22:6ω3). The number of ωx desaturase genes varied among species in Annelida. While most species typically possessed two desaturases—one Δ12 and one ω3—some species harbored 0, 1, 3, or even 4 ωx desaturase genes. The study confirms that annelids harbor diverse ωx desaturases capable of producing a broad range of LC-PUFA. The taxonomic distribution and functional plasticity of these enzymes suggest that annelids represent a valuable but underexploited resource for sustainable omega-3 fatty acid production. This work provides a foundation for future biotechnological exploitation of annelids in aquafeed formulation and contributes to circular economy models in aquaculture.

*(Continued on next page)*

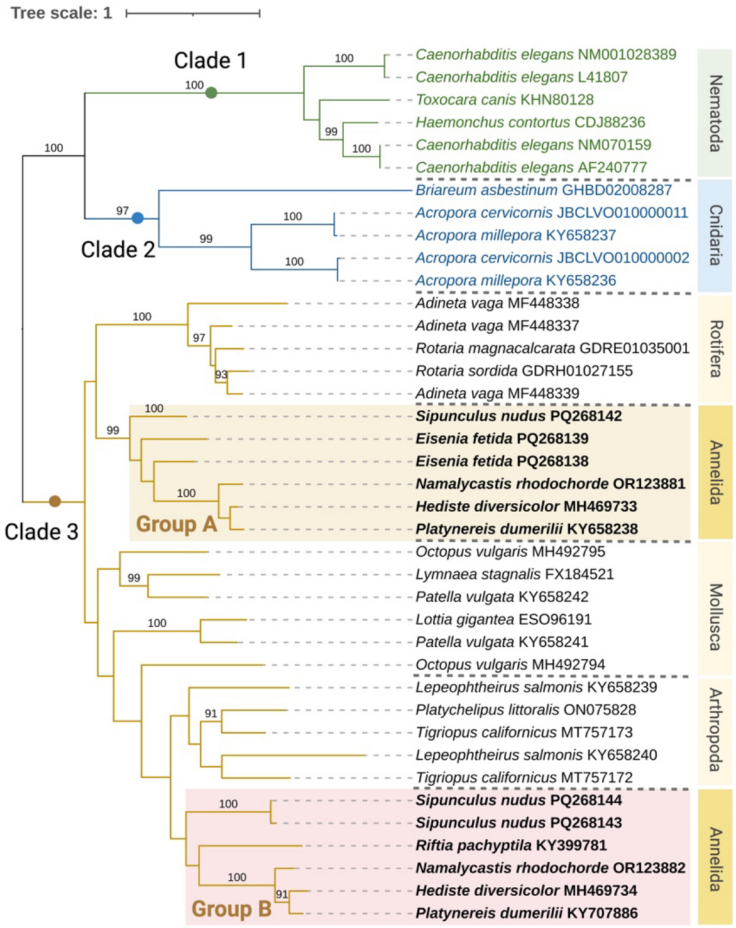

**Figure 1.** The phylogenetic tree of wx desaturase enzymes in Metazoa shows the evolutionary relationship between Annelida and other phyla of animals (Nematoda, Mollusca, Rotifera, Anthropoda, and Cnidaria). Clades 1, 2, and 3 were classified according to Kabeya et al. (2018). The numbers above indicate branches in the phylogenetic tree with support values equal to or exceeding 90%.

**Introduction**

Due to declining fish oil (FO) availability, sustainability concerns, and rising costs, the increasing demand for sustainable aquaculture requires replacing FO with alternative lipid sources such as vegetable oils (VO). To support this shift, the aquafeed sector increasingly aligns with the "Farm to Fork" Strategy, part of the broader European Union Green Deal. However, marine fish have a limited capacity to elongate and desaturate C-18 fatty acids and, therefore, require a dietary source of n-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFAs) to maintain growth and health. Ethyl esters (EE) oil, a by-product of human omega-3 supplement production from FO, is a promising source of n-3 LC-PUFAs. In the process of FO refining for n-3 LC-PUFA extraction for supplements to be used by humans, about 70% of FO is discarded as an EE oil by-product. This oil is rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (around 5-7%), cholesterol, and vitamin D, offering advantages over VO as a lipid source for marine fish. However, EE oil may not be as bioavailable as FO and VO triglycerides. Therefore, this study aimed to evaluate the effects of dietary inclusion of EE oil as a partial or total replacement of FO in European seabass diets.

**Materials and Methods**

Four isoproteic (48% crude protein) and isolipidic (16% crude lipid) practical diets were formulated, differing in lipid sources, as follows (% total lipid inclusion):

Diet 1 (D1): 72% FO, 28% rapeseed oil (RO), and 0% EE oil;
Diet 2 (D2): 28% FO, 72% RO, and 0% EE;
Diet 3 (D3): 28% FO, 44% RO, and 28% EE;
Diet 4 (D4): 0% FO, 28% RO, and 72% EE.

Chromic oxide was added as an external digestibility marker to the diets.

The experiment was performed at CIIMAR, Matosinhos, Portugal, and consisted of a growth trial and a digestibility trial. The growth trial was performed in a recirculating aquaculture system (RAS) at 23ºC for 88 days. Each diet was randomly assigned to three replicates, with fifteen European seabass (*Dicentrarchis labrax*) juveniles (initial body weight: 62g) per tank. Five fish from the initial stock population and three fish per tank at the end of the growth trial were euthanized (overdose of 2-phenoxyethanol), and the weight of the fish, liver, and viscera were recorded. Fish were then stored at −20 °C for whole-body composition analysis. The digestibility trial was also conducted at 23ºC in the RAS. Twelve groups of ten fish with an average weight of 161 g were established, and feces were collected over 15 days. Statistical analysis of the data was performed using one-way ANOVA. When $p < 0.05$, means were compared with Tukey's multiple-range test. All analyses were done with SPSS 29.0 software for Windows (IBM® SPSS® Statistics, New York, USA).

**Results**

Fish readily accepted the diets, and mortality during the trial was low and unaffected by diet composition. Final body weight, weight gain, and daily growth index showed no significant differences between dietary treatments. Feed intake, feed efficiency, protein efficiency ratio, nitrogen, and energy retentions (% intake) were also unaffected by dietary treatments. The hepatosomatic index and visceral somatic index, and the whole-body composition (dry matter, protein, lipid, ash, and energy) were also unaffected by dietary treatments. Moreover, the apparent digestibility coefficients (ADC) for dry matter, protein, lipid, and energy were similar between diets.

*(Continued on next page)*

## Conclusion

The present results indicate that EE oil can be included in diets for European seabass without compromising growth performance, feed utilization, or nutrient digestibility, highlighting its potential as an alternative to FO in aquafeeds.

## Introduction

The nutritional quality of dietary lipids plays a critical role in regulating physiological functions by modulating tissue fatty acid composition, metabolism, inflammatory and immunological responses, and cellular oxidative balance. The selection of dietary lipid sources influences growth performance and key health-related responses. In marine fish, fish oil (FO) remains the standard lipid source for providing essential n-3 LC-PUFA, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). However, alternative lipid sources have emerged as potential substitutes. Ethyl esters (EE) oil is a sub-product of omega-3 production for human consumption and may be valorized as an alternative lipid source in the context of a circular economy. EE oil differs from FO in molecular structure, which may alter its biological efficacy. Marine fish species rely on dietary sources of n-3 LC-PUFA to meet fatty acid requirements, as they cannot synthesize it from C18 precursors. Thus, understanding how EE oil impacts lipid metabolism and redox status is essential for optimizing feed formulations. This study explores the effects of partial or total FO replacement with EE oil on the fatty acid profile, plasma metabolites, and hepatic oxidative stress of European seabass (*Dicentrarchus labrax*), an important species for Mediterranean aquaculture.

## Materials and Methods

Four isonitrogenous (48% crude protein) and isolipidic (16% crude lipids) diets were formulated by varying the proportions of FO, rapeseed oil (RO), and EE oil in the total lipid blend, as follows (% total lipid inclusion): D1 (72% FO, 28% RO, 0% EE; EPA+DHA=12.8% FA), D2 (28% FO, 72% RO, 0% EE; EPA+DHA=4.2% FA), D3 (28% FO, 44% RO, 28% EE; EPA+DHA=4.9% FA), and D4 (0% FO, 28% RO, 72% EE; EPA+DHA=3.6% FA). Juvenile European seabass (*Dicentrarchus* labrax) with ~ 62 g initial body weight were randomly distributed into three replicate tanks under controlled temperature (23°C) in a RAS system for 88 days. Fish were fed to apparent satiation twice daily. At the end of the trial, blood, muscle, and liver samples were collected from three fish per tank for biochemical, fatty acid profile, and oxidative stress analysis. Statistical differences among treatments were evaluated by one-way ANOVA and Tukey's test when $p < 0.05$, using SPSS 29.0 (IBM® SPSS® Statistics, New York, USA).

## Results

The zootechnical performance of the animals was not the aim of this study, and the results are presented in another work at this conference. Briefly, diet composition did not affect growth performance and whole body composition. The fatty acid profile of muscle and liver tissues reflected dietary lipid sources and exhibited statistically significant differences. In the muscle, α-linolenic acid (ALA, C18:3n-3) levels were significantly higher in fish fed the D2 and D3 diets compared to D4 and D1 diets. However, EPA (C20:5n-3) levels were significantly higher in fish fed the D4 diet than in D2 diet, whose values were comparable to D1 diet. DHA (C22:6n-3) was highest in fish fed the D1. In the liver, saturated fatty acids (SFA), such as C14:0 and C16:0, were significantly increased in fish fed the D4, leading to the highest total SFA, while D2 showed the lowest level. Monounsaturated fatty acids (MUFA), particularly C18:1n-9, were significantly increased in fish fed the D2. Plasma glucose concentration was significantly higher in fish fed the D2 than in D3 diets. In contrast, total protein, triglycerides, total lipids, and cholesterol remained unaffected by dietary treatments. Liver oxidative stress biomarkers showed that glutathione reductase activity and lipid peroxidation levels were significantly lower in fish fed the D4 than in the D1 diets. No significant differences were observed for glutathione peroxidase (GPX), catalase (CAT), and superoxide dismutase (SOD) among the dietary treatments.

*(Continued on next page)*

## Conclusion

EE oil inclusion in European seabass juvenile diets altered tissue fatty acid profiles, reducing DHA and total n-3 PUFA compared to a FO-based diet. However, EPA levels were maintained, and hepatic lipid peroxidation was reduced. Overall, these results suggest the potential for dietary inclusion of EE oil in marine fish diets.

**Introduction**
Marine heatwaves driven by climate change threaten aquaculture sustainability in Mediterranean species such as European seabass (*Dicentrarchus labrax*) by disrupting physiological homeostasis, particularly metabolism and oxidative balance. Nutritional strategies to improve thermal resilience are increasingly needed. Fish oil (FO), rich in n-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFA), namely eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), faces sustainability challenges and is increasingly being directly used for human consumption. Ethyl esters (EE), by-products from FO refining for omega-3 supplement production, have recently emerged as a potential alternative lipid source. EE oil is rich in EPA and DHA, which are present as ethyl esters rather than triglycerides, and this may influence bioavailability under heat-stress conditions. Thermal stress can alter membrane fluidity, whose composition is modulated by the dietary lipid source. Previous studies have shown that EE oil has potential as a lipid source under normal temperature conditions, but its impact during thermal challenges has not yet been explored. This study evaluated the effects of dietary EE oil on body composition, fatty acid profile, and liver oxidative stress in seabass under simulated heatwave conditions.

**Materials and Methods**
Four diets were formulated as isoproteic (48% crude protein) and isolipidic (16% crude lipid), and the lipid sources (% total lipid) were as follows: D1 (72% FO, 28% rapeseed oil, RO; EPA+DHA=12.8% FA), D2 (28% FO, 72% RO; EPA+DHA=4.2% FA), D3 (28% FO, 44% RO, 28% EE; EPA+DHA=4.9% FA), and D4 (28% RO, 72% EE; EPA+DHA=3.6% FA). Firstly, a growth trial was performed at 23 ºC for 88 days with European seabass (*Dicentrarchus* labrax) juveniles with an initial weight of 62g. Then, a thermal challenge was imposed in two phases: 29 ± 0.5 °C for 7 days, followed by 31 ± 0.5 °C for 7 days. At the trial end, three fish per tank were euthanized (overdose of 2-phenoxyethanol) for measurement of body, liver, and viscera weights for hepatosomatic index (HSI) and viscerosomatic index (VSI), and whole-body composition (dry matter, crude protein, lipids, ashes, and energy). Liver and muscle were sampled from 3 other fish per tank to assess fatty acid profiles, and liver oxidative stress biomarkers, including glutathione peroxidase (GPX), glutathione reductase (GR), catalase (CAT), superoxide dismutase (SOD), and lipid peroxidation (LPO). Data was evaluated by one-way ANOVA and Tukey's test ($p < 0.05$) using SPSS 29.0 software for Windows (IBM® SPSS® Statistics, New York, USA).

**Results**
Under the thermal challenge, dietary treatments had no significant differences in whole-body dry matter, protein, lipids, ash, gross energy content and VSI. The HSI was significantly higher in D4 than in D2. Fatty acid profiles of muscle and liver reflected dietary lipid composition: DHA and total n-3 PUFA levels were significantly reduced in both tissues of fish fed the D4 diet. In muscle, EPA was higher in D4 than in the D2 and D3 diets but remained lower than in the D1. In the liver, EPA, DHA, and total n-3 PUFA were significantly reduced in fish fed the D4 diet compared to the D1 diet. In contrast, saturated fatty acids (SFA) increased significantly in D4, resulting in the highest SFA levels among all dietary treatments. Liver oxidative stress enzymes and LPO levels did not differ significantly among dietary treatments.

**Conclusion**
In conclusion, dietary EE oil inclusion altered tissue fatty acid composition, particularly reducing n-3 LC-PUFA and increasing SFA levels, without markedly affecting whole-body composition and oxidative stress responses under thermal challenge.

## Introduction

Body shape is a critical trait in aquaculture breeding and management, as it influences both the biological performance and the market value of fish. Body shape can vary considerably due to environmental conditions, and can be influenced by artificial selection. Shape can therefore serve as an indicator to study environmental adaptation of certain species. For species that are marketed as whole, shape is particularly important as it influences consumers' preference and the perceived quality of the product (Colihueque & Araneda, 2014).

However, the definition and quantification of body shape remains complex. Shape is not a single trait but a collective expression of various morphological attributes. In flatfish such as sole, shape can often be approximated with simple geometric measurements such as fitting an ellipse. For finfish such as gilthead seabream, shape quantification becomes more challenging and typically relies on multiple indicators derived from landmarks, ratios or manually annotated traits (Fragkoulis et al., 2021). These indicators might exhibit low genetic correlation with the shape outline and are not favoured by breeders for indirect selection.

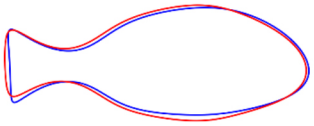

**Figure 1** Blue: average best contour; Red: average worst contour.

Besides quantitative measurements, shape is also assessed in breeding programs through expert grading, where visual scores are assigned based on pre-defined criteria. While this method reflects practical and market driven evaluations, it might suffer from subjectivity and low resolution (Blonk et al., 2010), restricting the coefficient of variation available for selection.

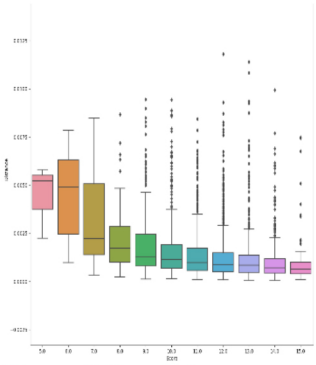

**Figure 2** Correlation between scores and DtB. X-axis: the combined score of all traits, ranging from 5 to 15; Y-axis: DtB value.

To overcome these limitations, we propose an analytical pipeline for automated quantitative analysis of the body shape in gilthead seabream (Sparus aurata). Based on the manual scores on selection candidates and their images, we defined a "Best" outline and a "Worst" outline and subsequently derived two novel traits for selection candidates: Distance to the Best (DtB) and Distance to the Worst (DtW). These traits quantify how closely each individual resembles the most, or least, desirable shape. Furthermore, we demonstrate that both traits exhibit genetic variance and can be integrated into breeding programs for shape improvement.

## Materials

Images were collected in 10 batches at harvest from 3,421 gilthead seabream (*Sparus aurata*), all of which were breeding candidates with known pedigree information. Each fish was visually scored on five morphological traits: head, ventral side, peduncle fin, caudal peduncle, and caudal side. Scores ranged from 1 to 3, with a score of 3 indicating the ideal condition for each trait.

## Methods

For each image the fish was segmented from the background using the Segment Anything Model (SAM). Contour detection was then performed using OpenCV, and Elliptic Fourier Descriptors (EFD) were applied to mathematically transform the extracted contours. Each contour was reconstructed using seven harmonics of the EFD, producing a smooth outline with 1,000 key points.

*(Continued on next page)*

The reconstructed contours were standardized in orientation using Principal Component Analysis (PCA), aligning them according to their first and second principal components. To ensure consistency, all key points on the contours were re-indexed starting from the anterior tip and proceeding clockwise.

An average contour was generated via Procrustes analysis using only the fish that received a score of 3 for all traits. The Procrustes distance from each individual's contour to this average was calculated and defined as a new trait: **Distance to the Best (DtB)**. The same process was repeated using contours from fish that received a score of 1 for all traits, producing a second trait: **Distance to the Worst (DtW)**. All image processing and distance calculations were conducted in Python 3.9.

Heritability estimates for DtB and DtW were obtained using a univariate animal model, and their genetic correlations with the original visual scores were calculated using a bivariate model. All genetic analyses were performed using ASReml-R.

**Results**

Figure 1 illustrates the average contours for the best-scoring and worst-scoring fish. The heritability estimates were $0.39 \pm 0.04$ for DtB and $0.27 \pm 0.03$ for DtW.

We evaluated the agreement between DtB and the original visual scores, with a particular focus on DtB. As shown in Figure 2, there was a general negative correlation between DtB and the manual scores, with a significant Pearson correlation of -0.12, indicating that higher-scoring fish tended to be closer to the ideal contour, with a smaller DtB value.

Genetic correlations of DtB and DtW with the original trait scores ranged from low to moderate. For example, the dorsal side score showed near-zero genetic correlation with both DtB and DtW, suggesting limited variance or low consistency in the manual grading for this region. In contrast, the ventral side score exhibited moderate genetic correlations: $-0.36 \pm 0.08$ with DtB and $0.27 \pm 0.03$ with DtW, indicating greater phenotypic and genetic variance in that area. This trend is visually supported by the contour plots in Figure 1, where the greatest divergence between best and worst shapes occurs along the ventral region. In comparison, the dorsal contours appear more aligned and parallel, suggesting lower shape variance and scoring sensitivity in that region.

# A VIRTUAL FARM TO SUPPORT CLIMATE CHANGE ADAPTATION STRATEGIES IN SALMON AQUACULTURE

Suleiman O. Yakubu*, Elisabeth Ytteborg, Lynne Falconer

*Institute of Aquaculture
University of Stirling
Stirling FK9 4LA, Scotland, UK
E-mail: s.o.yakubu1@stir.ac.uk

**Introduction**
Climate change impacts farmed salmon in open net-pens through stressors like increased temperature, pH and storms. To adapt, the industry needs robust tools that can help to better understand complex interactions between the farm environment and production factors. This study developed a dynamic simulation tool (Virtual Farm) which can serve as a digital representation of salmon production in open net-pen system, allowing for experimentation and analysis of management and climate adaptation strategies. The criteria for comparing between different strategies are set by users based on the chosen performance indicators such as dissolved oxygen (DO) level in the net-pen, standard feeding rate, disease risk period and average daily weight gain by the fish.

**Methods**
The Virtual Farm model was constructed using Vensim DSS 10.2.1 simulation software. The main components and feedback structure of the model were first captured in a causal loop diagram (CLD), based on information gathered from both stakeholder engagements and the literature. Then following the CLD, the Virtual Farm model was developed using stocks, flows, feedback loops and time delays that are connected using mathematical relationships derived from knowledge and data about real farm system interactions. The differential equations in the model are solved using Euler integration method, with a one-day simulation time step to reflect daily and seasonal dynamics of the model parameters. Data loggers were deployed at three salmon farm locations on the west coast of Scotland and used to collect data on sea temperature and dissolved oxygen (DO) for model calibration and validation.

The model requires the user to input time-series data for seawater temperature, salinity, wind speed, chlorophyll-a, and water current speed as well as initial values for DO and production related factors like stocking weight, to simulate DO dynamics in the farm environment. The farm environment determines how an individual fish in a net-pen would respond in terms of feed intake, metabolism, growth, and then scaled up to the population level to simulate overall implications for farm production (total biomass and potential risk periods).

**Results and Discussion**
Results show that the modelled DO compare well to measured data at the three farm locations. Further model testing and refinement is underway through an iterative process and consultation with industry stakeholders.

The Virtual Farm model is designed to simulate the effects of multiple stressors (environmental and operational) and can help farmers and researchers to better understand and respond to climate change impacts on salmon production.

[5]Jeju Bio Research Center, Korea Institute of Ocean Science and Technology (KIOST), Jeju 63349, Republic of Korea

E-mail: hsyang@kiost.ac.kr

*Turbo sazae*, a commercially and ecologically important marine gastropod historically found around Jeju Island, has recently shown signs of northward range expansion along Korea's eastern coast, likely driven by rising seawater temperatures. Concurrently, populations in Jeju have experienced a marked decline, with potential links to environmental stressors remaining unclear. To better understand the biological responses of *T. sazae* to changing thermal environments, this study integrated cellular immunological analysis and genetic connectivity assessments. Experimental exposure to elevated seawater temperatures (22°C–30°C over 9 days) revealed significant physiological stress, including reduced hemocyte phagocytic activity and increased reactive oxygen species (ROS) production. In parallel, mitochondrial COI sequence analysis from six populations across Jeju and the East Sea indicated genetic connectivity potentially facilitated by ocean currents, with a dominant shared haplotype (EJ1) suggesting historical gene flow. Despite low genetic differentiation, ancient divergence between populations was inferred, emphasizing the importance of ongoing genetic monitoring. Together, these findings underscore the dual impact of thermal stress on immune function and potential climate-mediated range shifts in *T. sazae*, calling for comprehensive conservation strategies.

# COMPARATIVE STUDY ON THE EFFECTS OF DL-METHIONINE AND HMTBa AS DIETARY METHIONINE SOURCES: GROWTH PERFORMANCE, FEED EFFICIENCY, AND ANTIOXIDANT ACTIVITY IN SIBERIAN STURGEON

Peyman Yarahmadi[a*], Amin Mansouri[a], Jalal Hassan[b], Ali Shojaei[a], Mohamad Sadraei[a]

[a]Arona chemie Co., Iran, Tehran
[b] Department of Comparative Biosciences, Faculty of Veterinary Medicine, University of Tehran, Tehran, Iran
*Email: Peyman.Yarahmadi@arona-chemie.com

This study evaluated the effects of DL-Methionine (DL-M) and 2-hydroxy-4-(methylthio)butanoic acid (HMTBa) as dietary methionine sources on growth performance, feed efficiency, and antioxidant activity in Siberian sturgeon (*Acipenser baerii*).

Experimental diets were formulated using equimolar quantities of each methionine source, incorporated into a commercial basal diet. Fish were fed four times daily according to the manufacturer's guidelines for 75 days. A total of 560 sturgeon (initial weight 961.41 ± 73.27 g) were allocated to 14 outdoor pools (two treatments, seven replicates). Environmental conditions were maintained consistently throughout the study.

Results showed no significant differences in final body weight, weight gain, or feed conversion ratio between the DL-M and HMTBa groups ($p > 0.05$). However, serum catalase (CAT) activity and total antioxidant capacity (TAC) were significantly higher in the HMTBa group ($p < 0.05$), while glutathione peroxidase (GPx) activity was higher in the DL-M group ($p < 0.05$).

In conclusion, HMTBa was as effective as DL-Methionine in promoting growth performance and enhancing antioxidant activity in Siberian sturgeon. These findings suggest that HMTBa is a viable alternative methionine source for sturgeon aquaculture.

# REMOTE MONITORING OF OFFSHORE AQUACULTURE STRUCTURES USING LOAD CELL SENSORS

Yassine Yazid*, Rosa Martínez Álvarez-Castellanos, Ivan Felis-Enguix

Marine Technology Center (CTN)
Spain
*yassineyazid@ctnaval.com

## Introduction

Offshore aquaculture cages are increasingly subjected to harsh marine conditions such as strong currents, wave action, and storm-induced loads, which threaten their structural integrity and can lead to significant economic losses, fish escape, safety hazards, and environmental damage [1]. To address these challenges, this study presents a real system deployment of a structural health monitoring solution that uses load cell sensors to measure cage tension and communicates data remotely via satellite. By integrating real-time sensing with satellite communication, the system enables continuous monitoring of environmental dynamics and timely detection of stress events in offshore fish cages.

## Materials and Methods

The load cell sensor is deployed on offshore fish cage mooring lines to measure tension in real time. The sensor, securely anchored to the seabed, connects via a waterproof cable to a data logger housed on a floating buoy. Data collected by the sensor is transmitted through satellite communication to a cloud server, enabling remote access through a dedicated web interface. Figure 1 illustrates the physical components of the system, the data transmission flow, and includes photographs that depict the real deployment of the buoy, anchor, and sensors in the field.

## Results and Discussion

Figure 2 presents a time series of load measurements captured by the deployed monitoring system, specifically showing the tension exerted on the floating buoy anchoring point. These values, transmitted via satellite, reflect how the buoy responds to changing marine conditions such as waves, currents, and wind. Peak loads exceeding 250 kg were observed during periods of intense environmental activity, followed by a gradual decline and stabilization—likely indicating calmer sea states or repositioning of the buoy.

This real-time monitoring demonstrates the system's effectiveness in capturing dynamic forces acting on offshore infrastructure. Satellite-based communication ensures uninterrupted data delivery, enabling remote analysis and early detection of abnormal stress levels on the buoy and the fish cages. Such insights are critical for maintaining system stability, guiding preventive maintenance, and improving the resilience of floating structures in offshore aquaculture operations.

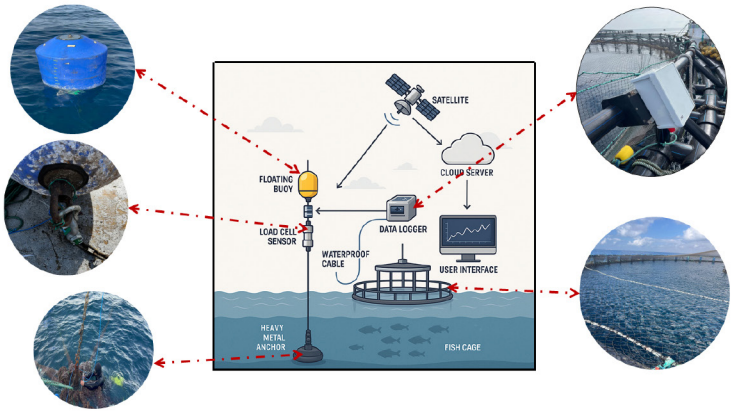

*Figure 1: Overview of the Smart Mooring Monitoring System and Its Components.*

*(Continued on next page)*

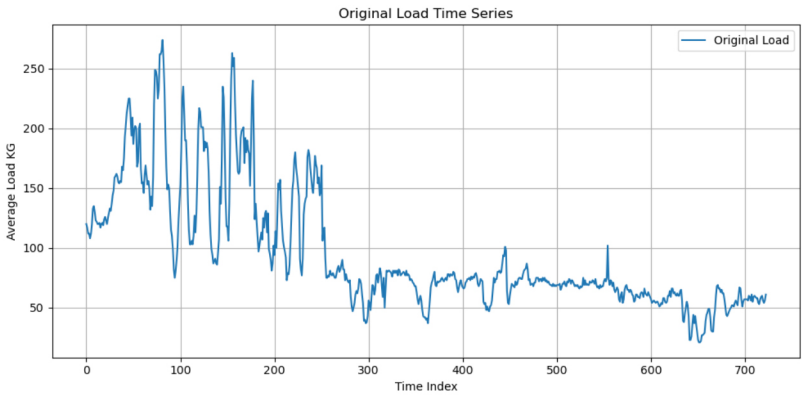

*Figure 1: An extract of remote Mooring Load Data Transmission and Monitoring Over Time.*

**Conclusion**

Our application demonstrates a reliable method for monitoring the structural health of offshore aquaculture in real time. The system facilitates prompt management actions to improve the resilience and sustainability of infrastructure by facilitating the early detection of stress events connected to tension. The sensor-driven monitoring is expected to be crucial for ensuring cage stability as aquaculture grows into more challenging marine settings and for facilitating long-term data collecting to create predictive models for proactive maintenance scheduling.

# RESOURCE RECOVERY AND INCREASING PRODUCTIVITY IN SUSTAINABLE INTENSIVE NEAR ZERO WASTE ASSIMILATION BASED RECIRCULATING AQUACULTURE SYSTEMS (AsRAS)

Uri Yogev[1], *Amit Gross, Ze Zhu, Orel Rachamim, Hiram Karanja, Avner Ronen, Dina Zilberg

[1]Aquaculturi B.V, 6129AX Urmond, Netherlands
[*]E-mail: uribenyosef5@gmail.com
[1]Zuckerberg Institute for Water Research, The Jacob Blaustein Institutes for Desert Research, Ben-Gurion University of the Negev, Midreshet Ben Gurion 84990, Israel

Conventional aquaculture systems typically release 70–80% of the N, P and C from feed into the environment, primarily through dissolved and solid wastes, thereby contributing to significant pollution. As an alternative to traditional approaches relying on nitrification followed by water exchange or denitrification, assimilation-based recirculating aquaculture systems (AsRAS)—including aquaponics, algaponics, and bacterioponics—offer a more sustainable solution. All AsRAS couple conventional RAS with an assimilation-based reactor in a symbiotic arrangement, whereby fish-generated wastes serve as nutrients for plants (in aquaponics), algae (in algaponics), or bacteria (in bacterioponics) (Zhu et al., 2024; Yogev & Gross, 2019). This configuration enables the biological assimilation of fish waste, which purifies the water for recirculation while simultaneously maximizing water and nutrient use efficiency, minimizing effluent discharge, and recovering or conserving energy.

Over the past few years, we have developed three distinct AsRAS configurations that operate on fresh or brackish water in multi-loop, near-zero waste setups. Each system maintains separate loops for fish production and assimilation-organism growth, optimizing conditions for both products. Our experimental trials demonstrated fish stocking densities as high as 80 $kg/m^3$ (with a typical density of ~50 $kg/m^3$), survival rates exceeding 95%, and feed conversion ratios between 1.1 and 1.4. Notable energy savings were observed: over 80% in aquaponic systems and about 50% in biofloc-based RAS. Furthermore, carbon sequestration in aquaponics reached levels 1.4 times higher than the carbon content in feed, achieving a 64% reduction in carbon footprint relative to conventional RAS; greater reductions are anticipated in algaponics-based AsRAS. In all systems, $N_2O$ emissions were significantly lower than those from traditional RAS.

These findings are among the first to demonstrate the viability of large-scale AsRAS production with near-zero water and waste discharge, coupled with substantial energy savings. We posit that AsRAS hold considerable promise for replacing traditional nitrification–denitrification-based RAS, thereby advancing more sustainable aquaculture practices.

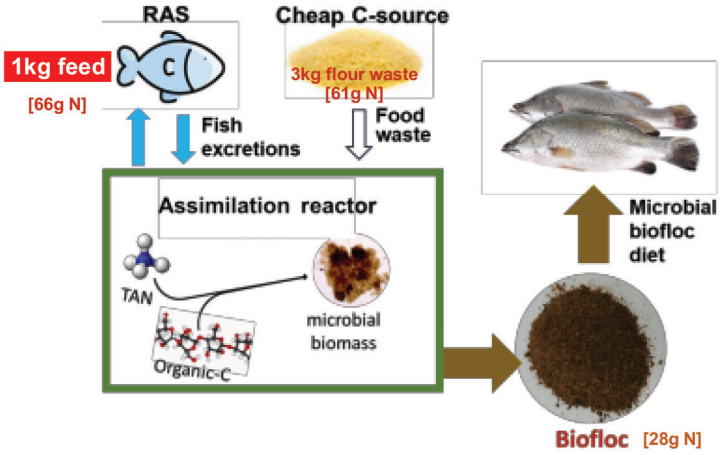
## Novel AsRAS: A novel microaerophilic assimilation reactor with RAS



# COMMERCIAL-SCALE TREATMENT FACILITY (DENITRIFICATION) FOR LAND-BASED MARINE RAS EFFLUENTS

Uri Yogev[1]*, Or Ohayon[2], Yuval Avni[2]

[1]Aquaculturi B.V., Stationstraat 72, Elsloo 6181AK, Netherland
[2]National Center for Mariculture, Israel Oceanographic and Limnological Research Institute, Eilat 88112, Israel
*E-mail: uribenyosef5@gmail.com

To date, marine land-based recirculating aquaculture system (RAS) still include effluent stream discharge. These effluents, originating from fish metabolism, feed residues, and sludge washouts, are rich in nitrogenous and organic compounds. Due to their salinity, such streams can not discharge to freshwater bodies or municipal wastewater treatment plants and are typically released into the sea. However, environmental regulations on nutrient discharge into marine environments are tightening globally, particularly regarding nitrogen and suspended solids. This creates an urgent need for effective, scalable, and regulatory-compliant treatment solutions. Denitrification, particularly heterotrophic, is the prevailing approach for nitrate (Nitrogen) removal from saline effluents, yet commercial-scale applications remain scarce.

**System description**

A full-scale effluent treatment system was established and operated to treat the discharge from a semi-commercial marine RAS (Fig 1). Effluents consisted of solids filter backwashes, sludge removal by floor suction, and tank overflow. These were collected in a sump and pumped into a ~30 $m^3$ denitrification reactor based on the activated sludge concept. The reactor was coupled with a pressurized settler (Soliquator SLS700) with optional flocculant dosing for enhanced separation. Polished water was filtered through twin sand filters before sea discharge. Excess sludge was diverted to an anaerobic stabilization pond (450–750 $m^3$), followed by a ~30 $m^3$ aerobic mixed reactor in a secondary tank and optional recirculation to the anoxic stage.

# ADVANCING MULTI-LOOP AQUAPONICS: INTEGRATING ANAEROBIC DIGESTION FOR CIRCULAR, DESERT-ADAPTED FOOD SYSTEMS

Uri Yogev[1,*], Ze Zhu[2], Amit Gross[2]

[1]Aquaculturi B.V., kanaalweg 15 urmond 6129AX, Netherland
[2]Zuckerberg Institute for Water Research, Jacob Blaustein Institutes for Desert Research, Ben Gurion University of the Negev, Sde Boker Campus, Midreshet Ben Gurion 84990, Israel
*E-mail: uribenyosef5@gmail.com

Aquaculture systems generate nutrient-rich effluents containing high loads of nitrogen, phosphorus, and organic matter, which can cause serious environmental harm if not properly treated. As a result, farmers are compelled to invest significant resources in waste management. Transforming these "wastes" into resources is a central challenge for sustainable aquaculture. Aquaponics—an integrated system that combines aquaculture with hydroponics—offers a promising solution by enabling the recovery and reuse of water, nutrients, and organic compounds. However, traditional one-loop aquaponics systems utilize only a fraction of the available nutrients, particularly those locked in solid waste (sludge). These systems are also limited by the tight coupling between the fish and plant units, which restricts the ability to optimize conditions independently and reduces system flexibility. Any malfunction in one component can negatively impact the entire system, compromising stability and performance.

This study presents a novel, zero-waste multi-loop aquaponics configuration designed to overcome the limitations of conventional one-loop systems. Our system integrates three independently optimized subsystems: (1) a recirculating aquaculture system (RAS), (2) deep-water hydroponics, and (3) anaerobic digestion units—one for fish sludge and another for plant residues. These digesters maximize nutrient mobilization and recovery. The system was deployed in a desert environment and operated under near-zero discharge conditions. Anaerobic supernatants were returned to the hydroponic loop as a nutrient-rich solution, while biogas was harvested as a renewable energy source.

Compared to traditional decoupled and coupled systems, the novel multi-loop system showed substantial improvements in resource recovery and overall productivity. Nutrient recovery rates for nitrogen and phosphorus reached 76% and 80%, respectively—up to twice the efficiency of standard one-loop designs. Plant productivity increased significantly, reaching 11.8 kg of lettuce per kg of fish feed, representing a 1.6-fold improvement over conventional systems. Furthermore, the system used 2.1× less water and required 16% less energy per kg of feed, with biogas production offsetting 84% of energy demand. Photosynthetic $CO_2$ sequestration further contributed to reducing the system's carbon footprint.

In summary, multi-loop aquaponics with integrated anaerobic digestion offers a scalable, circular, and resilient model for sustainable food production. By decoupling biological flows through engineered loops, this approach maximizes nutrient use, minimizes waste, enhances crop yields, and recovers may energy. These findings highlight its strong potential for sustainable agriculture in arid and urban settings where traditional farming methods are challenged.

# THE HIDDEN IMPACT OF INCREASING TEMPERATURES: HOW FISH LOSE THEIR RESILIENCE AGAINST OTHER STRESSORS

## Introduction

Human activities and anthropogenic greenhouse gas emissions have driven climate change at unprecedented rates (IPCC 2014, 2019). Continued emissions will lead to further atmospheric and oceanic warming, triggering long-term shifts in the climate system that will exacerbate existing risks and introduce new challenges for all life on Earth.

Aquaculture is increasingly affected by climate-related stressors, including rising temperatures, more frequent extreme weather events, ocean acidification, and shifts in salinity and oxygen levels. The severity of these impacts will vary based on multiple factors, as will the sector's capacity for adaptation (Falconer et al., 2022). In Norwegian aquaculture, high mortality rates stem from various causes, including pathogens, parasites, ulcers, gill diseases, and the strain of intensive handling procedures. As climate change accelerates, and its effects become more pronounced, environmental conditions will emerge as a significant risk factor - intensifying known threats as well as introducing new challenges to fish health. Notably, in 2024, injuries caused by jellyfish rose to rank among the top three causes of mortality in farmed salmon in Norway. Additionally, francisellosis, caused by *Francisella noatunensis*, reappeared in farmed cod after years without reported cases.

Temperature projections indicate that many regions in Norway may experience elevated temperatures over the next 10–15 years, including more frequent days exceeding optimal thresholds for currently farmed species. Suboptimal environmental conditions can induce micro-damages at the molecular and cellular levels in important organs, compromising fish health (Ytteborg et al., 2022). While ongoing technological advancements and new production methods continue to enhance fish health, the impacts of climate change may mask the benefits of these innovations.

## Materials and methods

Using downscaled temperature projections based on the Intergovernmental Panel on Climate Change (IPCC) climate models (Shared Socioeconomic Pathways, SSPs), we analyzed potential future temperature conditions at existing and planned Atlantic cod farms in Norway. Regional climate projections were assessed using the Challenging Conditions Index (CCI), a method developed by Falconer et al. (2024) that evaluates environmental suitability based on a species' thermal preferences.

To simulate near-future scenarios, a temperature trial was conducted, exposing farmed Atlantic cod (*Gadus morhua*) to three temperature conditions: low (12°C), high (17°C), and fluctuating (12–17°C) temperatures. The robustness of cod reared at suboptimal temperatures was further tested by exposing fish to either jellyfish fragments or *F. noatunensis*. Skin and gill samples were collected from all temperature groups - including exposed and non-exposed individuals - and analyzed using histology and transcriptomics.

## Results and discussion

The evaluation of climate projections for future cod farms indicates that several locations may experience temperatures exceeding those considered suitable for cod. The Challenging Conditions Index (CCI) further suggests that farming conditions over the next 10–15 years could become increasingly difficult.

Findings from the experimental trial revealed that temperature alone induce micro-damages in the epidermis of both skin and gills. Exposure to high and fluctuating temperatures led to increased breaches between individual epithelial cells, alongside heightened expression of stress-related genes such as *sod*, *hsp70*, and *catalase*. Following exposure to jellyfish fragments or *F. noatunensis*, fish exhibited increased mucus production, elevated stress responses, and a higher frequency of morphological lesions - effects that were more severe under high and fluctuating temperature conditions.

*(Continued on next page)*

Both skin and gills are highly sensitive to unfavourable environmental conditions, making their morphological analysis valuable for assessing the impact of environmental stressors and identifying potential challenges. The observed damage may reduce fish resilience, impairing their ability to withstand climate change-induced stressors, secondary environmental pressures, and general production-related stress. These findings underscore the importance of evaluating future environmental conditions and species-specific tolerances prior to site selection for future cod farming.

# PHYSIOLOGICAL AND METABOLIC RESPONSES OF COBIA (*Rachycentron canadum*) JUVENILES FED FISH OIL-FREE DIETS WITH DIFFERENT LC-PUFA/C18 PUFA RATIO

M. Zaminhan-Hassemer,[1*] S. V. da Costa[1], R. G. Moreira[2], R.M. Honji[2], J. Sousa Siqueira[1], P. H. de Mello[2] A.W.S. Hilsdorf,[1] B. C. Araújo[1]

**Introduction**

Fish oil (FO) has traditionally been used in marine organism diets as the main lipid source and key of essential long-chain polyunsaturated fatty acids (LC-PUFAs). However, its global availability has declined due to reliance on wild-caught marine fish and stagnant fishery production over the past three decades, making it unfeasible to support the fast growth of aquaculture with such a limited resource (Teles et al., 2015; Nordahl, 2011; Fao, 2024).

Alternative nutritional strategies aim to reduce dependence on limited ingredients like (FO) while ensuring safe and efficient diets for marine species. Replacing FO partially or entirely with vegetable oils is a common practice in aquaculture, but it changes the dietary n-3/n-6 ratio, potentially impairing immune responses, physiological functions, and growth performance in commercial fish species (Turchini et al., 2019; Magalhães et al., 2022).

Diet formulation should provide both adequate levels and an appropriate balance of fatty acids (FA), with particular emphasis on the dietary n-3/n-6 ratio, to optimize nutritional efficiency and the selection of lipid sources. Such strategies promote the development of healthier and more resilient fish, better able to cope with the physiological stresses of production cycle and environmental challenges encountered during production (Dong et al., 2023; Hundal et al., 2021).

In view of the above, this study aimed to evaluate different levels of soybean oil (SO) inclusion supplemented with the main LC-PUFAs as an alternative to FO, and to evaluate the effects of different 18:n-6/LC-PUFAs ratios on the fatty acid profile of liver and muscle tissue of juvenile *R. Canadum.*

**Material and Methods**

Fish handling followed the Ethics Committee's procedure protocols on the Use of Animals (CEUA nº 008/2017) of the University of Mogi das Cruzes (SP, Brazil). the animals were selected according to average body mass (10.70 ± 0.04 g) and transferred to 12 – 500 L tanks (15 animals per tank, in triplicate) in a recirculation aquaculture system (RAS) equipped with a UV, biological, and mechanical filters, pump, and water heater.

After producing the basal diet, the different experimental oils in FO, SO, docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA) and arachidonic acid (ARA) were incorporated using the vacuum coating technique as previously described by Lamichhane et al., (2015), respecting the basic LC-PUFA nutritional requirements described for this species (Fraser et al., 2009; Trushenski et al., 2011; Araújo et al., 2019).

The control diet (FO) was composed by 8.8% of FO, while in the other experimental diets were included 8.8% of an oil blend, composed by coconut oil (CO) as a saturated fatty acid source, SO as C18 polyunsatured source, and LC-PUFA (ARA, EPA and DHA) concentrated sources in different concentrations as presented below: Diet 1 (D1) consisted of 2% CO, 6% SO, and 0.2%, 0.5%, and 0.1% of EPA, DHA, and ARA extracts, respectively. Diet 2 (D2) was prepared of 2% CO, 4.5% SO, and 0.7%, 1.2%, and 0.4% of EPA, DHA, and ARA extracts, respectively. Diet 3 (D3) was composed of 2% CO, 3% SO, and 1.0%, 2.0%, and 0.8% of EPA, DHA, and ARA extracts, respectively.

*(Continued on next page)*

During the trial, the experimental animals were hand-fed twice a day (08:00 and 17:00 h) until apparent satiation with the appropriate experimental diet for 8 weeks (56 days). At the end of the trial three animals from each tank were euthanized by benzocaine overdose, totaling nine animals per treatment, and aliquots of liver and muscle tissues were sampled and immediately frozen in liquid nitrogen, and posteriorly kept at -80°C.

The FA profile of liver and muscle was initiated by lipid extraction using dichloromethane andfurther methylated following the transmethylation method described by Parrish et al. (2014). The FA composition was analyzed as methyl esters (FAME) using gas chromatograph Scion 436 equipped with a flameionizer (FID) and CP 8410 auto-sampler. Data are presented as a percentage of total FAME based on peak area analyzed. All statistical tests were carried out using SigmaStat statistical software version 7.0 (Sigma Stat Software, CA, USA), using a significance level of 5% ($P<0.05$).

**Results and discussion**

In general, both in the liver and in muscle, saturated fatty acids (SFAs) were found in significantly lower proportions, while monounsaturated fatty acids (MUFAs), polyunsaturated fatty acids (PUFAs), and long-chain polyunsaturated fatty acids (LC-PUFAs) showed higher deposition in all experimental groups, except in fish fed the FO diet, in which PUFA and LC-PUFA levels were lower. In muscle tissue, variations in total n-6 fatty acid levels were mainly determined by the pattern observed in 18:2n-6 concentrations, which increased in response to higher SO inclusion in the experimental diets (D1, D2, and D3, respectively). Similarly, significant differences were observed in ARA levels, with the lowest values in fish fed FO, followed by D1, D2, and D3. In the liver, the n-6 PUFA profile followed the same pattern observed in muscle, with higher levels in D1, intermediate in D2, and lower in D3, reflecting the different levels of SO inclusion in the experimental diets and, consequently, the variations in 18:2n-6 concentrations between groups.

Based on the composition of the experimental diets, a significantly lower deposition of SFAs and, conversely, a higher deposition of LC-PUFAs were observed in the tissues of the experimental animals. It is well established that, although there is a preferential order of fatty acids oxidation, aquatic organisms in general tend to preferentially oxidize nutrients that are present in excess in the diet, while conserving those supplied in limited amounts, a metabolic phenomenon known as fatty acid sparing effect (Turchini et al., 2011; Trushenski et al., 2013). The results observed in this study suggest a possible LC-PUFAs sparing effect, since compared to SFAs (primarily 12:0), DHA, EPA, and ARA were positively deposited, particularly in muscle tissue, even with relatively low percentages of these fatty acids in the experimental diets (especially D1 and D2).

**Conclusion**

In conclusion, SO supplemented with essential LC-PUFAs can effectively replace FO at different inclusion levels without compromising lipid metabolism in *R. canadum* juvenile. Moreover, the diet with the highest level of supplementation (D3) resulted in enhanced tissue deposition of LC-PUFAs, particularly in muscle.

# INFLUENCE OF ARA LEVELS ON PRODUCTIVE PERFORMANCE AND METABOLISM OF NILE TILAPIA (*Oreochromis niloticus)* JUVENILES MAINTAINED AT LOW TEMPERATURES

M. Zaminhan-Hassemer[1], B. C. Peres[1], S. V. da Costa[1], R. G. Moreira[2], R.M. Honji[2], Julia Sousa Siqueira[1], B. C. Araújo[1]

1 Center for Environmental Sciences, University of Mogi das Cruzes - Doutor Cândido Xavier de Almeida e Souza Avenue, 200, São Paulo, SP, Brazil. *E-mail: michelizam@hotmail.com
2 Department of Physiology, Institute of Biosciences, University of São Paulo, Rua do Matão, Travessa 14, 321, 05508-090, São Paulo, SP, Brazil

**Introduction:**
*Oreochromis niloticus* is the main fish species produced in Brazil. However, the leading producers in Brazil were established in the south and southeast regions, where the autumn/winter temperatures are out of the optimum range for this species.

Previous studies showed that better growth and survival of fish at low temperatures were obtained by the incorporation of higher dietary levels of long-chain polyunsaturated fatty acids (LC-PUFA), especially docosahexaenoic acid (DHA) and arachidonic acid (ARA).

Current studies observed better production performance of tilapias at suboptimal temperatures when fed DHA-rich diets. However, the underlying mechanisms are unknown. In addition, despite the promising results obtained with other fish species, no studies evaluating the dietary ARA influence on the performance and metabolism of tilapia juveniles at low suboptimal temperatures have been carried out.

Thus, this study aimed to evaluate the efficiency of diets with different ARA levels on the productive performance of *O. niloticus* juveniles kept at suboptimal temperatures.

**Material and methods:**
All experimental procedures involving animals and biological tissues were evaluated and approved by the Ethics Committee on the Use of Animals of the University of Mogi das Cruzes (CEUA, Protocol No. 005/2024), in accordance with institutional and national guidelines.

Approximately 400 juvenile Nile tilapia (*Oreochromis niloticus*) were obtained from the Brumado Fish Farm (Mogi Mirim, São Paulo, Brazil) and transported to the facilities of the Ponte Nova Dam Fish Farm (Salesópolis, São Paulo, Brazil). Upon arrival, the fish were acclimated in a 4 $m^3$ tank for 15 days prior to the feeding trial.

After the acclimation period, fish were individually weighed and measured to establish the initial experimental batches. Animals were then randomly assigned to 15 tanks representing five dietary treatments (CTRL, ARA1, ARA2, ARA3, and DHA), in triplicate. The tanks consisted of multifilament hapas with a mesh size of 10 mm and a capacity of 2.4 $m^3$, installed within an earthen tank with a total volume of 600 $m^3$. Each experimental unit contained 20 fish with an initial mean body weight of 37.9 ± 0.8 g. The experiment was conducted during the winter season, with an average water temperature of 20.5 ± 1.2 °C in the Ponte Nova Fish Farm facilities. Water quality parameters, including dissolved oxygen (mean: 6.55 ± 0.7 mg $L^{-1}$) and water temperature, were measured daily throughout the experimental period. A basal diet was formulated according to the nutritional requirements for *Oreochromis niloticus* juveniles as proposed by Furuya (2012) and the NRC (2011).

From the basal formulation, five experimental diets were prepared to be isoproteic, isolipidic, and isoenergetic. In the control diet (CTRL), soybean oil was the sole lipid source. Diets supplemented with arachidonic acid (ARA) contained the following inclusion levels of concentrated oil (40% of ARA): ARA-1: 0.40%, ARA-2: 0.80%, and ARA-3: 1.20%, with a corresponding reduction in soybean oil to maintain similar lipid levels. A fifth diet was supplemented with 0.20% concentrated docosahexaenoic acid (DHA) oil, without ARA inclusion. The infusion of concentrated ARA oil, as well as other oils, was performed using a vacuum coating process as described by Lamichhane et al. (2015). The proximate composition of the experimental diets was analysed following the methodology of AOAC (2015).

*(Continued on next page)*

Prior to the feeding trial, ten fish from the initial stock were euthanized by eugenol overdose (0.1 g L□¹), and liver and muscle samples were immediately frozen in liquid nitrogen and stored at −80 °C until further processing. During the 56-day trial, fish were fed to apparent satiation twice daily (08:00 and 16:00 h) with their respective diets. At the end of the experiment, three fish from each tank (nine per treatment) were euthanized under the same protocol, and liver and muscle samples were collected for molecular, metabolic, and morphological analyses conducted at the Laboratory of Physiology and Nutrition of Aquatic Organisms (LAFINUTRI/UMC).

Lipid extraction from ingredients, diets, and tissues was performed using dichloromethane, followed by methylation according to the transmethylation method described by Parrish et al. (2014). Fatty acid composition was analysed as fatty acid methyl esters using a Scion 436 gas chromatograph equipped with a flame ionization detector (FID) and an auto-injector. Separation was performed on a CP Wax 52 CB capillary column (0.25 μm film thickness, 0.25 mm internal diameter, 30 m length). The oven temperature program was as follows: 170 °C for 1 min, ramped at 2.5 °C min□¹ to 240 °C, held for 5 min, totalling 31 min per run. Injector and detector temperatures were 250 °C and 260 °C, respectively. Fatty acids were identified by comparing retention times with a commercial FAME standard mix (Supelco, 37 components).

**Results and Discussion:**

After 56 days of the feeding trial, no significant differences were observed in the productive performance parameters among fish from the different dietary groups. These findings contrast with previous studies reporting a positive relationship between dietary ARA incorporation and improved growth and survival in commercial fish species such as *Rachycentron canadum* (Araujo et al., 2019), *Morone saxatilis* (Araujo et al., 2021), and *Seriola dorsalis* (Araujo et al., 2022).

As expected, and widely reported in other studies (Tocher, 2010; Glencross, 2009), the fatty acid profiles of liver and muscle tissues closely reflected the composition of the experimental diets. In general, ΣSFA was lower in all ARA- and DHA-supplemented groups compared with the control, with a significant reduction only in the ARA3 group for liver. Conversely, ΣPUFA deposition tended to be higher in supplemented groups, suggesting that fish fed the control diet had a lower capacity for PUFA retention, since similar dietary levels of this fatty acid class were provided in the experimental diets. ΣMUFA levels showed reductions in the ARA2 and ARA3 groups compared with the control in liver, but no significant variation among treatments in muscle.

EPA content was significantly higher in the DHA group compared with the control, but this effect was only observed in liver, with no differences detected in muscle. DHA levels, in turn, were significantly higher in the control group compared with the DHA-supplemented group in muscle, despite the latter receiving 1.54% purified DHA oil in the diet. ARA deposition patterns did not fully reflect the dietary inclusion levels. While the lowest concentrations were observed in the control group, the highest values were recorded in the ARA1 group for muscle and in the ARA3 group for liver.

**Conclusion:**

Dietary supplementation with ARA- and DHA-rich oils did not affect the productive performance of O. niloticus reared under suboptimal temperatures; however, it significantly altered the fatty acid composition of liver and muscle. Overall, supplemented diets decreased SFA deposition and increased PUFA retention. These results indicate selective retention and/or enhanced catabolism of LC-PUFA when provided in excess, supporting the hypothesis of tissue-specific regulation of fatty acid utilization. Such metabolic responses should be considered in tilapia feed formulation to improve nutritional quality and resilience to low-temperature rearing.

# BUILDING IMPACT THROUGH LEARNING: EDUCATING CHILDREN AND AQUACULTURE PROFESSIONALS ON ALDFG POLLUTION MITIGATION AND SUSTAINABLE AQUACULTURE

Zantioti Christina[1*], Kostoula Konstantina[2], Kyriakou Aristea[3], Croci Samara[2], Veronika Mikos[2]

Laboratory of Applied Hydrobiology, Department of Animal Science, Agricultural University of Athens, Iera Odos 75, Athens, 11855
[2.] Healthy Seas Foundation, Abcoude, The Netherlands, 1390 AD
[3.] European Outdoor Education Hub, Thessaloniki, Nea Moudania 63200
E-mail: zantioti.christina@gmail.com

**Introduction**

The aquaculture industry relies heavily on plastics and will likely continue as the world depends more on oceans for high-quality protein (Skirtun et al., 2022). Plastic fragments from aquaculture can break down into microplastics, harming the marine environment (Tian et al., 2022). FAO highlights that marine aquaculture installations are major sources of abandoned, lost, or discarded fishing gear (ALDFG), worsening marine plastic pollution (Macfadyen et al., 2009). However, education on best practices and plastic management can improve decision-making and help address the issue (Sandu et al., 2022). This study aims to emphasise the role of education in tackling plastic pollution from ALDFG, presenting the results research from educational activities in Greece.

**Materials and methods**

This research was conducted as part of the Healthy Seas Foundation's academic outreach project in Western Greece focusing on educating primary school students, university students, and academic staff about the impacts of marine plastic pollution from ALDFG and positive sustainable aquaculture practices. Educational programmes engaged 165 primary school students and their teachers in Astakos, Nafpaktos, and Amphilochia. These activities incorporated outdoor learning to enhance engagement and knowledge retention. The partnering European Outdoor Education Hub contributed by integrating experiential outdoor education methodologies. Activities included hands-on engagement with coastal environments, observation-based learning, and experimental exercises to help students grasp the real-world impact of ALDFG pollution. Experiential field sessions on the school grounds and the local seashore encouraged direct participation, fostering a deeper connection to marine conservation efforts. Adult education involved 8 university faculties from the Universities of Patras and Ioannina, with 205 students and staff, covering topics like plastic pollution from ALDFG and waste management best practices. A webinar expanded the reach globally. To assess the impact, questionnaires were used to measure changes in knowledge and perceptions, focusing on plastic pollution awareness and sustainable aquaculture practices.

**Results**

The in-person activities reached 370 people, including 205 university students and staff and 165 primary school students and teachers. The webinar engaged 107 additional participants. The questionnaire analysis revealed that while most participants were initially unfamiliar with ALDFG, 99.5% reported increased understanding after the seminar. 55% felt their knowledge had greatly improved. Audiovisual materials helped 64.6% better grasp the content, and 20% showed interest in further studying sustainable aquaculture practices, indicating the potential of education to promote sustainability. Regarding the results of the primary school fieldwork, qualitative feedback from teachers and students indicated that outdoor, experiential learning played a key role in improving engagement and knowledge retention. Educators, through Likert-Scale and open-ended questions noted that students were more receptive to conservation messaging when involved in hands-on activities in natural environments. This aligns with broader research on outdoor education's effectiveness in environmental literacy and behavioral change.

*(Continued on next page)*

**Discussion**

Education and training of the aquaculture workforce can contribute to enhancing the sustainability of the sector and empowering coastal communities. (Berkowitz et al., 2022). Similarly, educating children is equally important, as it lays the foundation for the next generation to become environmentally conscious and actively contribute to the protection of marine ecosystems (Freitas et al., 2023). The integration of outdoor education as part of the activities further amplified this impact, reinforcing the importance of immersive, place-based learning in fostering pro-environmental attitudes (Sobel 2005). Beyond traditional classroom settings, experiential learning in natural environments has been shown to enhance ecological awareness and long-term behavioral change, making it a crucial component in sustainability education. Adults preferred visual materials to understand plastic pollution, supporting studies on audiovisual learning effectiveness. (Kolandai-Matchett et al., 2021). In conclusion, modern education methods are key to raising awareness of environmental issues.

**Acknowledgements**

We sincerely thank Drs. Bekiari, Theodorou, Kehagias, and Antonopoulou (University of Patras), Drs. Kati, Chela, Nathanailidis, Skoufos, and Gouva (University of Ioannina) for their support. We also extend our heartfelt gratitude to the students, teachers, and entire school communities of the Primary School of Astakos, the 3rd Primary School of Nafpaktos, and the 1st Primary School of Amphilochia, whose active participation and enthusiasm greatly contributed to the success of our educational initiatives. # GONADOTROPIN PLASMID GENE THERAPY TRIGGERS GAMETOGENESIS IN MALE AND FEMALE EUROPEAN EEL (*Anguilla anguilla*)

C. Cruz-Castellón[1,2], C. Zapater[1*], M. Morini[2], T.S. França[2], L. Pérez[2], J.F. Asturiano[2], A. Gómez[1]

## Introduction

The European eel is a species of high economic impact for both commercial fisheries and aquaculture in Europe. However, the eel does not reproduce naturally in captivity. Hormonal induction with traditional methods has been applied to address reproduction problems, including weekly administration of human chorionic gonadotropin (hCG) in males (Pérez et al., 2000) and salmon or carp pituitary gland extracts, followed by a final dose of progestogen to induce spawning, in females (Gallego et al., 2012). Despite their effectiveness, these methods are time-consuming and expensive. An alternative approach to induce gametogenesis in captivity can be the use of gene therapy using recombinant gonadotropin plasmids (Mazón et al., 2013). The present study tested the potential of this technique in male and female European eels, by transferring and overexpressing homologous gonadotropin genes.

## Materials and methods

Two independent experimental trials were conducted on immature European eel males maintained in seawater at 20 ºC: Experiment 1: Fish with an average weight of 142.64 ± 2.84 g were subjected to three treatments: i) fish injected with empty pCDNA3 plasmid (control), ii) fish injected with eel single-chain follicle-stimulating hormone (scFsh), and iii) fish injected with eel scFsh + eel single-chain luteinizing hormone (scLh). To monitor injection effectiveness, all groups were injected with 15 µg of sea bass (*Dicentrarchus labrax*) scFsh which can be monitored in plasma and has no functional effect in eel. Injections were performed in weeks 1, 3 and 6 in duplicate (reinjecting after 3 days each time), and total duration of the experiment was 9 weeks.

Experiment 2: Fish with an average weight of 103.54 ± 1.29 g were subjected to three treatments: i) fish injected weekly with hCG (positive control); ii) fish injected every three weeks with empty pCDNA3 plasmid (negative control), and iii) fish injected every three weeks with the combination of eel scFsh at a constant dose and increasing doses of eel scLh plasmids. Total duration of this experiment was 15 weeks.

One experimental trial was conducted on immature European eel females maintained in seawater at 20 ºC. Fish with an average weight of 756.95 ± 12.74 g were subjected to three different treatments similar to experiment 1 for males.

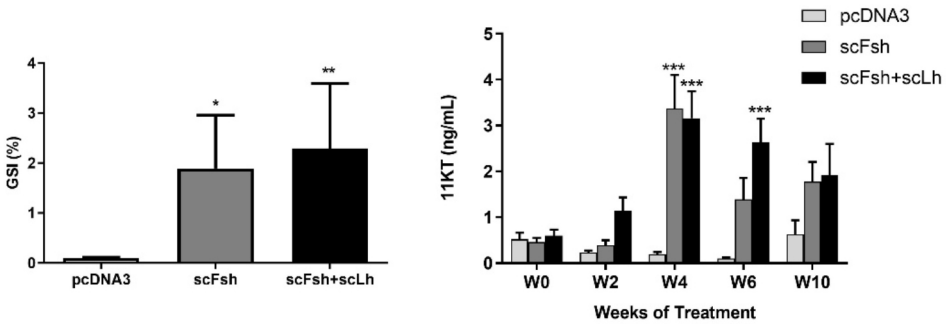

**Fig. 1.** Gonadosomatic index (left) and plasma 11 KT levels (right) in male European eels in experiment 1. Data are shown as mean ± SEM (n = 5, 6, and 8 per sampling and treatment). Asterisk indicates significant differences between treatments at the end of the trial.

*(Continued on next page)*

To evaluate maturation progression, blood samples were taken at the times of injections for steroid analysis, and biometric parameters (eye index, fin colour and weight) were recorded. Additionally, at the end of each experiment, the fish were sacrificed, the gonadosomatic index (GSI) was determined and tissue samples were preserved for histological analysis.

**Results**

In experiment 1, treated male European eels showed significantly higher GSI and plasma steroid levels compared to control groups (Fig. 1). These findings indicate that gene therapy with homologous gonadotropin effectively stimulates spermatogenesis. However, there was some variability among individuals, and only a subset of the treated eels progressed to spermiation.

To improve these results, the treatment protocol was optimized in experiment 2, and a positive control using traditional hCG treatment was included for comparative purposes. Results showed that GSI and steroid levels in plasmid-treated group were similar to the hCG group and significantly different from the control one, indicating enhanced effectiveness of the revised gene therapy protocol. Similarly, biometric parameters such as eye index and fin coloration increased over time in the treated groups, whereas they remained unchanged in the control group (pCDNA3). In addition, nearly all the treated specimens achieved spermiation by the end of the trial.

In the female experiment, treatment with European eel recombinant gonadotropin plasmids led to significant increases in biometric parameters, oogenesis progression, and sex steroid levels compared to the control group, highlighting the potential of gene therapy as an alternative method to induce reproduction of European eel females in captivity.

In conclusion, compared to conventional hormonal treatments, the results obtained in our study show that gonadotropin plasmid-based gene therapy offers a promising, cost-effective, and efficient alternative for overcoming reproductive dysfunctions in European eel aquaculture.

## Introduction

The aquaculture sector is susceptible to the contamination from microplastics (MP) which mainly derive from environmental pollution, the use of plastic tools, and fish feeds, whether in freshwater or marine farming. Although fish possess the ability to differentiate suspended MP from edible particles, the inherent contamination of aquafeeds presents a less detectable exposure route (Siddique et al., 2023). This results in increased MP ingestion by farmed fish, thereby posing potential health risks to the fish themselves and raising concerns for consumer safety. In fact, dietary MP smaller than 20 μm can be absorbed in the fish intestine, leading to a consequent translocation to other tissues, among which liver acts as a retaining organ (Cattaneo et al., 2024). This limits the accumulation in other sites but causes the triggering of oxidative stress. In this context, the dietary supplementation of natural antioxidants, like astaxanthin (AX), could strengthen the intrinsic defence mechanisms of fish, contributing to mitigate the MP-induced oxidative stress. Particularly, natural AX has a higher antioxidant efficacy compared to its synthetic counterpart. However, natural AX is characterized by a rapid degradation due to its low stability, particularly under industrial processing conditions. To address this limitation, microencapsulation techniques have emerged as promising strategies to enhance the stability of the AX molecule and improve its bioavailability and delivery through aquafeeds. Additionally, the microcapsules' wall matrix can have a crucial effect in preventing the MP absorption at fish intestinal level. In fact, starch, one of the most frequently preferred components for microcapsules preparation, has been demonstrated to aggregate MP in both suspended water and inside fish gut. Within this context, the present study aimed to: (i) implement fish feeds with natural AX included in microcapsules made of an organic starch-based wall matrix able to preserve it and, at the same time, to exert a crucial role in limiting the MP absorption at fish intestinal level; (ii) testing the experimental diets on European seabass (*Dicentrarchus labrax*) juveniles over a 60-day feeding trial; (iii) investigating the MP assimilation and accumulation in different fish tissues along with their overall health status.

## Materials and Methods

Starting from a control fluorescent MP-free diet (named C), a MP diet, was prepared by adding purchased fluorescent microbeads (range size 1-5 μm) to the control mixture (50 mg/kg feed). Then, the C+AX and MP+AX diets were prepared by adding 7 g/kg feed of AX microcapsules (corresponding to 175 mg/kg of AX) to the C or MP diets, respectively. Five hundred and forty European seabass juveniles were then divided in six experimental group (in triplicate) and were fed as follows: (i) C group: C diet for 60 days; (ii) C/C+AX group: C diet for the first 30 days and C+AX diet for the following 30 days; (iii) C+AX group: C+AX diet for 60 days; (iv) MP group: MP diet for 60 days; (v) MP/MP+AX group: MP diet for the first 30 days and MP+AX diet for the following 30 days; (vi) MP+AX group: MP+AX diet for 60 days. Growth indexes were calculated by weighting all the fish at the end of the trial. MP were localized with confocal microscopy in fish intestine, liver, blood, muscle and adipose tissue, whilst they were quantified on filters through epifluorescence microscopy after digesting the above-mentioned tissues with a KOH solution. Fish welfare was assessed with histological and molecular (real-time PCR on markers involved in immune and oxidative stress response) analysis on liver and intestine samples. Finally, to assess their potential role in MP aggregation, whole microcapsules (empty or filled with AX), and starch (as main microcapsules' component) were tested in an *in vitro* experiment.

*(Continued on next page)*

**Results and Discussion**

The different dietary treatments did not affect fish survival rate and growth performance and did not cause pathological alterations or signs of inflammation in the intestine as evidenced by both the histological indexes and the relative expression of immune response markers (*il1b*, *il10*, and *tnfa*). However, the dietary fluorescent MP microbeads were absorbed at intestinal level, leading to a consequent translocation and accumulation in the liver which caused, in fish from the MP group, a *sod1*, *sod2*, and *cat* upregulation. Interestingly, the dietary implementation of AX microcapsules led to a mitigation in the expression of oxidative stress markers, particularly in the MP+AX group where it reached levels comparable to those observed in all the controls. Additionally, the microcapsules used in the present study played a significant role in limiting the intestinal MP absorption. In fact, fish from MP+AX group revealed a significantly lower intestinal absorption of fluorescent microbeads, leading to a consequently reduced accumulation in all the organs analysed compared to those from MP group. Of particular interest was the absence in the muscular tissue. These results were supported by: (i) an *in vitro* coagulation test which demonstrated that the microcapsules (empty or filled with AX) and the starch, tested at the same concentration used in the experimental diets, effectively trapped the fluorescent microbeads, forming MP aggregates too large to be absorbed at the intestinal level; (ii) the number of fluorescent microbeads detected in the fish faeces samples which was significantly higher in both the MP/MP+AX and MP+AX groups compared to the MP one. These results can be of great interest for the aquaculture sector in light to promote fish welfare and quality product. Further studies are necessary to depict a more comprehensive overview of the effectiveness of this technology in relation to the wide variability of conditions within the aquaculture sector and the types of polymers that can be ingested by the fish.

## Introduction

Rainbow trout (*Oncorhynchus* mykiss) is the main freshwater species farmed at European level, both in terms of volume and value. In fact, almost all rainbow trout on the EU market comes from aquaculture since this species does not naturally reproduce in most of European aquatic basins, in both fresh and saltwater. The main EU member states farming this species are France, Italy and Denmark, accounting for 56 % of EU production. Monoculture is the most common rainbow trout farming, and intensive systems are considered necessary in most situations to make the operation economically attractive. The rainbow trout production cycle can be divided into different phases, each characterized by important critical aspects that must be considered to ensure high productivity rates and high-quality standards. The knowledge behind most of these phases has been deeply consolidated over the years, allowing farmers to minimize loss in the supply chain. The most critical step is still represented by the early embryo development, lasting from fertilization to the achievement of the eyed egg stage. Fertilized eggs are commonly incubated in vertical flow incubators, left undisturbed until the achievement of the eyed stage. Developing embryos are subjected to visual inspections and to the eventual manual removal of dead ones, followed by the use of chemicals for disinfection to prevent the spreading of infections. In fact, during this incubation stage, high mortality rates are caused by infections by ubiquitous Oomycete species (*Saprolegnia* sp.) and other pathogens that led, in some cases, to the loss of entire batches of embryos. Since oomycetes can colonize the surface of dead embryos while suffocating the surrounding living ones, a quick pathogen detection is necessary. However, if the infection is extensively spread and most embryos results infected after the visual inspection, the entire batch of embryos contained in the vertical incubator (infected and alive) is generally discarded. Within this context, the present research aimed to develop and validate a technological automatic vertical incubator prototype, equipped with a set of multi-spectral cameras and specific tools, able to gently lift the embryos and to quickly recognize and remove the non-developing or infected ones, in light to reduce possible food losses.

## Materials and Methods

In a preliminary stage, 50 batches of rainbow trout embryos, obtained from an Italian supplier, were analysed with XIMEA multi-spectral cameras. Particularly, embryos of each batch, both good (orange) and bad (white), were disposed on a single layer, and cameras acquisitions were performed in the visible (VIS) and near infrared (NIR) spectrum. The same procedure was conducted covering the single layer of embryos with water to simulate the state of immersion. The collected images (3 images per batch with and without water) were labelled by domain experts and then used to train a deep learning model able to detect eggs and assign label based on reflectance data. This preliminary research was necessary to identify (spectral) bands of interest.

A prototype of the vertical incubator was then developed integrating computer vision technologies and environmental sensors and tested in farm conditions over a seven-day period. Particularly, high-resolution Basler USB 3.0 cameras (constituting the vision system) acquired images in both RGB and grayscale format that were acquired by a computer equipped with a GPU that reduces the inference time of a deep learning model to detect healthy and diseased embryos. Inside the vertical incubator, a 45° tilted cochlea was placed to gently lift the embryos from the bottom of the system to the sorting area where multi-spectral cameras can discriminate them. The prototype was integrated with a Pacific system equipped with a series of probes and sensors to monitor water conditions (pH, temperature, dissolved oxygen, and $CO_2$) and ensure the correct functioning of the system. Finally, a water flow meter ensured that embryos were correctly lifted and transported by the cochlea without excessive turbulence or stagnation. The embryos were exposed daily to one complete transit in the cochlea and to the camera view (for selection). After the experimental period (7 days), the embryos were placed in traditional vertical hatchery systems until the hatching. Their hatching rate was then compared with that of part of the same batch embryos, reared in conventional hatchery systems.

*(Continued on next page)*

**Results and Discussion**

The prototype efficiently lifted the embryos without affecting their integrity and the cameras discriminated them with an overall accuracy of 94%. The RGB colour images allowed for more detailed analysis of the surface, while grayscale images allowed for greater precision in detecting changes in intensity that could indicate anomalies with the capability to filter specific band of interest. At the end of the experimental period, the hatching rate of the embryos reared in the prototype did not show significant differences compared to those maintained in conventional hatchery systems. This first-phase prototype completely automated the whole embryo selection process, reducing the need for manual intervention and increasing the selection accuracy. Furthermore, it was possible to continuously monitor both the state of the embryos and the water parameters, ensuring the maintenance of optimal environmental conditions for their development. The integration of high-quality cameras, powerful deep learning models and the environmental monitoring made the prototype extremely effective and precise, optimizing the success of the incubation process. In the next phase, the prototype will be further improved with a device able to remove bad eggs according to cameras-derived data.

Despite a not immediate large-scale application in a farming *scenario*, this device could improve up to 5% the number of embryos that achieve the eyed stage (less delicate), thus improving the whole productivity of rainbow trout farms.

## Introduction

The farming of Mediterranean mussel (*Mytilus galloprovincialis*) is a crucial sector for Italian aquaculture, accounting for the 45.6% of the national seafood production. Particularly, the western Adriatic Sea offers favourable environmental conditions for the extensive farming of this species. In this area, Mediterranean mussels are exclusively cultured in offshore waters using the long-line system which comprises a horizontal backbone from which multiple ropes colonized by mussels are suspended. Despite its simplicity, this farming technique represents a low-waste, cost-effective, and sustainable seafood production methods, while providing numerous ecosystem services including: (i) improvement of water quality due to the mussels' filtration activity; (ii) increasing the substrate complexity in sandy bottom areas, promoting biodiversity; (iii) safeguarding the coastline habitat preventing its erosion; (iv) reducing $CO_2$ emissions acting as a carbon sink deposited in their shells. This specific case study was performed in the Adriatic Sea, following a productive cycle that started in June 2024. The initial phase was the collection of seeds that derived either from natural settlement on farm infrastructure (ropes, cables, and buoys) or from routine cleaning operations residual. During the on-growing phase, mussels were subjected to seasonal changes, natural climatic conditions, seawater features, and eventual presence of predators that can variably affect the productive cycle. In addition, human intervention during the harvesting processes can introduce different stressors that can impair mussels' overall health and marketability. Particularly, a first harvest occurred in February 2025 during which mussels under market size were collected to be shipped to different marine farming areas for a final relocation phase that, due to the different seawater features, can enhance organoleptic properties and support the valorisation of regionally branded mussels. In this first harvesting phase, no cleaning procedure is allowed, and mussels socks are stacked on pallets and wrapped with cling film to ensure containment and to reduce desiccation during transport on refrigerated trucks. A second harvest, that occurred in May 2025, is intended for the local distribution and involves mussels at market size. At this stage, they were harvested and subjected to a cleaning procedure that, although necessary for commercial presentation, can damage shells and byssal threads, compromising mussel survival. Within this context, the aim of the present study was to monitor the productive cycle of a Mediterranean mussel farm located in the mid-western Adriatic Sea to investigate how the harvesting procedures can affect mussels' health status and marketability.

## Materials and Methods

The complete production cycle and the harvesting steps (in February for shipment and in May for local market) were monitored at a commercial farm named Sena Gallica Soc. Cooperativa (Senigallia, AN, Italy; 43°43′N, 13°13′E). During the first harvest, 36 socks (1 m each) were collected prior to the shipment and transported in seawater to the laboratory. A significant number of specimens were immediately sampled from 9 one-meter samples ($t_0$). Then, to replicate the transport conditions, the remaining 27 socks were stacked on three pallets (9 socks each), composing three layers (3 socks each) defined as follows: bottom (BOT), intermediate (INT), and top (TOP). The stacked pallets were then maintained in a climatic chamber set at 7 ± 1 °C for 17 hours, simulating the duration and temperature of typical refrigerated transport. At the end of the 17 hour-period ($t_1$), mussels were sampled from the socks located in each layer (BOT, INT, TOP) on each pallet to evaluate changes, resulting from the transport process, in marketable features and health status investigated through histological (application of histopathological indexes to determine the status of the organ) and molecular (real-time PCR on markers involved in general and oxidative stress response) analysis. During the second harvest, 9 socks were subjected to the cleaning procedure through the automatic machine (company: Cocci Luciano srl) that allowed the separation of all the mussels' categories: (i) cleaned mussels to be sold; (ii) mussel seed; (iii) dead mussels under market size; (iv) dead mussels at market size; (v) mussels damaged by the cleaning procedure. Finally, the percentage incidence of each category (based on their total weight) was calculated.

*(Continued on next page)*

**Results and Discussion**

Considering the first harvest, the simulated transport conditions slightly affected the health status of the mussels stacked in the lowest layer of the stack. In fact, at $t_1$, mussels from the BOT layers highlighted a significantly higher relative expression of markers involved in the oxidative stress response (*sod1* and *cat*) in the gills. This result was supported by a higher incidence of histopathological indexes in gills of mussels located in the BOT layers, including intracellular inclusion of lipofuscin-like substances, epithelium detachment or loss, and lamellar deformations. Differently, the health status of the digestive gland was not altered by the transport conditions as demonstrated by the absence of differences in both histological and molecular analyses. These outcomes can be explained by the higher susceptibility of mussels' gills to oxidative stress caused by environmental fluctuations. In fact, it should be considered that several factors that may occur during transport, including drastic temperature reduction, excessive air exposure or prolonged emersion, and hypoxia conditions due to the packaging method used, can contribute to trigger an oxidative stress response, possibly impairing: (i) survival rate for part of the specimens that are put back in the sea to complete the productive cycle; (ii) the nutritional quality features for the small fraction of specimens that are sold, immediately after shipment, to local market. Considering the second harvest, the percentage of mussels ready to be sold derived from the cleaning procedure accounted for the 77.17 ± 3.63 % of the total sock' weight. The second most represented fraction was the mussels seed that accounted for 14.85 ± 2.87 % of the total sock' weight. The mussels seed represents an interesting fraction: in fact, despite they don't constitute a sellable product, seeds are recovered by the farmer and are used as starting point for the following productive cycle. The dead mussels under market size (0.85 ± 0.12 %) constituted normal production losses since were specimens that died for natural reasons (environmental parameters or presence of predators) during the previous months. The real food loss sources were represented by the dead mussel harvested at market size (2.25 ± 0.53 %) and by mussels irreparably damaged by the cleaning procedure (3.27 ± 0.67 %) which affected the total farm production for 0.36 and 0.68 %, respectively. Differently, slightly damaged mussels, which accounted for 1.62 ± 0.29 % of the total sock' weight, were characterized by minor shell fractures that did not impair the survival from harvesting to the consumer. The discrimination of broken mussels according to the degree of the damage allowed to not overestimate the food loss sources introduced by the automatic cleaning machine. These findings highlighted the major food loss sources that affected the productive cycle analyzed within the present case study and could represent a starting point to be compared with other farms and to optimize the supply chain, minimizing losses.

**Introduction**

The rearing of new aquaculture-relevant species often faces challenges due to limited knowledge about nutritional requirements and other key parameters, frequently resulting in morphological deformities in embryos and larvae. Among the major bottlenecks in the successful cultivation of pikeperch is the low survival rate of larvae, which is often accompanied by a high incidence of malformations (Policar et al.2019; Colcen et al.2020). One of the suspected contributors to these deformities is the microbial environment, particularly the presence of pathogenic or toxin-producing bacteria. Stress sensitivity during critical development phases—especially during the transition to dry feed—can further exacerbate the impact of bacterial pathogens which may lead to the growth of harmful bacteria that produce toxins capable of inducing developmental abnormalities. To better understand and prevent such deformities, continuous monitoring of microbial community composition in the rearing water is essential. A simplified and largely automated system for detecting and quantifying microbial contamination—especially focusing on toxin-producing bacteria—would represent a valuable tool for hatcheries. It would support timely interventions, reduce economic losses, and contribute to higher larval quality and survival. Therefore, the aim of the study was to analyse and quantify specific pathogenic bacteria within the microbial community in the rearing water of pikeperch (*Sander lucioperca*) larvae. Key bacterial species were identified using qPCR and molecular biology techniques, and corresponding marker genes were developed to enable their rapid detection. In addition, the study investigated the relationship between microbial community composition, water quality, and larval deformities during early development stages. The findings contribute to the advancement of sustainable aquaculture practices and support the development of an automated QualiScore system for the early prediction of larval batch quality.

**Material and Methods**

Water samples were collected from a commercial pikeperch (*Sander lucioperca*) hatchery throughout the larval rearing phase to monitor microbial dynamics, starting from tank water without larvae ($t_0$) and continuing through key developmental stages: 4, 9, 12, 23, 30, 39, and 56 days post-hatch (dph), corresponding to major physiological changes such as mouth opening, swim bladder development, transition to dry feed, onset of cannibalism, disease occurrence, and size differentiation. Samples were taken from three different rearing tanks and a biofilter system, with six replicates collected per tank per time point (n = 168). At 56 dph, additional samples (n = 18) were collected from a single tank by separating larvae into small, medium, and large size groups. Bacterial DNA was extracted from 189 samples, and DNA concentration and purity were measured using a Nanodrop spectrophotometer. Microbial community composition was analyzed using 16S rRNA gene amplicon sequencing, and key bacterial taxa were identified. To enable rapid detection of pathogenic and toxin-producing bacterial strains, specific primers for marker genes were developed and quantified using qPCR.

**Results and Discussion**

Preliminary results showed that microbial analysis of pikeperch larvae revealed shifts in bacterial composition over time and differences by size at 56 dph, highlighting the emergence of Flavobacterium infections at later growth stages. Flavobacterium and Pseudomonas increased in abundance from 12 dph onwards, with early stages showing more diverse profiles. By 23 dph, these genera dominated, likely due to changes in environmental conditions or feeding. The shift towards Flavobacterium suggests a potential risk for emerging infections at later stages of growth.

*(Continued on next page)*

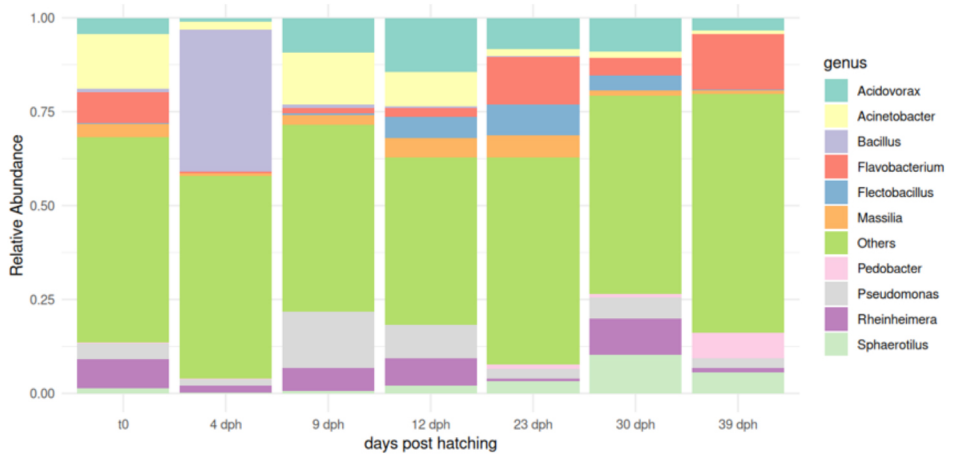

Fig.1. Microbial composition of pike perch rearing water over time.

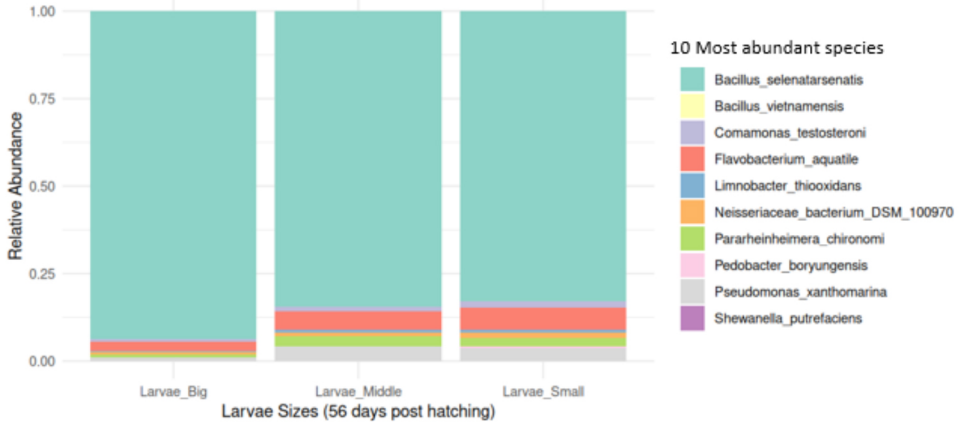

Fig.2. Microbial composition of pike perch larvae during rearing.

At 56 dph, larvae grouped by size showed a microbiome dominated by Bacillus species, with smaller larvae having higher levels of harmful genera like Shewanella and Pseudomonas, indicating greater vulnerability to pathogens. However, the high abundances of Pedobacter and Bacillus species suggest a stable microbial community at different developmental stages, which may contribute to disease prevention and better larval health. These findings emphasize the importance of monitoring entire microbial community composition, particularly emerging pathogens like Flavobacterium, to improve larval health and reduce mortality in hatcheries. The presence of beneficial bacteria like Pedobacter and Bacillus may also help prevent diseases in fish.

## Introduction

The aquaculture industry is expanding rapidly, with logistics accounting for 25% or even more of production costs. Improving transport efficiency while ensuring fish welfare and reducing environmental impact is critical for the sustainable growth of aquaculture. Live fish transport faces challenges such as hypoxia, poor water quality, and bacterial contamination, which can result in significant animal losses. Recent advancements in nanotechnology, specifically nanobubble oxygenation and antibacterial coatings, offer promising solutions to address these issues. Studies have demonstrated that hypoxia is a major cause of stress and mortality in transported fish (Berka, 1986; Gomes et al., 2003; Ren et al., 2022). Nanobubble oxygenators have been shown to improve oxygen levels in controlled environments, extending fish survival during transport (Wang & Wang, 2023). Additionally, antibacterial coatings can reduce microbial contamination in transport water (Dube, 2024). Therefore, the aim of the study was to develop an improved live-fish transport system that enhances welfare, lowers bacterial loads, and reduces costs and emissions.

Two experimental approaches were conducted: (a) testing antimicrobial coatings on tank surfaces to reduce pathogens like *Flavobacterium psychrophilum*, and (b) applying nanobubble oxygenation to improve live transport of rainbow trout. Laboratory trials used a bioreactor to assess bacterial growth and biofilm formation via microscopy and flow cytometry. In parallel, field tests evaluated nanobubble technology for enhancing oxygen supply and fish welfare. The combined aim is to support more sustainable and health-conscious transport systems for rainbow trout.

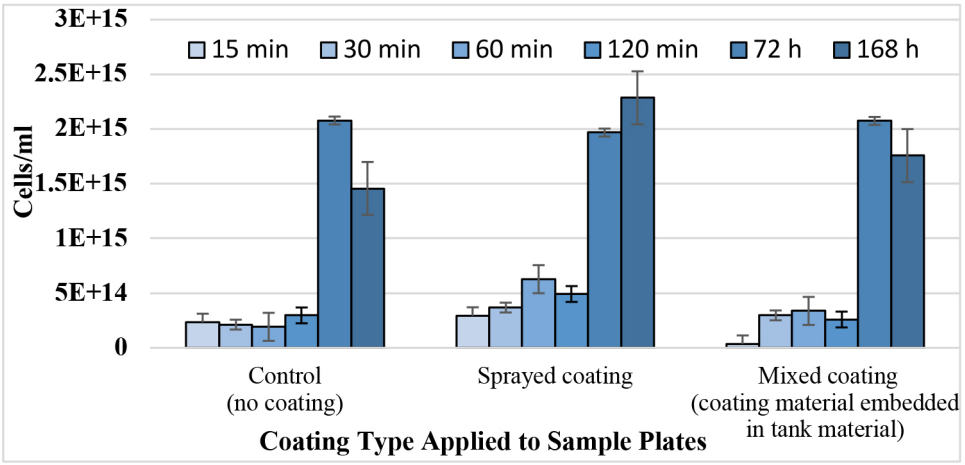

Fig. 1. Attachment of the test bacterial strain *Flavobacterium psychrophilum* over time on sample plates with different antibacterial coatings.

*(Continued on next page)*

**Material and Methods**

a) *Coating experiment*: In this experiment, we tested the antibacterial effectiveness of different coatings applied to sample plates—sections of tank wall material specifically cut and prepared for laboratory testing. Three coating types were investigated: (1) Control (no coating), (2) Sprayed coating, and (3) Mixed coating (coating material embedded directly into raw tank wall material). To assess bacterial attachment and biofilm formation, we first cultured the bacterium *Flavobacterium psychrophilum*, a pathogen commonly associated with disease outbreaks in rainbow trout (Oncorhynchus mykiss), our test species. The coated and control plates were then placed into a bioreactor system simulating aquaculture conditions. This system consisted of eight rotating sticks, each randomly fitted with one of the three coating types (four replicates per group). The coated plates were exposed to bacterial growth medium (TYES) for defined time intervals: 15 and 30 minutes, and 1, 2, 72, and 168 hours. After each time point, samples were taken, and the plates were stained using the DAPI method to visualize attached bacterial cells. Bacterial attachment and biofilm formation were then analyzed via fluorescence microscopy and flow cytometry to quantify cell numbers on each coating type.

b) *Nanobubble Experiment*: To evaluate the effect of nanobubble aeration on water quality during live fish transport, we conducted a transport simulation experiment using six tanks. Three tanks were equipped with a standard aeration system (control group), and three tanks used a nanobubble generator (experimental group). Each group included three replicates. Nanobubbles are extremely small gas bubbles, typically 100–200 nm in diameter, that can remain suspended in liquid for extended periods due to their neutral buoyancy and stability. These properties allow nanobubbles to deliver oxygen more efficiently than conventional aeration methods, potentially improving dissolved oxygen levels in closed transport systems. All tanks were filled with water directly pumped from rainbow trout rearing ponds to replicate real-world transport conditions. Throughout the experiment, key water quality parameters—including dissolved oxygen, ammonia, nitrite, nitrate, and pH—were continuously monitored. Water samples were collected at both the start and end of the experiment to assess bacterial load. These samples were analyzed using DAPI staining to count bacterial cells and via DNA extraction for later molecular analysis of the microbial community structure.

**Results and Discussion**

Attachment of the test bacterial strain *Flavobacterium psychrophilum* showed no significant differences between coating types and increased over time, with the highest cell counts observed at 72 and 168 hours. While some differences in cell counts were observed between the coatings, no consistent pattern or clear advantage of one coating over another could be identified (Fig.1). In the meantime, a new set of coated plates has been prepared for field testing at commercial trout farm. The plates will be submerged in pond water to evaluate coating performance under real environmental conditions. Further results from the coatings experiments are pending to confirm these initial findings and to evaluate potential trends and performance in live fish transport. In the nanobubble experiment, oxygen levels reached 200% within 15 minutes and exceeded the measurement limit after 60 minutes.

**Introduction**

Salmon lice (*Lepeophtheirus salmonis*) pose a serious ecological and economic threat to both farmed and wild salmon. Detection of salmon louse larvae—especially during pre-infective and infective stages—can be crucial for timely intervention. While polymerase chain reaction (PCR) offers high accuracy, it is costly and to date impractical for continuous real-time monitoring. Machine learning offers a promising alternative, but current models often fail in real-world conditions due to limited annotated data and training on simplified laboratory environments. Robust detection systems must perform reliably across changing water conditions and plankton communities, which requires diverse datasets based on samples collected in the field. This remains a major challenge to achieving generalizable and scalable solutions.

**Materials and methods**

To address these challenges, we propose a synthetic data generation framework based on the Segment Anything Model (SAM) tailored for the detection of salmon louse larvae across multiple developmental stages in real-world seawater conditions (Fig. 1). A total of 54 orthogonal experiments were conducted to optimize the parameter configuration, leading to the creation of a high-quality synthetic dataset comprising 120,864 images. To fully exploit the synthetic data and improve detection performance, we evaluated models from the YOLO series alongside the transformer-based RT-DETR-L model. Four distinct training strategies were systematically tested: (1) Baseline - trained solely on the original training set; (2) Synthetic-Only - trained only on the synthetic dataset; (3) Fine-tuning - pretrained on the optimal synthetic set, then fine-tuned on the original data; (4) Combined - trained on a merged set of synthetic and original data. The final model was further validated on real-world seawater samples to assess its generalizability and robustness.

**Results and Discussion**

Our experiments demonstrated that pretraining on synthetic data—followed by fine-tuning or combined training—consistently enhanced model performance across multiple evaluation metrics (Fig 2). For instance, the YOLOv8n model's F1-score improved from 70.6% to 87.7%, representing a substantial relative gain of 24.22%. In real-world seawater tests, models trained with synthetic data achieved an 11.0% increase in recall, reaching 87.0%, compared to models trained solely on original data. Notably, these models also outperformed experienced human biologists, further validating the effectiveness and practical applicability of the synthetic data generation approach.

Our synthetic data approach offers a flexible and scalable solution for marine parasite detection, with strong potential for transferability across regions, seasons, and species. Although initially developed using local samples, the model effectively captures broad plankton diversity. By integrating representative samples and synthetic data from new environments, it can rapidly adapt and improve based on real-world inputs. This adaptability enhances model robustness and enables large-scale, real-time monitoring of salmon lice and other marine organisms.

**Conclusion**

This study presents a scalable and effective approach for monitoring salmon louse larvae in complex marine environments. By leveraging synthetic data, it overcomes key challenges in data collection and annotation, enabling robust model performance under real-world conditions and rapid adaptation to new environments. The method outperforms expert detection, highlighting its strong potential for large-scale application in seawater surveillance and enhancing health management of both farmed and wild salmon populations.

## Introduction

Soybean meal (SBM) is a predominant plant-based protein in fish feed due to its suitable protein content (~48%) and amino acid profile (Bai et al., 2022). However, previous studies indicated plant-based proteins are closely linked to land use-related emissions (Simon et al., 2024), and contain antinutritional factors and limited concentrations of methionine and lysine. *Clostridium autoethanogenum* protein (CAP) is a novel bacterial protein produced via the gaseous fermentation of one-carbon gases ($CO_2$, CO, and $H_2$) primarily sourced from industrial waste streams (Wang et al., 2023). Compared to SBM, CAP has a higher crude protein content (~80%) and a suitable essential amino acid profile, and its feasibility as a replacement for SBM has been evaluated in the diets of various fish species (Wu et al., 2024). However, replacing SBM with CAP in experimental diets may require the inclusion of an inert bulk agent, such as microcrystalline cellulose (MCC), which can reduce the nutrient density of the diet and consequently trigger compensatory feed intake in fish (Lekva et al., 2010). The aim of this study, therefore, is to evaluate the effects of replacing SBM with CAP on the growth performance of rainbow trout while accounting for the dilution effects on nutrient density.

## Materials and methods

The growth trial was conducted for 67 days in a recirculating aquaculture system (RAS) at Qinghai University, Qinghai, China. A total of 840 fish (initial body weight: 84.10 ± 0.08 g) were acclimated for three weeks to adapt to the experimental conditions. Three iso-nitrogenous and iso-lipidic experimental diets were formulated: (1) control: 20% SBM and 0% CAP; (2) CAPS6: 10% SBM and 6% CAP; and (3) CAPS12: 0% SBM and 12% CAP. The control diet contained similar composition and nutritional profile as commercial diets. Appropriate amounts of lysine, methionine, and threonine were added to balance the amino acid profile, and MCC was included as an inert filler to adjust all diets to a standardized total of 100%. Fish were hand-fed to apparent satiation twice daily (at 09:00 and 17:00), and daily feed intake was recorded. All water quality parameters were maintained within the optimal range to support fish growth. Growth performance parameters, including final body weight (FBW), feed intake (FI), feed conversion ratio (FCR), and weight gain rate (WGR), were calculated. To correct for the nutrient dilution effects, corrected feed intake (FIc) and corrected feed conversion ratio (FCRc) were also calculated.

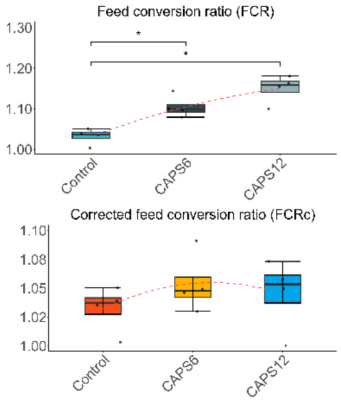

Figure 1. The feed conversion ratio of rainbow trout fed experimental diets. The red dashed line indicates the linear trend. The black dots indicate individual observations.

Figure 2. The corrected feed conversion ratio of rainbow trout fed experimental diets. The red dashed line indicates the linear trend. The black dots indicate individual observations.

*(Continued on next page)*

**Main results and discussions**

In present study, no significant differences in FBW, FI, or WGR were observed between CAP inclusion treatments and the control ($P > 0.05$). However, the FCR increased with rising CAP inclusion levels ($P < 0.05$) (Figure 1), whereas the FCRc remained comparable to the control ($P > 0.05$) (Figure 2). The current growth trial showed that CAP had no negative effects on rainbow trout growth. However, the inclusion of MCC may have introduced a nutrient dilution effect, thereby reducing the availability of digestible nutrients (Tran-Duy et al., 2008). As a result, fish may have responded by increasing feed consumption to compensate for the lower nutrient density (Costa et al., 2022). After correcting for nutrient dilution, FCRc in CAPS6 and CAPS12 was not significantly different from that of the control. Moreover, FIc showed a downward trend from the control to CAPS12, although the differences were not statistically significant.

**Conclusions**

This study indicated that completely replacing SBM with a novel bacterial protein did not significantly affect FBW, FI, or WGR. However, as the inert filler inclusion level increased, the nutrient density of the experimental diets was reduced, resulting in increased FCR as fish attempted to meet their nutritional requirements. Therefore, the nutrient dilution effects of inert fillers should be further investigated, especially in carnivorous species.

# ENVIRONMENTAL FACTOR MANIPULATION IN RECIRCULATING AQUACULTURE SYSTEMS (RAS): EFFECTS OF LIGHT WAVELENGTH, SALINITY, AND TEMPERATURE ON FISH GROWTH PERFORMANCE

Yafan Zhu*, Akihiro Takemura

Organization for Research Promotion
University of the Ryukyus
Senbaru 1, Nishihara, Okinawa 903-0213, Japan
xygz48@hotmail.com

Recirculating aquaculture systems (RAS) represent a crucial technological advancement in the aquaculture industry, with optimizing production efficiency. A key research priority remains to maximize and optimize the growth and reproduction of rearing fish species. Although environmental factors significantly influence fish growth, their systematic manipulation in RAS requires further investigation. This study examined the effects of specific environmental parameters on the growth performance of Malabar grouper (*Epinephelus malabaricus*), an economically important species in Asian markets. We evaluated the impacts of light wavelength, salinity, and temperature under controlled RAS conditions.

Under conditions of long-day photoperiod (light: dark = 14:10) and 21°C water temperature with red (peak at 632 nm), green (519 nm), and blue (465 nm) LED, and natural light, the specific growth rate (SGR) was significantly higher ($P < 0.05$) in fish exposed to blue LED light than to red LED light. In salinity trials conducted at 26°C, fish maintained at lower salinities (5 and 11 psu) demonstrated significantly higher SGR compared to those at higher salinities (22 and 34 psu) ($P < 0.05$). Temperature experiments revealed significantly enhanced fish SGR at 30°C compared to both 20 and 25°C ( < 0.05) under long-day photoperiodic conditions.

These findings demonstrate that the manipulation of environmental parameter can optimize fish growth in RAS operations. However, further research is needed to investigate potential interactive and synergistic effects among these environmental factors, which could provide additional insights for commercial aqua culture applications.

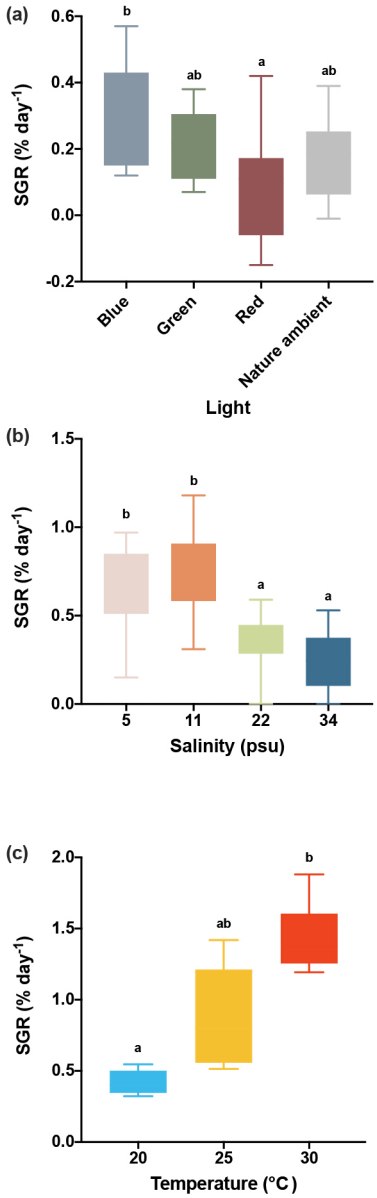

**Fig. 1. SGR of the Malabar grouper juveniles under different controlled RAS conditions: light wavelength, salinity, and water temperature.**

# META-LEARNING ENHANCED CNN TRANSFER LEARNING FOR INDIVIDUAL FISH IDENTIFICATION IN WILD POPULATIONS

Mohamad Mehdi Ziaei[1*], Petr Cisar[1]

[1]AquaVision, Faculty of Fisheries and Protection of Waters, CENAKVA, University of South Bohemia in Ceske Budejovice, Zámek 136, Nové Hrady 373 33, Czech Republic
Email: ziaei@frov.jcu.cz

## Introduction

Accurate monitoring of individual fish within their natural settings is needed for ecological studies, conservation schemes, and sustainable fisheries management. A reliable, non-invasive identification system could provide valuable insights into health, and population dynamics with minimal effect on their ecological routines. However, no specific, standardized method currently exists for individual fish identification in wild and open-group populations. Developing such a farmework may seem impractical due to the visual similarity among individuals. Nevertheless, recent advances in artificial intelligence particularly in computer vision, convolutional neural networks (CNNs) for performing biometric tasks [1], transfer learning, and meta-learning offer a promising pathway toward automating this challenging task [2]. Herein, we present a prototype of a meta-learning-based biometric system developed to identify and match individual rainbow trout. The system was evaluated using data collected over a 70-day period from rivers across the Czech Republic. Preliminary results from the individual matching via developed system demonstrate promising outcomes, highlighting the potential of this approach for reliable open-group identification in natural water bodies.

## Materials and methods

### Dataset

We utilized an open-group dataset, which included still images of trout captured out of the water. All fish were consistently oriented to the same side for image capturing to ensure uniformity. Data collection was carried out over 10 sessions, and in each session, fish were carefully captured from the river, photographed, and subsequently released back into the sampling fishing site. At the conclusion of the data collection process, the dataset consisted of 535 images representing 425 individuals. Among these, 67 individuals were observed across multiple more than one time across sessions, providing valuable data for cross-session matching. Expert annotators manually labelled the dataset to match the same individuals across different sessions. Both individuals who appeared more than once and those captured only once were assigned unique class labels (ID of individuals). These labelled classes served as the basis for training and evaluating the proposed biometric identification system.

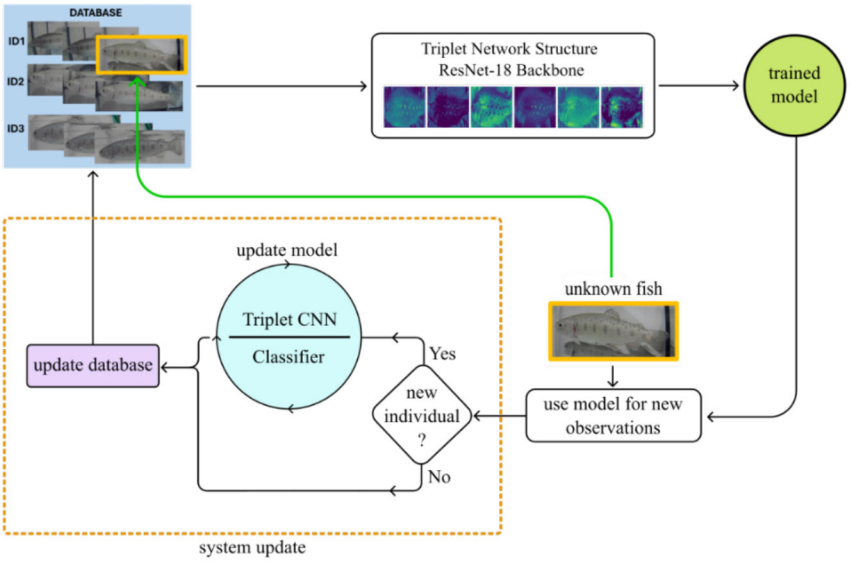

Figure1: Illustration of the proposed learning framework for open-group individual fish identification

*(Continued on next page)*

**Methodology**

The proposed system utilizes a triplet network with a ResNet-18 backbone for individual identification of trout. This method employs an incremental learning strategy, enabling the system to add new classes of individuals to update the model and database progressively. The model is trained from scratch on a dataset including five known individuals. After each training cycle, the model compares newly observed individuals with the existing database, adding into the individual's set if a match is found or assigning the image as a new class in case no match is detected. The model is continuously retrained after each cycle of database update with the transferred weights from the previous phase and improves the generalization ability effectively. A thresholding strategy is employed to balance the trade-off between confidence in matching and the risk of class fragmentation of the same individuals. This framework supports few-shot learning, enabling robust re-identification for limited observations.

**Results**

The preliminary results of the proposed method achieved a Top-1 identification accuracy of 80.3% at the final stage of the incremental learning process. A class prediction probability threshold of 0.33 yielded optimal performance, and few-shot evaluations on the dataset showed 84% accuracy with three or more observations per individual. The model also maintained strong identity grouping, with an Identity Consistency Rate of 89.7% and a Class Purity of 92.1%.

**Conclusion**

This study presented an incremental, meta-learning-based system for individual identification of open-group trout. The results demonstrate that the open-group identification of fish species can be achievable with a low number of observations per individual. By using a progressive learning strategy, the model achieved a satisfactory Identity Consistency Rate and Class Purity metrics, effectively demonstrating its ability to adapt to new individuals. This method also holds potential for practical applications in the field of aquaculture. Further development of the proposed system could provide a promising solution not only for ecological monitoring but also for advancing automated stock management in aquaculture.

# BLUE MUSSELS: SINNERS OR SAINTS? GREENHOUSE GAS EMISSIONS FROM SHELL FORMATION IN THE NORTH ATLANTIC

## Introduction

Farmed blue mussels (*Mytilus edulis*) are one of the animal-source foods with the lowest greenhouse gas emissions associated with their production, i.e. from material and energy use in spat collection to grow-out production (Gephart et al. 2021), mainly related to their independence from manufactured feeds. Feed often comprises the lion's share of farmgate emissions of farmed seafood (Bohnes et al. 2019). However, it has been suggested that the carbon dioxide released into the ocean during the calcification process of shells makes a non-trivial contribution to farmgate greenhouse gas emissions and excluding it may lead to an underestimation of total emissions (Ray et al. 2018). The Mussel Puzzle is a three-year project aiming to quantify the environmental impacts of different mussel production technologies across various locations using Life Cycle Assessment (LCA) while also assessing the potential for industry expansion and its related environmental trade-offs. Here, we quantify the carbon dioxide released over time from shell calcification in major mussel production areas in the North Atlantic.

## Methods

Carbon dioxide emissions from shell formation were calculated using the formula:
$CO_2$ Emissions = $\psi$ × Shell Mass × Percent $CaCO_3$ × Molecular Ratio

To do this, the buffering capacity ($\psi$) of seawater was calculated using the *psi* function within the *seacarb* package in R (Gattuso et al. 2024). This function estimates the seawater's buffering capacity under specified conditions. The $\psi$ calculation requires location-specific data on sea surface temperature, salinity, pH and the surface partial pressure of carbon dioxide in seawater ($spCO_2$). These data points were extracted from satellite data provided by the EU's Copernicus program. Carbon dioxide emissions from shell formation were then calculated on a monthly basis for the major mussel production countries in the North Atlantic, based on FAO production databases for the three most recent years available (2022 - 2024). Spain, as the most important European mussel producer, was included, although the main species produced is *M. galloproviancialis* rather than *M.edulis*.

## Results

Results show considerable variability in $CO_2$ emissions from shell formation across different sites, with Canada having the highest average emissions and Spain the lowest (Fig. 1). Emissions seem to be largely temperature-driven, as the ranking closely follows latitude. In particular, the northern latitudes show considerable seasonal variability, with higher emissions in the winter and lower in the summer, while seasonal variability in the southern latitudes is much smaller.

## Discussion

We show considerable variability in shell formation emissions across farming regions. In particular, northern latitudes show considerable temporal variation in emissions between summer and winter. It is important to note that not all of these emissions will reach the atmosphere and contribute to global warming, but it is difficult to determine exactly how much will. In our presentation, we will discuss this and relate the greenhouse gas emissions from shell formation to those generated by production processes, which have typically been included in greenhouse gas emission estimates. Whether mussels are sinners or saints, i.e. sources or sinks of carbon, also depends on what happens with shells after harvest and the time horizon in the assessment. We will discuss how to incorporate these findings into future greenhouse gas emissions accounting for farmed mussels.

*(Continued on next page)*

**Introduction**

Adriatic aquaculture, like marine aquaculture across the Mediterranean, faces significant losses due to infections caused by *Vibrio harveyi*, an opportunistic bacterium. The disease has a seasonal pattern, typically occurring during the summer months when sea temperatures exceed 21 °C (Montánchez & Kaberdin, 2020). Affected fish exhibit symptoms such as lethargy, loss of appetite, depigmentation, erosions, haemorrhages at the base of the fins, skin ulceration, keratitis, corneal opacity, exophthalmia, and pale gills with haemorrhaging. Without treatment, mortality rates can be substantial (Zupičić et al., 2019). Outbreak management of *V. harveyi* relies heavily on the use of antibiotics. While good aquaculture practices can help mitigate losses to some extent, no commercial vaccines are currently available to prevent outbreaks. Moreover, only a few studies have evaluated the efficacy of autogenous vaccines in Mediterranean aquaculture—primarily for species such as sole (Arijo et al., 2005) and, more recently, flathead mullet (Strem et al., 2023). In contrast, several studies from Asian marine aquaculture report successful experimental vaccinations using different vaccine types against *V. harveyi* (Chin et al., 2019; Abu Nor, 2020; Zhang et al., 2021; Erfanmanesh et al., 2024).

The Interreg Italy–Croatia project MARINET aims to develop an effective autogenous vaccine against *V. harveyi* and to monitor the duration of immunity under real farming conditions.

*Material and methods*

Selected *Vibrio harveyi* isolates were cultivated in tryptic soy broth (TSB) supplemented with 2% NaCl to produce a starter culture for vaccine production. This starter culture was then fermented in a bioreactor to generate a formalin-inactivated whole-cell vaccine (FMC), reaching a final optical density ($OD_{600}$) of 3.6.

Upon arrival at the experimental facility, seabass fry was tested for the presence of *V. harveyi*. The experimental design included six groups (n = 10 per group), with a mean individual body weight of 10 grams, each tested in triplicate: Groups 1 & 2**:** Immersion-vaccinated for 1 minute in a 1:10 vaccine dilution (final concentration: $2.5 \times 10^8$ CFU/mL); Groups 3 & 4**:** Intraperitoneally (i.p.) vaccinated with 0.1 mL per fish (dose: $1.1 \times 10^9$ CFU/mL); Group 5: Mock-vaccinated by immersion in seawater for 1 minute; Group 6: Mock-vaccinated by i.p. injection of 0.1 mL phosphate-buffered saline (PBS) per fish.

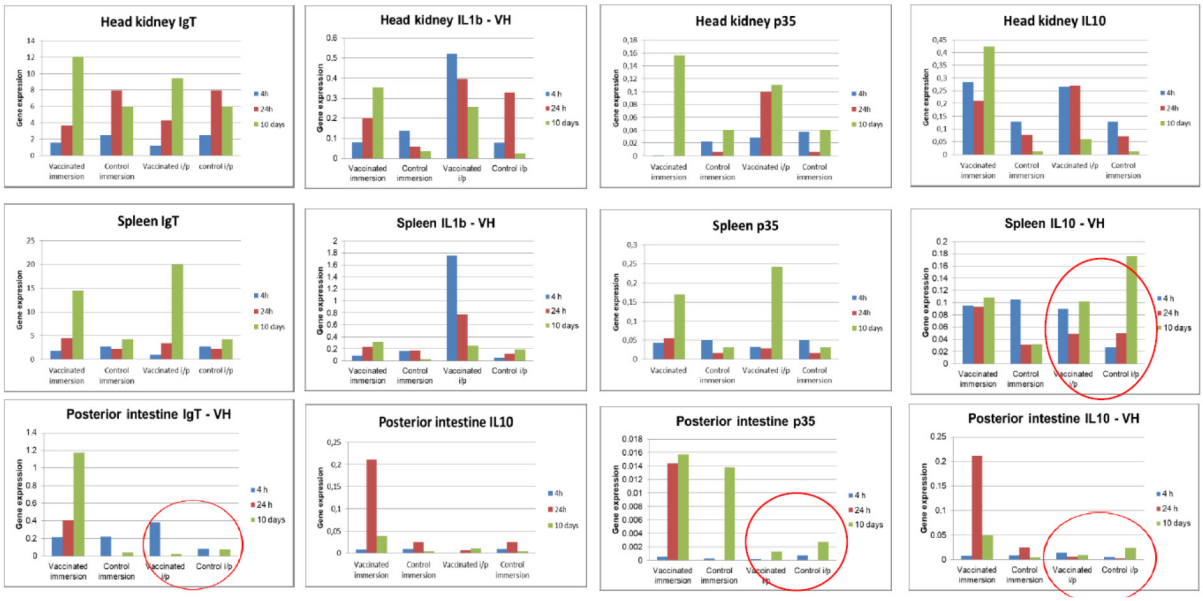
Vaccine efficacy was assessed by measuring specific IgM titers in sera collected one-month post-vaccination using ELISA. Additionally, head kidney, spleen, and intestinal tissues were collected from six fish per group at 4 hours, 24 hours, and 10 days post-vaccination. Samples were preserved in RNAlater and stored frozen for analysis of gene expression related to immune response (Mitler et al., 2009).

After 36 days in experimental tanks, all fish were challenged with a virulent dose of *V. harveyi*. Ten days post-challenge, the Relative Percent Survival (RPS) was calculated following the method described by Amend (1981).
Vaccinated fish from the farm trial were also tested for specific IgM titres and expression of selected immune-related genes.

*Results*

Based on the Relative Percent Survival (RPS) results, intraperitoneal (i.p.) vaccination provided the highest level of protection (RPS = 100), although immersion vaccination also yielded satisfactory results (RPS = 67). These findings confirm that the autologous vaccine against vibriosis caused by *Vibrio harveyi* offers effective protection for juvenile European seabass.

*(Continued on next page)*



Analysis of immune gene expression showed upregulation of IgT in all examined organs for both vaccination routes, except in the intestine of i.p.-vaccinated fish, where no upregulation was observed. IL-1β expression was upregulated in the head kidney and spleen—and slightly in the posterior intestine—of immersion-vaccinated fish, while it was downregulated in the posterior intestine of i.p.-vaccinated fish. p35 was upregulated in the head kidney and slightly in the posterior intestine of immersion-vaccinated fish, but downregulated in the posterior intestine following i.p. vaccination. IL-10 was upregulated in the head kidney and spleen of immersion-vaccinated fish, but downregulated in both the spleen and posterior intestine of i.p.-vaccinated fish.

Sera were collected from laboratory-vaccinated fish 30 days post-vaccination and tested for specific IgM against *V. harveyi* bacterin using ELISA. Results showed a slightly higher IgM titre in immersion-vaccinated fish compared to mock-vaccinated controls (Fig. 9a). In contrast, i.p.-vaccinated fish exhibited significantly higher

IgM titres compared to the PBS-injected control group. In farm-vaccinated fish, specific anti-*V. harveyi* IgM titres were slightly elevated two and ten months after vaccination, both in fish vaccinated solely against *V. harveyi* and in those vaccinated with a combined vaccine (*V. harveyi* and routine *V. anguillarum*). Titres were higher at two months post-vaccination compared to ten months, and were elevated compared to the control group.

These findings provide a solid foundation for further optimization of vaccine formulation and support additional testing under field conditions to improve protection against *V. harveyi* in commercial aquaculture.

e-mail: pzuanovic22@unizd.hr

Climate change threatens the sustainable cultivation of the Mediterranean mussel (*Mytilus galloprovincialis*) in the Adriatic Sea and affects its market quality. One measure of quality is the relative proportion of the edible part („meat“) measured by the condition index. In summer, at the time of highest market demand, high temperatures and fluctuations in water inflow from land can affect the reduced amount of food in nature and cause a drop in the condition index (CI=dry meat mass/shell mass) of cultured mussels. Time-limited shellfish farming in the recirculation system, along with controlled feeding, is a technological solution for mitigating the consequences of climate change. In this work, the influence of the size of the daily meal, of 3% ,4,5% and 6% dry matter of single-celled algae (*Tisocrisis lutea*) per gram of dry matter of meat on mussel CI, at three temperatures (12, 18 and 24°C), was evaluated. After acclimatization (7 days), after feeding for 14 days, and after starvation for 14 days, a sample of 15 individuals was taken from each pool to measure length, mass, mass of dried meat and calculate CI. The results obtained were tested by ANOVA Main Effects. The temperature had a significantly weaker effect than the size of a daily meal

# THE EFFECT OF INCLUDING FERMENTED AND HYDROLYZED *Rugulopteryx okamurae* IN THE DIET ON GROWTH AND FATTY ACID PROFILE OF EUROPEAN SEABASS

E. Zuasti[1], M. Ponce[1*], A. Morcillo-Guillén[2], A. Galafat[2], F.J. Alarcón-López[2], A.J. Vizcaíno[2] and I. Hachero-Cruzado[1]

**Introduction**

Since 2015, the expansion of the invasive macroalgae *Rugulopteryx okamurae* along the coastlines of Andalusia has resulted in the periodic accumulation of substantial quantities of algae on the region's beaches. In recent years, a variety of methods for the recovery of this algal biomass have been proposed, covering applications in various sectors, including cosmetics and pharmaceuticals, biogas production, the production of bioplastics and its use as compost (reviewed by Figueroa et al., 2025). Another particularly promising possibility for the valorisation of this biomass is its use as an ingredient and/or additive in animal feed, and more specifically in aquaculture, which could be of great interest due to the presence in algae of bioactive compounds with bactericidal, immunostimulant, and antioxidant properties (Barcellos et al., 2023; Cebrián-Lloret et al., 2024).). However, it has been demonstrated that pretreatment of the algal biomass is necessary, specifically through enzymatic hydrolysis and microbial fermentation, in order to improve its nutritional content and enhance nutrient bioavailability in the fish gut (Vizcaíno et al. 2024). The objective of the present study was to evaluate the influence of pretreated *R. okamurae* biomass dietary inclusion on European seabass (*Dicentrarchus labrax*) growth and fatty acid composition. In order to investigate this, European seabass juveniles were fed diets supplemented with pretreated *R. okamurae* biomass at levels of 5, 10, and 20% for a period of 110 days.

**Material and methods**

The algal biomass was collected from the coasts of the Strait of Gibraltar (Cádiz), subsequently washed and dried at 30°C for 12 hours, and subjected to a prior biotechnological treatment based on an enzymatic hydrolysis process followed by a fermentation process with microorganisms using a modification of the methodology described by Vizcaíno et al. (2024). In the feeding trial, four experimental isoprotein (44% dry matter [DM]) and isolipid (15% DM) diets were formulated. The control diet (CT) was prepared using a standard mixture of ingredients, without incorporation of algal biomass. The three other diets included processed biomass of *R. okamurae* at different inclusion levels: 5% (R5), 10% (R10), and 20% (R20), with wheat flour being mainly replaced. All experimental diets were developed by the Experimental Diets Unit of the University of Almería, based on previously validated formulations for juvenile European seabass according to Vizcaíno et al. (2024).

The *in vivo* feeding trial was conducted in Puerto de Santa María (Cádiz), at the facilities of the Institute for Agricultural and Fisheries Research and Training (IFAPA, El Toruño, Cádiz) of the Regional Government of Andalusia. The trial utilised 420 specimens, with an initial mean weight of 88.86 ± 1.45 g, provided by the aquaculture company CUPIBAR (Chiclana, Cádiz, Spain). Prior to the commencement of the feeding trial, the animals underwent a 15-day acclimatisation period, during which they were fed a commercial feed. The fish were then randomly distributed among 12 700-L tanks at a rate of 35 fish per tank, where they were fed the experimental diets for a period of 110 days. During the course of the trial, feeding was conducted using automatic feeders, with 20 daily rations being distributed over a 10-hour period (from 10:00 a.m. to 7:30 p.m.). Furthermore, feed quantities were modified on a weekly basis, with adjustments made based on a biomass estimate obtained from the most recent sampling data. These adjustments were made in accordance with feeding rates ranging from 1.5% to 1.8% of the total estimated weight. The experimental conditions were meticulously controlled and monitored to ensure optimal culture conditions. The temperature of the water was maintained at a constant level between 19°C and 20°C, and the photoperiod was set at 12 hours of darkness and 12 hours of light.

Total lipids (TL) were extracted using the chloroform: methanol method and gravimetrically quantified. For fatty acid methyl ester (FAME) determination, TL extracts were subjected to acid-catalyzed transmethylation and later they were separated and quantified by gas chromatography.

*(Continued on next page)*

**Results and discussion**

A significant decrease in the specific growth rate of juvenile sea bass was observed in fish fed diets containing 10% (SGR=0.74) and 20% (SGR=0.66) of pretreated *R. okamurae* biomass, compared to the CT treatment (SGR=0.80). No differences were detected in the vicerosomatic and perivisceral fat indices; however, a statistically significant decrease in the hepatosomatic index was observed in fish fed the R20 diet (HSI=1.49), respecting the CT group (HSI=2.22). This decline in the HSI was connected with a decrease in the lipids content of fish liver fed the R20 diet (59.0% DW) in comparison to the CT group (66.9% DW). Furthermore, a lower deposition of monounsaturated fatty acids (MUFA) and an increase in the relative levels of n-3 and n-6 polyunsaturated fatty acids (PUFA) were detected in liver in relation to the inclusion of RO in the diet. With regard to muscle lipid composition, no significant differences were observed in total lipids, saturated fatty acids (SAT), monounsaturated fatty acids (MUFA), and n-6 polyunsaturated fatty acids (PUFA) groups between experimental groups, although higher proportions of the polyunsaturated fatty acids arachidonic acid (ARA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) were detected in fish fed the R20 diet.

The present study found that fish fed diets comprising more than 5% of pretreated *R. okamurae* biomass exhibited a significant decrease in growth, demonstrating a clear dose-dependent trend. This decline in growth performance could be attributed to the low digestibility of this macroalga for a carnivorous species such as sea bass (Cebrián-Lloret et al., 2024). Furthermore, a progressive decline in the hepatosomatic index and hepatic lipid reserves was observed with increasing algal biomass inclusion, suggesting a lower accumulation of energy reserves in the liver, possibly due to suboptimal absorption of essential nutrients. Finally, the stability of lipids and fatty acids composition of Sea bass muscle suggests that the use of *R. okamurae* in the diet does not compromise the quality of the final product.

## Introduction

In recent years, recombinant gonadotropins (rGths) have become increasingly important among technologies to overcome reproductive dysfunctions of cultured fish and to advance puberty. The administration of species-specific recombinant gonadotropins (rGths) for flathead grey mullet *Mugil cephalus*, was effective in overcoming the severe reproductive dysfunctions observed in this species under captive conditions, ultimately leading to the production of high-quality fertilised eggs (Ramos-Judez et al., 2022; Cerrud-Barría et al., 2025). This study aimed to analyse the effectiveness of a single injection of rFsh in inducing spermatogenesis in juvenile flathead grey mullet *Mugil cephalus* with recently differentiated testes and no signs of spermatogenic activity.

## Material and Methods

Grey mullet juveniles were caught from the wild population from Ebro river Delta and reared at IRTA (Ràpita, Spain) under controlled photoperiod. On 16 May 2024 (day 0 of the experiment) untreated fish (group C-0; N = 9) were sampled to assess the reproductive state on the day the other groups were treated. Treated fish (group rFsh-T; N = 10) were administered a single dose of 12 µg $kg^{-1}$ rFsh. Control fish (group C-7; N = 9) were given a single injection of 0.35 mL of saline solution. Fish from groups rFsh-T and C-7 were anaesthetised, sacrificed and sampled 7 days after treatment. Blood samples were taken and centrifuged to collect plasma for measuring 11-ketotestosterone (11-KT) concentration (EIA essay; Cayman Chemical Company, USA). Fish total length (TL, in cm), body mass (BM, in g) and gonad mass (GM, in g) were measured and gonadosomatic index (GSI) was calculated as 100 x GM/BM. Small testis slices were fixed in Bouin's solution and embedded in paraffin wax. Deparaffinized sections were stained with hematoxylin-eosin and proliferating spermatogonia were identified through the immunohistochemical detection of the proliferating cell nuclear antigen (PCNA; Santa Cruz Biotechnology Inc., Dallas, Texas).

## Results and Discussion

The GSI of the rFsh-T group was significantly higher than that of the C-0 group (0.06 ± 0.03 vs. 0.03 ± 0.02; $P < 0.05$), but not different from that of the C-7 group (0.06 ± 0.03 vs. 0.05 ± 0.01; $P = 0.34$). In both control groups, small seminiferous tubules were observed, which were predominantly composed of single undifferentiated type A (type $A_{und}$) spermatogonia (Fig. 1a). Among the ten fish treated with rFsh, six individuals displayed a testicular appearance similar to that of the control groups and were classified as non-responsive to rFsh treatment, whereas four rFsh-T individuals showed more advanced stages of germ cell development, including committed spermatogonia and spermatocytes (Fig. 1b), and were classified as responsive to rFsh treatment. No responsive fish were observed in control C-7 group. The diameter of the seminiferous tubules in responsive fish (42.5 ± 3.2 µm) was significantly larger than that of both control groups (C-0, 27.0 ± 3.8 µm; C-7, 28.4 ± 2.9 µm) and non-responsive rFsh-T individuals (32.9 ± 6.5 µm) ($P < 0.05$ in all comparisons). The rFsh-T responsive fish displayed a significant increase in proliferating committed spermatogonia compared with C-0 and C-7 ($P < 0.05$ in both comparisons) (Figs. 1c and 2a, b). The 11-KT plasma concentration was significantly higher ($P < 0.05$) in rFsh-T responsive fish compared to both control groups and non-responsive fish ($P < 0.05$) (Fig. 2c).

The results of the present study indicate that rFsh administration was effective in stimulating testis growth, proliferation of spermatogonia committed towards meiosis and 11-KT secretion in 40% of immature grey mullet with quiescent testes that did not show sign of spermatogenetic activity. This study suggests the potential suitability of the produced recombinant gonadotropin in advancing puberty in immature grey mullet reared under farming conditions.

zupan@unizd.hr

European flat oyster (*Ostrea edulis*) is a highly priced sea food product, while oysters from Mali Ston Bay (South Adriatic Sea) are labelled with designation of origin (PDO) due to interaction of environmental conditions and quality of the oysters. The aim of this work was to determine the changes of chemical composition in oysters preserved by using IQF technology, with a goal of freezing oyster during the period of the best quality (March/April).The oysters were sampled from the bivalve farms at Mali Ston area and the Krka River estuary in March 2023, when they are characterized by a high condition index, frozen in whole shell with liquid nitrogen at -80 °C, divided and stored at two temperatures: -18 °C and -60 °C for 3 months. No significant differences were observed in the increase in total volatile base nitrogen (TVB-N) with respect to freezing temperatures, while the pH value increased slightly only during the first month of storage, for both sites, respectively. Mass fraction of saturated fatty acids (SFA) in oyster samples from both sites increased slightly during storage or had values close to the initial ones at both temperatures. In both types of oysters and at both storage temperatures, the mass fraction of polyunsaturated α-linolenic fatty acid (C18:2 *cis*) decreased, while the proportions of α-linolenic (C18:3n3) and *cis*-13,16-docosadienoic acid (C22:2) increased during storage. The greatest change in the proportions of polyunsaturated fatty acids occurred with the decrease in the proportion of linoleic acid in Ston oysters, mostly during the first month at both temperatures. Compared to the initial samples, a higher mass fraction of monounsaturated fatty acids (MUFA), namely palmitoleic acid (C16:1) was quantified and the mass fraction of oleic acid (C18:1 cis) was quantified in a lower mass fraction, respectively. The results obtained show that the IQF technology is a good method for preserving oysters and that the storage temperatures of -18 °C and -60 °C do not affect their quality and remain acceptable to consumers.

# ADDENDUM

## EGNOS FOR AQUACULTURE OPERATIONS

R. García Quiñones

European Satellite Services Provider
Control de Tránsito Aéreo
ENAIRE Centro de, Ctra. Base
KM 0.8, 28850 Torrejón de Ardoz
Madrid, Spain
raul.garcia@essp-sas.eu

Aquaculture is evolving towards increasingly technological and sustainable practices, requiring innovative solutions. Among these innovations, the European Geostationary Navigation Overlay Service (EGNOS), Europe's regional Satellite-Based Augmentation System (SBAS), provides enhanced Global Positioning System (GPS) performance by improving accuracy, availability, and reliability. EGNOS is freely accessible and offers significant benefits for multiple aquaculture applications.

Here is presented the potential of EGNOS to support key operational areas in aquaculture. First, support in geofencing/marking of aquaculture zones and elements: precise delimitation of aquaculture zones is essential for safety, environmental monitoring, and efficient operations. EGNOS enables reliable geofencing and management of aquaculture areas. Second, support in vessel navigation for aquaculture: efficient vessel navigation is necessary in coastal aquaculture for transport, inspection, and maintenance activities. Third, support in autonomous vehicles—both surface (USVs) and underwater (AUVs, ROVs)—is increasingly deployed for inspection, monitoring, and maintenance. Their efficiency and safety rely heavily on high-accuracy positioning and trusted navigation data, which can be effectively provided by EGNOS.

The integration of EGNOS into aquaculture practices can enable smarter farm management, improve resource allocation, and reduce operational costs. Additionally, by supporting the adoption of intelligent feeding systems, EGNOS contributes to more sustainable aquaculture production. In summary, EGNOS stands out as a free, robust, and accessible solution to enhance positioning and navigation for aquaculture, paving the way for safer operations and the deployment of innovative technologies in the sector.

# SUSTAINABLE SOLID REMOVAL WITH ORGANIC COAGULANTS: OPPORTUNITIES FOR DOWSTREAM USE IN INTEGRATED AQUACULTURE

R. Gebauer*[1], S. Ahani[1,2], A. Tellbüscher[1]

## Introduction

Flocculation and coagulation are critical processes in aquaculture systems for removing suspended solids, organic matter, and colloidal particles. However, commonly used inorganic and synthetic coagulants present several drawbacks, such as optimal pH levels that fall outside the range typically achievable in aquaculture environments, sensitivity to the system's pH, or the toxicity of the substances and their residues (Ebeling et al., 2003). As a result, organic and bio-based flocculants/coagulants—such as those derived from starch or chitosan—are emerging as promising alternatives. Despite their higher costs and price volatility, which currently limit broader adoption (Chik et al., 2024), these organic agents offer the advantage of being biodegradable. The resulting sludge may therefore hold additional value for circular processing applications, including biogas production or microbial stabilization, with the potential to repurpose the liquid fraction or solid residues as fertilizer. The primary objective of this study was to evaluate the performance of selected inorganic and organic coagulants for solids management in a recirculating aquaculture system (RAS).

## Materials and methods

To assess the effect of flocculants and coagulants, jar tests were performed. The raw water was sourced from the backwash collection tank of a drum filter installed in a RAS with African catfish (for more details see Tellbüscher et al., 2025). The initial characteristics of the water were determined as follows: sludge volume was measured using Imhoff cones in triplicate, and a 100 mL supernatant sample was collected for analysis of total organic carbon (TOC), total nitrogen (TN), and orthophosphate ($P\text{-}PO_4^{3-}$). The pH and temperature were recorded immediately after sampling. Sludge dry matter content was determined using a moisture analyzer. 500 mL of raw water was transferred into each of four beakers using a graduated cylinder, with three beakers receiving the flocculant/coagulant treatment and one serving as a control. The equivalent volume of liquid to be replaced by the flocculant/coagulant was removed prior to addition. The beakers were placed in a jar test device with paddles positioned approximately at mid-water level. The samples were stirred at 200 rpm for one minute (mixing phase), followed by 20 rpm for 30 min (agglomeration phase). Subsequently, 100 mL of supernatant was collected from the middle of the water column using a 100 mL syringe and transferred into a 150 mL beaker. The pH was measured immediately, and residual turbidity was determined. Additional 50 mL of supernatant was filtered through a CA syringe filter, acidified with 200 µL of concentrated HCl, and stored at 4°C until further analysis. The results are presented as a percentage change to the initial sample parameters.

## Results

The percentage changes of the TOC, $P\text{-}PO_4^{3-}$ and FNU after the addition of different dosages of the tested coagulation agents are shown in Figure 1. All the organic and bio-based coagulants increased the TOC in the water, while the TOC concentrations increased with the coagulant dose. On the other hand, iron- and alluminium based coagulatns decreased the TOC concentrations. Phosphates were unaffected by the organic and bio-based coagulants compared to the synthetic ones wich decreased the concentrations almost 80-90% even with the lowest dosage tested (50 mg $L^{-1}$). No effect was found in turbidity (FNU) either among the tested coagulants/flocculants neithger among their different dosages.

*(Continued on next page)*

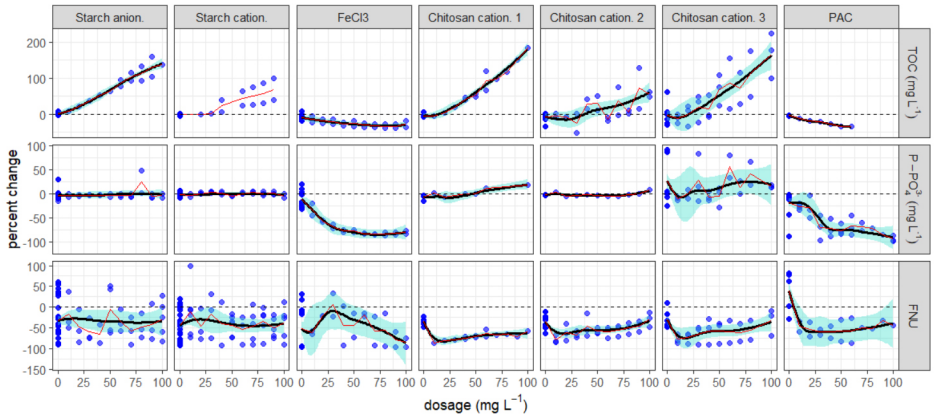

Figure 1. Percentage changes of the TOC, P-PO43- and FNU after the addition of different dosages of the tested coagulation agents.

## Discussion and conclusion

Ebeling et al., (2023) documented 89 and 93% phosphate removal efficiency for $AlCl_3$ and $FeCl_3$, respectively. Similar phosphate removal was achieved with the $FeCl_3$ and PAC in the present study while chitosan- and starch-based coagulants were not effective in phosphate removal. The low phosphorus removal was because the charge density of organic- and bio-based coagulants was low. In case of $FeCl_3$, there are other mechanisms such as formation of precipitates. A similar process has been described for alum. Chik et al. (2024) documented 90±0.72% turbidity removal using 10 mg $L^{-1}$ chitosan in the aquaculture wastewater. Similar result was achieved with chitosan-based coagullats while the starch-based ones were inconsistend in the turbidity removal. The different results might be due to differences in deacetylation degree. The starch-based coagulants are most likely effective at different condition (e.g. stirring).

# ELECTROCHEMICAL STIMULATION OF CORAL GROWTH IN *Echinophyllia lamellosa* UNDER CONTROLLED AQUARIUM CONDITIONS

Laura Medina Carbonell*, Francisco Montilla

Departamento de Química Física and Instituto Universitario de Materiales de Alicante (IUMA)
Universidad de Alicante
Carretera San Vicente s/n
03690, Alicante, Spain
E-mail: laura.medina@ua.es

## Introduction

Coral reef degradation is accelerating worldwide, demanding novel restoration strategies. Electrochemical mineral accretion through seawater electrolysis has emerged as a promising technique to promote calcium carbonate deposition, thereby providing a substrate for coral growth. However, fundamental studies under controlled laboratory conditions remain scarce, with most previous research limited to in situ trials.

## Materials and methods

An integrated 1400 L reef aquarium system was employed, comprising two 600 L frag tanks and two 100 L cubic tanks with independent filtration, circulation, and thermoregulation.

The seawater is prepared using deionized water as solvent and synthetic sea-salt formulated specifically for coral cultivation. Physicochemical and Major ions are monitored to encompass factors influencing the health of the marine ecosystem.

Conductive carbon paper cathodes were polarized to induce hydrogen evolution and oxygen reduction, generating hydroxyl ions that promoted local mineral deposition of aragonite and brucite (Figure 1). *Echinophyllia lamellosa* fragments were placed directly on preconditioned cathodes, while controls were placed on inert plastic grids (Figure 2).

## Results

Preliminary studies covering nearly 4 weeks, the growth of the different individuals on the cathode polarized electrode and on the control, grid was determined.

Figure 5 shows the variation of the area measured after this period for both sets of fragments. It is observed that in the electrochemical system the increase in area was around 10%, while in the individuals located on the control grid the growth was roughly half (increase in area of around 5%).

## Discussion and conclusions

Preliminary results confirm that electrochemical stimulation promotes coral growth under controlled aquarium conditions, supporting its potential as a complementary tool for reef restoration. Further optimization of electrolysis parameters and long-term trials are ongoing to evaluate species-specific responses and ecological feasibility.

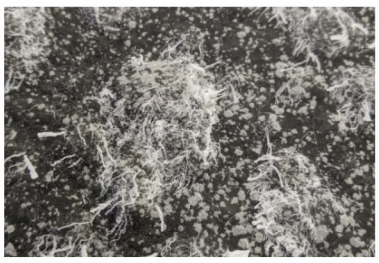

Fig. 1: Mineral deposition in cathode.

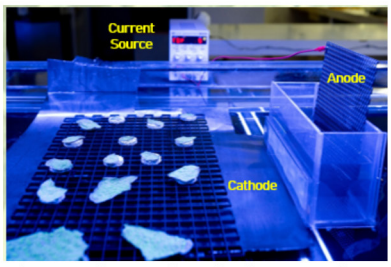

Fig. 2: Electrochemical set-up for coral growth

To analyze coral growth, a series of photographs were taken weekly. These images were classified chronologically and analyzed with ImageJ software, which allowed the measurement of coral area (Figure 3 and 4).

# GALILEO SERVICES FOR AQUACULTURE: ACCURATE, RESILIENT, SUSTAINABLE AND SAFER OPERATIONS

Miguel Rodríguez*[1], Manuel López[2]

[1] European GNSS Service Centre (GSC)
miguel.rodriguez@gsc-europa.eu
[2] European Union Agency for the Space Programme (EUSPA)
manuel.lopezmartinez@euspa.europa.eu

**Introduction**
Galileo is the European Global Navigation Satellite System (GNSS), under civil control, that provides Positioning, Navigation and Timing (PNT). As connected aquaculture operations expand offshore and face growing GNSS threats such as jamming and spoofing, there is an increasing need for precise and resilient positioning and navigation solutions. Galileo provides free services that enhance operational efficiency, sustainability, and safety for aquaculture stakeholders worldwide.

**Galileo Services and Implementation**
In addition to the Open Service (OS), Galileo's portfolio includes the Open Service Navigation Message Authentication (OS-NMA), the High Accuracy Service (HAS) and the Search and Rescue Service (SAR). These differentiators have potential to support aquaculture activities such as site selection, farm zoning, offshore structure deployment, autonomous monitoring, route optimization and product traceability among others.

- High Accuracy Service (HAS): Provides free centimetre-level accuracy (<20 cm horizontal, <40 cm vertical) using a Precise Point Positioning (PPP) algorithm. This enables eco-friendly site location with reduced habitat damage, and optimized routing for inspections.

-Open Service Navigation Message Authentication (OS-NMA): Enhances resilience by protecting against spoofing and jamming incidents, ensuring GNSS signal authenticity for product traceability and autonomous operations.

-Search and Rescue Service / Return Link Service (SAR/RLS): Supports maritime safety by locating people and vessels in distress and confirming reception of emergency alerts.

- Implementation: Most GNSS devices already support Galileo OS. Integration of Galileo differentiators for aquaculture activities can be straightforward and cost-effective. Free advice and support are provided by the European Union Agency for the Space Program (EUSPA) and the European GNSS Service Centre (GSC).

**Conclusion**
Galileo delivers free, accurate, and resilient positioning services that directly support the sustainable growth of aquaculture. By enabling precision farming, strengthening digital trust and enhancing safety at sea Galileo contributes to efficient, ecological and safer aquaculture operations in Europe and worldwide.

# REDUCTION OF SKELETAL DEFORMITIES IN SENEGALESE SOLE BY DIETARY SUPPLEMENTATION WITH *Skeletonema costatum*

## Introduction

Skeletal malformations in farmed fish affect productivity, growth, reproduction, survival and increase susceptibility to stress and pathogens, but they also downgrade the quality of the produced fish, preventing it from being marketed (Boglione 2013). These deformations have a multifactorial origin and constitute one of the main constraints in fish farming, requiring strategies to reduce and mitigate their incidence. Species produced in southern Europe, like sea bream (Sparus aurata), sea bass (Dicentrachus labrax) or Senegalese sole (Solea senegalensis) often reach levels above 50% of malformations during larval and juvenile stages, and the industry can benefit greatly from technical improvements that can promote a reduction in the incidence of these malformations.

Nutritional imbalances affecting bone development are one of the main factors affecting the incidence of skeletal deformities, which are acknowledged to constitute one of the major constraints in the production of high-quality fish. It has recently been shown that the use of microalgae like *Skeletonema costatum* as supplement in fish feeds produces beneficial effects, by improving fish quality and reduction of skeletal malformations in *S. aurata* and *Danio rerio* (Carletti 2023). *S.costatum* is a known source of antioxidants and essential nutrients such as vitamins, minerals, and polyunsaturated fatty acids, and is capable of producing numerous bioactive molecules with nutraceutical and pro-osteogenic properties (Carletti 2023).

Our objective was to determine the effects of a dietary supplementation with *S. costatum* during larval and early juvenile stages of *Solea senegalensis* over the growth and survival performances and on the development of skeletal deformities.

## Materials and Methods

Solea senegalensis larvae at 13 dph were distributed into 6 flat bottom tanks with 0.1m$^2$ at a density of 300 larvae per tank. The tanks were randomly assigned in triplicates to two dietary treatment groups: control group fed *Artemia* enriched with *Nannochloropsis* sp.; and an experimental group fed *Artemia* enriched with a blend of *Nannochloropsis* (75%) and *Skeletonema costatum* (25%).

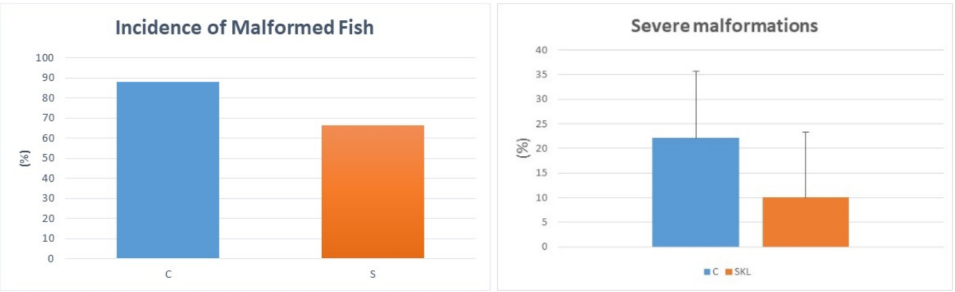

Figure 1- Incidence of skeletal malformations and incidence of severe malformations in Senegalese sole fed control diet (C) and *S. costatum* supplemented diet (S).

*(Continued on next page)*

A large batch of Artemia was enriched at the beginning of the experiment with either *Nannochloropsis* sp. alone or a mix of *Nannochloropsis sp.* (75%) and *Skeletonema costatum* (25%). After the enrichment the nauplii were collected, counted and frozen in portions of 20k. Fish were fed 3 times $day^{-1}$ at 4% BW and the portions were adjusted daily to sustain growth. Mortality was registered daily. Water temperature was maintained at 20.5 ± 1ºC, D.O. 95-100%, and salinity 36 ± 1ppt. Growth in length and dry weight was assessed at 23 dph and 33 dph. At the end of the trial (33dph) a sample of 30-35 specimens per replicate was collected to determine skeletal deformities and mineralization and 5 fish per replicate were collected for determining oxidative status.

**Results**

At the end of the trial the larvae from the treatment group presented a larger length (10,86 vs 9,46 mm) and weight (3,31 vs 2,59 mg) compared to the control and

A marked reduction of 20% was observed on the incidence of malformations on the group fed Skeletonema costatum supplemented diet and a high reduction on the number of fish presenting severe deformities was also observed.

In addition, the number of deformities observed per fish was reduced from 4,2 in control to 3 in the treatment group. The incidence of malformations affecting the caudal and pre-hemal vertebrae were also reduced, translating into fish with greater quality and less prone to development of vertebral curvatures like lordosis-kyphosis and scoliosis, that significantly deteriorate fish quality.

**Discussion**

In this study we tested the use of a diet composed of artemia enriched with 25% Skeletonema costatum, and evaluated the effects on growth, survival, and on the frequency and severity of skeletal malformations in *Solea senegalensis* larvae, a species with high commercial value and very susceptible to developing deformities during larval stages (Gavaia et al., 2002). Our results showed that S. costatum induces a protective effect of on the development of skeletal deformities during early stages, with a reduction on the number, charge and severity of skeletal malformations. In addition, the larvae treated with the S. costatum enriched diet presented a better growth performance, with greater length and weight at the end of the experimental period. The fact Skeletonema costatum presents a nutritional profile rich in fatty acids, antioxidants, minerals and biocatives (Hemaiswarya et al., 2011, Carletti et al., 2023) indicates that it is providing a more balanced nutritional profile to the diet during larval growth, sustaining a more harmonious growth and improving the quality of the produced specimens.

email: rshtay@foodtech.uni-kiel.de

The aim of our work is to use the biosynthetic potential of blue mussels as a natural biofactory for the formation of tailored valuable biocompounds by varying the genotype, farming conditions and applying stress interventions. We aim to explore the biochemical potential by using a broad range of cutting-edge analytical techniques. We aim to identify novel compounds and novel functions by fundamental characterization of physicochemical and technological properties relevant for food and non-food applications. We are aiming for tailored compounds by using fractionation and isolation strategies that follow the requirements of the target compounds as well as the principles of bioraffination.

**Background**
Amongst marine organisms, mussels are very unique. During their lifespan, they undergo dramatic changes leading to strong variation in the metabolism of the organism. After its planktonic stage the organisms transform into a sessile mussel and grows tremendously within the first months until the mussels reach a plateau phase during the colder winter months and start to prepare for propagation in the next spring using up stored lipids and proteins. Blue mussels (*Mytilus edulis trossulus complex*), keystone species in the Baltic Sea ecosystem, represent one of the major aquaculture shellfish species. Although their popularity as sea food has increased over the last years because of their protein-, omega-3 long chain polyunsaturated fatty acids (LC-PUFA) and iodine content their potential as source for tailored biochemicals, in particular functional proteins, has been rarely explored. At the same time blue mussels also dominate the production of waste material in the shellfish sector, as only intact mussels of a certain age and size are commercially used as sea food. Shells, undersized, broken and those used for water engineering purposes are discarded.. Further, the metabolism of organism underlies external factors such as seasonal changes, feed source,and water depth. Finally, the mussel shells is a resource of biominerals comprised of two polymorphs of CaCO3, calcite and aragonite (mother of pearl). To date, some applications of shells as use for chicken feed, as a low-value material for concrete production or for the treatment of polluted soil and waters are described.

**Selected results**
Blue mussels were produced by Kiel Marine Farm in long-line farming systems and provided to CAU. Subsequently, Mussels were dissected into their components (shell and mussel meat). The mussel meat was fractionated to isolate proteins and lipids. Proteins. In order to characterize the protein profile of mussels SDS-Page electrophoreses were conducted. Using a multistep purification procedure we aimed for highly valuable myofibrillar proteins. Sarcosplamatic proteins together with other water soluble proteins were collected for further characterization. A special aspect is that black colouring occurs during the fractionation of mussel proteins. For the analysis of the physico-chemical and technological properties of mussel proteins a wide range of methods has been established (FT-IR, fluorescence spectroscopy, zeta-potential, hydrodynamic diameter). Fundamental properties such as solubility and surface charge (zeta potential) at different pH values have been examined for the myofibrillar fraction to give indications for the range of application. E.g. increased water binding capacity can be expected above a pH of 6. Stabilization of emulsions increases with amount (negative of positive value) of the Zeta-potential indicating repulsive forces above and below a pH value of 4.

To make wide use of mussel meat, a product is required with low taste, flavor and light color but high nativity of the functional proteins. This was conducted by applying several non-thermal procedures resulting in a meat homogenate. Subsequently, prototyües of innovative mussel food products were developed and underwent sensory evaluation. Furthermore, the utilisation potential of undersized mussels was contemplated. A comparison of cohorts revealed a significant variation in the meat-shell ratio, which was found to be dependent on age. The analysis revealed that mussels one year old contained 33% mussel meat, while those that were three years old contained 22%. This observation is of great significance for the economic production of biocomponents in musselsn this study, the meat of undersized mussels was utilised in the development of pet food products exhibiting a high protein value and quality.

The mussel shell resulted as by-product, we developed powdered fractions to be used in non-food application (e.g. cosmetics and filtermaterials). In addition, the blue pigments found in mussel shelll are of great interest due to their rarity in natural sources.

# FROM FARMED TO WILD: ISOTOPIC MARKERS FOR THE DETECTION OF ESCAPEES AND THE ASSESSMENT OF TROPHIC POSITION AND POTENTIAL NICHE OVERLAP IN GILTHEAD SEABREAM (*Sparus aurata*), EUROPEAN SEABASS (*Dicentrarchus labrax*) AND MEAGRE (*Argyrosomus regius*) IN THE WESTERN MEDITERRANEAN

## Introduction

Marine aquaculture is expanding rapidly to meet global seafood demand (FAO, 2024), but escape events pose ecological and management challenges. Up to 9.6% of *Sparus aurata* and 0.6% of *Dicentrarchus labrax* annual landings in the Mediterranean originate from escapes (Toledo-Guedes *et al*., 2024). However, extreme storms like Gloria (2020) can cause total stock loss. Escapees interact ecologically with wild fish (Arechavala-Lopez *et al*., 2017) and are often sold as wild, violating EU traceability rules (Jackson *et al*., 2015). The GLORIA-TOOLS project, building on the Fundación Biodiversidad GLORiA initiative, develops tools for escapee detection, including stable isotope analysis (SIA) of muscle tissue.

## Materials and methods

A total of 102 muscle samples of seabream, seabass and meagre were collected from aquaculture sites and fish markets in Alicante and Murcia (Spain). Stable isotope analysis was performed at the University of A Coruña (SAI) using a MAT253 IRMS (Thermo Finnigan) with FlashEA1112 elemental analyzer. Tin-encapsulated samples were combusted at 1020 °C in a quartz column containing chromium oxide and silvered cobaltous/cobaltic oxide. Excess oxygen and nitrogen oxides were reduced in a copper column at 650 °C, and the resulting $N_2$ and $CO_2$ gases were separated by gas chromatography before entering the IRMS. $\delta^{13}C$ values were lipid-corrected (Post *et al*., 2007), and $\delta^{13}C/\delta^{15}N$ data were used in PERMANOVA to test for differences between wild, escaped, and farmed groups. Results were visualized in $\delta^{15}N$ vs. corrected $\delta^{13}C$ scatterplots.

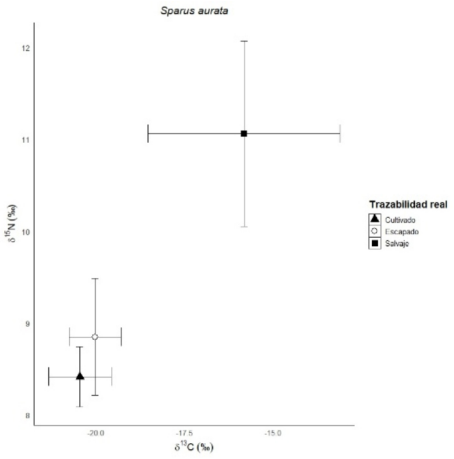

Figure 1. $\delta^{15}N$ vs. corrected $\delta^{13}C$ seabream (Sparus aurata) scatterplot.

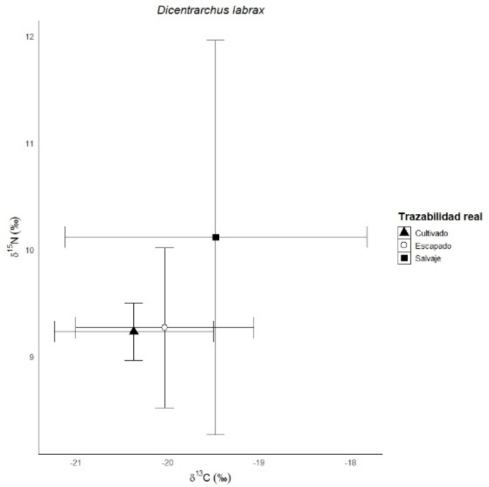

Figure 2. $\delta^{15}N$ vs. corrected $\delta^{13}C$ seabass (*Dicentrarchus labrax*) scatterplot.

*(Continued on next page)*

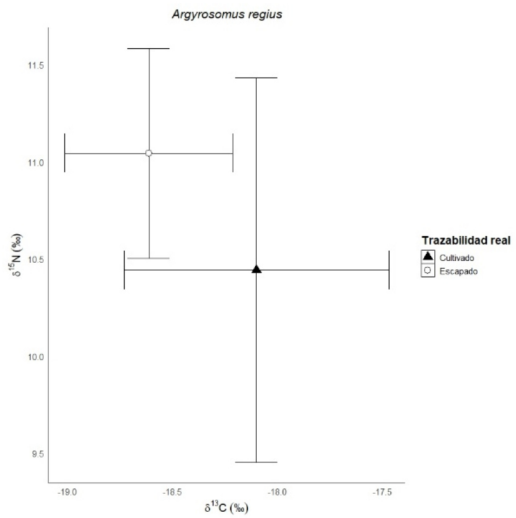

Figure 3. $\delta^{15}N$ vs. corrected $\delta^{13}C$ meagre (*Argyrosumus regius*) scatterplot.

**Results**

Sea bream showed clear, significant isotopic separation (Fig. 1): farmed fish had lower $\delta^{15}N$ and $\delta^{13}C$, wild fish were enriched, and escapees clustered in between.

Sea bass showed no apparent isotopic distinction among groups (Figure 2), which resulted in non-significant results.

Meagre lacked wild references, but $\delta^{15}N/\delta^{13}C$ scatterplots (Fig. 3) showed visual separation between farmed and escapees, with only marginal statistical differences.

**Discussion**

Sea bream showed clear isotopic separation, likely due to its omnivorous diet and plant-based feed, distinct from wild sources. In contrast, sea bass's piscivorous habits and animal-protein-rich feeds lead to overlap between wild and farmed signatures. Meagre lacks wild references, escapees are usually captured near cages shortly after escaping, still feeding on pellets, and then disperse to deeper habitats. These results show that SIA works best in species with distinct diets and lower trophic levels. In carnivorous fish, feed similarity reduces resolution, and complementary tools (e.g., stomach content or genetics) may be required.

GLORiA-TOOLS aims to develop and transfer tools and technologies reaching Technology Readiness Levels (TRL) 4–6, with the potential to enhance the environmental and socioeconomic sustainability of offshore fish farming under global change, particularly addressing the impact of fish escapes on marine ecosystems and consumer safety. Building on the outcomes of previous GLORiA and GLORiA2 projects, which identified key escape-related risks and suitable traceability markers, GLORiA-TOOLS focuses on delivering functional prototypes and decision-support systems to support escape management from aquaculture facilities.

The project is structured around six specific objectives: (1) to create a web-integrated GIS-based tool for spatiotemporal modelling and prediction of escape risk and its environmental impact; (2) to assess the socioeconomic consequences of escapes and provide training and decision-support resources to stakeholders; (3) to design a biosensor prototype based on traceability biomarkers for fish origin identification; (4) to identify and validate genetic traceability markers for farmed and wild fish; (5) to develop an artificial vision system for fish recognition in realistic settings; and (6) to promote user-driven evaluation and prepare prototypes for real-world deployment.

GLORiA-TOOLS will provide beta-phase tools for environmental modelling, genetic analysis, biosensing and machine learning, all validated through interdisciplinary research and prior field experience. These tools will contribute to informed management, policy development, and traceability enforcement across the aquaculture sector.
