PAW was produced using a CAP jet (flow rate 0.5 L/min, nozzle–water surface distance 4.3 mm). The peak-to-peak voltage was 7.2 kV (100 kHz). The process time was 16 min for 20 mL water samples treatment. After CAP treatment, RONS were measured as approximately 40 mg/L for H_2O_2, 0,80 mg/L for NO^{2-} and 12 mg/L for NO^{3-}. Gilthead sea bream (*Sparus aurata*) fillets were used as the case study food product. The fillets were immersed into i) PAW (with the RONS displayed above), ii) deionized water and iii) artificially produced water with equal concentrations of PAW RONS. In all cases, the optimized fish:antimicrobial agent ratio of 1:6 and treatment time for 15 min was used. All fish fillets after the immersion time were immediately packed asseptically in transparent plastic bags and stored at 4°C.

During a 10-days storage period, quality was characterized in terms of color, texture, microbial load (total aerobic bacteria, lactic acid bacteria, yeasts/molds, *Pseudomonas*, *Enterobacteriaceae*, *Brochotrix thermosphacta* and H_2S producing microorganisms), lipids oxidation and sensory evaluation.

(Continued on next page)

Results

In general, CAP treatment appeared to significantly affect the total microbial load of fish fillets, since a 1.20 log CFU/g reduction was measured (3.60 log CFU/g for the CAP treated fillets compared to 4.78 log CFU/g for the control samples). The same trend was observed for all the microorganisms tested with variability in the reduced load. Artificially produced water with equal RON concentrations to PAW also resulted in microbial load reduction but not as much as the one obtained from PAW application (the corresponding value for the total microbial load exactly after treatment was 4.20 log CFU/g). This decrease in the microbial load at time zero was observed during the whole shelf-life period of the fillets. For the CAP treated fillets, a shelf life of 8 days was estimated (shelf-life was determined as the time to reach a total plate count value of 7.00 log CFU/g). The corresponding values for the control and the artificially produced water treated fillets were 4 and 5 days, respectively. Concerning the quality parameters, the color of all samples exhibited decrease of lightness and increase of redness vs storage time, which was more pronounced for the untreated products. The hardness of the fish fillets was slightly decreased for all samples, during shelf-life. The PAW fish fillets did not exhibited different oxidation values during storage compared to the other samples. In general, the promising results validate that PAW could act as an effective antimicrobial agent for fish decontamination, offering potential alternative options for future application to other seafood as well, increasing their shelf-life.

Conclusions

The proposed technology for seafood (especially for whole fresh fish and fish fillets) processing and shelf-life extension is very promising -considering also that other technologies cannot be applied to these products- allowing for seafood waste reduction.

EFFECT OF DIFFERENT DISSOLVED OXYGEN CONCENTRATIONS ON DIGESTIBILITY AND GASTRIC EVACUATION RATES OF EUROPEAN SEA BASS (*Dicentrarchus labrax*) AND GILTHEAD SEA BREAM (*Sparus aurata*)

Lydia Katsika[1], Ioannis Papadakis[1], Panagiota Tsoukali[1], Stavros Chatzifotis[1]

Introduction

Low levels of dissolved oxygen in farm water and high temperatures are potential stressors parameters that affect fish growth, digestion, behavior and health (Petersen & Gamperl, 2010). Changes in oxygen levels can affect the morphology of the gut and the ability to digest nutrients (Tran-Ngoc *et al*., 2016). Under the same rearing and diets conditions, understanding the relationship between digestion and gastric evacuation can help to estimate the time of appetite return (Riche *et al*., 2004). Information of how dissolved oxygen could affect the feed digestibility and the gastric evacuation rates of fish are useful for feeding frequency estimation aiming at more efficient nutrient utilization and establishing an appropriate feeding protocol. The aim of this work was to measure feed digestibility and gastric evacuation rates of sea bream and sea bass in 3 different dissolved oxygen rages.

Materials and Methods

Two digestibility and gastric evacuation rates trials were conducted at the Aqualabs facilities of the Institute of Marine Biology, Biotechnology and Aquaculture (IMBBC) of the Hellenic Centre for Marine Research (Heraklion, Greece), both for European sea bass and Gilthead sea bream. Fifteen fish (250 gr initial body weight) were placed in 3 closed recirculation systems each consisting of tanks of 500 L capacity under fully controlled oxygen, light and water flow conditions. A different level of oxygen saturation in the rearing water was applied to each closed recirculation system (80-100% DO, 60-80 DO and 40-60% DO) at 26.5 ^{o}C water temperature. The fish were hand-fed a commercial diet (**Table 1**) to satiation after additing of 1% celite® as an inert marker in the feeds, three times daily. Feed and feaces proximate compositions were determined according to (AOAC, 1990). Apparent digestibility coefficients of nutrients and energy of the diet were calculated using the following formulas: ADC = 1–(F/Dx Dm/Fm); where: D=% nutrient (or MJ/kg gross energy) of diet; F=% nutrient (or MJ/kg gross energy) of feaces; Dm=% digestion marker (AIA) of diet; Fm=% digestion marker (AIA) of feaces. For the gastric evacuation rates determination, after feeding a single meal, 3 fish were killed every 3h over a period of 24 h and the digestive tract contents were collected and the dry weight were measured.

Results and Discussion

Apparent digestibility coefficient values of tested diet under different oxygen saturation regime for sea bass and sea bream are showed in **Table 2**. Apparent digestibilities of nutrients and energy for sea bass were not affected by the oxygen level (P>0.05). Crude protein and fat digestibility (86-89% and 85%, respectively) for sea bream were not significantly (P>0.05) different among three dissolved oxygen levels. Energy, Dry matter and organic matter were more digestible (P<0.05) in the group with 60-80% DO. Energy and dry matter digestibility showed the lowest values in the 80-100% DO group, whereas organic matter digestibility did not differ between the 60-80% and 40-60% DO groups (P>0.05). Digestibility coefficients values were high for all oxygen levels for both species comparing with previous studies (Ballester-Moltó *et al*., 2017). Gastric evacuation times are summarized in **Table 3**. Oxygen saturation had a significant effect on the rate of digestion of

Table 1. Proximate composition of nutrients and energy of feed for European sea bass and Gilthead sea bream

40-60% DO	After 13 hours	

the digestive system for both species. The evacuation rate of the digestive system, influenced by the different oxygen levels in sea bream, appeared to modify the feed transit rate and its presence in the intestine. No differences were found for sea bass ADCs under different oxygen levels in contrast to the different evacuation rates among groups. The gastric evacuation rates for the two species were significantly different ($P<0.05$), with the sea bream emptying its digestive tract completely after 18 hours while the seabass after 27 hours for the high DO group (80-100%) or more than 27 hours for 60-80% and 40-60% DO groups.

Introduction

The global and regional declines of wild stocks of Atlantic cod (*Gadus morhua*) prompted for the establishment of The National Cod Breeding program in Norway in 2003. The main selection criterium has been rapid growth, specifically body weight at 2+ age, after approximately 22 months of sea-rearing. It is well established that body weight is highly genetically correlated with gutted weight and filet weight, e.g., in Nile tilapia, rainbow trout and gilthead seabream (Gjerde et al. 2012; Kause et al. 2002; Navarro et al. 2009). This relationship has not been established in Atlantic cod.

Atlantic cod is a lean fish. Skeletal muscles contain only minute amounts of fat, whereas large amounts of fat can accumulate in liver. Enlarged liver has been frequently reported in practical cod aquaculture. This can be a consequence of unlimited access to feed that is not optimal or optimally utilized (Ingebrigtsen et al. 2014), but genetics may also play a role. In addition to the unfavourable distribution of ingested energy, large livers may be a welfare issue in aquaculture cod.

In this study we analysed slaughter data of Atlantic cod to get deeper insight of the genetic variation in body weight and carcass composition traits and assess the magnitude of the genetic and phenotypic interrelationships between these traits.

Material and methods

Data comprised records from 2557 individually tagged Atlantic cod from 218 full-sib families (158 sires and 134 dams) representing the fourth generation of selectively bred cod of National Cod Breeding Program. *A priori* power calculations (Kettunen and Lillehammer, 2019) were conducted to optimize the experimental design to obtain reliable estimates of heritability and genetic correlations. Fish were slaughtered at 948 days age from hatching and individual records for body weight traits (round RWT, gutted GWT, headed-and-gutted HGWT), body length (LENGTH), liver weight (LIVERWT), intestine weight (INTWT) and head weight (HEADWT) were registered. Hepatosomatic index (HSI), HEAD% and INT% were calculated as a percentage of LIVERWT, HEADWT and INTWT of RWT, respectively.

Estimates of heritability were calculated from variance components estimated with a univariate animal model using ASReml (Gilmour et al. 2015):

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_A\mathbf{a} + \mathbf{Z}_C\mathbf{c} + \mathbf{e},$$

where, is the vector of the phenotypic observations; is the vector of fixed effect of sex; is the vector of random family effects; is the vector of random additive genetic effects; is the vector of random residual effects. Bivariate animal model was used for estimation of phenotypic and genetic correlations.

We also calculated conditional heritability for LENGTH, carcass weight traits (LIVERWT, INTWT, HEADWT) and HSI to examine the magnitude of genetic variation displayed in these traits independent from the genetic variation in RWT (Kause et al. 2002):

$$h^{2*}_{bodycomp} = h^2_{bodycomp} * (1 - r_g^2).$$

Results

Moderate estimates of heritability, ranging from 0.27 to 0.29 (±0.07), were obtained for RWT, GWT and HGWT from a univariate model. Slightly higher heritability was estimated for LIVERWT (0.32±0.08) and HEADWT (0.39±0.08), whereas LENGTH, INTWT, and INT% expressed relatively low heritability: 0.15-0.19 (±0.06-0.07). HSI and HEAD% were shown to be highly heritable traits (0.47±0.09 and 0.43±0.05). Proportion of family variance from phenotypic variance varied between 0.02-0.08. Conditional estimates of heritability for LENGTH, LIVERWT, INTWT and HEADWT (0.06-0.11) indicated that although a significant proportion of the genetic variation is dependent on RWT, this dependency is not complete. The conditional heritability for HSI was identical with the original estimate: 0.46.

(Continued on next page)

Genetic correlations between RWT and GWT/HGWT were close to unity (0.98). RWT was highly genetically correlated with LENGTH, LIVERWT, INTWT and HEADWT (0.75-0.87). LIVERWT, INTWT and HEADWT were strongly genetically intercorrelated (0.54-0.78). Low phenotypic (0.30±0.03) and non-significant genetic correlation (0.15±0.17) was estimated between RWT and HSI. Negative genetic interrelationships, with high standard errors of the estimates, were estimated between RWT and HEAD% (-0.29±0.10) and INT% (-0.48±0.20).

Discussion

As RWT, GWT and HGWT are genetically same trait, selection for RWT will result in feasible genetic change also in the valuable proportion of carcass in Atlantic cod. The selection for increased body weight at 2+ will increase the absolute weight for intestine, head, and liver. In contrast, selection for RWT will genetically reduce HEAD% and INT%, albeit these changes are expected to be minimal. HSI is not genetically strongly affected by selection for RWT, as indicated by non-significant genetic correlation between RWT and HSI. This observation is also supported by the high conditional heritability for HSI. Given high (moderate) heritability and moderate (high) phenotypic variation of HSI, CV=13%, (LIVERWT, CV=26%) selection for smaller liver is expected to be successful. This said, holistic understanding of the underlying biological reason(s) for frequently reported large liver in cod aquaculture is imperative before pursuing selective breeding against large liver size.

Introduction

In vitro maturation (IVM) of oocytes is a reproductive technology that enables mature eggs to be produced *ex*. This approach is becoming a useful tool in aquaculture, for further understanding of oogenesis, refining spawning practices and providing alternative methods of egg production. Hormonal stimulation and media composition are crucial parameters to consider in IVM protocols. In fish, gonadotropins and maturation-inducing hormones, such as 17α,20β-dihydroxy-4-pregnen-3-one (DHP), are commonly used to induce maturation of isolated ovarian follicles. Addition of prostaglandins (PGs) has been shown to induce follicle rupture after steroid-induced maturation (Takahashi et al., 2018). Incorporation of protein sources, such as serums and bovine serum albumin (BSA), into the culture media was reported beneficial for cytoplasmatic maturation and maintaining the fertilizing ability of ovulated oocytes (Seki et al., 2008).

The aim of this study was to establish a culture system that would support development of fertilizable eggs from immature, postvitellogenic ovarian follicles isolated from African catfish (*Clarias gariepinus*). High growth rate and stocking density have made this species a popular choice for cultivation, especially in tropical and subtropical regions. Therefore, improvements of artificial reproduction of African catfish are of great value. In addition, its spawning in captivity relies on artificial hormonal stimulation of both males and females and does not occur spontaneously, which make it a good model for *in vitro* gametogenesis studies.

Materials and methods

Unprimed adult females of African catfish were euthanized and ovaries were immediately excised. Fully grown, postvitelogenic ovarian follicles were manually isolated and sorted in cell culture plates with maturation media consisting of 90% Leibovitz L-15 medium (pH 7.6, 285 mmol/kg), supplemented with antibiotics. Throughout treatments, the follicles were incubated at 25 °C, under gentle agitation. For *in vitro* maturation experiments, follicles were placed in media with DHP (1 µg/ml), hCG (20 IU/ml) and without hormones (control). Effect of human chorionic gonadotropin (hCG) on DHP-induced maturation was evaluated by pre-treating and co-incubating the follicles with hCG. Resumption of meiosis and maturation was evaluated by scoring the percentage of follicles that underwent germinal vesicle breakdown (GVBD) and ooplasm clearing, compared to control. For *in vitro* ovulation experiments, prostaglandins F2α ($PGF_{2\alpha}$) and E2 (PGE_2) were added to the incubation media containing DHP. Ovulation was monitored by checking the integrity of the follicular layer. Immediately after ovulation, oocytes were transferred to a clean dish and fertilized using sperm freshly extracted from testes of one male. Following insemination, eggs were incubated at 25 °C and monitored regularly until hatching. The effect of additional protein supplementation on maturation, ovulation and fertilization was assessed by adding 0.5% BSA to the treatment groups.

Results and discussion

After isolation, postvitellogenic ovarian follicles of African catfish do not mature spontaneously under *in vitro* conditions. By adding DHP to the culture medium, we were able to stimulate maturation in a time-dependent manner, with the highest percentage of GVBD (81 ± 7%) observed after 12 h. Exposure to hCG did not promote GVBD and had no discernible effect on steroid-induced maturation. Prolonged treatment with DHP did not lead to ovulation. Addition of both $PGF_{2\alpha}$ and PGE_2 caused rupture of the follicular layer in DHP-matured follicles, in a concentration-dependent manner. The highest ovulation rate was observed in treatments with 5 ug/ml $PGF_{2\alpha}$ (71 ± 8%). This is in agreement with previous reports that $PGF_{2\alpha}$ is a major mediator involved in fish ovulation (Takahashi et al., 2018). *In vitro* matured and ovulated oocytes obtained in this study maintained their developmental competence and were successfully fertilized. The fertilization rate was 39% after 24 hours, while the percentage of hatched larvae was 8%. Although the addition of 0.5% BSA to the culture medium did not influence follicle maturation, it significantly lowered the percentage of $PGF_{2\alpha}$-induced ovulation (39 ± 3%). No fertilization was achieved with oocytes that were ovulated in media supplemented with 0.5% BSA. These results demonstrate that the presence of BSA in culture medium is not necessary to improve fertilization and hatching rates.

(Continued on next page)

Conclusions

An *in vitro* maturation protocol was successfully developed for African catfish ovarian follicles. The culture media consisting of Leibovitz L-15 media, without any additional protein supplementation, maintains viability and responsiveness of follicles to hormones. Treatment of freshly isolated follicles with DHP successfully promotes their cytoplasmatic and nuclear maturation, while subsequent ovulation is achieved by adding prostaglandins to the media. This combination of optimal media composition with a two-step hormone stimulation produced mature eggs which could be artificially fertilized and give rise to developing embryos.

VGLL3A ALLELES AFFECT THE BRAIN-PITUITARY-GONAD AXIS IN ATLANTIC SALMON (*Salmo salar*) VIA REGULATION OF *FSHB*

Introduction

Early male maturation represents a major problem in Atlantic salmon farming, both in sea cages and in recirculation aquaculture system facilities. Problems caused by pre-harvest maturation include significantly increased disease susceptibility and osmoregulatory problems, causing higher mortalities, reduced animal welfare, and production losses. We and others have previously reported a strong association between alleles in the *vgll3a* locus and time of maturation in Atlantic salmon, however, the molecular mechanisms and roles of *vgll3a* alleles in controlling time of puberty are largely unknown. Previous studies have indicated a potential role of *vgll3a* in the salmon gonad, where expression of *vgll3a* is regulated in Sertoli cells upon entry into puberty, suggesting a possible connection between *vgll3a* and the brain-pituitary-gonad (BPG) axis. However, it is unknown which proteins link *vgll3a* alleles to the BPG axis.

Results

To search for a possible connection between *vgll3a* alleles and the BPG axis, we used an RNA-Seq approach to identify genotype-dependent gene expression in testis, pituitary and belly flap in fish stimulated to enter maturation. We uncovered several differentially expressed genes potentially involved in regulating the onset of puberty under the control of *vgll3a* alleles, including pituitary *follicle-stimulating hormone subunit beta* (*fshb*), the major hormone triggering puberty in vertebrates. Interestingly, the pituitary displayed low levels of *vgll3a* expression when measured by RNA-Seq and qPCR, prompting us to investigate if we could detect the presence of one or more endocrine factors in plasma with stimulatory or inhibitory effects on *fshb* expression. We therefore performed *ex vivo* incubations of pituitaries from immature males with plasma from immature males homozygous for the Early (EE) and Late (LL) maturation genotypes. Interestingly, we observed a significant decrease in *fshb* expression in pituitaries incubated with plasma from immature LL fish compared to pituitaries incubated with plasma from immature EE fish or negative controls (medium only). We additionally performed incubations where we boiled the plasma before the incubations to denature plasma proteins. Boiling the plasma removed the previously observed down-regulation of *fshb* expression in pituitaries incubated with LL plasma, indicating the presence of one or more protein/peptide factors in plasma from LL fish with the ability to potentially delay maturation.

Introduction

Using sterile salmon in aquaculture could mitigate sustainability challenges including precocious male maturation and genetic introgression from farmed escapees to wild populations. By knocking out *dead end* (*dnd*-KO), we have created germ cell-free (GCF), sterile salmon with the potential to remain immature throughout life. While these are promising commercial traits, more knowledge is needed on potentially unwanted effects of the loss of *dnd* function. In this study, *dnd*-KO GCF and wild type (WT) Atlantic salmon were reared in an indoor common garden setup with natural light and temperature for 3 years and then terminally sampled. Fish performance in terms of growth, welfare indictors, gene expression in non-target tissues and fillet quality were evaluated.

Results

Regarding growth performance, GCF males were smaller only when compared to WT females early in life, however, this difference disappeared later. At harvest size, WT males was the largest group. Smoltification markers (mRNA levels of gill Na+/K+-ATPase [NKA] subunits) showed normal up (*nka α-1b*, *nka α3*, *nka β-1*) or downregulation (*nka α-1a*) from the freshwater to the seawater stage in both WT and GCF salmon. However, plasma stress indicators including lactate and osmolality concentrations were higher in GCF than WT plasma 24 hours after transfer to seawater, but these differences disappeared after 6 months in seawater. In postsmolts after 6 months in seawater, no differences for any plasma stress markers were detected, while in adults at harvest size we observed some differences in plasma pH (higher in WT and GCF males than in WT females), lactate (higher in WT females than in GCF females and males), Na+ and osmolality (higher in WT females than in GCF males). No differences were detected between WT and GCF transcriptomes of selected non-target tissues (muscle and pituitary) in postsmolts after 6 months in seawater. Results also showed that the prevalence of vertebra deformities was similar and within a normal range in both WT and GCF fish. No differences were found in hepatic or cardio somatic indexes (HSI/CSI) in postsmolts after 6 months in seawater, however in adults at harvest size HSI was higher in WT than in GCF fish, while CSI was unaffected. No sexual maturation was detected in GCF fish of either sex throughout the study period, in contrast to their WT counterparts. Fillets from WT and GCF salmon at harvest size showed no significant difference in proximate composition (protein, dry matter or total fat). Interestingly, the relative content of the omega-3 fatty acid DHA 22:6n-3 was higher in GCF compared to WT males despite having the lowest total amount of fatty acids.

Conclusions

GCF males lack the growth boost observed in WT males during the start of puberty, resulting in a smaller harvest size if harvested at this stage. To avoid any differences in growth it may be needed to grow GCF fish to a larger size, which is expected to be beneficial since GCF fish will not experience any growth inhibition due to sexual maturation. We also observed larger livers in WT compared to GCF salmon, which may reflect altered metabolism in line with the onset of sexual maturation, indicating that nutritional needs may differ between WT and GCF fish. Since GCF individuals were not more prone to develop deformed vertebra than their WT counterparts, GCF farmed salmon may potentially have less problems with quality downgrading losses at harvest with respect to deformities than the currently used triploid sterile salmon. Although the fillet transcriptome (postsmolts) and proximate composition (harvest size) did not differ between WT and GCF salmon, the finding of increased relative amount of DHA 22:6n-3 in GCF males compared to WT males may represent a more favorable fillet composition for consumers.

DEVELOPMENT OF A MASSIVE OPEN ONLINE COURSE (MOOC) IN SUSTAINABLE AQUACULTURE FOR LOW TROPHIC SPECIES

Adrianna Kochańska* and Michaela Aschan

UiT The Arctic University of Norway, Norwegian College of Fishery Science, N-9037 Tromsø, Norway
E-Mail: adrianna.kochanska@uit.no

Introduction

The expectations for sustainable food production in aquatic systems are high, especially of low trophic species products with a low carbon footprint. To enhance the knowledge among students, practitioners, and teachers, we are developing a massive open online course (MOOC) in sustainable aquaculture for low trophic species (SALTS). The course will contribute to the much-needed increased literacy in the field necessary for enhanced and diversified aquaculture production. In this presentation, we describe the methodological approach for MOOC development, present the course content and structure, and demonstrate a pilot module.

How to develop a MOOC

According to the constructive alignment theory, deciding on learning outcomes is the first and the most important step in developing a course. Learning outcomes will guide what material should go into the course and what type of assessments will be used. SALTS is a master level course, which means we expect the students to acquire higher levels of cognitive learning (Revised Bloom's Taxonomy – Apply, Analyse, Evaluate, and Create). Higher levels of learning expect students to have a good knowledge of the concepts. Therefore, some learning activities and assessments must occur at the lower levels of cognitive learning (Remember, Understand). The aim is to cover the value chain of several low trophic species through 10 modules. The AquaVitae Horizon 2020 project scientists provide the recent research-based content needed.

Course modules and the pilot

The modules are: 1) Sustainability of Low Trophic Aquaculture (LTA), 2) Governance of LTA, 3) Food nutrition and safety, and consumer perspectives 4) Business, economics, and markets, 5) Production systems, 6) Macroalgae, 7) Echinoderms, 8) Molluscs, 9) Herbivorous finfish, and 10) Future of LTA. Each module begins with a short introduction video followed by an engagement activity. The module contains 2-3 sub-topics, including videos, quizzes, reading material, advanced assessment and additional material. We aim to create educational material for online students, and for teachers who will utilise the material in a flipped classroom format. The entire course is equivalent to 5 ECTS[1] points (125-140 hours in total). Each module will take approximately 13 hours to complete. The pilot topic on Sea Urchins will be presented in more detail to exemplify the process and the outcome. We also wish to make the pilots available for testing online so that the interested attendant can provide feedback. The course will be available on the Open edX platform and disseminated through the ALTANet platform.

THE WAY TO SHORTEN THE GENERATION INTERVAL IN SELECTION PROGRAM OF COMMON CARP REARED UNDER TEMPERATE CLIMATE

M. Kocour, J. Zhao, M. Prchal, Ch. Steinbach, J. Křišťan, D. Gela, H. Kocour Kroupová, O. Malinovskyi, T. Policar

e-mail: kocour@frov.jcu.cz

Introduction

Selective breeding is based on genetic improvement through cumulation of genetic gain over generations. So, it is required to shorten the generation interval (GI, the age of the fish when firstly used for artificial reproduction). In common carp reared outdoor under temperate climate, the GI for females is about 5 years. However, in tropical zones, common carp females can mature in 1-2 years. It is said that common carp females need to collect 10,000-12,500 °D (°D = the sum of the average daily temperatures of the water in which the fish live) of water temperatures over 15°C to reach adulthood (Horváth, 1985). It must be also remembered that potential breeding candidates of common carp should stay before own selection challenge under the pond conditions to avoid bias of selection process. In Amur mirror carp (AM) it was found that if selection for faster growth or the proportion of edible parts were done in two-year old fish, it would have similar effect as doing the selection at market size (Prchal et al., 2018).

We therefore studied whether the GI in AM can be shortened to three years using RAS.

Material and methods

Experimental fish came from a population established in 2017 by artificial spawning using a partial factorial design of 27 dams and 29 sires of AM. The progeny was kept communally in ponds under standard stocking densities and conditions (Prchal et al., 2018). In April 2019, the following groups of fish were formed:

- A stock of i) fish selected for faster growth (group S) and ii) randomly collected fish (group A), both being kept in RAS for a year at water temperatures between 18-23 ° C and fed daily with a commercial diet for carps in a dose of 1.0-1.5% of the stock weight.
- Czech Republic (temperate climate).

From April 2019 to April 2020, ~ 6 females and 6 males from groups A and B were sampled monthly to monitor gonad development and condition. A sample of gonads was taken for histology. The gonadosomatic index (GSI) and the Fulton's condition coefficient (FC) were calculated. Water temperatures in RAS and pond were recorded at hourly intervals. As monitoring showed that group A unlike group B had reached the readiness for artificial spawning, the spawning according to the standard methodology (Kocour et al., 2005) of group S was performed in May 2020 after back adaptation of fish to pond conditions from March 2020. For the comparison, fish of the same breed in age of 6 years (group C), i.e. common broodstock, were spawned together with group S. To confirm whether the fish left in the RAS until May (group A) are still ready to be spawned even if kept all the time at higher temperatures (18-21°C), 12 fish that visually looked ready to be spawned were also included in an artificial spawning a week after spawning of group S and C. Reproductive parameters were determined in females of groups S, C and A (Tab. 1). No exact parameters were recorded in males as they were almost mature already at the age of two years.

Tab. 1. Reproductive parameters of females. **RS** – reproduction success (**NFI** – number of females included into reproduction/**NFS** – number of females successfully stripped), **WE** – weight of eggs, **NE1G** – number of eggs in 1 g, **AWF** – absolute working fecundity, **RWF** – relative working fecundity, **EY** – relative egg yield, ***** - significantly different value ($p < 0.05$) from the others within given column.

Fish group	RS (NFI/NFS)	WE (g)	NE1G	AWF (*1000)	RWF (*1000)	EY (%)
S	95.2 (60/63)	253 ± 153.3	598 ± 73.0	158 ± 91.9	43.5 ± 21.5	7.0 ± 4.06
A	50.0 (6/12)*	214 ± 73.0	-	-	-	5.1 ± 73.0
C	92.9 (13/14)	473* ± 121.7	550 ± 59.4	256* ± 58.7	90.1* ± 18.8	16.4* ± 3.51

(Continued on next page)

Results and Discussion

It was found that fish kept in RAS grew faster. Females of group A (2682 ± 791.6 g) were twice bigger in February 2020 than females of group B. In males the difference was also significant but a bit lower (2376 ± 772.0 g vs. 1307 ± 228.7 g). Also, FC was in both sexes higher in RAS. Gonad development started to be significantly different from October 2019 in females. The highest GSI value observed in group A was 13.3 ± 1.8 (February 2020) compare with 5.3 ± 2.5 in group B (December 2019). In group B, GSI increased significantly in April 2020 (8.4 ± 2.9) while in group A it decreased (9.7 ± 4.9). However, histologically the fish in group B were not fully mature unlike females of group A. In males, the GSI was almost identical in RAS and pond, and histologically males of both groups were mature. Most reproductive parameters of females in group C were better than in group S (Tab. 1). Still, the reproductive success (RS) of females out of group S was comparable with group C which is the most important for selection program. RS of group A was significantly lower. It shows that females after maturation shall be kept at temperatures below 15°C until preparation phase to artificial spawning. Fertilization and hatching rates in group S and C were comparable unlike group A. It was calculated that females of groups A and S collected 10,590 °D with daily average water temperatures over 15°C at the end of October 2019 and 12,900 °D in February 2020 while females of group B collected only 9,055 °D. Thus, it seems that information published by Horváth (1985) concerning °D needed for common carp females to reach the maturity is useful tool and that indoor RAS combined with pond culture are efficient in common carp for shortening of generation interval to three years.

INTEGRATION OF TRANSCRIPTOMICS AND METABOLOMICS TO IDENTIFY POTENTIAL GENE-METABOLITE INTERACTIONS AFFECTING SIZE AT HARVEST IN FARMED ATLANTIC SALMON (*Salmo salar*)

Miyako Kodama

Center for Evolutionary Hologenomics, GLOBE institute, Faculty of Health and Medical Sciences
Email: miyako.kodama@sund.ku.dk

Introduction
One key challenge facing salmonid aquaculture is the considerable losses due to wide (largely unpredictable) variation in growth rates and hence size at harvest - with adult weight at harvest sometimes varying by an order of magnitude within a single sea pen. Although attempts to reduce such phenotypic variation have traditionally been performed under the 'phenotype = genotype*environment' model, successes are limited. Based on the recent advances in omics technologies, multi-omic approaches have been adopted to reveal genetic mechanisms underlying various commercially important traits in a wide range of species. Here, metabolome-transcriptome integration analyses were performed on farmed salmon of various sizes to identify potential gene-metabolite interactions that underlie the variation in harvest sizes, attempting to further bridge the gap between this trait and genotype.

Methods
We sampled the gut epithelium tissue and the gut content from two groups of salmon, each of which contained 180 individuals ranging from 1kg to 8.5kg. Gene expression profiles were assessed using shotgun RNA-seq data obtained from the gut tissue, and metabolomic profiles were obtained using untargeted metabolomics based on the gut content. Each layer of data was analyzed separately by 1) identifying differentially expressed genes based on the transcriptomic profiles, and 2) identifying differentially abundant metabolites in small (1 to 3kg) vs. large (6 to 8kg) groups of salmon. Subsequently, a linear modeling approach was applied to identify significantly correlated gene-metabolite pairs, assuming that co-regulation patterns reflect functionally related genes and metabolites.

Results
We identified 24 significantly differentially expressed genes (DEGs), and 113 significantly differentially abundant metabolites (DAMs). Some of these metabolites were identified as omega3 fatty acid, polyunsaturated fatty acids, as well as bile acid involved in the emulsification of fats. A fraction of DEGs and DAMs are thought to form significantly correlated gene-metabolite pairs based on the linear model.

Conclusions
The results indicate the importance of employing multi-omic approach when elucidating the genetic mechanisms underlying size at harvest in salmon. The gene-metabolite pairs identified in this study may have a role in determining the harvest size in the Atlantic salmon, and further validation may lead to the discovery of effective biomarkers for monitoring fish growth and health throughout the production cycle.

A METHOD TO ASSESS GAPING IN SPARIDAE SPECIES FILLETS

Dimitra Kogiannou*, Mado Kotsiri, Kriton Grigorakis

Sensory lab, Institute of Marine Biology, Biotechnology & Aquaculture, Hellenic Centre for Marine Research, Anavyssos (Greece)
E-mail: dkogiannou@hcmr.gr

Introduction

Numerous methods have been proposed to evaluate the degree of gaping in fish fillets, measuring either the quantity and size of slights in the fillet (Andersen, 1994) or evaluating the area covered by gaps (Kiessling et al., 2004). Automated and semi-automated methods have been also proposed for assessing fillet gaping, thus providing objective, accurate as well as re-analysable data (Ashton et al., 2010; Balaban et al., 2011; Merkin et al., 2013). However, the existing methodologies are limited to assessing gaping severity in salmonids. Sparidae species, namely gilthead sea bream (*Sparus aurata*) and red sea bream (*Pagrus major*), also suffer from gaping and consequently economic losses burden their industry. The extrapolation of methods developed for salmonids to other fish species might be inappropriate or erroneous since gaping and muscle textural characteristics are species-specific and, on the other hand, commercial fillet sizes largely differ.

The aim of this study was to develop a semi-automated method, by using digital photography and computer image analysis, for measuring gaping in Sparidae species fillets. Furthermore, the data from applying this method were used to train assessors in order to speed up the measuring process and to make the scoring procedure accessible to all commercial gilthead sea bream and/or red sea bream processing plants.

Materials and methods

Market-size (400-800 g) gilthead sea bream and red sea bream were harvested from sea cage farms during the summer period and filleted using a filleting-machine. Fillets were placed skin side down on a polypropylene surface with a convex curvature of 165 degrees of a circle with 4.5 cm diameter. A 12-megapixel camera was mounted on a retort stand and clamped 15.5 cm above the apex of the curved surface. Fillet images were taken individually and the records were digitally analysed by using ImagePro-Plus 4.5 software. The software was used to manually highlight the total surface area of the fillet as well as the number, diameter and surface area of the gaps. Due to the curvature, a percentage of inaccuracy was found in the measurement located away from the focal point of the image, which determined to be less than 5%.

Three assessors were trained to quantify gaping severity on Sparidae species fillets according to the gaping scale proposed herein. The training was considered successful only when their performance was accurate more than 95%.

The degree of gaping expressed as a % of surface covered by gaps in each of the studied fillet has been computed against the number of gaps and the maximum size of biggest gap in order to examine correlations. For method validation a $\chi 2$ method was adopted to examine a) if assessors rated in a uniform way with each other and b) to see if ratings deriving by image analysis (true) and those made by the assessors (observed) differed. A two-tail Pearson correlation was conducted to evaluate how sample scaling results correlate with gaping area percentage.

Table 1. Gaping score scale obtained by image analysis data of fillets (N=38) suitable for measuring gaping severity in Sparidae. Scale was based on the area of gaping ex-pressed as % of the total fillet area. Additional characteristics for each gaping score point are also described

Gaping score	Area (a) of gaping as % of the total fillet area	Gaping severity (Additional characteristics)
0	0	Absence/ No gaping
1	$0<\alpha<2$	Slight/Subtle gaping (up to 5 small[a] gaps)
2	$2<\alpha<4$	Mild gaping (up to 7 small gaps)
3	$4<\alpha<6$	Moderate gaping (up to 7 large[b] & few small gaps)
4	$6<\alpha<8$	Severe gaping (up to 7 large and/or many small gaps)
5	$8<\alpha$	Extreme gaping/ Non-marketable fillet (over 7 large gaps)

a: small gaps <5mm
b: large gaps >5 mm

(Continued on next page)

Results

The area of gaping (expressed as % of the total fillet), contrary to the mean number of gaps and the mean diameter of largest gap, was found to be the most suitable parameter for determining gaping severity for Sparidae species. Consequently, a six point scale (from 0 to 5), based on the fillet gaping area, was proposed (Table 1). In order to facilitate gaping classification by the assessors, additional characteristics for each gaping point were also included.

Conclusion

The developed six-point method, based on the digital photography and computer image analysis, represents a sensitive approach for evaluating gaping in Sparidae species fillets. Assessors training is a rapid and effective process and more than 95% accurate. These indicate that the proposed method for evaluating gaping severity in Sparidae species is easy to apply in practice thus allowing the scoring procedure to be accessible to all commercial gilthead sea bream and/or red sea bream farms.

Introduction
Efficiency assessments of marine ingredient use in aquaculture are required to fully understand their contribution to global seafood supply and their impacts on all UN Sustainable Development Goals. Fish In: Fish Out (FIFO) ratios have become the principal metric used to ensure aquaculture does not negatively impact wild fish stocks. However, several approaches have been advocated to calculate the FIFO ratio and there have been criticisms that the different approaches employed lead to over- or under- estimates of the dependence of aquaculture on marine ingredients. Critically, FIFO does not align with Life Cycle Assessment as a measure of other environmental impacts. In this paper we present an alternative method to calculate the FIFO ratio based on the principle of economic allocation (economic Fish In: Fish Out – eFIFO) as commonly used in Life Cycle Assessments. Economic allocation acts as a proxy for the nutritional value of ingredients and places higher importance on the more limiting co-products generated and their relative demand.

Methods
The FIFO ratio represents the amount of fish used to produce 1kg of farmed fish. The amount of fish required is dependent on the amount of feed necessary to support 1 kg of growth, or the (economic) Feed Conversion Ratio (eFCR), and the fraction of feed that is fishmeal and fish oil multiplied by the embodied fish per kg of fishmeal and fish oil. In the eFIFO method the amount of embodied fish in fishmeal and fish oil was calculated based on a global average yield of 22.5 kg fishmeal and 5 kg fish oil per 100kg of fish processed. To divide or allocate the fish that is being used the economic allocation principle was used, in this method the raw material input, i.e. fish, is allocated to the co-products based on the economic revenue created. Attributing relatively more of the input to the product that creates more revenue to the producer, reflecting the socio-economic drivers for marine ingredient production and the resulting pressure on fisheries.

Results
Substitution of marine ingredients by alternate feed ingredients has significantly reduced the amount of fishmeal and fish oil in aquafeed formulations for most farmed fish species, resulting in a continually decreasing FIFO ratio. Results show that most aquaculture species groups assessed in this study are net producers of fish, while salmon and trout aquaculture are net neutral, producing as much fish biomass as is consumed, significantly lower than previous papers suggested (Figure 1). Overall, global fed-aquaculture currently produces three to four times as much fish as it consumes (figure 2).

Conclusion
Our study highlights that previous assessments of FIFO ratios can be misleading and resulting in adverse opinions in the scientific community, as well as on a retailer and consumer level. These can then in turn lead to several socio-economic and environmental implications, including failure to provide authentic information for marine resource planning, a lack of comprehension of realist goals and attainment of viable management pathways for use of commodities like fishmeal and fish oil for sustainable aquaculture practices. Marine ingredients continue to be essential in the diets of most aquaculture species, but re- search has been continuing on ways to use them more strategically in commercial diet formulations to optimize their value. Additionally, the strategic utilisation of fish by-products in feed results in a more efficient use of valuable marine resources. Therefore, it is imperative that models are based on a sound data platform and reflect accurately demand and supply to form a more robust and objective scenario for marine ingredient utilisation in aquaculture. This tool would enable policy makers and people in the industry to make well informed choices. Such a strategy contributes to the sustainable growth of the aquaculture industry and its crucial role in the global food system and nutritional security, being a valuable source of essential nutrients in the human diet.

COMPARISON OF LAB SCALE AND COMMERCIAL PRODUCTION RESEARCH RESULTS IN SALMON FED DIETS WITH DIFFERENT LEVELS AND TYPES OF TRACE MINERALS

M. Kokkali[1*], J-E. Dessen[2], T. Larsson[2], L. Sveen[3], E. Kvamme[4], K. Kousoulaki[1]

[1]Department of Nutrition and Feed Technology, Nofima, Norway

Introduction

Inorganic minerals are routinely added in commercial fish feeds, and there is increasing evidence that different trace mineral and phosphorous sources have different bioavailability (Maage and Sveier, 1998; Standal et al., 1999) and physiological effects (Berntssen et al., 2018). The relative levels of naturally occurring and added trace minerals in different forms will vary in diets changing from marine to plant based with unknown consequences for fish physiology. Skin ulcers and low stress tolerance are likely to be linked to sub-optimal mineral and vitamin nutrition, whereas poor smoltification and transfer performance may be linked to inadequate essential amino acid and mineral status of the fish. Fillet quality degrading conditions, as for instance gaping, liquid losses, suboptimal pigmentation, and melanin spots may also be affected by variable mineral nutrition status of the fish. There is a trend in nutrition of farmed land animals, such as poultry and swine, to replace inorganic trace mineral sources with lower amounts of bioavailable organic trace mineral sources which results in minimizing the excreted amounts of minerals, such as copper (Cu), in the environment, but also have the potential and have shown improvements in trace mineral-associated functionalities (Abdallah et.al., 2009). Organic Se sources have been shown to be assimilated more efficiently than inorganic compounds and are less toxic (Pacitti et al., 2016; Silva et al., 2019). Also, there are studies which have reported better Se apparent availability and Se retention in fillet of salmon fed organic Se diets (Sele et al., 2018; Silva et al., 2019). Reevaluation of organic minerals requirements may be necessary as studies has shown reduced levels required when organic minerals were used (Apines et al., 2003; Lin et al., 2010; Pierri Bruno da Silva et al., 2021). For example, Cu requirements for juvenile grouper, *Epinephelus malabaricus*, were reduced in half when organic Cu was included in the diets (Lin et al., 2010). Regarding mineral bioavailability, emphasis should also be placed, on the release rate of minerals to the environment when difference mineral sources are used. Russel et al. (2011) outlines the excess use of Cu and zinc (Zn) in Scottish Atlantic salmon farming, with concentrations 3-4 times more than required. In the same study, they concluded that Cu and Zn elevated levels on the sediment may cause adverse effect on the local environment around the sea farm. The scope of this study was to compare lab scale and commercial production results in salmons fed diets with either organic (OM) or inorganic (IM) trace minerals in different inclusion levels and their effects on Atlantic salmon performance, skin health and tissue mineralization.

Materials and Methods

In lab scale, 18 groups of Atlantic salmon smolt with initial mean body weight 150g were fed for 12 weeks 1 of 8 experimental diets with 3 replications. At trial end mean fish body weight was approx. 450g. The diets contained either organic or inorganic mineral premixes in 4 dietary supplementation levels (Se: 1.2-1.5ppm, Cu: 10-24ppm, Mn: 55-100ppm, Zn: 80-180ppm and Fe: 300-500ppm). The trial design included an undisturbed feeding period at start and end and 3 weekly handling stress treatments half-way the experimental period. Feeding rates, FCR, biometrics, fillet and skin technical quality, tissue mineral levels and skin histology were evaluated. In the commercial production trials we used salmon of approx. 500g body weight at start to slaughter, fed 4 different diets containing either organic or inorganic minerals at two supplementation levels (Se: 0.6-0.8ppm, Cu: 17-25ppm, Mn: 65-85ppm, Zn: 180ppm and Fe: 226-275ppm) and 2 replicate cages per treatment. All other farming operations were based on common praxis including for instance lice treatments. The mineralisation of whole body and different tissues (liver, skin, fillet, gills, and spleen) was studied at trial start, mid (when fish weighed approx. 2kg) and end (4.5 kg). Biometric and welfare measurements were taken at mid and end sampling, and liver and skin histology were evaluated at trial end. Growth and FCR at sampling points in commercial production were estimated based on collected daily farm feeding data and biomass and mean fish body weights at slaughter.

(Continued on next page)

Results and Discussion

There is an increasing interest of comparing the bioavailability of organic and inorganic minerals in fish diets, but the available data are still scarce and inconsistent (Dominguez et al. 2017; Antony Jesu Prabhu et al. 2016). Our results can fill some gaps on the bioavailability of organic and inorganic minerals and highlight the difference between mineral accumulation on tissues based on their origin (organic/inorganic) and dietary level. In lab scale, we saw significantly higher fish performance, in the organic as compared to the inorganic mineral treatments. A significantly positive correlation between dietary organic mineral level and skin Zn was also observed. Whole body mineral composition did not differ for the two mineral forms, with the exception of Se which showed a tendency for higher accumulation in the organic mineral treatments, whereas a significant negative correlation between organic Cu supplementation and whole body Cu was seen. Accordingly, in a meta-analysis by Antony Jesu Prabhu et al. (2016), it was highlighted that organic forms of Se, like SeMet and Se yeast, are more bioavailable compared to selenite; however, for other trace minerals like Zn and Mn the published results were conflicting. Comparative results with the cage trial data will be presented.

TIME- AND DOSE-DEPENDENT EFFECTS OF DIETARY DEOXYNIVALENOL (DON) IN RAINBOW TROUT (*Oncorhynchus mykiss*)

Introduction

Lately, the aquaculture industry has shifted towards the formulation of more sustainable diets, characterized by a higher inclusion of plant-based ingredients - even in feeds for carnivorous fish species like salmonids. Because plant-based ingredients are susceptible to fungal growth, the risk of mycotoxin contamination has been increased in aquaculture. In combination with climate change, fungal growth and distribution might be affected and lead to uncertain mycotoxin profiles in feeds. A recent survey in aquafeeds highlighted deoxynivalenol (DON) as the most potent toxin for European aquaculture. The same study with a meta-analysis showed that DON reduces fish productivity due to impaired feed intake and recognized rainbow trout as the most sensitive fish species. Previous experiments in rainbow trout were performed within *ad libitum* exposure to DON, either in the natural form (coming from naturally contaminated ingredients) or pure (commercial powder). However, *ad libitum* exposure reduces the feed intake masking the effects on growth related to the toxin itself. Also, pure DON has less severe effects than the natural source, since in the last case a synergism might exist due to the co-occurrence of different toxins. Therefore, the current study aimed to elucidate the effects of two different types of DON (natural or pure) on growth performance and liver histopathology. Firstly, rainbow trout were fed restrictively and equally the experimental diets for six weeks to detect the potential effects of DON related to the toxin itself and not due to differences in feed intake. An intermediate sampling point was implemented after a week of feeding to investigate whether DON effects change over time. Finally, the experiment continued with two weeks of *ad libitum* exposure that could reveal potential DON impact on the feed intake capacity.

Material and methods

A feeding experiment was performed with rainbow trout fingerlings (8 g) to evaluate the effects of DON at realistic doses (up to 1600 µg/kg) on growth performance and liver histopathology. Thirty fish were randomly assigned to one of the five different dietary treatments with three replicates each: (1) control (CON) diet (DON < 100 µg/kg), (2) naturally DON-contaminated diet (ND1) with 700 µg/kg feed, (3) and 1200 µg/kg (ND2), (4) pure DON-contaminated diet (PD1) with 800 mg/kg, and (5) 1600 µg/kg (PD2). The feeding trial lasted eight weeks and included two feeding regimes: six weeks of restrictive feeding (12 g/kg MBW) followed by two weeks of *ad libitum* feeding. At the end of each feeding period, batch weighting was performed to calculate growth performance parameters. Initial and final crude protein (CP) and gross energy (GE) body composition at the end of the restricted period (day 40) were determined from 20 fish and five fish/tank, respectively. CP was calculated based on nitrogen x 6.25 using the Kjeldahl method, and GE measured with the adiabatic bomb calorimeter method. Two fish per tank or six per treatment (CON, ND2 and PD2) were sampled for histological assessment at two different time points of restricted feeding period (day 6 and 40). At the end of the satiation feeding period, growth and the feed intake capacity was measured, and liver samples were collected for histological assessment. Liver sections were stained with Periodic acid-Schiff's (PAS) to detect lipid-type and glycogen-type vacuolisation, and with haematoxylin and eosin (H&E) to evaluate pathological parameters based on a quantitative scoring system. The IBM Statistical Package for the Social Sciences (SPSS) program (v 23.0; New York, NY, USA) was used to perform the statistical analyses.

Results

Restrictive exposure to DON for six weeks did not affect the growth performance of trout but reduced retained protein in fish treated with ND2 and PD2. The last finding supports the hypothesis of DON inhibiting protein synthesis or increasing maintenance requirements and leads to increased protein catabolism and impaired nutrient utilisation. Liver histological assessment revealed altered nuclei characteristics and haemorrhages in the high DON-treated fish (ND2/PD2) after six days of restrictive DON exposure, but effects faded out over time (40 days). The latter may imply adaptation mechanisms in rainbow trout to recover after exposure to a certain DON amount. However, when ad libitum DON exposure was applied, hepatic damage aggravated: reduced glycogen vacuolisation, altered nuclei characteristics, necrosis and haemorrhages incidences were noted (Fig 1). Hepatic damage was more severe in PD2 than ND2 treatment, which might be explained by the higher DON content (1600 µg/kg vs 1200 µg/kg). Surprisingly, ad libitum exposure did not affect the feed intake capacity; maybe because rainbow trout had been exposed earlier to a restrictive exposure to DON for six weeks they had adapted. Finally, ad libitum exposure led to reduced body weight gain and altered feed efficiency in ND2 and PD2 treatments. The latter observation suggests the feeding regime determines the actual amount of ingested DON and the severity of the effects on rainbow trout.

Introduction

Protein deposition in fish muscle tissue (i.e. fillet) is an energy-demanding process in which amino acids (i.e. absorbed protein) can act as building blocks or as energy substrates. Because protein is the most expensive macro-nutrient of commercial fish feeds, fish nutritionists intend to maximize the use of amino acids as building blocks instead of energy substrate. This is often achieved by increasing the non-protein energy content of fish feeds via inclusion of lipids and carbohydrates, thereby decreasing the dietary protein-to-energy ratio (P:E). For the sake of feed efficiency, much effort has been dedicated to defining optimal dietary P:E for farmed fish species like Nile tilapia (*Oreochromis niloticus*)[1–3]. Yet, published estimates vary largely, with optimal P:E ranging from 16 to 29 g/MJ for Nile tilapia[3,4]. Most published estimates were determined from feeding trials in which contrasts in dietary P:E were achieved by diluting dietary proteins with lipids and carbohydrates. Often, this has led to simultaneous changes in protein and energy intake, thereby making it impossible to distinguish the separate effects of protein and energy intake on growth. In addition, the emphasis placed on whole body mass gain changes with dietary P:E may have masked more meaningful underlying changes in nutrient partitioning. We conducted a meta-analysis and a dose-response trial to overcome these limitations and determine if there is a single optimal P:E for Nile tilapia feeds.

Material and methods

A systematic literature review was conducted to aggregate published feed, growth and body composition data of Nile tilapia growth trials. A total of 75 cases (i.e. dietary treatments) reported in 11 publications were selected for analysing the effects of dietary P:E on nutrient partitioning. These 75 cases provided data for Nile tilapia ranging from 6 to 250 grams and fed diets varying in crude protein (195 – 565 g/kg of dry matter) and gross energy content (17 – 24 MJ/kg of dry matter). In addition, a dose-response balance trial was conducted with all-male Nile tilapia (initial body mass = 64 g) at the Aquatic Research Facility of Wageningen University (NL) to test the separate effects of protein and non-protein energy intake on nutrient partitioning and growth. The trial consisted of a 2×8 factorial design in which duplicate 60 litres tanks of 30 fish were randomly allocated to one of 2 levels of digestible non-protein energy intake (16.0 and 22.4 kJ/day) and one of 8 levels of digestible protein intake (0.44 – 1.25 g/day). The 32 tanks were individually equipped with a settling faeces collection device and connected to a single recirculating aquaculture system kept at 28°C. Fish were hand-fed restrictively twice a day and faeces were collected overnight. Nutrient apparent digestibility was calculated via the indirect method using yttrium oxide as dietary inert marker. Initial and final body composition were determined from 20 fish and 10 fish/tank, respectively. For all analyses, crude protein was calculated by multiplying the Kjeldhal-analysed N content by 6.25. Growth, feed, faeces and body composition data collected from the literature review and obtained in our balance trial were used to calculate nutrient balances. The effects of changes in dietary P:E and digestible protein and non-protein energy intake on nutrient balances were analysed by linear regression, using SAS software package version 9.4 (SAS Institute Inc., Cary, NC, USA).

Results and discussion

Protein retention efficiency (Fig. 1A) increased linearly with decreasing dietary P:E, thereby illustrating a protein-sparing effect of increasing dietary non-protein energy content. The fact that this effect was linear across a wide range of dietary P:E contradicts the concept of a single optimum in the dietary P:E of Nile tilapia. Protein gain increased close to linearly with digestible protein intake in our dose-response trial (Fig. 1B), with neither the intercept nor the slope being affected by non-protein energy intake level ($P = 0.67$ and 0.11, respectively). This indicates that protein – and not non-protein energy – intake limited protein deposition throughout the entire range. Again, this contradicts the concept of a single optimal balance between dietary protein and energy intake above and below which protein deposition would be limited by energy and protein, respectively. Instead of a single fixed value, the optimal P:E for Nile tilapia feeds is more likely to reflect situation-specific compromises between dietary protein cost and factors such as constraints on nitrogen discharge, body fat content and fillet yield.

GOOD AQUACULTURE PRACTICES; THE COLLABORATIVE USE AND BENEFITS

B.Koonse

POB 1129, Harpers Ferry, WV 25425
Brettkoonse@yahoo.com

The Joint Institute for Food Safety and Applied Nutrition (JIFSAN) is a collaboration between the United States Food and Drug Administration (FDA) and the University of Maryland (UM). JIFSAN has developed an aquaculture program that links food safety and disease prevention. It's called Good Aquaculture Practices (GAqPs). GAqPs are widely used and implemented around the world. This presentation is a short synopsis on GAqPs and a request for to help take GAqPs to the next level where it can be universally used and recognized for a wide variety of purposes. GAqPs could be used or integrated into new or existing programs to show food safety and disease controls are in place by the following:

- Individual aquaculture farms for their buyers;
- Governments for their farm and or processor registration and certification programs;
- Private third-party certification programs to verify food safety and disease prevention;
- Processors in their HACCP or Preventative Control programs to act as their food safety controls for aquaculture related food safety hazards;
- Academia to train future aquaculture professionals in food safety and disease prevention;
- The aquaculture industry and others to demonstrate to the general public that aquaculture products are safe, sustainable, and free of hazardous residues and pathogens

DIET COMPOSITION, GROWTH, GUT FUNCTION, AND GASTROINTESTINAL PATHOLOGIES OF FARMED ATLANTIC SALMON FROM SIX SITES ALONG THE NORWEGIAN COAST DURING SEAWATER GROW-OUT

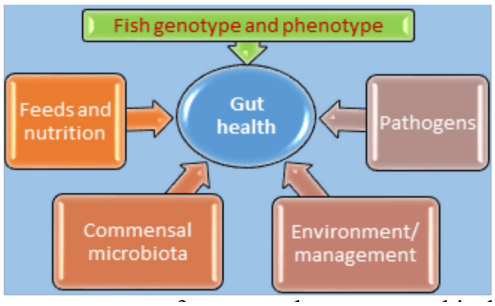
Introduction
Optimal intestinal health and digestive function are prerequisites for efficient feed utilization and for production of robust fish that will better cope with disease, stress and farming conditions. Gastrointestinal pathologies, such as inflammation and lipid malabsorption, have been underestimated challenges in farmed Norwegian salmon. Recent observations of sea-raised Atlantic salmon suggest that both conditions prevail in commercial Atlantic salmon farming. Previous research suggests that the increasing levels of plant ingredients in feeds, with their inherent antinutritional factors and fibers, can be important contributing factors. However, the significance of dietary contaminants, gut microbiota, nutritional and disease status, and developmental stage of the fish, as well as exogenous factors such as geographical location, other environmental conditions, and various management practices are not well understood. A more thorough understanding of the interplay between these factors is necessary to define causal relationships and subsequently prevent losses due to gut disease (Figure 1). A widely faceted research collaboration – the **GutMatters** project- was therefore initiated with the aim to document gut health disorders in commercial salmon farming, to further unravel the causative mechanisms, and to stimulate further control and remediation of both conditions. The project comprises extensive studies of fish from the field, and the conduct of several controlled feeding experiments. A summary of the main findings from the field study will be presented.

Materials and methods
Six marine Atlantic salmon farming sites were recruited for participation in the field study; two in the southwestern, two in the middle, and two in the northern part of the Norwegian coastline. Sampling was conducted at three timepoints following spring entry 2017: shortly following sea transfer, as well as 6-8 and 12-15 months after sea transfer. For each sampling event, complete sample sets of faeces, blood, gut and liver tissues were collected from a minimum of 12 individual fish, and used for detailed downstream nutritional, biochemical, histopathological, transcriptome, metabolome and microbiome analyses. In addition, feed samples, population data (feeding, estimated growth) and environmental variables (water temperature, dissolved oxygen, salinity) were provided by the managers of each participant site. The complete data set is currently being investigated by multivariate data analysis for capturing discriminant data acting as biomarkers of well-being or gut-disorder stress in farmed salmon.

Results and discussion
The histopathological evaluation revealed major differences between the sites and sampling time points with regards to inflammatory signs in the distal intestine, with an increase in both prevalence and intensity of inflammatory findings with time. All of the populations had fishes with moderate or marked inflammatory score in the final pre-harvest sampling. There were also clear differences between the populations with regard to lipid vacuolization of the pyloric caeca (Figure 2), indicating lipid malabsorption. Especially in the final sampling, severe vacuolization of the mucosal cells was seen in the majority of fishes from two of the populations.

(Continued on next page)

Figure 1 Causal factors affecting intestinal health



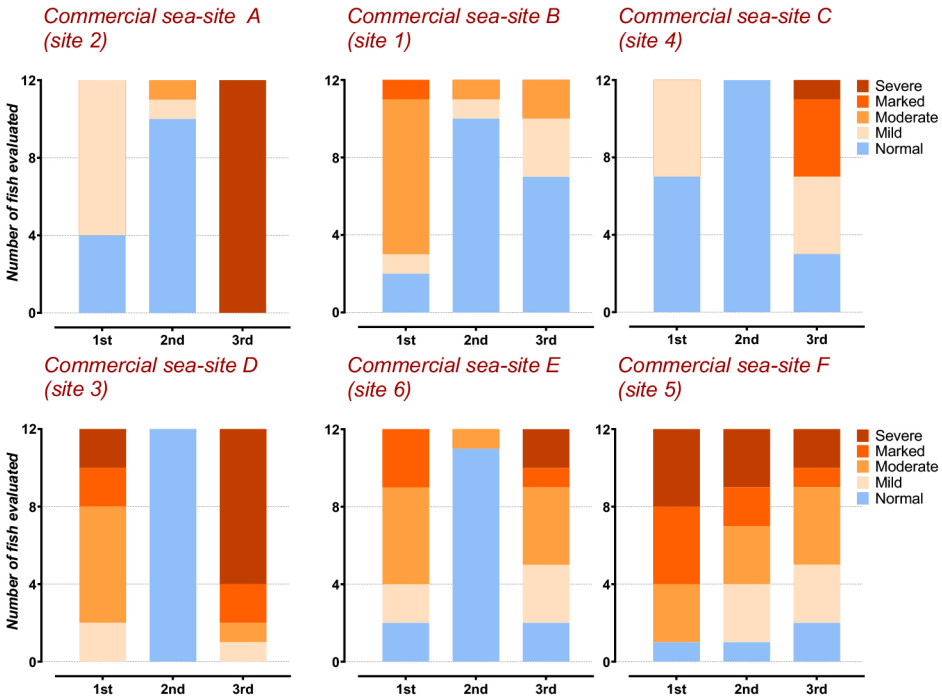


Figure 2: Prevalence and degree of lipid vacuolisation of the mucosa in pyloric caeca

Transcriptome, microbiome and metabolome profiling of gut content, tissue and blood demonstrated both site-specific signatures, and overall temporal changes that could reflect fish growth and development during production, irrespective of production site. Preliminary searches for correlation between omics data and pathology did not yet show strong relationships, but multivariate analyses of environmental, production and biological data are still ongoing. Regarding the feed analyses, the general picture indicates similar strategies among the feed companies and farmers regarding macronutrient composition of the diets throughout the production period. To conclude, the study clearly demonstrated that well-known gut health disorders are frequently found commercial Norwegian salmon farming. Holistic systematic investigations are currently ongoing to unravel causal relationships, develop non-invasive diagnostic tools and implement preventative measures for the observed gut disorders.

Funding

The experiment is one of a series conducted under the GutMatters project funded by The Norwegian Seafood Fund (FHF, project 901435).

VARIOUS MODIFIED ATMOSPHERE PACKAGING (MAP) CONDITIONS EFFECTS ON CHEMICAL SHELF-LIFE OF EUROPEAN SEA BASS

Kotsiri Mado1, Kogiannou Dimitra1, Gogou Eleni2, Grigorakis Kriton1

1Institute of Marine Biology, Biotechnology & Aquaculture, Hellenic Centre for Marine Research, Anavyssos, Greece (mkotsiri@hcmr.gr, kgrigo@hcmr.gr)
2Laboratory of Food Chemistry and Technology (School of Chemical Engineering), NTUA, Athens, Greece

Introduction

European sea bass (*Dicentrarchus labrax*) is an important marine species with major importance in the Mediterranean mariculture. Gutted sea bass is a value-added product that exhibits increasing demand in the international seafood market. Nevertheless, fresh seafood products are highly perishable and their quality deterioration could be a result of microbial activity, chemical oxidation, or autolysis. Storage temperature and packaging atmosphere influence microbial growth and thus the shelf-life of seafood (Odeyemi et al., 2018). Modified Atmosphere Packaging (MAP) can effectively alter the spoilage process and extend the shelf life of fresh fishery products (Tsironi and Taoukis, 2018).

It is based on altering the composition of gases in contact with food by replacing the air in a sealed food package with strictly controlled gaseous mixtures, containing oxygen (O2), carbon dioxide (CO2), and nitrogen (N2), or others. Their concentrations in the package headspace depend on the specific fish product and the mechanism of spoilage that limits the shelf life of the final food product (Tsironi and Taoukis, 2018).

The objective of this study is the evaluation of the active modified atmosphere packaging on the freshness and shelf life of gutted sea bass.

Materials and methods

Fresh gutted sea bass (weight: 400-600 g) was obtained in ice by a Greek aquaculture company (Selonda S.A.). Samples were transported to the Laboratory of Food Chemistry and Technology (School of Chemical Engineering, NTUA) and packed in high-density polyethylene pouches in modified atmosphere consisted of 50% CO2-50% air with two different CO2 emitters (PAD1 dimensions 300 mm × 130 mm × 40 mm and PAD2 dimensions 366 mm × 127 mm × 50 mm) (McAirlaid's Inc., Steinfurt, Germany) and under vacuum (V-PAD2) were used in order to evaluate the effect of active MAP on shelf-life extension. Samples were stored at controlled isothermal conditions (0, 2.5, 5 and 10 ˚C) in high precision incubators for 22 days. These samples were transported to the Sensory lab of HCMR for chemical freshness analysis.

Freshness assessment of the sea bass was based on ATP breakdown products analysis (*K*-values freshness index) and on free fatty acids (FFA) content. Extraction of ATP breakdown products took place from the dorsal muscle. The extraction of ATP-breakdown products and the HPLC *K*-values analysis has been previously described (Grigorakis et al., 2004)

A method for FFA detection was developed. FFA were extracted according to Bligh and Dyer (1959), separated using a NH2 SPE cartridge and esterified. The organic phase was then analyzed using gas chromatography-mass spectrometry (Agilent Technologies, Santa Clara, CA, USA). An extract aliquot of 1 μl was injected into the GC/MS in a split mode (1:25) and separation was achieved on an Agilent DB-23 capillary column (60 m 0.25 mm, coated with a 0.25 μm film thickness).

Identification of fatty acids was carried out by comparing the retention times with the FAME standards. Nonanoic acid methyl ester was used as an internal standard to quantify the contents of the fatty acid methyl ester assuming the detector response to each fatty acid was identical. The content of each fatty acid was expressed as mg/100g of wet matter.

Results & Discussion

The *K*-values for 5ºC increased from the initial 20% on day 0 to reach 90%, respectively, on the 22th day of storage in all conditions. The acceptability limit of 60% *K*-value corresponding to the sensory shelf life of aerobically stored fresh sea bass (Grigorakis et al., 2004) was herein reached very early, in 5th day.

ATP, ADP, and AMP remained at low concentrations throughout the storage, while IMP, Ino, and Hx exhibited some differences in their patterns. The FFA contents fluctuated throughout storage without a specific pattern (Fig. 1). FFA are the main substrates for lipid oxidation and play an important role in the flavor formation of fish products.

(Continued on next page)

Introduction

Edible coating or film is defined as a thin layer of material used for coating or wrapping food products, with the aim to extend their shelf life. Edible films are prepared separately and then applied to the food, while coatings are formed directly on the food surface (Tsironi and Taoukis, 2018). When properly formulated, both methods are considered to improve the organoleptic characteristics of packed food products. In addition, they can retard oxidation and/or delay microbial spoilage by integrating antibacterial and antioxidant agents. In order to develop edible films and coatings for food products, several materials may be used. These materials should be capable of forming a film and must be dissolved in a suitable and safe solution, that is, also compatible with the particular plasticizers, antioxidants, and/or antimicrobials. The prospective materials can be classified as hydrocolloids (e.g., polysaccharides, alginates), proteins (e.g., gelatin, casein), lipids (e.g., triglycerides, waxes), and composites (Oreopoulou and Tsironi, 2021).

Silk fibroin is an extensively investigated biomaterial for its potential in several applications, such as textile, biomedical, photonic, and electronics. Silk fibroin is a structural protein, like collagen, which has a unique feature: it is produced from the extrusion of an amino-acidic suspension by a living complex organism (while collagen is produced in the extracellular space by self-assembly of cell-produced monomers). The application of micrometre-thin silk fibroin membrane around the surface of strawberries and bananas has been reported as an effective management method of postharvest physiology of fruits (Marelli et al., 2016). The objective of the study was the investigation of the development of an edible food packaging material based on silk fibroin and the applicability on fresh shrimp for improving so the general freshness maintenance, as enzymatic post-mortem melanosis, commonly named black-spot (Goncalves & Oliveira, 2016).

Materials and methods

Cocoon was obtained from Bombyx Mori and used as fibroin source. Extraction of silk fibroin (SF) was performed using standard degumming processes (Marelli et al., 2016). The application of the silk fibroin based edible coating on the surface of whole, unpeeled shrimp was implemented by an immersion step, so as appropriate covering of the shrimp surface was achieved. Untreated (Control) and SF-coated samples were individually packed at aerobic consitions and stored at controlled isothermal conditions (0°C) in high-precision (±0.2°C) low-temperature incubators (Sanyo MIR 153, Sanyo Electric, Ora-Gun, Gunma, Japan). Temperature monitoring in the incubators was based on electronic, programmable miniature dataloggers. Quality evaluation was based on microbial spoilage, instrumentally measured colour and texture, enzymatic browning (polyphenol oxidase), and sensory freshness.

Results

The application of SF edible coating resulted in a significant inhibition of microbial growth and enzymatic browning of refrigerated shrimp, leading to 4-5 days shelf life extension at 0°C compared to the untreated (Control) samples with shelf life of 7 days.

Discussion and conclusion

The results of the study show the potential of SF edible coating to preserve the quality and extend the shelf life of refrigerated seafoods. Optimized production conditions were selected based on the stability of the packaged products. This novel, edible coating might serve as the basis of an eco-friendly, active food packaging system, by the addition into the film formulation of natural antimicrobial and/or antioxidant bioactive compounds.

Introduction

Skeletal abnormalities are an important issue for the quality of reared fishes, with either an emerging or well-established production. Skeletal abnormalities develop mainly during the larval and early juvenile stages, due to a variety of causative factors (Boglione et al. 2013), thus making important key-performance-indicators (KPI) for hatcheries. The goal of the present study was to identify and characterize the currently most important skeletal abnormalities in commercial seabream hatcheries, and to examine the variability of relevant KPIs in four seabream hatcheries in comparison with the genetic structure of the hatchery populations.

Material and Methods

From each of the four participating hatcheries, 1-3 populations per month were randomly selected during a full production year, to be monitored for their rearing parameters and examined for skeletal abnormalities. A total of 74 (17-20 per hatchery) populations were analyzed. Samples for quality control were taken on the day of fish removal from the larval-rearing tank (26-70 days post-hatching, dph; 9-19 mm mean total length, TL). A random sample of 50-100 larvae from each population was anaesthetized and fixed in phosphate buffered 5% formalin (pH=7.2).

Fish samples were stained for bone and cartilage (Walker and Kimmel, 2007) and examined for the presence of skeletal abnormalities, following the terminology of Koumoundouros (2010) and Fragkoulis et al. (2018). Besides the abnormalities frequency, examined KPIs included the frequency of fish with normally inflated swimbladder at 16 dph, specific growth rate (SGR) and heterogeneity of fish TL (coefficient of variation, CV) at quality control, survival rate (Sur) and productivity (Prd).

Four microsatellites (SauK140INRA, SaI12, Saimbb26 and Fd-78-H) were used to infer genetic structure based on validated primer sets. The Structure program was used to infer the number of Gilthead seabream (K) in the collected samples, and the phylogenetic analysis was carried out using the R package APE based on the pairwise Fst values for every locus, which was extracted using the MSA 4.05 program.

Results & Discussion

At the end of the larval rearing phase (38.6±5.8 dph), gill-cover and upper-jaw abnormalities of any severity degree were the most frequent skeletal defects observed, with a mean frequency of 11.3±17.9 % and 6.0±7.2 % respectively. At quality control, the mean fish size was 13.5±2.6 mm TL and mean CV was 11.6±2.6 (Fig. 1a, 1b). The recorded rate of normally inflated swimbladder was 92.3±7.4% (Fig. 1c). Mean survival rate was 25.9±21.0% and mean productivity was 43.2±44.5 fish per volume unit (L) of the larval-rearing tank (Fig. 1d).

Phylogenetic analysis indicated a clustering of samples according to the hatchery geographical location, while best K values, indicated K=4 for gilthead seabream. Plotting the q-values for each of the individual samples revealed admixture patterns with clear distinctions based on their geographical origin, the possible result of an extensive exchange between breeders in combination with company specific selective breeding, which could support the variability observed in different populations.

To our knowledge, this is the first study examining the variability of KPIs in commercial finfish hatcheries at a large scale (i.e. 4 hatcheries, 17-20 populations per hatchery) offering the opportunity to estimate reference values for benchmarking.

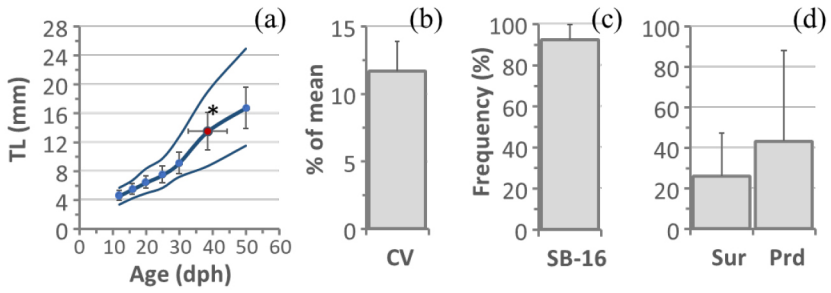

Fig 1. Mean values of the recorded KPIs. a) Average TL during the larval rearing and weaning period. Asterisk (*) indicates the mean TL and age of the fish samples at quality control. b) Coefficient of variation of fish TL at quality control. c) Mean frequency of normally inflated swimbladder at 16 dph. d) Average survival rate (Sur, in %) at 50-60 dph. Prd indicates the mean number of fish survived (50-60 dph) per volume unit (L) of the larval-rearing tank (fish/L). Error bars equal ±1SD.

PERFORMANCE OF NOVEL LOW TROPHIC RAW MATERIALS IN ATLANTIC SALMON *(Salmo salar)* DIETS

K. Kousoulaki[1*], T. Larsson[1] and L. Sveen[2]

[1]Department of Nutrition and Feed Technology, Nofima, Norway

E-mail: katerina.kousoulaki@nofima.no

Introduction

Many different raw materials are considered as candidates for replacing fish meal (FM) and fish oil FO) in diets for salmonids, particularly focusing on locally produced low trophic level organisms with higher sustainability and circular economy potential. However, most of these novel raw materials differ from fish, containing e.g., high levels of complex carbohydrates or fully saturated triglycerides, and their nutritional value and nutrient bioavailability must be investigated before their use in commercial feeds.

Materials and Methods

In the current study, a control diet was created using high quality organic FM (25% in the diet) and FO (10% in the diet). Large parts of FM, FO or both were replaced by one of the following test ingredients: tunicate (*Ciona intestinalis*) meal, black soldier fly larvae meal (*Hermetia illucens*), cell wall disrupted phototrophic microalga *Phaeodactylum tricornutum* biomass, and spray dried heterotrophic microalga *Schizochytrium limacinum* biomass to create four test diets TM, BSFL, PT and HT, respectively. In a fifth diet (FutureEUAqua 0FM0FO) all the above test ingredients were combined at the same levels as when tested alone, and no FM or FO was used. The diets were balanced for protein, essential amino acids, EPA+DHA and n-3/n-6 ratio, phospholipids, and soluble P, using wheat and horse beans, crystalline amino acids, plant oils, lecithin, and monosodium phosphate, respectively. The experimental diets were fed to triplicate salmon smolt groups of 50 fish per tank, with initial mean fish body weight 142 and final mean body weight 433 g. Dietary effects on tissue composition, nutrient ADC, fish biometrics, skin histology and blood chemistry were evaluated.

Results and Discussion

We saw significantly higher growth rate in the control group as compared to the test groups. TGC was similar and high (approx. 4) among the single test ingredient experimental groups and higher as compared to the FutureEUAqua treatment lacking FM and FO. Growth mostly correlated with feed intake, thus FCR was similar among treatments and low FCR (Fig 1). TGC correlated significantly and positively with serum K, ASAT, ALAT and CK. ADC was significantly affected by dietary treatment for most nutrients analyzed except Cu, Zn, Se, Mn and 22:0.

Dermis was thinner for the FutureEUAqua fish, dense connective tissue (DCT) was thicker for the BSFL group than the PT group and scales areas followed a similar pattern as dermis with lowest values for the FutureEUAqua fish (Fig 2). There was no effect on epidermal area or number and area of mucous cells, and the epidermis of fish studied looked healthy.

The diets with alternative protein sources (BSFL and TM) had lower ADC of protein (86.6 and 85.3%, respectively) than the FM (91.7%) control. Their combination reduced ADC of protein further in the FutureEUAqua treatment (81.7%). Similar pictured showed the ADC of most amino acids, though their dietary levels were balanced, which may indicate suboptimal processing of these new raw materials still in development (e.g., excess heating). ADC of lipids was lowest in the HM diet, as reported in short term trials before (Kousoulaki et al., 2015) due to the high levels of tripalmitin in HM oil (Bogevik et al.,2018). HM had also slightly lower ADC of MUFA, n-6PUFA, n-3PUFA and EPA+DHA as compared to the control and test diets, except the FutureEUAqua which had surprisingly the highest levels among all the groups (Fig 3).

Introduction

African catfish or sharp tooth catfish (*Clarias gariepinus*) is farmed in numerous African, Asian, and European countries, and its production has grown significantly worldwide during the last decades in intensive systems (IS). The production cost in IS is highly influenced by the feed cost, which is even more significant for species requiring high protein content. Some of the ingredients can be replaced by alternatives to reduce this cost: many experiments have been performed to replace animal protein with plant protein in several fish species, but this generally had a negative effect on the growth rate and health status (Gómez-Requeni et al. 2004, Pongmaneerat et al. 2011). However, recent research suggests that the utilisation of the feed can be improved by selection (Callet et al. 2017). Our long-term goal is to create an African catfish line selected for a low fish-meal feed, which has a similar or better growth rate than those fed with conventional feed. It could reduce production costs and provide more sustainable farming methods. Our aim is to isolate genetic markers that could be used for the prediction of phenotypic traits, and thus marker-assisted selection in the near future.

Materials and methods

African catfish (*Calrias gariepinus*) was selected and investigated on a half-industrial scale, in a flow-through system using 2 m^3 tanks at the Győri Előre Fisheries Co. site. Altogether 16 females and 18 males were selected as brooders to produce the F1 generation and offspring were fed with a widely used commercial (control) feed and an experimental feed with low fish-meal content in duplicate groups. Size selection was performed repeatedly to avoid cannibalism resulting in 3 different size groups in each experimental and control group. F2 offspring were generated by 4 multifactorial crosses of 5 male and 5 female individuals from each F1 group. Additionally, 3 groups were created from the biggest specimens fed with the low fish-meal feed to produce the positively selected line in triplicate. The body mass of 1846 and 1783 individuals from the F1 and F2 generations was measured, respectively on market-sized individuals, 8 months post-hatching, and data analysis was performed by R version 3.5.3. The effect of feed and sex on the body mass was evaluated by ANOVA analysis with a 5% significance level. Fischer's exact test was performed to investigate the association between sex and feed.

Results

Small differences were found in the sex ratios, although the association between sex and feed was non-significant. The average body mass in the F1 generation was 1461.60±490.34g for the control group and 1180.26±550.987g for the experimental groups, which is significantly lower. Additionally, a significant interaction was found between the feed and sex, suggesting that utilization of different feeds might have been affected by sex. Females had higher body mass in the experimental groups (males: 1126.05±538.45, females: 1216.36±498.65), while males had a higher average in the control groups (males: 1540.02±493.41, females: 1394.38±478.57). No difference was found in the F2 generation between the average body mass of the control (1597.05±399.49g) and the non-selected experimental (1578.34±550.98g) groups. However, the average body mass of the positively selected line (2297.41±463.78 g) showed a significant difference compared to the biggest individual in the non-selected experimental groups (2017.41±358.85g).

Discussion and conclusion

Our findings suggest that the groups fed with the low fish-meal diet had a lower growth rate compared to the control group in the F1 generation, which is in agreement with previous results (Gómez-Requeni et al. 2004, Pongmaneerat et al. 2011). However, no significant difference was found in the body mass of the control and experimental groups of the F2 generation, which might be explained by habituation. The selection had a remarkable effect on the growth rate: the selected lines grew significantly faster compared to the non-selected groups, fed with both the control and experimental feeds. The calculated average gain was around 14% in the F2 generation. In addition, feed had a significant interaction with the sex, females having higher average body mass fed with the experimental feed, suggesting that spawners might utilize plant protein more effectively than milters. In contrast, in the control groups, males had a higher growth rate, which is widely known for African catfish (Henken et al. 1987). Further research on positive selection for an African catfish line for better utilization of low fish-meal feeds and its sex interactions is recommended.

GUT HEALTH EFFECTS IN ATLANTIC SALMON (*Salmo salar* L) OF LOW DIETARY FISH MEAL LEVEL CAN BE LIMITED BY DIETARY SUPPLEMENTS

Introduction
A survey of gut health at three timepoints during one year after sea transfer, in six Atlantic salmon farms along the coast of Norway, conducted in the years 2018 to 2019, showed frequent signs of steatosis in the proximal intestine and inflammation in the distal intestine (Kortner et al. 2021). A controlled experiment was conducted to find if low level of fish meal in the diet might explain these findings. A second goal was to find if the symptoms might be diminished by supplementation with choline, known to be necessary for efficient lipid transport in the intestine, and nucleotides and β-glucans, claimed to improve gut immune status.

Materials and methods
Two diets series were made. Each comprised eight diets in which fish meal levels varied from 0 to 40%, replacing a mixture of plant protein sources. One series was made without supplementations (Ref), the other was supplemented with a mixture (Mix) of 3000 ppm choline chloride, 500ppm nucleotides (Lallemand®) and 500ppm β-glucans (Biorigin®). The diets were fed for 62 days to Atlantic salmon in tanks with salt water, 45 fish per tank with average start weight 186g, final weight 511g. At termination of the feeding period, from 12 fish per tank, whole body and carcass weight and body length were measured, and blood samples taken for observation of plasma biomarkers of nutritional status. These fish were divided in two groups of six fish. From one of these groups, samples of digesta and mucosa were taken for observation and analyses of weight of liver, pyloric region, mid and distal intestine, activity of digestive enzymes and concentration of bile salt. From the other group, samples were taken from the mucosa of the pyloric and distal intestine for histology and gene expression analyses, and from the digesta for metabolome and microbiota analyses.

Results
Neither dietary fish meal level nor the Mix supplementation affected growth or feed conversion ratio significantly. Fish fed the Ref diet series, showed significant effect of fish meal level on the somatic indices of the pyloric intestine (PISI) and liver (HSI) (Fig. 1, left), and the difference between the two diet-series was significant for both. The Mix decreased the indices greatly, most pronounced for the PI, and the dose-response effect of fish meal level, almost disappeared. Results of histological evaluation of the PI of the fish showed severe steatosis in fish fed low fishmeal diets without Mix (Fig. 1, right), decreasing with increasing fish meal level. Previous studies of effects of supplementation with choline alone, have shown similar effects on PISI. Our conclusion is, therefore, that the present results confirm that low fish meal diets are choline deficient. The results indicated that the level of choline in the diet with 11.4% fish meal in the supplemented series, contained sufficient choline for efficient lipid transport across the intestinal mucosa. Analyzed value of choline in this diet was 4240 ppm, a number substantially higher than the 3400 ppm estimated to be required in the study by Hansen et al (2020).

Increasing level of fish meal did not clearly affect histological signs of inflammation in the distal intestine, which in general were very mild, without or with the Mix in the diet.

Expression of genes in the mucosa of the distal intestine, showed clear correlation with fish meal level for many genes of key importance in digestive and immune functions. The effects tended to diminish with increasing fish meal level. Table 1 shows correlation coefficients (Pearson) for a number of functional groups. The results also showed that the Mix modulated these effects and reduced the effects of fish meal level.

The results of the metagenome analyses showed increasing α-diversity, i.e. number of different bacteria with increasing level of fish meal. However, supplementation with the Mix eliminated this effect and reduced α-diversity at high fish meal levels. Also, β-diversity, taking into account which bacteria were present, differed between fish fed low and high fishmeal diet, and, again, the Mix diminished this effect.

Introduction

Marine resources provide an affluence of bioactive substances that could possibly serve as novel food additives and nutraceuticals to enhance human diet and animal feed. With regards to sustainable resource exploitation, it is particularly useful to uncover the nutritious potential of highly abundant yet underutilized biomass, such as jellyfish. The endosymbiotic mangrove jellyfish *Cassiopea andromeda* might be an exceptionally promising species in this context. Next to fast growth rates, wide global distribution and robustness towards environmental change (e.g. Mammone et al., 2021), *C. andromeda* is a semi-sessile benthic species, which makes it very well suited for captivity culture (Pierce, 2005). Moreover, recent studies have revealed the presence of nutritionally valuable algae composites such as carotenoids, in other endosymbiotic jellyfish (Leone et al., 2015). As functional pigments carotenoids have strong nutraceutical properties, they can act antioxidative, anti-cancerous, anti-obese, anti-inflammatory, and cardioprotective (e.g. Van Chuyen and Eun, 2017). Hence, in this study, we investigated the pigments contained in *C. andromeda* and its endosymbiotic algae. In addition to the characterization and quantitative estimation of pigments, the potential of light spectra changes for the manipulation of the pigment composition and amount was tested.

Materials and Methods

Over a period of four weeks, *C. andromeda* specimens were exposed to four different light spectra (1. full-spectrum, 2. green-blue, 3. green-red and 4. blue-red) at a constant light intensity (250 µmol/m²/s). Over the experimental time, growth (weight and diameter) and activity (umbrella pulsation) of the jellyfish was monitored. Moreover, the photosynthetic efficiency of the endosymbiotic zooxanthellae was determined by measuring the maximum quantum yield of photosystem II (photosynthetic efficiency; Fv/Fm), using a portable pulse amplitude modulation (PAM) chlorophyll fluorometer. Pigment analyses were performed using reversed-phase high-performance liquid chromatography (HPLC).

Results

Four light accessory pigments (chlorophyll c2, β-carotene, diadinoxanthin and peridinin) were found next to chlorophyll a, in the endosymbiotic jellyfish *C. andromeda*. With a peak concentration of 480 µg/g dry weight, peridinin was the most prevalent carotenoid, followed by diadinoxanthin and β-carotene. The concentration of all pigments was generally highest, although not significantly, when the jellyfish were exposed to green-blue light. The four different light spectra did not significantly affect jellyfish growth and photosynthetic efficiency. However, jellyfish treated with green-red light conditions exhibited significantly lower umbrella pulsation rates.

Discussion and Conclusion

This study revealed that next to chlorophyll, three carotenoids, namely peridinin, diadinoxanthin and β-carotene, are the dominant light accessory pigments in the endosymbiotic jellyfish *C. andromeda*. Next to the well-known provitamin A activity of β-carotene, previous studies have identified strong anti-cancer properties of peridinin (Yoshida et al., 2017). To our knowledge, the dietary potential of diadinoxanthin has not been studied yet, however, many reports demonstrated that marine carotenoids have higher bioactivities than those from plant sources or synthetic compounds (reviewed by Van Chuyen and Eun, 2017). Hence, the carotenoid profile exhibited by *C. andromeda* can be considered of high nutritional and nutraceutical value. Although not significant, the changes of carotenoid concentrations at the different light spectra indicate promising perspectives, to enhance the production of target compounds, such as carotenoids, through the manipulation of key parameters in captivity culture. Given that the uptake of carotenoids is indispensable for animals and humans, the exploration of natural carotenoid sources is highly relevant to enhance its accessibility for human consumption and animal feed. This study provides first insights into prospecting and manipulating the *C. andromeda* holobiont for marine carotenoids. We propose to further investigate the nutritional value (e.g. antioxidants, fatty- and amino acids) of *C. andromeda* and explore its potential to counteract malnutrition, especially in countries of the global south.

Introduction

Gilthead seabream (*Sparus aurata*) is one of the most farmed fish in Mediterranean Europe, yielding significant economic turnover in the EU over the last few decades (FAO, 2005). However, in recent years an oversupply due to increased production efforts have led to a decline in seabream price value (Llorente et al., 2020). In order to secure future markets and value without the expansion of production efforts, farmers and businesses should focus on ameliorating the morphological quality of their current production. In fact, major economic losses are directly due to the development of skeletal disorders altering the external shape of reared seabream, i.e. opercular and vertebral column deformities. Fish with such deformities are rejected by the potential retailers or customers thereby representing a significant economic loss for the fish farmers (Verhaegen et al., 2007). Such deformities require tedious technical effort and time to manually cull out from the productive cycle; which should be done as early as possible in order to not waste resources on growing suboptimal fish. In this scenario, automatic sorting of deformed fish could represent an essential tool used to reduce the time and costs of manual selection and elimination of severely deformed fish from the reared stock, as well as be used to rapidly identify the best practices to reduce the deformation rate. Unfortunately, the present tools for the recognition of deformation are mainly based on the application of Geometric Morphometrics (Loy et al., 1997; Prestinicola et al., 2013) that require the manual selection of homologous landmark points in the form of *x* and *y* coordinates on fish' images, which again is a time consuming task that demands expertise and practice with mathematical modelling. In this scenario, the aim of this research was the setting up of an automatic recognition program developed by Geometric Morphometrics and Artificial Intelligence, in order to accurately estimate the percentage and severity of deformed gilthead seabream from digital radiographs in a sound and rapid way, without the need for manual inputs.

Materials and Methods

The methodology is based on applying Convolutional Neural Networks (CNNs), a popular deep learning procedure used in computer vision tasks such as *pose-estimation* and *hand-gesture recognition* systems. Our dataset consisted of radiograph images (digital DXS Pro X-ray, Bruker) of 875 (mean weight: 55g) randomly sampled seabream reared at the Instituto Portugues do Mar e Atmosfera in Olhão Portugal. Radiographic images were used to perform a skeletal analysis (see Prestinicola et al., 2013). According to the methodology described by Loy et al. (1997), we manually selected 19 homologous landmark points in the form of *x* and *y* coordinates on each image (FIJI, Schindelin, 2012), in order to characterize each specimen by a landmark configuration (Fig. 1). In this approach, a supervised learning algorithm is used in which labelled image data are presented to the CNNs during training to learn to automatically detect the landmark locations on the image. In particular, instead of outputting the single numbers (*x* and *y* coordinate positions per landmark), we manipulated the learning algorithm to output the probability heatmaps that signify the likely rather than exact location. For the output, we used Gaussian heatmaps for each landmark location generated by setting the location coordinates as mean (center) and 5 pixels as the standard deviation. In brief, our methodology can be considered to be a Gaussian heatmap-based regression learning in which the final output is the probability heatmap for each landmark location. To implement the learning algorithm, we use UNET (Ronneberger et al. 2015), a widely used CNN architecture in medical image analysis tasks. This architecture is based on the convolutional and deconvolutional operations used in deep learning to learn the tasks' specific features that aid the network to detect the locations of the landmarks. To implement the network architecture, we use Tensorflow and Keras libraries, and Python as the programming language.

To train the CNNs, we split the image dataset into *training*, *validation,* and *test* sets. The pre-labelled *t*raining set is presented to the CNNs for learning; the *validation* set is used for hyperparameter tuning (parameter optimization), and the *test* set is used to evaluate the performance of the CNN after it is trained. We trained our network for 1000 iterations until we optimized the CNN based on its performance in the *validation* set.

(Continued on next page)

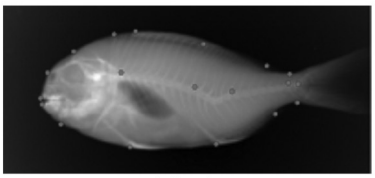

Fig 1

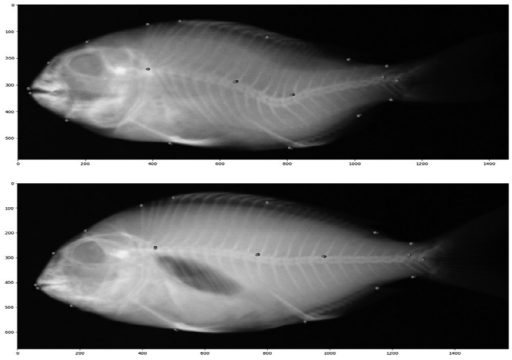

Fig 2

Results and Conclusions

The *test* set was used to measure the performance of the CNNs model. We used Mean Square Error (MSE) as the metric for measuring the squared difference (in pixels) between actual landmarks locations and predicted locations. Sample predictions from the *test* set are shown in Fig. 2. Blue dots represent the actual landmark locations whereas red dots represent the locations predicted by our model. In this way, the program is able to automatically predict the landmark locations on the radiograph images of pre-ongrowing seabream without any manual input of landmarks.

The next steps will be to couple the external shape with the inner anatomy (i.e., skeletal quality) of each fish and classify them based on different anomalies typologies. This model could be used to assist researchers in the field of aquaculture to automatically perform morphometric analyses with less time and effort, as well as aid technicians during sorting processes, thus reducing manual labor and handling stress on the fish. Furthermore, we are going to extend this approach to post-larval and juvenile stages with different image modalities (RGB, microscopic, histological). Ultimately, the plan is to make the program available online as an interactive web interface (Cytomine ,Maree et al. 2016, *Bioinformatics*) in which farmers and researchers are able to upload images and receive quick and sound data regarding the prevalence and severity of skeleton deformity types among their stock

Introduction

Arctic charr *(Salvelinus alpinus)* is an economically important farmed species in Sweden. Selective breeding success for growth was achieved in the Swedish breeding program since the early 1980s. However, the farming industry of Arctic charr is relatively small (global production totaled 5000 - 6000 t per year (FAO, 2020)) and limited by the poor reproductive performance of hatchery-origin broodstock (Jeuthe et al., 2016). An in-depth study of limiting factors in fertilization success and hatching rates is needed to expand the Arctic charr production.

This study aimed to gain extensive knowledge regarding factors that affect sperm quality in selectively bred Arctic charr. The main parameters of male gametes' quality, including motility characteristics and velocity, were examined by a computer-assisted sperm analysis (CASA) system. Furthermore, we estimated inbreeding coefficients using available pedigree records. Finally, the resulted inbreeding levels were tested for the linear relationship with sperm quality using Pearson correlation coefficient.

Materials and methods

Arctic charr of year class 2017 from the national Swedish breeding program were used in this study. Sperm samples were collected from over 500 males between October and November 2020. Males with recorded data were separated into group A and B. Animals from group A comprised a test group held with higher water flow and a control group with regular water flow. Animals from group B were separated into the test group, which was exposed to water cooling (from July to November) by 3 °C lower temperature than in the control group with natural water temperature. The number of animals recorded per each group is specified in Table 1.

The evaluation of sperm motility and velocity, including average path velocity (VAP), curvilinear velocity (VCL), straight-line velocity (VSL), was performed by using a computer-assisted sperm analysis (CASA) system and SCA® Motility imaging software. Sperm density was measured using NucleoCounter® SP-100™ (Chemotech, Denmark). Basic statistics were computed for CASA-system parameters using statistical software packages in R (version .4.0.2).

Furthermore, the inbreeding coefficient for full-sibs was derived from the available pedigree recordings spanning since the 1980s using the INBUPGF90 v1.43 software from the BLUPF90 suite (Misztal et al., 2018). Finally, a total of 84 males were used to produce full-sib families (n = 127).

Results

According to the results obtained, milt density ranged between 0.003 - 13.54 $\times 10^9$ cells/ml (mean 3.27×10^9) for group A and 0.02 - 9.40 $\times 10^9$ cells/ml (mean 3.23×10^9) for group B. In group A, 10% higher density was observed in the test group exposed to higher water flow compared to the control group. However, this difference was not significant. Similarly, in group B, no significant differences were found in sperm density between the control and test groups when applying water cooling.

Table 1 Number of animals recorded per each group

	Group A			Group B			
Parameter	Test	Control	Total	Test	Control	Total	Overall
Density	219	175	394	101	66	167	561
Motility	219	172	391	97	17	114	505

(Continued on next page)

The mean sperm motility of 74% (range 5% to 99%) and 65 % (range 8% to 99%) was found for group A and B, respectively. The average VAP, VSL, and VCL for group A were equal to 52.8 μm/s, 38.5 μm/s, and 76.6 μm/s, respectively. The corresponding mean values of 47.9 μm/s (VAP), 33.3 μm/s (VSL), and 72.2 μm/s (VCL) were estimated for group B. A high positive correlation of 0.95 - 0.99 ($p < 0.05$) was observed between sperm velocity parameters (VAP, VSL, and VCL). The differences in the percentage of motility and sperm velocity between control and tested males in either group A or B were not significant.

The inbreeding coefficient amongst the studied animals ranged between 0.0 - 0.18, with a mean value of 0.07. A Pearson correlation coefficient close to zero was obtained between the inbreeding coefficient and sperm quality parameters.

Discussion and Conclusion

This study covered the males' gamete quality evaluation related to milt density, motility, and velocity characteristics. No significant differences in the sperm quality parameters were found between the control and test animal groups kept under conditions with lower temperature or higher water flow.

The inbreeding coefficient was estimated based on the available pedigree records for animals from the 1986 - 2017 year classes, which did not exceed 0.18. The correlation estimated between the inbreeding coefficient with milt quality parameters was close to zero.

A particular emphasis should be given to the application genomic technologies for identifying regions with a potential effect on gamete quality. Our prior studies have shown that genotyping using the double digest restriction-site associated DNA sequencing (ddRAD-seq) can provide essential information regarding the genetic diversity of broodstock and underline the genetic architecture of traits of interest (Palaiokostas et al., 2020). Further research will focus on applying the ddRAD-seq platform in studying the genetic factors influencing sperm quality and fertility in selectively bred Arctic charr.

Introduction

Presently, seahorse species (*Hippocampus* spp.) have become of major concern, as most of them are now globally threatened mostly due to overexploitation, incidental by-catch, habitat loss and degradation. Seahorse aquaculture has been growing rapidly in the past few decades, particularly in the hobbyist trade. As a result, efforts have been made to develop sustainable hatcheries with close attention to creating healthy and proper care of captive organisms. (Koldewey & Martin-Smith, 2010) Seahorses have also been raised in captivity to provide a venue to better understand several aspects of these species' biology and behaviour. Still considered as candidate species for aquaculture, in the 1990s seahorse aquaculture was ravaged by innumerous zootechnical problems mostly related to feeding and disease outbreaks. However, increasing attempts to breed the species was reflected in an increasing contribution of captive-bred seahorses to the aquarium trade. Currently, the majority of seahorse aquaculture involves small-scale for the home aquarium market (Curtis, 2006; González *et al*., 2006). Although, there are still considerable technical problems with diseases and species-specific problems in several species, including the *Hippocampus hippocampus* (Ofelio *et al*., 2014; Balcazar *et al*., 2014). To minimize these constrains when breeding it, and aware of the environmental threats presently faced by this species, it is of outmost importance to determine which microorganisms can co-exist in symbiosis, thus allowing a better management and protection when breeding seahorse in captivity. This information also extends to the wild populations, which presently face a risk of local extinction, independently of their symbolic status in the Ria Formosa where the EPPO is located. This assay and bacteria storage will later allow identification of potential pathologies, probiotics, development of more effective treatments and data acquisition that will optimize or inhibit the growth of these microorganisms (Kumaravel *et al*, 2012). This study will help to improve the seahorse production in captivity, facilitating potential re-stocking actions of the species in the Ria Formosa and protecting the existing natural populations.

This work aimed to investigate the bacterial presence and suitable treatments to overcome some specific case mortality observed in seahorse cultured at CCMAR.

Table 1. Biometric data of seahorses, *Hippocampus hippocampus* used in pathological analysis.

Fish number	1	2	3	4	5	6
Weight (g)	9.5	4.8	10.3	8.2	4.7	7.1
Total Lenght (cm)	10.5	12.9	9.8	14	11	10.1
Sex	Male	Female	Female	Male	Female	Female

For microbiological analysis, kidney, liver, and spleen samples were streaked in TSA (tryptone soya agar) and TCBS (Thiosulfate-Citrate-Bile-Salt Sucrose Agar), the plates were incubated at 24ºC for 24h. Successfully isolated bacteria were selected for biochemical identification. Also, an antibiogram was performed with the antibiotics, enrofloxacin, oxytetracycline, florfenicol and flumequine, using all the bacteria directly from the sample. For the bacteria identification, microscopy, biochemical tests and morphological observations were used and API 20E and API 20NE kits (bioMérieux) as a confirmation. Afterwards, using the "Vibrio2008" probability matrix of the IDENTAX software and bioMérieux kit codes it was possible to identify the isolated bacteria.

(Continued on next page)

Material and Methods

Six diseased seahorses *Hippocampus hippocampus*, reared at University of Algarve with erratic behavior, were sacrificed according to the ethical guidelines regarding animal welfare followed by the IPMA, and later analyzed to interpret the cause of mortality. The sacrificed seahorses were sampled biometrically and microbiologically. The biometrical analysis is shown in table 1.

Results & discussion

The sampled fish analysed in this study presented two clear symptoms; an erratic behaviour characterized by an almost constant swimming pattern, only addopted by seahorse species when a stress factor is present and small skin lesions (usually less than 3-4 per animal) characterized by skin discoloration and abrasion. Reared fish with visible symptoms only represented a small percentage (aprox. 5%) of the total produced fish. After running the biochemical tests, it was possible to identify three different *Vibrio* spp. species. *Aliivibrio logei*, *V. penaecida* and *V. agarivorans*. Two of these *Vibrio* spp. were present in two seahorse internal organs and one, was only identified in the skin. It's important to highlight that *A. logei* was considered as a *Vibrio* spp. until Urbanczyk *et al*., 2007 reclassification, previously described as *V. logei* and has been isolated from ocean waters, surfaces, fish, and marine mammals. Furthermore, *V. agarivorans* accommodates two agarolytic, halophilic, fermentative bacterial strains isolated from Mediterranean Sea water, described by Macián *et al*. 2001. From the successfully isolated vibrio, *V. penaecida* is a pathogenic bacterium that affect shrimp and other marine invertebrates (Lorgeril *et al*., 2005), however its effects on fish, namely seahorses, are little or not known. The antibiogram results classified all bacteria present in the samples as sensitive to the four antibiotics tested. All the bacteria described in this study have been found for the first time in seahorses, therefore further studies are recommended.

Introduction

Rainbow trout (*Oncorhynchus mykiss*) is a fish that is particularly sensitive to changes in water quality. Global warming is expected to increase the frequency and intensity of heatwaves, resulting in more common combined acute hyperthermia and hypoxia conditions in fish farms (Reid et al., 2019). Such poor thermal and oxygenation conditions induce problems including growth losses, increased mortality and pathogens pressure. However, genetic selection to breed more robust fish is an interesting option to improve fish tolerance to non-optimal water quality (Vandeputte and Prunet, 2002).

Some research studies have already highlighted the potential of genetic selection for acute hypoxia and temperature resistance traits in fish (Chen et al., 2015; Ineno et al., 2005; Prchal et al., Unpublished data). In order to improve our understanding of the genetic architecture of these two traits, we used six isogenic rainbow trout lines. Within a line, all fish have the same genotype and preliminary tests revealed contrasting levels of resistance to hypoxia and temperature between lines. Using this research model, the objectives of the study were to: i) confirm the existence of genetic variability for resistance to hypoxia and high temperature; ii) investigate the ranking stability of genotypes at different ages for hyperthermia and hypoxia resistance traits, which is an essential information to determine the stage at which fish should be phenotyped in a breeding program; iii) determinate the relationship between hyperthermia resistance and hypoxia resistance.

Materials and methods

Six heterozygous rainbow trout isogenic lines were produced at the INRAE experimental fish farm (PEIMA, Sizun, France) by crossing one homozygous isogenic line providing eggs and six homozygous isogenic lines providing sperm. Each of the six lines were reared in separate tanks, in triplicates. Half of the fish of each triplicate were PIT-tagged at 16±9 grams and all lines were then pooled into the six tanks (~50 fish of each line in each tank) for the 6 early challenges (3 temperature and 3 hypoxia). The other half stayed in separate tanks for one more year and at 236±36 grams were PIT-tagged and mixed for the 6 late challenges (3 temperature and 3 hypoxia).

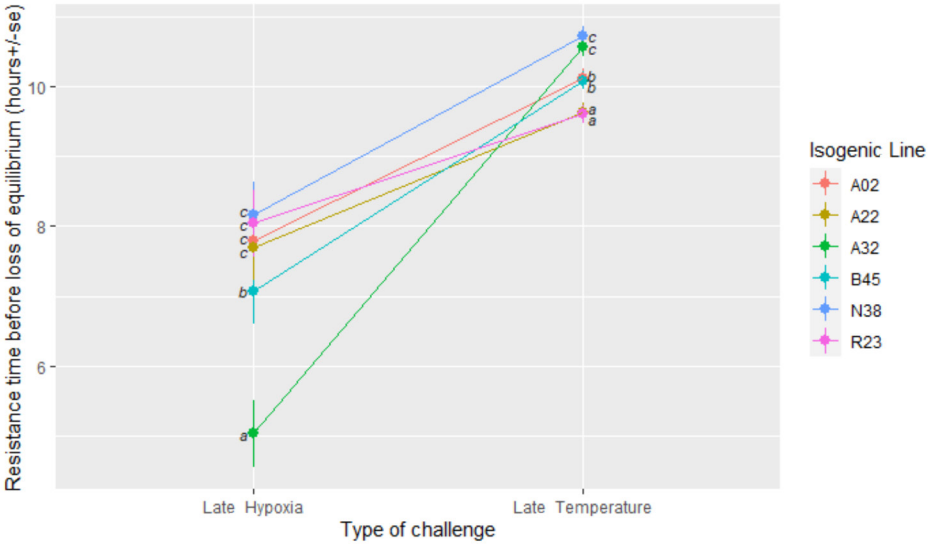

Figure 1: Relationship between late hypoxia and late temperature resistance. Means followed by a common letter are not significantly different.

(Continued on next page)

In hyperthermia challenge, temperature was gradually increased up to 27.5°C during 12 hours by adding heated water from a buffer tank. Oxygen concentration was maintained above 8mg/L. In hypoxia challenge, the level of oxygen was gradually reduced by bubbling nitrogen and reducing water renewal during 12 hours. In both challenges, fish were removed from the tank after loss of equilibrium and their PIT-tags and exact time were recorded. Fish were then individually weighted, anaesthetized and euthanized.

Resistance trait was analyzed as the time at loss of equilibrium of fish with the isogenic line as a fixed effect, the body weight as a covariate and the replicate as a random effect in a mixed linear model for each of the four challenges. When adequate, the resistance means of the different isogenic lines were compared using post-hoc Tukey tests with statistical significance set at 0.05. All analyses were completed with R software (V4.0.3).

Results and discussion

i) The fixed effect isogenic line was statistically significant in all challenges, confirming the effect of genetic variability on resistance to acute temperature or hypoxia stresses. Body weight effect was more complex with noticeable differences between early and late challenges. The interaction between isogenic line effect and body weight effect was significant in the two early challenges but not in the late challenges. Moreover, in hypoxia late challenge, body weight effect was significant while it was not in temperature late challenge. As a result, the resistance ranking of the genotypes was not stable in the early range of body weight (10 to 20 grams) because of the heterogeneity of slopes but stable in the late range of body weights (150 to 300 grams). It is therefore likely that the minimum phenotyping weight for resistance to acute temperature and hypoxia stress in rainbow trout falls between these two weight ranges.

ii) In the late challenges, i.e. once the ranking of genotypes was stabilized (with respect to weight), no clear rule appeared on the link between resistance to temperature stress and resistance to hypoxic stress (fig. 1). These results evidenced, at least partially, that resistance to hypoxia and resistance to temperature are two genetically different traits.

Introduction

Skeletal deformities observed in teleosts – e.g. vertebral malformations such as kyphosis, lordosis, scoliosis, and vertebrae fusion – negatively impact fish health and welfare, and, in the case of commercial species, cause production losses and reduce fish market value. The factors triggering these skeletal deformities are mostly related to nutritional, environmental, and genetic factors. Among the solutions proposed to improve the skeletal status of farmed fish species, the nutritional supplementation of fish feeds with marine compounds that stimulate skeletogenesis has been seen as a sustainable and competitive manner to address the problem. In this regard, we have used zebrafish (*Danio rerio*) *in vivo* systems to identify microalgae extracts with osteogenic properties and used them as dietary supplements to improve fish skeletal status. We have gathered consistent results regarding the ethanolic extracts of two microalgae species, produce and commercially available in Portugal. Importantly, microalgae extracts containing osteoactive compounds can be produced in rather considerable quantities and used to supplement large batches of feed. In this work, the effect of the ethanolic extracts as diet supplements was first tested in zebrafish, to evaluate performance indicators, skeletal parameters, and dietary toxicity, and to refine working concentrations. A proof-of-concept experiment was then performed using gilthead seabream (*Sparus aurata*), an aquaculture species of great economic value and whose skeletal deformities are well documented.

Materials and Methods

Extracts were prepared through the maceration of freeze-dried biomass of *Skeletonema* sp. and *Tetraselmis* sp. (Necton S.A.) with 96% ethanol. Ethanol extracts were coated on fish commercial diets (Sparos, Lda) at 0.5% and 2.5% for zebrafish and 0.5% for seabream. Zebrafish larvae at 5 days post-fertilization (dpf) were maintained in 2.5-L tanks in static conditions (60 larvae/L) and co-fed 3 times/day with the supplemented diets and rotifers, that were gradually reduced to address the weaning from live feeds. At 20 dpf, fish were moved to 3-L tanks in recirculating system (23 larvae/L) and fed 3 times/day with supplement diets until 50 dpf. Mortality and toxicity parameters were monitored throughout the entire experiment. At the end of the experiment fish were given a lethal anaesthesia and sample to assess performance indicators, calcium and phosphorus content, type, severity and number of skeletal deformities, and the expression of several marker genes of bone development and oxidative stress. Seabream larvae of 30 days after hatching (dah) were fed *at libitum* 3 to 4 times a day until 60 dah with supplemented diets. Larvae were maintained in cylindroconical 100-L tanks in a semi-closed RAS with an initial density of 52 larvae/L and a photoperiod of 10h light:14h dark. Environmental parameters and mortality were monitored daily. At the end of the trial larvae were euthanized and sampled to assess biometric parameters, oxidative status, digestive capacity, calcium and phosphorous levels, skeletal deformities, and the expression levels of marker genes for bone formation and oxidative stress.

Results and Discussion

Zebrafish is a well-established animal model for a wide range of research areas and has recently emerged as a good model fish for research in aquaculture, where it is expected to provide applicable results in the areas of husbandry and survival, immune response, nutrition and growth. In this regard, zebrafish exhibits several technical advantages over aquaculture fishes, e.g. it is eased to handle throughout breeding and experimentation, has short generation times and large numbers of eggs per breeding event, and the costs associated to its maintenance are lower, thus it allows to perform trials with a high number of specimens and to test different parameters. We have used this model to first test two different concentrations of each extract in the supplemented diets and evaluate their effect on fish survival rates and performance indicators, as well as to monitor the possible toxic effects of the extracts, prior evaluation of the feds using seabream larvae. We show that the extracts, independently of the concentration tested, did not impact on zebrafish survival rate, with inclusively, a slight decrease in mortality for groups treated with *Tetraselmis* sp. Also, an increase in fish length, despite only significant for fish treated with *Skeletonema* sp. at 2.5%, was reported for all the treatments in comparison to control fish. None of the diets

(Continued on next page)

triggered toxic effects. We then tested the supplemented diets, at the lowest concentration, on seabream larvae, and saw a similar response in terms of survival rates, with no significant alterations upon treatment. Though, the condition factor for specimens treated with *Tetraselmis sp*. significantly increased as well as the relative growth rate between 30 and 60 dah, indicating a positive effect of this diet on fish biometric parameters. For both species, the impact of the supplementation of the extracts on calcium and phosphorous content did not reveal significant changes, with the optimal ratios maintained. The skeletal deformities observed for both zebrafish and seabream are mostly associated with the caudal vertebrae and caudal fin complex, independently of the treatments, however, they appear to be less severe for fish treated with *Skeletonema* sp. The expression of marker genes for oxidative stress were also shown to be upregulated (e.g. *cat*, *sod1, gsr*) suggesting a protective effect of the treatments by the activation of antioxidant mechanisms. Several marker genes of bone formation were also differentially expressed (e.g. *oc1, mmp9, sp7, col1a1*) indicating a direct impact of the extracts on bone regulatory mechanisms in both fish species. The data gathered in this study indicates that the use of microalgae osteogenic extracts as fish meal supplements could be a cost-effective solution to improve fish skeletal status, without compromising their growth and welfare, and acknowledges the use of zebrafish as a primary platform for nutrition research directed to aquaculture species.

Introduction

Epigenetic mechanisms are involved in the long-term persistence of physiological effects resulting from events that occurred earlier in the life of an animal. We aim to investigate the potential role of epigenetic marks in the expression of phenotypes and their variability in fish, in particular to study whether the epigenetic marks established in response to an environmental stress depend on the genetic background. In this context, rainbow trout isogenic lines (Quillet et al. 2007) are the material of choice. Within each line, all fish have the same genome i.e. there is no genetic variability. This allows the comparison of epigenetic marks among several individuals with the same genotype. The environmental stress chosen here is temperature, a known induction factor of epigenetic marks in fish. A recent study has shown that temperature experienced during development has prolonged effects on DNA methylation levels throughout the genome of threespine stickleback (Metzger and Schulte 2017). We have demonstrated that thermal history during embryonic development alters genome-wide patterns of DNA methylation at eyed-stage, but to a greater or lesser extent depending on the genetic background (Lallias et al. 2020). The objective of this study was to investigate the persistence in time of genome-wide patterns of DNA methylation established in response to early temperature regime in rainbow trout isogenic lines.

Material and methods

Eight rainbow trout isogenic lines were produced at INRAE PEIMA. For each line, half of the eggs were incubated at standard temperature (11°C) and the other half at high temperature (16°C), from eyed-stage to hatching. Just before hatching and for the rest of the rearing, all batches were reared at 11°C. Liver samples (central organ for intermediary metabolism) were collected on 4 month-old juvenile fish, snap frozen in liquid nitrogen and kept at -80°C until DNA extraction.

Global methylation levels were quantified using LUminometric Methylation Assay (LUMA) for 80 juvenile fish (8 lines x 2 temperature regimes x 5 fish per condition). Statistical analyses were performed using non-parametric tests suited for small samples (permutation tests for two/K independent samples with Monte-Carlo sampling; coin plug-in in RCommander).

Genomewide patterns of DNA methylation were analysed by Reduced Representation Bisulfite Sequencing (RRBS) on 40 juvenile fish (4 lines x 2 temperature regimes x 5 fish per condition). RRBS libraries were prepared on the same DNA extracts used for LUMA and then sequenced on an Illumina NovaSeq6000 sequencer to produce 100 bp paired-end reads (Integragen SA, France). Trimmed reads were aligned to the current reference genome with the bisulfite mapping tool Bismark. Differential methylation analyses were performed using methylKit. Identified DMCs (Differentially Methylated Cytosines) and DMRs (Differentially Methylated Regions) were finally annotated. All steps are monitored using a homemade pipeline previously described (Perrier et al. 2018).

Results

As for results obtained at eyed-stage, there was no overall effect of temperature regime (11°C vs 16°C) experienced during embryonic development on global DNA methylation of liver samples of 4 month-old juvenile fish ($z = 1.5705$; $p=0.116$) but significant differences between lines at 11°C (chi-squared = 15.224; $p=0.033$) and 16°C (chi-squared = 18.586; $p=0.010$).

An average per individual of 41 million paired-end reads were obtained (lowest: 23 million; highest: 77 million). Bisulfite conversion rates were very high (>99%). Total mapping efficiency of the RRBS reads to the reference genome ranged between 74 and 79%, but only 50% on average mapped uniquely and were used for subsequent analysis. Preliminary results reveal that the numbers of DMCs and DMRs are relatively low but vary greatly depending on the line. Further analysis is ongoing.

(Continued on next page)

Discussion

Rainbow trout isogenic lines are a unique and powerful biological model to study whether the methylation marks established in response to an environmental stimulus (temperature here) depend on the genetic background, persist in time (several months after exposure) and can impact the response to later challenges. Our results suggest some level of persistence in time of methylation marks established in response to an early temperature stress.

SPONTANEOUS SPAWNING OF CAPTIVE GREATER AMBERJACK (*Seriola dumerilii*) REARED IN SEA CAGES AND TRANSFERED TO LARGE TANKS DURING THE SPAWNING SEASON

S. Lancerotto*, I. Fakriadis, I. Sigelaki, and C.C. Mylonas

P.O. Box 2214, Iraklion, Crete 71003, Greece.
Email: s.lancerotto@hcmr.gr

Introduction

Up to date, the most effective method to obtain good quality eggs from Mediterranean greater amberjack (*Seriola dumerili*) has been to (a) maintain breeders in sea cages during the year -where they undergo full gametogenesis- and then (b) move them to land-based tanks after gonadotropin-releasing hormone agonist (GnRHa) induction of spawning (Fakriadis et al., 2019, 2020). In order to reduce the reliance of the industry on the usage of hormonal treatments for spawning induction, and potentially also improve egg quality parameters, we examined the hypothesis that using large diameter tanks for spawning, would allow spontaneous maturation and spawning of fully vitellogenic females and spermiating males.

Materials and Methods

Reproductively mature breeders were maintained in a sea cage over the year and were transferred to two 75-m^3 tanks supplied with filtered surface seawater for the spawning period. Fish were selected based on evaluation of ovarian biopsies and sperm production. In the first tank, fish were given (GnRHa) in a controlled release implant (Induced, six males of mean ± SD weight of 22.1 ± 1.6 kg, and four females of 25.0 ± 2.03 kg). In the second tank (Spontaneous, five males of 19.0 ± 0.56 kg and four females of 29.7 ± 0.92 kg), fish did not receive any hormonal treatment. Reproductive success was evaluated through fecundity and fertilization success. Computer-assisted sperm analysis (CASA) was used to assess sperm quality of the selected males. Statistical analyses were done using t-test or two-way ANOVA ($P \leq 0.05$).

Results

The mean oocyte diameter of the largest vitellogenic oocytes was 675 ± 38 and 645 ± 16 for the Induced and Spontaneous group respectively. Some females in each tank were in early oocyte maturation (lipid droplet coalescences and germinal vesicle migration). These females presumably were the ones that spawned the next day. Females treated with GnRHa spawned 12 times, out of which 8 were the following days after hormonal therapy (Fig. 1A). On the contrary, the Spontaneous group spawned less frequently for a total of 6 times (Fig. 1A). The mean spawning batch relative fecundity (t-test, $P = 0.009$) (Fig. 1B) and fertilization success (t-test, $P = 0.001$) (Fig. 1C) of the Spontaneous group were higher than the Induced group. Additionally, embryo survival of eggs from the Spontaneous group reached 99 ± 0.3% and was also significantly different than from the GnRHa-induced group (t-test, $P = 0.009$) (Fig. 1D). Sperm quality parameters diminished after 24 days in the spawning tanks, in both GnRHa-treated and non-treated males (two-way ANOVA, $P \leq 0.05$).

Discussion

Inappropriate environmental conditions in captivity may lead fish to exhibit reproductive dysfunctions (Mylonas et al., 2010). Providing greater amberjack with a large-volume tank, allowed spontaneous and consistent spawning with excellent fecundity, fertilization and embryo survival, which were higher than the values obtained from GnRHa-induced breeders. Sperm quality parameters after 24 days were similar between GnRHa-treated and non-treated males, indicating also in the males, that allowing greater amberjack to spawn in large tanks is supportive of reproductive performance.

Introduction

An increasing tendency was observed in the angling interest at lake Balaton since 5 years ago. The growing angling demand directly affects the natural populations of the common gamefish (e.g. common carp). The angling management belongs to the Balaton Fish Management Non-Profit Ltd who is responsible for the annual reintroduction of the natural populations in the same time. Recirculating aquaculture system (RAS) allows a controlled propagation and a larvae rearing in a constant safe environment.

Materials and methods

In our experiments, stripped egg batch (332 g) from 1 female was fertilized using pooled sperm (7,5 mL) from 5 males. Hatched larvae were reared at a "Rack" system in a RAS. The infrastructure was performed using 10 L plastic tanks. The water quality was maintained with a programmable logic controller (PLC system) as well as using UV, mechanical and biological filtration. Larvae were reared at a density 50 individual L^{-1}. Feeding was carried out 4 times per day (*ad libitum*) with freshly hatched *Artemia salina* nauplii. Standard length (mm, *N*=20), average body weight (mg, *N*=20) and larvae malformation (*N*=10, curved body, deformed tail development: eye deformity, yolk-sac deformation, craniofacial malformation, edema, somites deformation) was recorded at 3 developmental stages (1. hatched, 2. non-feeding: 3 days post hatching and 3. feeding: 7 days post non-feeding).

Results

Results showed a slight increment in the ichthyologycal parameters between the hatched (standard length: 4.4±1 mm, average bodyweight: 1.0±0.3 mg) and non-feeding larvae stage (standard length: 5.5±0.5 mm, average bodyweight: 1.5±0.1 mg). A notable increasing tendency was recorded at the feeding larvae stage in standard length (10.5±0.7 mm) and average bodyweight (12.1±1.7 mg). A negligible prevalence of malformations was observed at the 3 different larvae stages. A high survival rate (94±2%) was recorded at the end of the experiment (10 days post hatching).

Discussion and conclusion

The results can contribute: 1. to the efficiency of the hatchery process in the mentioned carp landrace; 2. to maintain the natural population at Lake Balaton; 3. to satisfy the increasing angling demand.

UNRAVELLING *Rhodomonas salina*

C. Latsos*, J. van Houcke

HZ University of Applied Sciences, P.O. Box 364, 4380 AJ Vlissingen (The Netherlands)
Email:christos.latsos@hz.nl

Introduction

The microalgae species *Rhodomonas salina* is known to be an excellent diet for many aquaculture species. It has been shown that *R. salina* contributes to egg production, growth, survival, reproduction and lipid content of copepods, brine shrimps and scallops (Seixas et al. 2009; Guevara et al. 2011; Arndt and Sommer 2014)fish and cephalopod species. The improvements of both Artemia growth and its biochemical composition are key issues for the suitable use of Artemia biomass in these rearing processes. In this study we evaluated the growth and survival rates of Artemia fed with the cryptophyte Rhodomonas lens in comparison with different microalgal species commonly used in aquaculture: the prasinophyte Tetraselmis suecica, the prymnesiophyte Isochrysis galbana Parke, and the eustigmatophyte Nannochloropsis gaditana. Microalgae were cultured semi-continuously in nutrient saturated conditions and with a daily renewal rate of 30% of the volume of cultures, to obtain biomass of controlled and optimized composition. Considerable differences in Artemia growth were observed, as well as in the survival rate. At day 8 of rearing, Artemia fed R. lens had the highest length (4.9 ±0.6 mm, $P < 0.001$ and as specialty diet in the refinement of oysters (van Houcke et al. 2017). The beneficial aspects of using *R. salina* as feed are attributed to their favourable content of polyunsaturated fatty acids (PUFAs), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are essential for the growth, survival and pigmentation of the aquaculture species mentioned above (Caramujo et al. 2008). In addition, *R. salina* contains, besides the common pigments such as chlorophyll a/c and several carotenoids, the water-soluble pigment Cr-phycoerythrin 545 (PE) that harvests light in the green wavelength ($\lambda max = 545$ nm) (Doust et al. 2006). PE is also used in food colouring and cosmetics (Sudhakar et al. 2015) and linked to anti-parasitic and anti-tumour activities in studies using the marine mollusc *Aplysia californica* (Coelho et al. 1998). Optimization of *R. salina*. cultivation has been conducted in aspects of biomass production rate and biochemical composition, but no commercially stable cultivation plan has been applied in aquaculture yet (Seixas et al. 2009; Oostlander et al. 2020; Yamamoto et al. 2020) fish and cephalopod species. The improvements of both Artemia growth and its biochemical composition are key issues for the suitable use of Artemia biomass in these rearing processes. In this study we evaluated the growth and survival rates of Artemia fed with the cryptophyte Rhodomonas lens in comparison with different microalgal species commonly used in aquaculture: the prasinophyte Tetraselmis suecica, the prymnesiophyte Isochrysis galbana Parke, and the eustigmatophyte Nannochloropsis gaditana. Microalgae were cultured semi-continuously in nutrient saturated conditions and with a daily renewal rate of 30% of the volume of cultures, to obtain biomass of controlled and optimized composition. Considerable differences in Artemia growth were observed, as well as in the survival rate. At day 8 of rearing, Artemia fed R. lens had the highest length (4.9 ±0.6 mm, $P < 0.001$. The goal of our research was to optimize the biomass, fatty acid and PE production, by altering the nitrogen availability and the light quality.

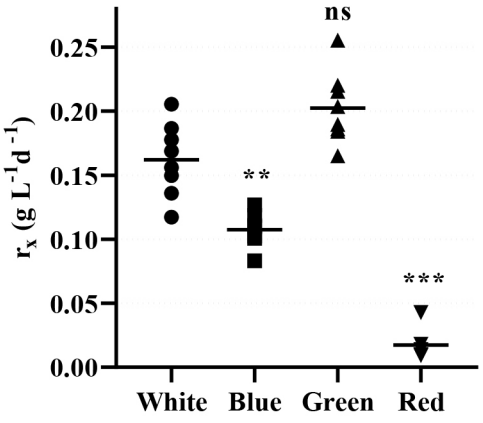

Figure 1. The effect of different wavelengths (blue, green, red, white) on volumetric productivity r_x (g L^{-1} d^{-1}) of R. salina. (indicates the significant difference after ANOVA test and t test of pairwise comparison between the groups ns $p>0.05$, *$p<0.05$, **$p<0.01$, **$p<0.0001$)*

(Continued on next page)

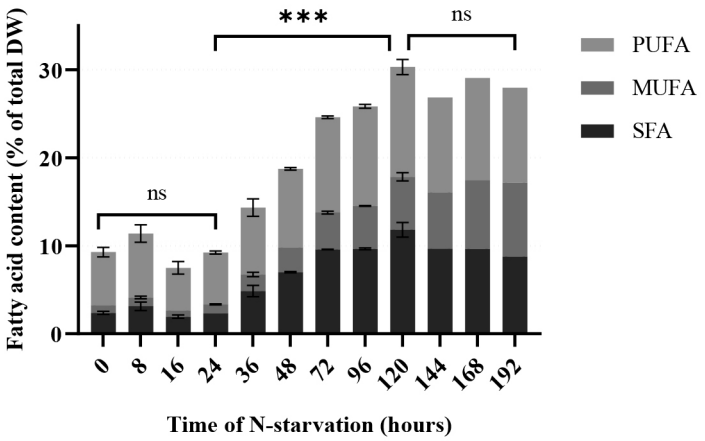

*Figure 2. Fatty acid concentration of R. salina during a 192 h N-starvation period. SFA: Saturated fatty acids, MUFA: Monounsaturated fatty acids and PUFA: Polyunsaturated fatty acids. Data are expressed as the average of three replicates _ SD. *Indicates the significant difference after ANOVA post hoc test. ns P > 0.05, ***P < 0.001.*

Methodology

Two experiments were conducted in order to optimize *R. salina* production: 1. Effect of light wavelength on growth rate and biomass composition of *R. salina*. 2. Effect of nitrogen starvation on the lipid profile of *R. salina*. In both experiments *R. salina* was cultivated in 400 ml photobioreactors (Algaemist-S), where temperature was stable at 22 °C and pH at 7.5, regulated by CO_2 flow.

In the first experiment *R. salina* cultures were exposed to 50 $\mu mol_{photons}\ m^{-2}\ s^{-1}$ of four different light wavelengths, blue (380-520 nm), green (520-600 nm), red (600-700 nm), and warm light as reference. The photobioreactors were maintained in turbidostat mode with outgoing light of 15 $\mu mol_{photons}\ m^{-2}\ s^{-1}$.

The second experiment was divided into two stages. In the first stage *R. salina* was cultivated under optimal conditions in turbidostat mode, which reached a dilution rate of 1.3 d^{-1}. The turbidostat was maintained for more than a week to reach a steady culture. Samples were taken every 24 hours. In the next stage, the biomass was washed and transferred in a reactor filled with N^- depleted medium. During nitrogen starvation, samples were taken over a period of 8 days. Samples were taken for biomass concentration, cell size, PE, and fatty acid composition.

Results

The results of the first experiment demonstrate that the highest productivity in volumetric biomass (0.20 $g_{dry\ weight}\ L^{-1}\ day^{-1}$) was observed under green light conditions. Blue and red light illumination resulted in lower productivities, 0.11 $g_{dry\ weight}\ L^{-1}\ day^{-1}$ and 0.02 $g_{dry\ weight}\ L^{-1}\ day^{-1}$ respectively. The differences in production could be ascribed to increased absorption of green and blue wavelength by phycoerythrin, chlorophyll and carotenoids, causing higher photosynthetically usable radiation (PUR) from equal photosynthetically absorbed irradiance (PAR). Moreover, phycoerythrin concentration (281.16 mg $g_{dry\ weight}^{-1}$) was stimulated under red light illumination. Because photosystemII (PSII) absorbs poorly red light, the algae had to induce more pigments in order to negate the lower absorption per unit pigment of the incident available photons. The results of this study indicate that green light can be used in the initial growth of *R. salina* to produce more biomass and, at a later stage, red light could be implemented to stimulate the synthesis of PE.

The results of the nitrogen starvation experiment demonstrate that the lipid content of biomass increased significantly from t=0h to t=120h from 6% to 28.2% of dry weight respectively. Furthermore, the highest increase within 120h was illustrated for C16:0, C:18:1, C18:2, C18:3. However, the maximum EPA and DHA concentration was observed after 48 hours of stress, while the maximum DHA to EPA ratio was detected at the end of the starvation.

Introduction

Recirculating aquaculture systems (RAS) provide possibilities to rear fish in a highly controlled environment. Some of the advantages of RAS-based farming include minimum water use, improved biosecurity, efficient control of production parameters, better protection from challenging environmental conditions, among many others. All these contribute to ensuring an ideal environment that fosters health, welfare and performance. Disinfection strategies play a crucial part in maintaining optimal water quality and preventing disease outbreaks. These protocols are adapted to different levels of farm operations – from materials and ancillary equipment used daily, to intake and RAS loop water and to system-wide disinfection after each production cycle. This paper summarises different aspects of disinfection in both freshwater and brackish water RAS of Atlantic salmon aquaculture. This study discusses the effects of disinfection on both the fish and the RAS environment.

Materials and methods

Four studies are included in this paper, each covering different aspects of disinfection in RAS. ***Sub-study 1*** surveyed different salmon RAS farms in Norway and North America to benchmark the current disinfection protocols. ***Sub-study 2*** established the thresholds and biological consequences in post-smolt of the use of ozone in brackish water RAS. ***Sub-study 3*** explored the health and welfare aspects of using peracetic acid as a routine disinfectant in RAS. Lastly, ***Sub-study 4*** explored biosecurity breach in RAS and system disinfection following an outbreak. *Yersinia ruckeri* was used as a model pathogen.

Results

Sub-study 1: Twenty-five (25) salmon RAS farms participated in total. The survey highlighted that: 1) despite having disinfection protocols in-house, majority of which were not experimentally verified; 2) Norway and North America differed on the disinfectants commonly used; 3) efficacy and safety were the common criteria for selecting the disinfectant in both regions.

Sub-study 2: A 10-day exposure trial identified that the range 300-350 mV was the safe range for ozone use in salmon brackish water. Higher than 350mV resulted in substantial mortality and health issues. The long-term trial using the identified safe dose revealed that ozone use had minor effects on survival, external welfare and production performance. It had a favourable impact on gill health. Ozone exposure did not alter the ability of salmon to respond to the secondary stressor.

Sub-study 3: In the brackish water experiment, we found that daily PAA dosing triggered a slight local and systemic oxidative stress. Pathological alterations were predominant in the gills, where cases of epithelial lifting, hypertrophy and clubbing were prevalent. Lastly, oxidant exposure did not alter the ability of salmon to mount robust physiological stress responses to a secondary stressor. In the freshwater trial, continuous and pulse application resulted in the modulation of antioxidant defence genes in the mucosal organs. Histology revealed minimal changes in the key structures of the skin, gills and olfactory organ.

(Continued on next page)

Sub-study 4: The biosecurity breach simulation studies found that the breach through intake water resulted in higher mortality than introducing an infected fish to the system. Mortality was similar whether biosecurity was breached via the intake water once or for 3 successive days. Diseased fish developed classical external signs of yersiniosis, including skin darkening, exophthalmia, and haemorrhaging. Disinfection of the system using pH manipulation following a *Yersinia* outbreak was effective.

Conclusions

Disinfection is an integral component of a RAS facility. This series of studies revealed that disinfection strategies varied between regions, disinfection of the RAS loop water was crucial to maintain optimal water quality but could impact fish health and welfare when not appropriately managed, and biosecurity breach simulations offered insights into the dynamics of infection in RAS. These results are expected to contribute to developing a system-wide disinfection protocol in salmon RAS.

FISH CELLS CAN "SMELL" ROTTEN EGGS: MOLECULAR INSIGHTS INTO THE RESPONSES OF ATLANTIC SALMON TO EXOGENOUS HYDROGEN SULPHIDE

Introduction

Hydrogen sulphide (H_2S) is a naturally occurring compound generated either endogenously or exogenously and is common in many physical and biological systems. The endogenously generated H_2S is a known gasotransmitter and redox-active sulphur species that acts as an antioxidant and signalling molecule to support cellular functions. On the other hand, the exogenous form produced by anaerobic bacterial decomposition of protein and other sulphur-containing organic matter is a water-soluble and colourless gas with the distinct odour of rotten eggs. In recent years, H_2S-related mortality is prevalent in Atlantic salmon reared in recirculating aquaculture systems. Significant advances have been made in understanding its formation in these systems, however, the biological consequences of H_2S are largely unknown. Its toxicity is known since it can cause sudden mass mortality, but the physiological processes leading to this endpoint are yet to be unravelled. In this study, we investigated the underlying molecular mechanisms behind salmon-H_2S interactions. We used two *in vitro* model systems: first, the nasal leukocyte model to explore immune functions of H_2S, particularly at the mucosa that serves as a point of interaction; and second, hepatocytes (liver cells), a traditional model for xenobiotics research in fish.

Materials and methods

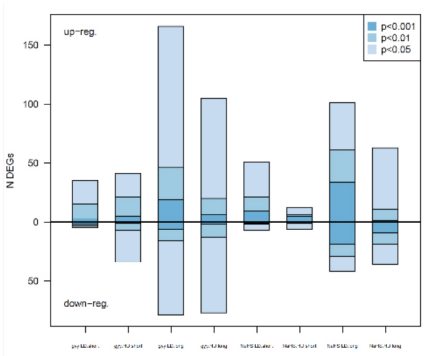
In this study, we used two kinds of sulphide donors: the salt form, *sodium hydrosulfide* (NaHS) and the synthetic analogue, *morpholin-4-ium 4-methoxyphenyl(morpholino) phosphinodithioate* (GYY4137). NaHS releases H_2S instantaneously into an aqueous solution, while GYY4137 is a slow-releasing H_2S donor.

The cells were isolated from salmon smolts weighing around 500-700 g. Primary cultures of nasal leukocytes and hepatocytes were prepared using enzymatic digestion and cells were cultured in the laboratory for two days before H_2S exposure. For the leukocytes, cells were exposed to three concentrations (1, 10, 100 μM) of either of the two sulphide donors NaHS and GYY4137 for 24 hrs. Thereafter, the cells were collected for molecular analysis. For the hepatocytes, the cells were exposed to either low (20μg/ml) or high (100μg/ml) dose of the two hydrogen sulphide donors. Two exposure durations were tested, transient (for 1 hr) and prolonged (for 24 hrs). Samples for microarray were collected 24 hrs after the addition of the H_2S donors to the cell cultures. The viability of the cells was likewise checked after exposure. The cells were subjected to microarray analysis using the Nofima 15K array and annotated through the bioinformatics pipeline STARS.

Results and Methods

Responses of nasal leukocytes to H_2S. Cellular viability was minimally affected by the exposure to two H_2S donors, nonetheless, GYY4137-exposed cells exhibited reduced viability compared with the NaHS group at the highest dose. There were apparent concentration-dependent H_2S-induced transcriptomic changes in the nasal leukocytes regardless of the kind of sulphide donors. A larger number of differentially expressed genes (DEGs) were identified in the NaHS-exposed versus GYY4137-exposed groups across concentrations. In all comparisons, at least 53% of the DEGs identified were significantly upregulated. Gene ontology (GO) terms enriched in the lists of upregulated DEGs at higher concentrations included ferric iron binding. A comparison of the two sulphide donors showed a clear grouping of different GO terms relative to concentrations. Pathway enrichment analysis revealed a significant influence in VEGF ligand-receptor interactions, oxidative stress, innate and adaptive immunity, and interleukin signalling, especially at higher concentrations. Congruence analysis demonstrated that there were 16 GO terms overlapping; of these, 12 were upregulated by both sulphide donors, including several involving iron-binding and transport.

(Continued on next page)



Number of DEGs. The four bars to the left show numbers for GYY4137 and the four bars to the right, numbers for NaHS. The four bars represent the four treatment groups (short or long treatment, high or low dose). Each bar was split for three p-value levels, represented by shades of blue.

Responses of hepatocytes to H_2S. Prolonged exposure reduced cell viability. These changes were significantly affected by the type of sulphide donors and duration of exposure, however, these alterations were not dependent on H_2S concentration. A similar tendency was identified in the proliferative potential of the hepatocytes. Further, it was determined that there were significant interactions between sulphide donors and concentrations, as well as sulphide donors and exposure duration. Transcriptomic analysis revealed that GYY4137 caused a slightly more substantial effect than NaHS. However, the impact of both treatments was very different from each other. Since both sulphide donors demonstrated different response profiles, particularly the number of DEGs and expression dynamics, similarities in each set were analysed separately from each other. Of the two factors studied (i.e. concentration and duration), the duration had a more substantial effect, and this was exhibited by the two sulphide donors. Overall, the number of DEGs in NaHS was lower compared with the GYY4137-exposed group.

Conclusions

The two *in vitro* models provide the first insights into the molecular processes governing how exogenous H_2S affect salmon. To our knowledge, this is also the first report to provide this level of resolution for this interaction in teleost fish in general. The two cell models demonstrated different transcriptional responses to H_2S. NaHS-exposed leukocytes showed a higher number of DEGs than GY4137; an opposite trend was observed in the hepatocytes. Responses to the sulphide donors showed a clear concentration-dependence in the nasal leukocytes, but the hepatocytes did not exhibit this feature. In the latter, duration of exposure and sulphide donors elicited more robust responses. Molecular pathways affected by H_2S were clearly identified in the leukocytes, but no clear predictions can be made from the hepatic transcriptome. The H_2S-responsive molecules identified can be explored further as potential biomarkers for environmental H_2S.

Introduction

The genetic impact of escaped farmed Atlantic salmon on wild populations has been identified as being the largest current threat to wild salmon populations. Further, sexual maturation is a major economic and welfare problem for the industry due to negative impacts on somatic growth, flesh quality, hypoosmoregulatory ability and immune function. Also, control of intellectual property is difficult for the salmon breeding companies since the eggs/fish will be able to reproduce. Farming of sterile fish should provide a solution to several of these challenges. However, triploid salmon perform poorly under suboptimal environmental conditions, and gene edited sterile salmon in aquaculture production raises serious ethical and legal concerns. We have developed an alternative strategy for producing sterile salmon by ablation of the primordial germ cells (PGC) using antisense oligos for mRNA degradation of the key PGC factor Deadend (DnD). Here we examine pubertal changes of the brain-pituitary-gonad (BPG) axis in sterile and intact fertile salmon males by inducing sexual maturation using an out-of-season photoperiod/temperature regime.

Materials and methods

Germ cell ablation was achieved by microinjection of *dnd* Gapmers in fertilized Atlantic salmon eggs delivered by AquaGen breeding company. The *dnd*-morphants and intact fertile control fish were held under continuous light at 6-10ºC until august 2018 at the Aquaculture research station at Kårvika, Tromsø. Totally 360 fish were Pit-tagged and transferred into six 500-L freshwater tanks for triplicate analysis. Smoltification was induced by exposing the fish to a photoperiod of daily 6 hours light (6L:18D) and water temperature of 5-6ºC for eight weeks followed by continuous light and 10ºC throughout the experiment. 10-12 fish were randomly sampled from each tank at three time points T1 (24.10), T2 (14.11) and T3 (05.12). Blood was sampled from caudal vessels, and body weight and length were recorded before the fish were opened for dissection of brain, pituitary and gonads. Tissues were stored in RNAlater until gene expression analyses using real-time quantitative PCR (qPCR).

Results

Microinjection of *dnd*-antisense oligos resulted in undetectable *dnd* mRNA levels and complete loss of gametes in the string-like gonads of almost all (92 %) males and females about two years after the treatment. This contrasted with the high *dnd* expression in the intact fertile gonads containing differentiating gametes. Precocious maturation was induced in about one-third of the sterile males and in almost two-thirds of the fertile males based on the bimodal frequency distribution of several hallmark indicators of puberty onset. Both maturing sterile and fertile males showed upregulated expression of pituitary *fshβ* concomitant with elevated plasma androgen levels together with reciprocal levels of testicular *igf3* and *amh* mRNAs.

Conclusions

This study shows that the germ cells are not required for the activation of the BPG axis and for the production of gonadal sex steroids at least not at the freshwater stage. The highly reliable sterilization method supports ethical and legal guidelines for animal breeding to achieve long-term environmental sustainability of our seafood supplies. However, an efficient antisense delivery strategy is needed for large-scale production of sterile salmon.

Introduction

For aquaculture to grow to meet world food demands, more intensive and sustainable farming practices must be implemented. This requires developing more effective ways to monitor and control the factors that influence fish health and welfare and to identify more efficient and sustainable ways of feeding fish. This reduces pressure on source ingredients, such as agricultural crops and wild-caught fish. More intensive aquaculture production requires greater control and monitoring to reduce mortality. This can be achieved through integrating a) optimisation of feeding regimes, b) observation of fish behaviour, and c) expansion of the use of sensory technology to measure water quality. Farmers will have greater and more precise information when it comes to decision making, which will reduce stress and increase overall fish health and welfare. The ambition of iFishIENCi project in which this research is taking place, is to develop and demonstrate disruptive IoT/AI based innovations, considering the feeding value chain and addressing commercially important species, with fish quality as focus. Through close collaborations between engineers and fish biologists, the smart feeding and monitoring systems will be more elaborate and precise. New value chains will be identified for the valorisation of specific waste from different production systems. This cutting-edge research is being combined with a holistic understanding of how new technologies interact with society and stakeholders in terms of economy, politics, social welfare, animal welfare and ethics under an RRI framework.

iBOSS platform

Information about fish behaviour, physiology and their environmental conditions can be collected in real-time from a variety of fish farms, and then securely transferred to a digital representation of a real fish. The digital fish will then send a message back to the monitoring system, which can then either inform the farmer, or make an automated change. The core of the iFishIENCi platform, is named iBOSS, is based on the NGSI-LD specification produced by ETSI and made open-source within the FIWARE ecosystem. From a technical perspective, FIWARE brings a curated framework of open-source software components which can be assembled together and combined with other third-party platform components to build platforms easing the development of smart solutions and smart organizations in multiple application domains: cities, manufacturing, utilities, agrifood, etc. The Digital Twin data representation is built based on information gathered from many different sources, including sensors, cameras, farm information systems and farmers observation. It is constantly maintained and accessible in near real-time. Applications constantly process and analyze this data (not only current values but also the history generated over time) in order to automate certain tasks or bring support to smart decisions by end users.

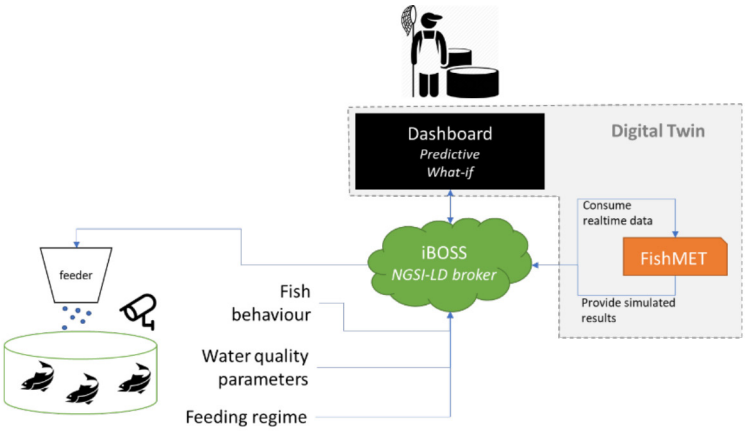

Figure 1: Overall schematic of digital twin integration in a fish farming system.

(Continued on next page)

Digital Twin purpose

The digital twin model is based on understanding the whole fish organism as an adaptive agent, robust, testable biological theory that is implemented in the computer code. This means that the model not only describes a specific aspect of fish nutrition, energetics, growth or behaviour in the form of an equation or system of equations. Instead, the digital twin aims to work as a digital organism simulating the most crucial aspects of physiology, neurobiology and behaviour in a digital environment. The agent can therefore act autonomously, make decisions in response to the internal and external environment with continuous feedbacks at multiple biological levels. This means, for example, that the simulation system aims to predict voluntary behaviour and food intake of the fish. This digital twin for feeding will enable running various scenarios and predict the response including unplanned, emergent and stochastic effects. Such a capacity will provide an indispensable tool for decision support and operational optimization and can be run in the AI-controlled precision fish farm environment of iBOSS.

FishMet model

The fish digital twin model accepts the basic biological parameters of the fish as input, such as body size, energetic characteristics, and is built on experiments and literature-based parameters of fish physiology. Environmental inputs include the physical characteristics of the feed, feeding schedule, ambient temperature, oxygen level. The model will then output fish appetite, food intake, feed conversion efficiency, waste production and growth. The autonomous agent type of the model also allows to collect additional outputs, such as behavioural patterns, and predict the internal state of the fish, e.g., motivation and stress level, responses to unexpected change of the feed, stochastic environmental perturbations etc. The modular organization of the model allows to simulate a single fish or a large group in an individual-based model. Water quality, environmental data, fish physiology and behaviour data are collected and made available to the FishMET model in real time through the NGSI-LD data broker of the iBOSS. FishMet is a digital simulation of feeding, fish behaviour, physiology, and metabolism, which consists of differential equations that define feed intake, stomach filling, digestion, absorption, retention of nutrients and will be developed to include feeding behaviour and waste production. The FishMet model include new knowledge about physiological factors that affect appetite and feed intake. Intestinal passage and postabsorptive processing are principal elements. A central part of the model focuses on the changes that occur due to variations in feed type, feeding amount and frequency as well as how environmental factors including temperature, oxygen availability and stress (e.g. handling) will affect feeding behaviour and processes leading to growth. The software engineering work aims to produce a highly modular and customizable system that can run as a separate application and be embedded into the larger decision-support and intelligent fish farm control system iBOSS (Figure 1). Specific experiments that will provide appropriate datasets to the modelling activities are currently being performed. In addition to environmental data, individual and shoal behaviour, such as swimming speed and direction, will be monitored with cameras detecting individually marked fish before, during, and after feeding. The fish will also be fed a diet containing a marker to allow correlations between gut transit and feeding behaviour.

FUNCTIONAL NUTRITION MITIGATES THE IMPACT OF REPETITIVE NON-MEDICINAL INTERVENTIONS IN SEAWATER ATLANTIC SALMON

Introduction

Non-medicinal interventions against parasitic infections have unequivocal benefits but impose repetitive exposure to external stressors and associated handling with the potential of severely compromise fish health and performance. Strategies that bolster mucosal robustness and mitigate physiological stress are therefore critical to support current de-medication effort. The study applied a repetitive-stress model mimicking current commercial practices against ectoparasites to evaluate the putative benefits of a blend of functional feed ingredients on the fish stress, oxidative, immune and mucosal status with the view to mitigate the impact of such practices. The blend consisted of a multi-strain yeast fraction product (MsYF; Rawling et al.; 2021) along with a Melon Pulp Concentrate (MPC) rich in the primary antioxidant superoxide dismutase (SOD; Carillon et al., 2013) previously shown to stimulate skin SOD level in Atlantic salmon (Barbé et al., 2018).

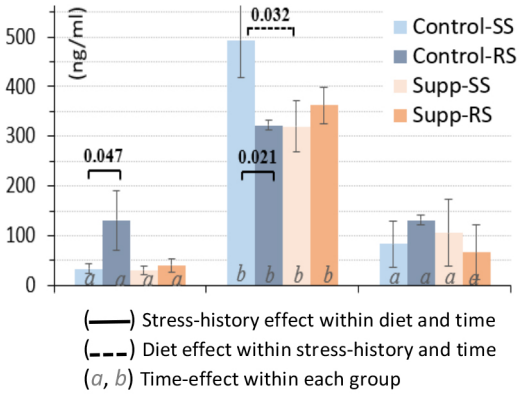
Materials and Methods

The 9-week trial tested 4 groups (2 diets x 2 stressors schedule) in triplicate using 500 g Atlantic salmon (37 fish / tank; 12°C, 36 ppt). The test diets consisted of a baseline diet non-supplemented (**Control diet**; BioMar) or supplemented (**Supp diet**) pre-extrusion with MsYF and MPC (800 g/t feed and 50 g/t respectively; Lallemand SAS, France); fed ad-libitum over the trial duration. The stressors schedule consisted of exposure to either a **single-stressor** (**SS**) or to **repeated-stressors** (**RS**) as follow: after a 5-week preparation phase, the RS group was crowded and netted-out 3 times at weekly intervals for immersion into 2 freshwater bath (1h) and a hydrogen peroxide bath (H_2O_2; 30 min; 1500 mg/L) then given a 2-week recovery period. In comparison, the SS group was exposed to the H_2O_2 bath only (no prior handling). Sampling was performed immediately prior (T1), 1 h (T1+1h), 48 h (T1+48h) and 2-week after (Tend) H_2O_2 exposure. Sampling documented the primary stress response, antioxidant status, mucosal integrity, innate immunity, plasma biochemistry and fish performance over time. Data were analysed by a Linear model ($P < 0.05$) and presented as mean ± SEM.

Results and Discussion

In the control-diet, the RS-schedule significantly increased baseline cortisol level (T1) and reduced the acute response to an immediate stressor (H_2O_2-bath, T1+1h) (**Fig 1**). This characterizes a state of chronic-stress and a subsequent exhaustion of the primary stress-axis which were not observed in the Supp diet. This apparent state of chronic stress was associated with a statistically higher skin goblet cell coverage (GCC, RS compared to SS at T1 in Control diet, **Fig 2**) without further increases upon H_20_2 exposure (T1+48h) suggesting an exhaustion of the mucosal response. Indeed, in the Supp diet; there was no apparent effect of stress-history on baseline skin GCC (SS compared to RS at T1) but a significant increase upon exposure to H_20_2 (T1+48h) indicating the persistence of a functional mucosal response to H_20_2-exposure. Exposure to RS also impacted intestinal architecture which was partly mitigated by the Supp diet (not shown).

Fig 1: Plasma cortisol level



(Continued on next page)

Fig 2: Skin goblet cell coverage

(——) Stress-history effect within diet, time
(– – –) Diet effect within stress-history, time
(*a*, *b*) Time-effect within each group.

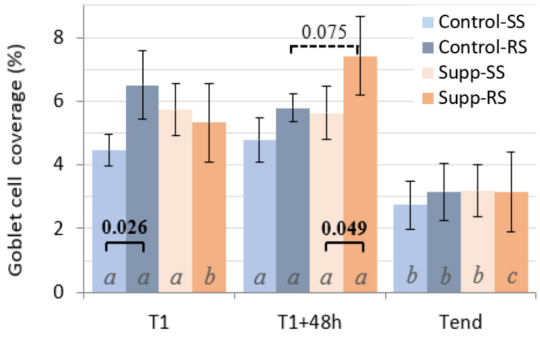


Fig 3: Skin SOD level

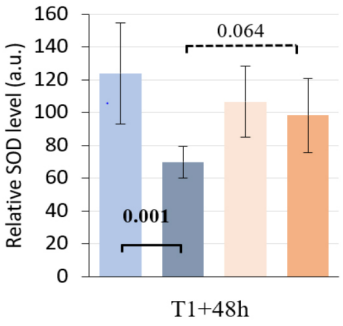

Fig 4 Hepatosomatic Index

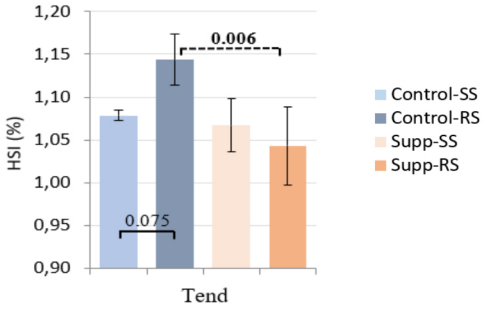

Similar to serum values (not shown); skin SOD was depleted under RS compared SS in the Control but not in the Supp diet (**Fig 3**) shortly after H_20_2 exposure (T1+48h). The Supp diet therefore appeared to prevent low SOD levels induced by RS exposure.

There was no effect of the diet or stress-schedule on growth performance. However, RS was associated with a significant increase in Hepatosomatic Index (HSI) in the Control but not in the Supp diet (**Fig 4**), suggesting a contribution of the test against the tertiary impact of chronic stress on resources allocation and animal energetics.

Conclusion

By applying a commercially relevant repetitive-stress model, the study documented the negative effect of repetitive-stress exposure on the physiological and mucosal health of SW Atlantic salmon. Dietary supplementation with a blend of primary antioxidant and yeast-based ingredient was able to mitigate the pernicious effects of repetitive-handling and associated losses of mucosal robustness, responsiveness and recovery capacity. This is expected to have clear benefits at animal and farm level over the production cycle.

Funding The authors are grateful for the support received from SAIC (UK; SF_2018_01)

Introduction

Mechanical disruption of the skin barrier function can quickly lead to morbidity and secondary infections with the potential of significant biological and market value losses in aquaculture. Yeast β-glucans are known modulators of skin wound healing acting both indirectly via their immune functionalities as well as directly by promoting re-epithelization (Majtan and Jesenak; 2018). More commonly addressed for topical application in mammals, they are seldom studied as skin health ingredients in aquafeed. The study compared the effect of a standard a yeast β-glucans to a multi-strain yeast-fraction (MsYF) ingredient on full-thickness skin wound healing using an adult zebrafish model. The MsYF and its mucosal immune properties are further described in Rawling et al. (2021) raising promising prospects as skin wound healing promoter.

Materials and Methods

Wild-type adult zebrafish (20 L tanks; 28°C; 25 fish/tank) were fed one of three test diets for 7 weeks prior to being inflicted a full-thickness dermal wound (2 mm Ø biopsy punch). Four experimental groups were tested in quadruplicate: 1) negative control (not wounded, basal diet), 2) positive control (wounded, basal diet), 3) β-glucans (wounded; basal diet + 315 g/t feed of β-glucans) and 4) MsYF (wounded; basal diet + 1.5 kg/t feed of MsYF).
Wound-healing was assessed over time by computer-assisted measurement of gross wound-surface area on individual fish, (quantitative) histopathology, transcriptional and immunoblotting analysis at the wound-site. Datasets were analysed by ANOVA with Bonferroni's post-hoc test or unpaired two-tailed t-test where significance occurred ($p < 0.05$) and are presented as mean ± SEM.

Results and Discussion

Wound surface contraction first occurred from 2 to 4 dpw in 18%, 78% and 72% of the Control, β-glucans and MsYF fish, respectively, such that mean wound-size decreased in the test groups but further increased in the Control (**Fig. 1**). Subsequently, gross healing remained superior in the MsYF compared to the Control (significant at 16 dpw with MsYF = 66 ± 4% and Control = 53 ± 4% contraction).

Histopathological diagnostic of the wound margins revealed a higher prevalence of inflammatory cells at 1 dpw followed by a greater scab clearance at 4 dpw in the β-glucans and MsYF group; as well as a thicker granulation tissue in the MsYF group. At the wound-bed, the thickness and transversal surface area of the granulation tissue (new connective tissue) was significantly higher in the MsYF while differences between the β-glucan and Control groups were observed (**Fig. 2**).

Transcriptional and immunoblot analysis at the wound-site supported the observed promotion of early-stage wound-healing by the test compounds. The apparent advantage of MsYF was associated with a significant up-regulation of matrix metalloproteinase genes (**Fig. 3a**) known to be involved in extra-cellular matrix remodelling during skin tissue regeneration; as well as with a more balanced (anti)-inflammatory process at an early healing stage compared to the control and β-glucans (e.g. hsp90 and il-10; **Fig. 3b**).

Conclusion

The study establishes in-feed yeast-based ingredients as promoters of fish skin wound healing. The MsYF ingredient had a clear benefit over established yeast-β-glucans by promoting the early formation of new connective tissue filling the wound bed, i.e. wound closure, and holds the benefit of being suited for continuous in-feed application. This comparative study deciphers the distinct properties and modes of action of different yeast-based ingredients opening the way to further optimizing their potency as skin health promotors in aquaculture.

UNLOCKING THE WILD POTENTIAL: INTEGRATION OF GEOGRAPHIC DIFFERENTIATION IN DOMESTICATION PROCESSES TO FACILITATE FISH AQUACULTURE DIVERSIFICATION

T. Lecocq*, L. Toomey and P. Fontaine

University of Lorraine, INRAE, UR Animal and Functionality of Animal Products, Team Domestication in Inland Aquaculture, Nancy, France

*Presenting author: thomas.lecocq@univ-lorraine.fr

Context and aims

One way to promote the aquaculture sector sustainability relies on the production diversification, notably through the domestication of new species. However, domesticating new species remains a long and challenging process often resulting in unfruitful attempts because of technical issues, socio-economic limitations, or biological features of species (Teletchea and Fontaine 2014). Most incipient domestication programs often consider species as a unity, disregarding a part of the biodiversity: the wild intraspecific geographic differentiation. Yet, this differentiation can shape local genetic, phenotypic, and ecologic specificities, affecting the domestication predisposition or the socio-economic attractiveness of a particular population (Toomey et al. 2020)disregarding a part of the biodiversity: the wild intraspecific geographic differentiation. Yet, this differentiation can shape local specificities, which could lead to different domestication predisposition or socioeconomic attractiveness between populations. Therefore, considering this population- specific potential could facilitate domestication and subsequent production of new candidate species. Here, we propose a three-step integrative approach to standardise and facilitate new domestication attempts by taking advantage of wild geographic differentiation. Step 1 consists of classifying the wild biodiversity to identify prospective units (i.e. groups of differentiated allopatric populations. Therefore, choosing wild populations exhibiting a high potential for aquaculture (i.e. presenting interesting expression of key traits) could facilitate the domestication and production of new species. Here, we (i) introduce a new method to integrate geographic differentiation in domestication programs and (ii) apply it on a species of interest for inland aquaculture diversification, the European perch (*Perca fluviatilis*).

A 3-step integrative approach to integrate geographic differentiation in domestication programs

We propose a 3-step integrative approach to standardize and facilitate new domestication attempts by taking advantage of wild geographic differentiation (Toomey et al. 2020)disregarding a part of the biodiversity: the wild intraspecific geographic differentiation. Yet, this differentiation can shape local specificities, which could lead to different domestication predisposition or socioeconomic attractiveness between populations. Therefore, considering this population- specific potential could facilitate domestication and subsequent production of new candidate species. Here, we propose a three-step integrative approach to standardise and facilitate new domestication attempts by taking advantage of wild geographic differentiation. Step 1 consists of classifying the wild biodiversity to identify prospective units (i.e. groups of differentiated allopatric populations. Step 1 consists of classifying the wild biodiversity to identify prospective units (i.e. groups of genetically differentiated allopatric populations), which are likely divergent for key traits. Step 2 aims at comparing performances of these units in standardized conditions (i.e. rearing system) through a multi-function and multi-trait assessment. Finally, step 3 highlights units with highest potential for aquaculture through the calculation of an aquaculture potential score (Toomey et al. 2021).

The European perch case study

The 3-step integrative approach has been applied to compare the aquaculture potential among prospective units of the European perch (Toomey et al. 2021). More specifically, we aimed at finding units with the best performance in larviculture, a critical stage in the *P. fluviatilis* production. The step 1 allowed identifying five prospective units across 84 West-Palearctic sampling sites using mitochondrial and microsatellite markers: the European Plain, Danube, Northern and Eastern Fennoscandia, Eastern Europe, and the Balkans units. At the step 2, we compared performances of key traits for fish larviculture for three of these prospective units in standardized recirculated aquaculture system. A geographic differentiation was highlighted for six important traits for perch larviculture: survival rate, swim bladder inflation rate, deformity rate, length at hatching, mean of interindividual distances, and change in activity following a stress event. Along with fish farmer-advice-based weighting of the traits, the calculation of an aquaculture potential score allowed identifying, during the step 3, the populations from the Danube region as the most interesting to potentially overcome current bottlenecks in European perch larviculture.

(Continued on next page)

Prospects

Overall, the early applications of the 3-step approach support that it could allow facilitating domestication of new species or species at incipient stages of domestication which face major bottlenecks. So far applied to fish culture for human consumption, the approach also aims at being extended to other taxa (e.g. crustaceans, mollusks) and other production goals. Nevertheless, the implementation of the approach is still challenging due to some method limitations, pragmatic concerns, and legal regulation constraints needing future improvements to further facilitate aquaculture development.

***Introduction**:*
The massive blooms of jellyfish (JF), that more and more frequently explode in European seas, usually negatively impact human health and activities in coastal waters, representing a nuisance or damage for marine and maritime activities. As an alternative, these marine gelatinous organisms, should be viewed through a more positive perspective as a new important bio-resource. Indeed, known for their nutritional and medical value in the Chinese pharmacopeia, increasing attention has been pointed to jellyfish as an unexploited source of essential nutrients, novel bioactive metabolites, and lead compounds.

Within the H2020 European GoJelly project, JF and their biodiversity, were analysed as an available and abundant source of new natural health-promoting compounds. Different species, *Rhizostoma pulmo* (Macrì, 1778) that undergoes recurrent outbreaks in the Mediterranean coastal waters, and the zooxanthellatae JF species, as *Cotylorhiza tuberculate and Cassiopea andromeda,* this last one not native of Mediterranean Sea), were considered as source of new bioactive compounds, both proteinaceous (such as collagen) and non-proteinaceous compounds, as the hydroalcoholic-soluble extracts.

R. pulmo peptides were analysed for their antioxidant activity in vitro and in HEKa cell cultures, and the potential immunomodulatory activity of low molecular weight peptides were investigated in monocytes-macrophages couture system (De Domenico et al., 2019). Hydroalcoholic extracts from *C. tuberculata* and *C. andromeda* moreover, were assayed for their cytotoxicity effects on cancer cells and for their ability to modulate Gap Junction Intercellular Communication (GJIC) (De Rinaldis et al., in preparation).

Material & Methods:
From 2017-2020, target jellyfish species *R. pulmo and C. andromeda* were collected at Marina di Ginosa (Taranto, Italy) and in two different locations of Palermo (Sicily, Italy) harbour. Samples were individually frozen in liquid nitrogen, stored at -80 °C, and lyophilized. *R. pulmo* lyophilized tissues were subjected to aqueous protein extraction by phosphate-buffered saline (PBS) to separate the hydro-soluble proteins from the insoluble ones, which were exposed to a two-step sequential enzymatic hydrolysis, as described in Figure 1 (Leone et al., 2013-2015). Soluble proteins (SP), Hydrolysed by Pepsin JF peptides (HPJp) and Hydrolysed JF Collagen peptides (HJCp) were molecular weight (MW)-fractionated by membrane filtration and each fraction was analysed for antioxidant activity in vitro and for their effect on cultures of Human Epidermal Keratinocyte, adult (HEKa) cells. MTS assay was used to analysed HEKa cells vitality, when exposed to different peptides concentrations and under oxidative stress conditions (H_2O_2 0.1 mM). Calf skin collagen (Vertebrate Collagen, VC) was used as control. Zooxanthellatae species were lyophilized and subjected to aqueous and/or hydroalcoholic extraction (80% ethanol) and further to the same sequential enzymatic digestions. Extracts were essayed on cancer and non-cancer human cell cultures.

***Results**:*
Jellyfish proteins and peptides obtained from enzymatic hydrolysis showed significant antioxidant activity. In particular, collagenase-hydrolysed collagen resulted in peptides with different range of molecular weight (MW lower than 3 kDa, ranging 3–10 kDa or 10–30 kDa), with antioxidant activity inversely proportional to MW. No cytotoxic effect was detected on cultured human keratinocytes (HEKa) except for soluble proteins higher than 30 kDa, likely containing the jellyfish venom compounds, which were easily neutralized by mild thermal treatment. Furthermore, hydrolyzed jellyfish collagen peptides showed a significantly AA and provided a protective effect against oxidative stress in HEKa cells (Figue 2). Some of the jellyfish hydrolized proteins, showed also anti-inflammatory activity on appropriate cell culture.

Finally, non-proteinaceous extracts from zooxanthellatae jellyfish showed a noticeable anti-proliferative effect on cancer cell culture (MCF7).

(Continued on next page)

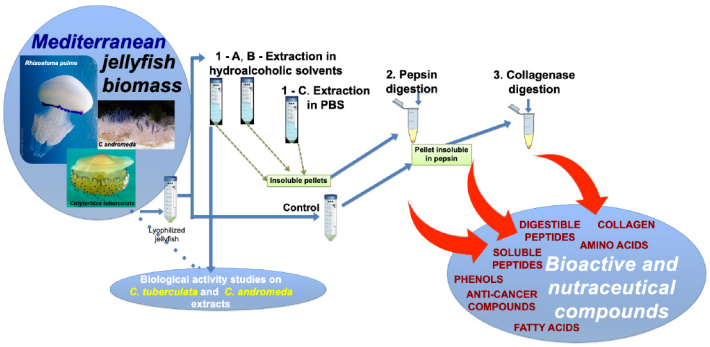

Figure 1: Schematic representation of the procedures used for the extraction of bioactive compounds from Mediterranean jellyfish species.

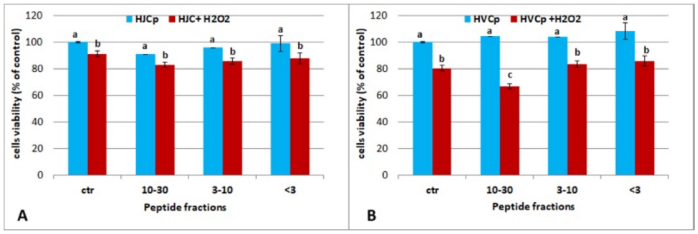

Figure 2: Effect of oxidative stress on HEKa cells of different concentration of jellyfish (A) and calf skin (B) collagen hydrolyzed peptides with different MW

Discussion & Conclusion:

Due to a high biodiversity and reproductive potential, jellyfish may represent a potential socioeconomic opportunity as a source of natural bioactive compounds, with far-reaching beneficial implications. Eventually, improvements in processing technology will promote the use of untapped marine biomasses in nutraceutical, cosmeceutical, and pharmaceutical fields, turning marine management problems into a more positive perspective.

Introduction

European aquaculture is facing the challenge of satisfying the growing seafood demands and reducing the pressure on fishing areas. Aquaculture feeds use 70 percent of the world's fishmeal and fish oil, obtained from overexploited small pelagic fish (Froehlich et al., 2018). By 2040, the demand for fishmeal and fish oil will exceed the supply, emphasizing the need for novel feed ingredients to enhance production. Recently, new protein sources include fish by-products, poultry by-products, insects, and algae, displaying promising results towards optimal fish growth (Beheshti Foroutani et al., 2018).

The ongoing Interreg AdriAquaNet project is dedicated to enhancing the innovation and sustainability of Adriatic aquaculture. Within the project, new feeds were designed and tested at a laboratory scale on sub-adult European sea bass. For the present study, three of the five tested diet formulations were selected for a comprehensive exploration and comparative transcriptomics of European sea bass intestines after performed feeding trial.

Material and methods

Selected formulations included two control diets, one rich in fish-derived ingredients (CF) contained 85 % and 66 % of fish-derived protein and lipid, and one rich in plant-derived ingredients (CV) contained 85 % and 66 % of plant-based protein and lipids. Test diet (VH10P30) contained the same vegetable: fish lipid ratio as the CV diet, replacing crude proteins from the plant-based sources with 10 % of crude proteins from a commercial defatted *Hermetia illucens* pupae meal and 30 % of poultry by-product meal. The experimental diets were formulated to be iso-proteic (45%), iso-lipidic (20%), isoenergetic (20.3 MJ kg^{-1}) and to meet the dietary requirements of sub-adult European sea bass.

Based on quality, 24 samples of total RNA were selected for cDNA library preparation, comprising 4 biological replicates per feeding treatment of two selected intestinal parts, pyloric caeca, and distal intestine. One biological replicate corresponded to a single fish, meaning pyloric caeca and distal intestine were paired as subsamples. Single-end 3'UTR sequencing was performed using NextSeq 500 System (Illumina, San Diego, CA, USA).

Results and discussion

Two analyses were performed for differential expression analysis, comparing the VH10P30 test treatment to CF treatment as positive control, and comparing the VH10P30 test treatment to CV treatment as negative control. In total, 1,963 (915 up and 1048 down) differentially expressed (DE) genes were found in the distal intestine of European sea bass in the VH10P30 treatment vs. CF treatment. Using CV treatment as the negative control, there were 711 (439 up and 272 down) DE genes in the distal intestine of European sea bass in the VH10P30 treatment. In contrast to the distal intestine, no clear differences were detected between the diet treatments in the pyloric caeca of the experimentally fed European sea bass. Previously performed gene expression profiling revealed functional specialization along the intestinal tract of European sea bass. Molecular and cellular functions related to feed digestion and nutrient absorption and transport were over-represented in the anterior and middle part of the intestinal tract, while the initiation and establishment of immune defense mechanisms became especially relevant in the distal intestine (Calduch-Giner et al., 2016). Although this could offer an explanation why there were such pronounced differences in this study in the distal part of the intestine between treatments, and at the same time no differences detected in the pyloric caeca, it is also possible that 24 h starvation prior to fish sampling affected obtained results. While the digestion was still active in the distal intestine at the time of the sampling, the active part of the digestion in the pyloric caeca was probably finished. This is also supported by functional analyses of DE genes in this

(Continued on next page)

study, which revealed over-representation of gene ontology terms in signal transduction, transport and various metabolic processes (for example cellular nitrogen compound, small molecule and lipid metabolic process) in the distal intestine, to name a few, while the immune response was generally absent, for both comparisons (using CF and CV as control, respectively). Taking into account growth performance and overall fitness of the European sea bass in the VH10P30 treatment, *H. illucens* larval meal and poultry by-product meal demonstrated great potential as alternative protein sources for European sea bass aquaculture.

Acknowledgments

The authors are thankful to all members of the Laboratory of Aquaculture in Split for their help during the feeding trial and sampling. Financial support for this study has been provided by Interreg AdriAquaNet (Project ID 10045161) and Joint EuroMarine-EMBRC 2020 grant to I. Bušelić.

Introduction

The rationale of the EU Horizon 2020 funded COASTAL (Collaborative Land-Sea Integration Platform) project is to improve land-sea synergy. The project uses a participatory modelling approach divided into several steps: a multi actor analysis with mind mapping, system modelling with data collection, definition of scenarios and transition pathways, and finally business road mapping for policy solutions, focusing on marine spatial planning and environmental protection. The approach is applied to six different European case studies called Multi Actor Labs (MAL). The French MAL consists of the Charente river basin and adjoining Pertuis sea coastal zone in the South-West of France, where oyster farming plays an important role in the local economy.

Modeling the oyster farming system in System Dynamics

One objective of the approach is to foster dialogue among all stakeholders of the land- sea system, and use system dynamics modeling to simulate the evolution of the regional system and its components over time. System dynamics is a methodology and mathematical modeling technique to frame, understand, and discuss complex issues and problems using computer simulations. We used a visual programming language (Vensim PLE) that was particularly well suited to stakeholder interactions. It provides a graphical modeling interface with stock and flow and causal loop diagrams, on top of a text-based system of equations in a declarative programming language.

In the first round of sectoral workshops, stakeholders from the aquaculture sector identified system components and processes they believed played a role in the functioning of the aquaculture sector within the land-sea system, and gave perspectives of shellfish farming in synergy with other activities. Currently, more than 75% of the oysters sold under the regional label are grown in other regions or abroad during a part of their life, notably in the Northern Sea where water quality is the most suitable. While the capture of spats is currently at an acceptable level, it may be affected in the future if coastal water quality continues to worsen. Like all bivalve shellfish, oysters are highly sensitive to the quality of water in the marine environment.

In the Charente coastal zone and hinterland, there is growing concern about water supplies (increased domestic water uses caused by residential population and waves of tourists in summer, and water for irrigation). Over the past few years, water shortages in summer have become more and more frequent. Downstream shellfish production needs fresh water from streams - particularly the Charente River - to maintain water with a desirable level of salinity. Other concerns include reduced water quality in coastal zones caused by high concentrations of pesticides, originating mainly from agricultural sources upstream, and bacteriological contamination caused by seasonal overloading of waste water treatment plants. This pollution affects downstream oyster production with bans on sales, and has a direct impact on juvenile mortality.

The water quality factors considered in the oyster model are water salinity and concentration in trophic resources (phytoplankton) in coastal zones depending of the discharge of the Charente river. Other factors considered are the density of oyster production (number of oysters grown per bag) and the type of bags (on tables or floating) affecting the quantity of nourishment oysters have access and ingest over their lifetime.

(Continued on next page)

According to our stakeholders, there are two complementary techniques that can help to completely relocate oyster production: improving the quality of locally-grown oysters and maintaining current spat catch levels. On one hand, given the downstream location of oyster parks and spat catching sites, changes in upstream activities (more sustainable agriculture and better treatment of wastewater) could have a positive effect on water quality in the estuary and thus on oysters farming. On the other hand, technical solutions (such as rearing oysters in floating bags instead of on tables, or reducing the number of oysters in bags) could provide better-quality oysters. To assess scenarios, the oyster farming model simulates spat capture, oyster flesh content (depending on water quality), rearing techniques, and the proportion of production carried out locally.

As part of our integrated land-sea model, this allows us to assess how changes in farming practices and other upstream activities, along with market demand, may impact overall oyster production. Key indicators (model outputs) are tracked over time to respond to the needs of the shellfish farming sector: quality index (oyster flesh weight to total weight ratio), spat capture and purchase, weight of oysters produced, and gross margin. The objective of increasing the quality index responds to market demand, with higher sale prices. The quality of oysters depends predominantly on the quantity of trophic resources assimilated during their life time. To meet production targets, oyster farmers seek to collect as many spats as possible, because these spats can be labelled. In the model, the capture of spats depends on coastal salinity and concentration in trophic resources. In case of insufficient catches or mortality, spats can also be purchased in nurseries.

The proportion of local oysters represents the percentage of oysters produced only in the local area, without any transfer to other regions. With the objective to relocate oyster production, this share should be as high as possible. However, relocation will be possible only if yields can generate sufficient profits. Availability of labor is also considered in the shellfish model.

Given that most oyster parks are located downstream, most of the changes in activities upstream will have an effect on the estuary's environmental conditions, thus affecting oyster growth. In the overall land-sea model, oyster production is impacted by several decision variables of other submodels linked with the oyster submodel, such as changes in the cropping pattern determining the quantity of irrigation water use, population determining domestic water use, or performance of wastewater treatment facilities.

Overall, our model helps simulate the roadmap and scenarios designed by the actors, and results are further discussed with them to decide collectively on the course of action that will be preferable for all. First results of scenarios for shellfish sector with interactions with other sectors are presented.

Conclusion

Developed in estuaries and coastal zones, shellfish farming is dependent on the quality of marine coastal waters which in turn depend of the impact on these marine environments of other economic sectors on the coast and upstream. To achieve sustainable development in these areas while maintaining other economic activities, there needs to be a consensus between all stakeholders, underpinned by research and evidence-based solutions. The proposed approach and the model developed in system dynamics could be replicated in other places where aquaculture plays an important role in the local economy.

WHAT DRIVES THE UNCERTAINTY IN MAPPING OFFSHORE AQUACULTURE POTENTIAL?

Matt Lewis [1], Peter Robins [1] David Christie[1] Jonathan Demmer[1] and Simon Neill[1]

[1] School of Ocean Sciences, Bangor University, UK

m.j.lewis@bangor.ac.uk

Uncertainty of offshore aquaculture resilience to physical conditions is a barrier to mapping locations and assessing the economic potential of offshore aquaculture. Quantifying oceanographic conditions requires long time-series of high resolution data, yet coarse ocean models and simplified variables are used to map offshore aquaculture potential in a variety of methods. Here, we hypothesise uncertainties within oceanographic data is greater than uncertainty of resilience thresholds (e.g. sites of waves < 4 m and currents < 1 m/s); and we apply a sensitivity test to explore the impact on mapping sea-space and location. Using data from a range of ocean models, the impact of spatial and temporal resolution to mapping based on extreme event intensity is determined: 1km to 10km spatial resolution ROMS and AMM15 tidal models; and wave data from ERA5, at hourly to daily mean values, resolving annual and inter-annual variability. Furthermore, the persistence of an extreme event is also calculated (number of hours above resilience threshold), and spatial differences in the maps compared. Differences in the mapping (km^2) of potential offshore aquaculture sites, based on data not physical condition thresholds, was found to be larger than differences in sea-space when changing resilience thresholds by 50% - consistent with spatial variability at such location (e.g. <2m or <6m in Hs, versus <0.5m/s to <1.5m/s). We therefore find a need for a common framework for physical ocean condition assessment, which could then be used to inform future generations of resilience offshore aquaculture – as is done in other marine industries (such as oil and gas).

REPRODUCIBLE CHANGES IN THE INTESTINAL MICROBIOTA OF ATLANTIC SALMON FED DIETS CONTAINING BLACK SOLDIER FLY LARVAE MEAL

Yanxian Li[1*], Karina Gajardo[1], Alexander Jaramillo-Torres[1], Ikram Belghit[2], Erik-Jan Lock[2], Trond M. Kortner[1], Åshild Krogdahl[1]

Introduction

Limited availability of sustainable feed ingredients is a major obstacle in the continuous growth of salmon aquaculture. Being part of the natural diet of salmonids, insects are a good source of nutrients for salmon. Insects possess an outstanding capacity to upgrade low-quality organic materials, require minimal water and cultivable land, and emit little greenhouse gases (Van Huis, 2013). Among the insect species suitable as feed ingredients, black soldier fly (*Hermetia illucens*) has been produced at an industrial scale for its good nutritional value (Barroso et al., 2014). In recent years, extensive research efforts have been directed to investigate its potential as a sustainable feed ingredient for various fish species including Atlantic salmon (*Salmo salar*). However, less is known regarding its influence on the intestinal microbiota. Herein, we report the response of intestinal microbiota in pre-smolt Atlantic salmon fed an insect meal diet containing 60% black soldier fly larvae meal for 8 weeks.

Materials and methods

Atlantic salmon with a mean initial body weight of 49 g (1.5 g SEM) were randomly assigned into 8 fiberglass tanks (450 L, 100 fish per tank). Quadruplicate tanks of fish were fed either a commercially relevant reference diet (REF), or an insect meal diet (IM) wherein black soldier fly larvae meal accounted for 60% of total ingredients. At the end of the feeding trial, digesta and mucosa samples from different intestinal compartments (proximal and distal) were collected in addition to feed and water samples from both dietary groups. Samples were processed along with positive and negative controls. Microbial communities were profiled by sequencing V1-2 regions of the 16S rRNA gene.

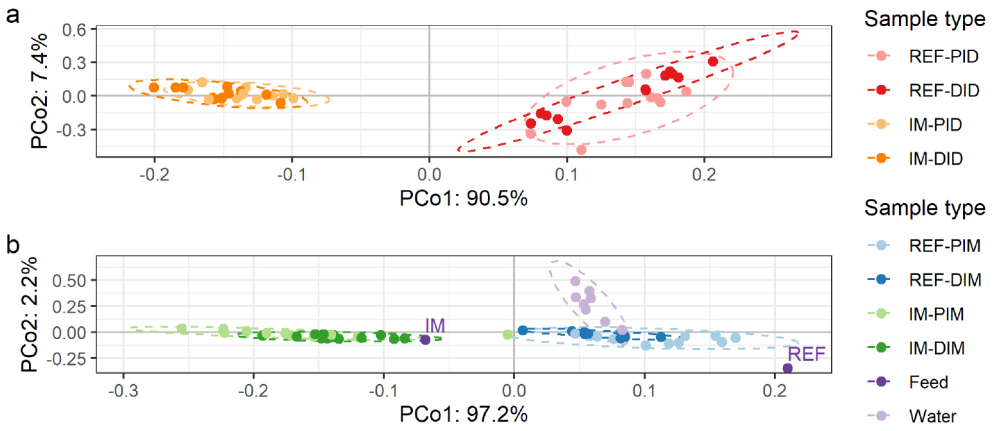

Fig.1. Beta-diversity visualized by robust Aitchison PCA. Upper plot (a), beta-diversity of digesta samples; lower plot (b), beta-diversity of mucosa, feed and water samples. Abbreviations: PCo, principal coordinate; REF, reference diet; IM, insect meal diet; PID, proximal intestine digesta; DID, distal intestine digesta; PIM, proximal intestine mucosa; DIM, distal intestine mucosa.

(Continued on next page)

Results

Overall, the microbial diversity was lower in the digesta of fish fed the insect meal diet but higher in the mucosa. Regardless of the intestinal compartment, the insect meal diet markedly modulated the intestinal microbiota composition in both digesta and mucosa (Fig.1). The diet effect on the mucosa microbiota, however, was stronger in the proximal intestine than the distal intestine. We also found that the feed-borne microbiota showed close resemblance to those observed in the intestine, whereas the water microbiota was distinct from the others. Irrespective of the intestinal compartment, bacterial taxa classified as *Actinomyces*, *Bacillaceae*, *Bacillus*, *Beutenbergiaceae*, *Brevibacterium*, *Corynebacterium 1*, *Enterococcus*, *Lactobacillales*, *Microbacterium*, *Oceanobacillus,* and *RsaHF231* were enriched in both intestinal digesta and mucosa of salmon fed the insect meal diet.

Discussion and conclusion

Our current study largely reproduced what we found in a previous experiment wherein post-smolt Atlantic salmon were fed an insect meal diet containing 15% black soldier fly larvae meal for 16 weeks (Li et al., 2021). Despite the huge difference in the inclusion level of black soldier fly larvae meal, marked changes in the digesta- and mucosa-associated intestinal microbiota were observed in both studies. In particular, insect meal diets seem to enrich specific microbial clades in the salmon intestine as outlined in the Results section. Notably, most of these taxa were also found in the feed pellets. As sequencing-based methods do not differentiate between living and dead cells, the viability of these bacterial taxa in the salmon intestine warrants further investigations. Potential implications of the changes in the intestinal microbiota for salmon physiology and health are being analyzed and will be discussed in the context of their associations with host response data that we reported elsewhere (Li et al., 2020).

ONE GENERATION OF GENOMIC SELECTION IMPROVES WHITE SPOT SYNDROME VIRUS (WSSV) RESISTANCE IN *Litopenaeus vannamei* SHRIMP

M. Lillehammer[1*], R. Bangera[2], M. Salazar[3], S. Vela-Avitua[2], E. C. Erazo[3], A. Suarez, J. Cock[3], M. Rye[2], and N. Robinson[1]

Introduction

White spot syndrome virus (WSSV) is among the most damaging diseases in global shrimp aquaculture regarding production and economic losses (Sánchez-Paz, 2010). Resistance to WSSV in *L. vannamei* has previously been reported to have low but significant heritability in adult shrimp (Gitterle et al., 2006; Caballero-Zamora et al., 2015) and moderate heritability in juveniles (Trang et al, 2019). Selective breeding is therefore one method that is being used to increase WSSV resistance (Cock et al., 2015). Genomic selection has been predicted to be a powerful and accurate way of selecting among non-infected candidates based on challenge test results from relatives and estimated genomic relationships.

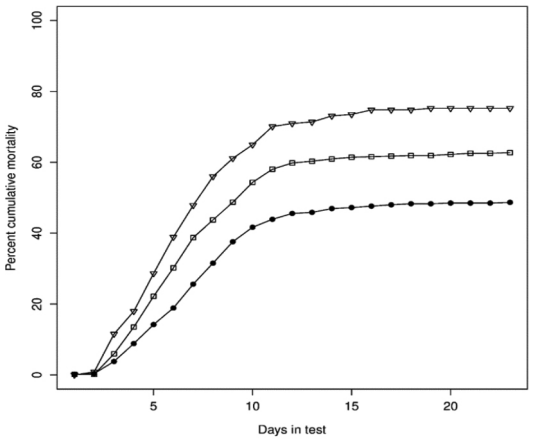
Materials and Methods

Two domesticated shrimp lines were used in this study, known to be resistant (R-line) or susceptible (S-line) for WSSV. Purebred S and R animals as well as crosses between them were produced. From this population 1151 individuals (597 males and 554 females) were used as selection candidates, while 1447 individuals were used as test animals. Selection candidates and test animals were genotyped for 18,643 SNPs to estimate a genomic relationship matrix. The juvenile stage test animals were exposed to a per os infection with WSSV infected tissue in artificial seawater at 30 ppt salinity and 26°C temperature. Genetic parameters and genomic breeding values (Meuwissen et al, 2001) were estimated for survival, and these breeding values were used to select the top 60 high ranking breeding value male and female and the bottom ranking 20 breeding value male and female candidates. These were used to produce 32 resistant and 8 susceptible full sib families. For comparison, 20 random families were produced from candidates not selected for any of these lists. The offspring (1885 individuals) were tagged by family and challenged with WSSV in a controlled test. Mortality of each family was recorded, and genetic parameters were re-estimated in the offspring generation from a sire-dam model, with and without the effect of selection group fitted. For full details on the experiment, see Lillehammer et al., (2020).

Results

Cumulative mortality at the end of the test was 75% in the susceptible, 63% in the random and 49% in the resistant group (Figure 1). The G1 random gEBV group final cumulative mortality during the test was the same as in the G0 training, and the difference between the selection groups was statistically significant. Estimated heritability of WSSV resistance in the offspring was 0.47±0.09, but reduced to 0.41±0.09 if selection groups was accounted for.

Figure 1: Cumulative mortality of high (closed circles), random (open squares) and low (open triangles) selection groups



(Continued on next page)

Discussion and Conclusion

The large, significant, difference in cumulative mortality between the selection groups demonstrate that genomic selection can be used to increase WSSV resistance. Significant and moderately high (>0.4) heritability of WSSV resistance in the offspring population suggest that repeated selection in future generations will lead to further genetic improvement.

To avoid exposing selection candidates for pathogens, family selection without individual selection is commonly used for disease traits. With genomic selection, individual selection is possible without exposing the breeding candidates to the virus. Thus, with genomic resources selection intensity and genetic gain increases. The SNP genotyping we used was sufficient to obtain genomic breeding values suitable for individual selection. This opens the way to genetic improvement of traits not measured on the breeding candidates.

Email: adriano.lima@unive.it

Introduction
The virtual, digital counterpart of a physical object referred as digital twin derives from the Internet of Things (IoT) and involves real time acquisition and processing of large data sets. A fully implemented system ultimately enables real-time and remote management, as well as the reproduction of real or forecasted scenarios. Despite such potential, the adoption of digital twin features by smaller enterprises, including by aquaculture SMEs, has been comparatively slow (Uhlemann et al., 2017).

Under the emerging framework of Precision Fish Farming, we set up digital twin prototypes for land-based farms of Rainbow trout (*Oncorhynchus mykiss*), European seabass (*Dicentrarchus labrax*) and Gilthead seabream (*Sparus aurata*), with the aim of supporting producers in optimizing feeding practices and oxygen supply with respect to 1) growth performances; 2) fish welfare, and 3) environmental loads. The digital twins were conceptualized targeting rearing cycles at Preore Farm (Trentino-Alto Adige, Italy), for trout, and Vigneto Farm (Tuscany, Italy), for seabass and seabream. The twins rely on integrated mathematical models which are fed with farm data sets and simulate several dynamic processes, allowing the estimation of key parameters such as feed digestibility, fish appetite, ammonia excretion rate, fish size distribution and dissolved oxygen consumption.

Methodology
For the trout cultivation system, the envisaged digital twin block is to be implemented to the liquid oxygen storage and supply system, whereas for the seabass and seabream plant, the focus is on optimizing feeding. These twin blocks will be interconnected to bioenergetic, population management and dissolved oxygen dynamic models, schematized in Figure 1.

The bioenergetic model (Brigolin et al., 2014) simulates the fish growth and metabolism. The forcing variables input to this model are water temperature, feeding rate, feed composition, initial average fish weight and population dynamics variables, which are associated with the population management model. In addition, husbandry parameters are input, including species-specific optimal and lethal extreme temperatures and energy consumed by respiration. The resulted calculated fish biomass is then input into a dissolved oxygen (DO) transport model (Royer et al., 2021; Lima et al., 2021), with the aim to assess the rapidly changing DO concentration in the cultivation ponds.

Results and discussion
The results demonstrated the potential of the models to provide the digital twins with short-term response capabilities, specifically intra-hour adjusted oxygen supply and daily adjusted feeding. The bioenergetic model provided robust estimates for the evolution of individual fish and total biomass weights, based on a single initial value for fish weight. With these values as inputs, the feeding table in the envisaged digital twin is automatically corrected on daily basis. At present, in contrast, these corrections tend to occur at longer time windows, and weight estimates are provided based on sampling. It is noticeable that the uncertainties in sampled fish weights may be significant, as indicated by the fact that farmers may back calculate fish weights once the biomass has been fully harvested.

The assessment of oxygen dynamics in the trout cultivation system considered scenarios based on current practices at the farm, fish welfare, the quality of the water discharged from the cultivation tanks and temperature changes. The results for DO concentration in a spatial-temporal frame obtained from the model indicate that the consumption of liquid oxygen can be reduced significantly with a real-time control.

APPLIED HOLOGENOMICS: LEVERAGING MICROBIOTA SERVICES THROUGH HOLO-OMIC ANALYSES IN FARMED FISH

Morten Limborg*

Center for Evolutionary Hologenomics, GLOBE institute, Faculty of Health and Medical Sciences
Email: morten.limborg@sund.ku.dk

Introduction

Emerging evidence across all areas of life has revealed the evolutionary importance of the intimate biological interactions between animals and their associated microbiota. Both the host genotype and the host microbiota have been shown to influence host phenotypes, such as growth and disease states. The hologenome concept maintains that the host genome and the host microbial metagenome are subject to essential biological interactions; thus, both should be considered simultaneously as a single interconnected 'holobiont system' when investigating how animals respond to e.g., diet and disease.

Methods

Based on challenges in aquaculture, we leverage current knowledge in molecular biology and host microbiota interactions to propose an applied holo-omic framework [1] that integrates molecular data including (meta)genomes, (meta)transcriptomes, epigenomes, and (meta)metabolomes for analysing fish and their associated gut microbiota as interconnected and coregulated holobiont systems (figure 1).

Results

I will present data and results from a suite of ongoing projects - including HoloFish [2] and HoloFood [3] - that all apply our holo-omic framework to understand the essential molecular interactions by which the gut microbiota shapes phenotypic traits in both Atlantic salmon and rainbow trout. In particular, we look at traits related to growth, novel feed additives, and response to a pathogenic bacterium.

Conclusions

I will discuss the feasibility and potential of using our holo-omic framework to combine large -omics data sets for more coherent analyses of host – microbiota systems to help steer a more sustainable growth of aquaculture.

EVALUATION OF DIETS USING INSECT FLOUR ON THE GROWTH OF GREEN FROG (*Phelophylax perezi*) TADPOLES

J. Lopes[1,2,*], C. Batista[1], V. Morais[1]

[1] Instituto Politécnico de Viana do Castelo, Escola Superior Agrária
[2] Centre for Research and Development in Agrifood Systems and Sustainability – CISAS
Email: juliocesar@esa.ipvc.pt

Introduction

With the growing need to reduce the use of fishmeal in aquaculture diets, it is important to evaluate the possibility of alternative sources that allow, in a sustainable way, to ensure the increase in aquaculture production (Barroso et al., 2014; FAO, 2020; Van Huis, 2020).
The production of amphibians, particularly in the case of the green frog - *Phelophylax perezi*, has been increasing in interest within Europe. However, there is no diet developed specifically for their food on the market, with producers using feed for carnivorous fish and, as such, highly dependent on fish meal (Finke, 2002; Makkar et al, 2014).

The larval stage is extremely important in the development of amphibians because the tadpoles, when in good nutritional status, produce more resistant imagoes, increasing the probability of a decrease in mortality in the following stages.

Although frog culture is well developed in several countries, little is known about the nutritional needs of amphibians, even more so in the case of green frogs.
The present work intended to start the process of understanding these needs.

Material and methods

From different spawns of *P. perezi*, 360 tadpoles were selected in phase 25 (Gosner, 1960) and divided into 12 groups of 30 tadpoles in 40 liter tanks under a water recirculation regime. Four diets were formulated corresponding to two levels of energy (5000 and 5500 kcal/kg) and two of protein (38 and 44% CP) using raw materials of vegetable origin and insect flour (*Tenebrio molitor*).

Diets were randomly assigned by three repetitions, being fed ad libitum and the animals weighed weekly for 9 weeks. The first two weeks were considered as weeks of adaptation to the controlled environment and experimental diets. Each group was monitored daily, with residues and food not consumed by siphoning and dead animals being removed.

The animals that complete the metamorphosis were transferred to the growth sector.

The comparison of the average daily gain between the experimental diets was carried out, as well as the mortality and metamorphosis rates.

Comparisons were performed using ANOVA and Tukey LSD tests from the SPSS 22 statistical package.

Results

Mortality and metamorphosis rates did not show significant differences between diets ($p>0.05$), varying between 26.05 ± 0.01 and 30.04 ± 0.17% for mortality and between 32.78 ± 0. 08 and 49.11 ± 0.09% for metamorphosis during the test weeks.
The average daily gain varied between 3.79 ± 0.77 and 8.92 ± 1.05 mg/day, with significant differences ($p<0.05$) between the diets being observed.

Conclusions

The observed results indicate a better performance with diets with lower energy value, however, it will be necessary to extend the comparisons to different protein:energy ratios in order to understand the real effect of this relationship.

LET CONSUMERS DESIGN THE PACKAGING FOR FISH PRODUCTS

L. López-Mas*, A. Claret, A. Bermúdez, M. Llauger, & L. Guerrero

Institute of Agrifood Research and Technology (IRTA), Monells (Spain)
*E-mail: laura.lopezm@irta.es

Introduction

Food packaging is no longer a mere structural element but also a powerful marketing tool able to affect product perception, purchase decision, and consumers' food choices (Ares and Deliza, 2010). Packaging can be the most direct and influential communication element at the point of purchase (van Rompay and Veltkamp, 2014), where most purchasing decisions are made (76%) (POPAI, 2014). Thus, incorporating consumers' opinions during food packaging design (co-creation) could enhance its potential success in the market (Moon et al., 2018).

Packaging attributes could be divided into two groups, (A) visual, which draw attention and transmit non-verbal information (e.g., colour); and (B) textual, which transmit verbal or numerical information (e.g., claims).

This study aimed to involve consumers in the design of a fish product packaging in order to know the combination of visual and textual attributes that best fit into their preferences and expectations.

Materials and methods

An online survey with 200 Spanish participants was conducted to let consumers choose which packaging attributes (visual and textual characteristics) preferred for a 'meagre burger with mushrooms (black trumpet)', an aquaculture fish product developed within the MedAID project (European Commission, Horizon 2020, No. 727315).

Visual attributes of the packaging included the type of container (bowl, bag, tray, box), colour (61 options), window presence and type (16 options), image presence and type (six options), typeface (15 options), package presentation (individual, per serving, without divisions), and product quantity (one, two, four, or more than four servings). Textual attributes were divided into three groups according to the three dimensions of the quality (searched, experienced, and credential). Three conjoint analysis were performed, one per each quality dimension, and four factors were included in each one: (1) convenience, price, products' presentation (e.g., individually wrapped), and recyclability (searched quality), (2) freshness, texture, flavour, and novelty (experienced quality), and (3) health, natural, animal welfare, and sustainability (credential quality).

Table 1. Most frequently selected options of visual attributes (%).

Attribute	%	Selection	Attribute	%	Selection
Container	66.5	Tray	**Typeface**	17.0	Arial Rounded MT Bold
	20.5	Box		11.5	Rage Italic
Colour	12.5	White	**Presentation**	43.0	Packed per serving
	10.0	Light blue		36.5	Individually packed
Window	29.5	Full	**Quantity**	45.0	2 servings
	12.0	Large left side		38.0	4 servings
Image	48.0	Dish ready-to-eat			
	35.5	Ingredients			

Table 2. Mean importance of the textual attributes grouped by quality dimension (%).

Searched		Experienced		Credential	
Factor	**Importance (%)**	**Factor**	**Importance (%)**	**Factor**	**Importance (%)**
Convenience	18.9^{b}	**Freshness**	29.8^{a}	**Health**	25.1^{ab}
Price	29.3^{a}	**Texture**	19.3^{c}	**Natural**	20.7^{b}
Presentation	22.5^{b}	**Flavour**	23.5^{bc}	**Animal welfare**	31.1^{a}
Recyclability	29.4^{a}	**Novelty**	27.4^{ab}	**Sustainability**	23.1^{b}

Superscript a–c: different letters in the same column differ significantly ($p < 0.05$).

(Continued on next page)

Results

The visual attributes of the packaging preferred by consumers for a meagre burger are presented in Table 1. The tray was the most widely selected option, maybe because it is the most common container for burgers (both meat and fish) in Spanish supermarkets. Colours white and light blue were alike in preference, as they may evoke the sea. Participants preferred to see the raw product, through a wide window on the package. Besides, they chose to have a picture of the burgers ready-to-eat or the raw ingredients (e.g., fish, black trumpet) printed in the package. Typefaces most selected were 'Arial Rounded' and 'Rage Italic'. Regarding the presentation, packaged per serving (2 burgers per serving) was the most chosen option, followed by individually packaged burgers. Lastly, two and four servings were picked out a higher number of times, probably due to that 64% of participants had between three and four people living in their household.

The textual attributes preferred by participants are presented in Table 2. 'Recyclability' and 'Price' played the most relevant role when it came to the searched quality. Therefore, it could be hypothesised that claims related to the packaging' disposal and material (i.e., 80% recyclable packaging) and price (i.e., now 5% cheaper) would be positively valued by consumers. On the other hand, 'Freshness' and 'Novelty' were the most important factors for experienced quality. Freshness is regarded as a critical aspect of fish quality, as it is a highly perishable product. Claims like 'New product', also attracted consumers' attention. Finally, 'Animal welfare' and 'Health' stood out for credence quality. Animal welfare and ethical issues have been gaining special attention over the last decades, which explains why consumers are demanding welfare standards for the fish they consume. Health, instead, has been for a long time a consumption driver of fish.

Conclusions

Consumers have clear preferences for specific package designs, both visual and textual. Thus, involving consumers in the final design of a product might improve its potential success in the market.

Introduction
In recent years, several aquaculture technologies have been implemented by some producers. Considering that consumers tend to be concerned about the use of new technologies in food production (Yeung and Morris, 2001), it is of great interest to know how they perceive them. Understanding consumers' perceptions, feelings, and opinions is a key element in designing communication and marketing campaigns and in providing guidelines for producers and policymakers, with the ultimate goal of improving the overall perception of aquaculture and aligning it with the green deal strategy.

This study aimed to understand European consumers' perception of new production systems and new managing technologies applied in the aquaculture industry.

Materials and methods
One focus group was carried out in each of the three EU countries under study (France, Italy, Spain). Between seven and eight participants took part in each focus group. Participants met the criteria of being 50% women, older than 18 years old, responsible for food purchase and preparation within their household, and fish consumers (≥ once a week).

During focus group discussion, consumers were asked about their perceptions of different aquaculture production systems (Aquaponics, Recirculating Aquaculture Systems (RAS), Biofloc Technology (BFT)) and new aquaculture managing technologies (Artificial Intelligence (AI), Electrochemical biosensors, Prediction models), all of them explored within the NewTechAqua project (European Commission, Horizon 2020, No. 862658). Sessions were audio/video recorded for further analysis. A subsequent content analysis procedure was carried out to synthesize the main insight that came out during sessions.

Results
A summary table of consumers' perceptions about different aquaculture production systems and managing technologies is shown in Table 1. As a general trend and, as expected, there is a widespread lack of knowledge of all the technologies presented.

Aquaponics was perceived rather positively. Some participants related it with the concept of 'hydroponics' and other plant growing techniques. Natural, sustainable, and environmentally friendly also came out, in addition, avoiding wastes and clean were mentioned. RAS perception was twofold. Participants rejected if it means dirty and not renewed water and appreciated if it means water filtration, recycle water, sustainability, ecological, *etc*. Biofloc technology was perceived unanimously as positive. The main reason is its name, as the prefix 'bio' generates good feelings among participants.

AI was probably the most known technology, and its perception was generally positive. Future, automation, and control were the most cited terms. AI suggested better management, keep standards, mass production, and clean the sea. However, in France, some level of distrust came out due to the relative novelty of this technology. Electrochemical biosensors were mainly associated with control (i.e., fish, water, production). Most participants showed a lack of knowledge about this technology. Finally, Prediction models were perceived rather positively. Control was frequently mentioned (i.e., production, quality, economic), as well as better management and yields. Overconsumption and sustainability aspects also came out.

Conclusions
Understanding consumers' perception, feeling, and opinions of new aquaculture production systems and new aquaculture managing technologies should be the basis for future communication and marketing campaigns in order to promote their general acceptance, especially in those aspects identified as more controversial. Consumers' knowledge and understanding of the new aquaculture production systems and managing technologies seems to be the key element in guaranteeing their acceptance.

TEMPORAL CHANGES IN SKIN AND GILL MICROBIOMES ARE IMPACTED BY DEVIATIONS IN THE MICROBIAL COMMUNITY OF REARING WATER IN A RECIRCULATING AQUACULTURE SYSTEM

Introduction
Atlantic salmon (*Salmo salar*) aquaculture continues to grow and intensify in line with a continually expanding world population. Such demand for sustainable protein sources has driven the expansion of land-based production in recirculating aquaculture systems (RAS). Microbes associated with fish mucosal surfaces are an important component of health and immunity and have become of increasing interest in recent year, particularly in RAS where microbes are also a key component in maintaining high water quality. External mucosal surfaces, skin and gill, are the first lines of defence against opportunistic pathogens as they are in constant contact with surrounding water, but the stability of mucosal microbiomes over time in RAS is unknown.

Materials and methods
We analysed the temporal dynamics of the microbial communities associated with skin and gill mucus in Atlantic salmon during smoltification in a commercial RAS facility and following transfer to a commercial sea site. Mucus swabs were taken from 6 fish from triplicate tanks at 4 timepoints in freshwater (FW1-4) and at 1- and 4-weeks post-seawater transfer (SW1/SW2). Sequencing of the V3/V4 variable region of the bacterial 16S gene was carried out on the Illumina MiSeq platform. DADA2 (Callahan, McMurdie et al., 2016) was used to determine microbial composition in skin and gill mucus, water and diet samples at the level of amplicon sequence variants (ASVs). Functionality was inferred using Piphillin (Iwai, Weinmaier et al., 2016).

Results
Microbial diversity and richness were temporally dynamic in both skin and gill mucus ($p<0.001$) with a distinct and significant drop at FW2 followed by a rising trend to FW4 and stability post-SWT. The drop in diversity in FW was the result of a surge in relative abundance of two taxa belonging to the genus *Hydrogenophaga*. These dynamics were mirrored in tank water samples. Beta diversity revealed more separation between sampling points than between tissues at a single sampling point.

The numbers of identified core microbial taxa (present in >90% of samples) generally increased over time in both skin and gill mucus, and overlap was observed between the two. However, coincident with the surge in *Hydrogenophaga* at FW2, few core taxa were identified and all of these cores were also identified in tank water.

Functional inference identified metabolic pathways associated with microbial communities. Coincident with the surge in *Hydrogenophaga* at FW2, 'Xenobiotics biodegradation and metabolism' increased in contribution at the detriment of 'Carbohydrate metabolism' in both skin and gill mucus.

Discussion and conclusions
Microbial diversity in skin and gill mucus were temporally dynamic in fish reared in a FW RAS during the parr – smolt transformation. A distinct drop in diversity was identified at FW2, coincident with a spike in the relative abundance of two taxa belonging to the genus *Hydrogenophaga* and suggested the occurrence of a dysbiotic event.

Hydrogenophaga is an autotrophic de-nitrifier associated with RAS biofilters (Rurangwa, Verdegem 2015). Previous work in RAS has shown that biofilter-associated taxa are not restricted to the biofilter and have the potential to colonise fish mucus (Schmidt et al., 2016, Minich et al., 2020). The *Hydrogenophaga* spike was associated with 'Xenobiotics biodegradation and metabolism', suggesting a role for this genus in metabolism and bioremediation of potentially harmful inorganic compounds in RAS tank water and mucosal surfaces.

(Continued on next page)

Despite disruption of the mucosal microbiota, no adverse impacts on health or growth were observed, indicating functional redundancy and potentially protective functions of individual genera. This study highlights the importance of considering temporal dynamics when interpreting results of microbiome studies and inferring wider significance.

This work was funded by BBSRC grant RobustSmolt (BB/S004270/1). The authors would like to thank John Richmond, MOWI and ARCH-UK for their contributions to this work.

Introduction

The high mortality rates occurring during larval development, together with the high running costs of larval rearing systems and juvenile production, remain the major bottlenecks to the full cycle production of sea urchin (Carboni et al., 2012). For this reason, it is necessary to improve experimental protocols for larval production. The provision of optimal feeds is a key factor for successful larval culture. The nutritional value of a diet influences directly the larval growth, condition, and survival. Some nutritional characteristics, such as high carotenoids and lipids levels, are already known to improve larval development. The present study aimed to evaluate the effects of diet nutritional value (lipid and carotenoid content) on larvae of *Paracentrotus lividus* (Lamarck, 1816) by comparing several morphometric indicators of larval growth and condition between dietary treatments and by analysing the reciprocal correlation between the microalgae and larvae Fatty Acids (FA).

Material and Methods

The larval rearing experiment was carried out in triplicate tanks, at a density of 6 ind.mL^{-1}, using nine 50 L cylindroconical tanks in a closed system and organized in a Latin square design. During the experiment, larvae were maintained in aerated static seawater (35 ppm), with an average temperature of 19 °C and continuous fluorescent light (11.14 µE.m^{-2}.s^{-1}). The larvae were fed with three microalgae species, *Rhodomonas* sp. (Rho), *Chaetoceros calcitrans* (Chae) and *Dunaliella tertiolecta* (Duna) as monospecific diets. The feeding doses were standardized to cell volume supplying equal bio-volume of microalgae and adapted to larval stages as follows: for Rho diet, the larvae with 4, 6, and 8-arms were fed with 3600, 7200 and 14400 cells.mL^{-1}.day^{-1} respectively; for Chae and Duna diet, the 4, 6, and 8-arms larvae were fed with 7200, 14400 and 28800 cells.mL^{-1}.day^{-}1 respectively. Larval body length (BL), body width (BW), post-oral arm length (POAL) and stomach length (SL) were measured to characterize growth and morphology of larvae fed with the different diets. Larval survival rate (%) was assessed volumetrically every two days and age-at-competence was defined as the number of days post-fertilization (DPF) required for at least 75% of the larvae attain competence for settlement. The larval condition was assessed empirically by analysing the deviation of the larvae size from the expected tendency obtained by fitting linear models BW~BL (model A), SL~BL (model B) and POAL~SL (model C). The FA composition was determined for microalgal diets and larvae by gas chromatography. Total lipids and carotenoid pigments were quantified only for microalgae diets, by spectrophotometry and by High-Performance Liquid Chromatography, respectively.

Results

The larvae attained the competence for settlement at 18 DPF in all dietary treatments. At this stage, the larval survival rate was 2.03 ± 3.29 % for Rho, 4.88 ± 6.29 % for Chae and 1.67 ± 0.60 % for Duna treatments, without significant differences between diets (H_{KW} = 7.44, df=2, P = 0.189). Larvae fed with Chae showed the shortest BL and BW at 12 DPF (BL: 242.76 ± 15.76 µm; BW:182.09 ± 13.21 µm) and 16 DPF (BL: 286.51 ± 57.78 µm; BW:253.05 ± 38.47 µm). And at 18 DPF, these larvae showed the largest stomach (SL: 147.54 ± 20.59 µm) and the shortest POAL (319.69 ± 39.80 µm). The analysis of the residuals of condition model A showed that the larvae fed with the Chae presented the smallest BW, while model B showed that the larvae fed with Duna presented in average the smallest stomachs and model C showed that the larvae fed with Duna presented the longest post oral arms. The microalgae Rho and Duna presented the highest lipidic content. Particularly, Rho showed the highest content in PUFAs (65.34 %), the highest content in docosahexaenoic acid (DHA) and the highest content in erucic acid (C22:1n-9). Reciprocally, larvae fed with this diet also showed a high content of C22:1n-9 and DHA. On the other hand, Chae presented the highest content in arachidonic (ARA) and eicosapentaenoic (EPA), but low content in linoleic acid (LA) and α-linolenic acid (ALA). The larvae fed with this microalga were characterized by a relatively high content of total PUFA (46.06 %), total MUFAs (25.62 %) and EPA/ARA ratio (5.37), but low DHA/EPA ratio (0.11). The microalgae Duna presented the highest content of ALA, LA and total n - 6 PUFA (14.03 %) and the lowest content of n-3/n-6 (2.72). The larvae fed with Duna showed high content of ARA, ALA and LA. Although Duna

(Continued on next page)

did not show any content in EPA, a relatively content of EPA was found when larvae was fed with this diet. Regarding the carotenoid content, Chae presented the highest ß-carotene content (122.51 ± 2.93 $\mu g.mg^{-1}$) and is the only one that presents fucoxanthin (36.55 ± 4.08 $\mu g.mg^{-1}$) of the three microalgae cultures.

Discussion

Age of competence of *P. lividus* larvae was independent of the microalgae nutritional value, and their relatively low survival rate of advanced stages (2-5 %) was apparently related with the high stocking density. Several studies indicate that larvae raised in lower densities show higher survival rates at competence (Suckling et al. 2018)"ISSN":"0044848 6","abstract":"In this study, we present the results of two experiments; in the first one we evaluated the effects of four larval dietary treatments on the survival and growth of the sea urchin Paracentrotus lividus, larvae and post-larvae. In the second experiment we have measured the effects of two different settlement substrates, combined with the presence of conspecifics, on metamorphosis, survival and growth of post-larvae. The microalgae dietary treatments consisted in: Dunaliella tertiolecta (Duna. The larvae FA profile reflected the assimilation of the microalgal diets provided. The increase of EPA and ARA levels in larvae fed with Duna diet, suggests active biosynthesis of EPA and ARA from LA and ALA through the "Δ8 pathway" (Kabeya et al., 2017). The data suggested that high carotenoids content, specific fatty acids, low DHA/EPA ratio and high EPA/ARA ratio and n-3/n-6 ratio present in *C. calcitrans* enhanced larval growth (largest stomach and shortest POAL) and condition. Further research should look to a larger number of phytoplankton species to determine what nutritional characteristics should be supplied to enhance larval development and condition.

Introduction

The sea urchins' welfare is highly affected by changes in water quality. For this reason, it is crucial to understand their tolerance limits in closed and semi-closed aquaculture systems, where the levels of harmful or toxic substances can be higher that normally occur in natural environments (Albrizio *et al.,* 2019). The harmful substances can affect the immune system of sea urchins, particularly the activity of their immune cells, the coelomocytes. The coelomocytes are responsible for cellular responses to external agents and produce a wide variety of humoral factors that are important defences against pathogens (Fernandez-Boo *et al.,* 2018). The main objective of this study was to evaluate the effect of two diets (a macroalgae diet and a dry diet) in the immune response of sea urchins subject to acute exposure to high temperatures.

Materials and Methods

Adult sea urchins (N = 228) with 40 mm test diameter were maintained in two RAS with a density of 0.38 ind./L^{-1} and fed three times per week for 3 months with two diets: a macroalgae (*Ulva rigida*) diet and dry diet formulated with vegetable-based ingredients. During the nutritional trial, the sea urchins were subject to three acute exposure experiments (AEE), at the beginning, mid and at the end of trial. In each AEE, a randomly selected group of urchins of each diet were exposed to high temperature (24ºC) for 24 hours and compared to a control group under ambient temperature. After exposure, the righting response (behavioural test measuring the time the urchin takes to recover its aboral position) of all urchins (exposed and control group) was evaluated. Then, the urchins were measured (test diameter), individually and their gonads weighed, and maturity level assessed. For all urchins (exposed and control group), it was collected a sample of coelomic fluid to determined cell immunity parameters and measure the humoral response parameters. For cell immunity analysis, the different immune cells were identified: phagocytes (pha); colorless granulocytes (cg); red granulocytes (rg) and vibratile cells (vib) and counted using a Neubauer chamber under 400x magnification microscope. For humoral response analysis: lysozyme concentration, protease activity and nitric oxide concentration was quantified by turbidimetric test, azocasein hydrolysis assay and Griess reaction, respectively, following Fernandez-Boo *et al.,* (2018).

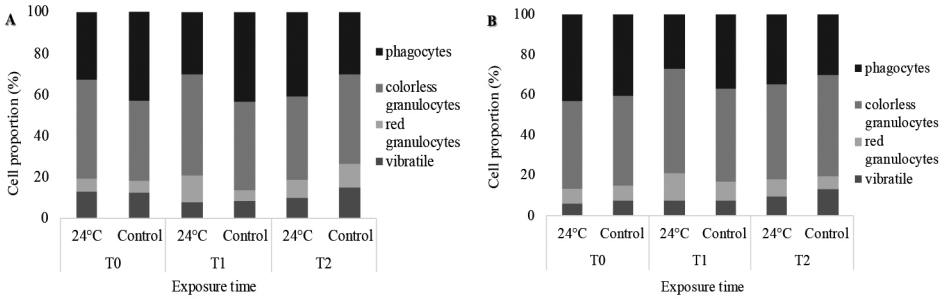

Figure 1- Percentage of different immune cells in the coelomic fluid of *Paracentrotus lividus*, after the three acute exposure experiments: T0- initial experiment, T1– mid trial experiment and T2– final experiment, A- macroalgae diet (*Ulva rigida*) and B- dry diet.

(Continued on next page)

Results

Both diets promoted identical level of gonad maturity, while in the end of the study the dry diet promoted higher GI (12.50 %) than the macroalgae (3.53 %). After the AEE to high temperature, the righting response varied between 01:01 to 03:13 minutes. The sea urchins fed with the macroalgae and exposed to 24°C showed longer righting behaviour time, when compared to the control group. In all the AEE, the most abundant immune cells were the cg (52%) and pha (31%), followed by rg (12%) and vib cells (2%). The macroalgae promoted higher percentage cg and rg and lower percentage of pha and vib whereas the dry diet promoted higher percentage of pha and rg and lower cg and vib when compared to the control group. For the humoral response parameters, lysozyme concentration (0.53 to 2.18 μg/mL) was higher in the sea urchins fed with the dry diet, when compared to the control group. The protease concentration (12 to 18%) was lower in both diets when compared to the control group and nitric oxide production (0.14 to 2.59 μM/mL) only occurred in the dry diet.

Discussion and Conclusion

The coelomic fluid of the sea urchins fed with dry diet and exposed to 24°C presented higher proportion of phagocytes and granulocytes (cg and rg) than the control groups. These results suggest that dry diet can promote a quicker activation of cellular immunity. On the other hand, the rg were the only cells that showed an increased production in both diets. Branco *et al*., (2013) suggests that this cell type plays an important role in the innate immune response, on different types of stress, including lesions on the skeleton and dermis and environmental contamination. Additionally, the increasing lysozyme concentration and the production of nitric oxide in the urchins fed with dry diet also support the conclusion that dry diet can promote sea urchins' innate immunity. Additionally, higher protease activity was observed in sea urchins fed with the dry diet. This result is supported by the study conducted by Johnston & Freeman (2005), which observed an increase of protease activity in the crab *Leptograpsus variegatus* fed with a mixed diet (plant and animal material). The information about sea urchins' immune response to acute changes in the environmental conditions is still scarce and the future research should be carried out to assess the immune response and the physical behavior of *P. lividus* exposed to different extreme environmental conditions and fed with different diets.

Introduction

The recent decade has seen increasing attention on the subject of the welfare of fishes in aquaculture operations. This trend is due to the constant global growth of the aquaculture sector since the late 1980s. The sector is expected to continue its growth at a rate of approximately 2.3% per annum until 2029 and is projected to overtake capture fisheries in total fish production by 2024 (OECD 2021). This growth is mainly due to three progressions:

1.) expansion, 2.) intensification, and 3.) diversification,

with all three of these potentially leading to numerous new welfare implications and challenges on the farmed specimens. Today, the fulfillment of good husbandry and welfare practice in aquaculture operations is often impaired by the lack of fundamental knowledge addressing the species- and life-stage specific welfare needs of the vast variety of different aquatic organisms. In contrast to terrestrial livestock farming, aquaculture, of finfish in particular, has to cope with an X-fold higher species diversity than all terrestrial animals combined. Fish account for around 60 % of all global vertebrate species (Nelson et al. 2016), and the FAO (2018) reports more than 350 finfish species to be currently cultivated in aquaculture. According to Mood & Brooke (2012), an estimated 79,3 billion individual farmed fish were slaughtered each year by 2010, compared to 63 billion terrestrial livestock, of which 86% accounted for chicken alone. These sheer numbers reveal the need to safeguard fish welfare during all stages of the production cycle. However, a monitoring system consolidated across different stakeholders of the sector has yet to be developed.

Figure 01: Word-cloud on main topics and terms generated from multiple discussion panels with different stakeholder groups. Major topics are feed, staff-competence, health, stocking-density, behaviour and stunning.

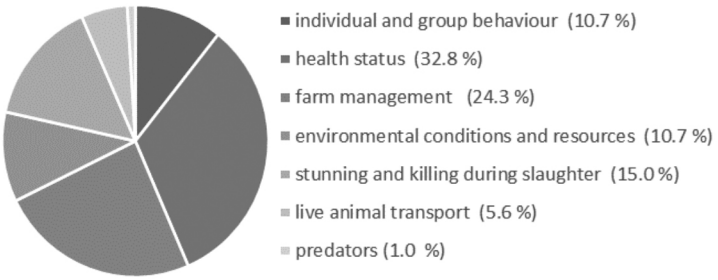

Figure 02: A model of the ideal quantitative distribution of all welfare indicators across the seven key areas (clockwise) desired for a monitoring system as identified by different stakeholder groups and the literature.

(Continued on next page)

Materials and methods

To address the respective welfare needs of the fish, and select a widely accepted, yet broad baseline set of welfare indicators (WIs), we collected and reviewed 109 articles, scientific publications, book chapters, databases, and legal frameworks, as well as guidelines and recommendations from the European Union, expert panels as well as national and international associations. We organized five national meetings with representatives of the scientific community, fish health services, aquaculture associations, national authorities, as well as fish farmers, and the interested public. The meetings were organized in two stages. In the first stage, we collected and discussed main topics and terms regarding potential welfare constrains in aquaculture production (Fig. 01). We then sorted and assigned these terms to the corresponding WIs found in the literature. In the second stage, we asked stakeholders to rank each identified WI for its suitability on a score from 0 (lowest) to 3 (highest) by three different criteria each: validity, reliability, practicability. We merged the results based on multiple statistical selection criteria, to identify those topics and WIs that have the most common denominators across all stakeholder groups.

Results

During the meetings, we collected 234 different terms related to fish welfare in aquaculture. Out of these, we identified 160 individual WIs which can be referred to by the international literature. Indicators fall into two distinct categories: single indicators and combined indicators. All indicators can be classified into seven key areas: individual and group behaviour; health status; farm management; environmental conditions and resources; stunning and killing during slaughter; live animal transport; predators. WIs related to health status dominated (32.8%), followed by management measures (24.3 %), and stunning and killing during slaughter (15.0%) (Fig. 02). Overall, we identified 36 WIs from all key areas to be the most common denominators in fish welfare across all stakeholder groups.

Discussion and Conclusion

Stakeholders have a very diverse view regarding fish welfare indicators and monitoring systems. Some group representatives stated, that only animal-based WIs with regard to the health status were eligible to adequately reflect the state of fish welfare, while others endorsed growth performance to be solitarily sufficient. However, the majority of stakeholders supported a holistic welfare approach, with a broad view across all seven thematic areas. All groups agreed, that water quality parameters are among the most important, yet most complex WIs, due to their strong interconnection among each other, seasonality, and daily rhythms. It was suguessted to closely monitor water quality parameters, and interlink these to the farm management, and the overall staff competence.

THE SEA-URCHIN *Paracentrotus lividus* PRODUCTION: OPTIMIZING LAND-BASED CULTURE

Ricardo Luís[1,2]*, Ricardo José[2,3], Carlos Andrade[2,3,4]

Introduction

As sea-urchin gonads (roe) became more popular after the 1950s, many *Paracentrotus lividus* populations were exploited in a boom-and-bust model, resulting in a sharp decline of their wild stocks. In this context, aquaculture culture emerges as one of the solutions for the ineffective resource management policies, as a sustainable exploitation of this product.

Sea ranching, and land-based culture have both been utilized for grow-out of sea-urchins. Land-based industrial culture requires large capital costs, and intensive management, while sea ranching is less costly but often results in low recapture rates. Thus, a significant increase in efforts to develop cost-effective, and sustainable methods to culture sea urchins has been observed including research aiming to optimize the reproduction, and juvenile production. A better knowledge in the control, and understanding of the factors controlling sea-urchin's growth, gametogenesis, spawning, and survival is essential for a sustainable production, and supply of the increasing demand for eggs and larvae. This communication presents the broodstock, and gonadossomatic conditioning pilot systems as well as protocol optimization for broodstock rearing, and spwan induction methods at Centro de Maricultura da Calheta.

Material and Methods

For this work, *P. lividus* with test size superior of 35 mm were collected from intertidal rock pools in the southern coast of Madeira island, Portugal. The broodstock rearing system consisted of two 750 liters (L), and one 500 L (quarantine) cylindrical tanks. Temperature was 22.82 ±0.80 ºC, and X L/h of water renovation. Feeding was established at 5% weight. week^{-1} of maize (*Zea maes*). The population collected (n=20) was analyzed *a priori* to determine the gonadal index (GI), and compared with conditioned sea-urchins (n=20) after three months. Four spawning methods were evaluated: KCl 0.5M injection; agitation; microalgae addition, and cospecific gametes addition (spermatozoa), by assessing the spawning response within 30 minutes, and survival up to five days, in wild-caught, and conditioned individuals.

Results

Results indicate that three months conditioned sea-urchins GI average was 8.46 ±2.90 in which 25% of the individuals presented a GI $\geq$ 10, as opposed to wild caught sea-urchins that presented a GI average of 2.84 ±1.93. In the spawn induction techniques evaluation, all methods were able to trigger spawning, and mortality was only observed with KCl 0.5M injection method. The agitation was chosen to induce spawning without impairing broodstock survival, with gamet ejection within 30 min. Further experiments are undergoing to allow improvements in the larvae rearing methods for *P. lividus*.

A COMPLETE RISK MODEL FOR AQUACULTURE COMPANIES

M. Luna*, L. Luna, J.L. Fernández-Sánchez and I. Llorente

Business Management Department, University of Cantabria, Santander, Spain
E-mail: manuel.luna@unican.es

Introduction
In recent decades, aquaculture has established itself as a flagship industry in the agri-food sector. It is at the top of the food production industries in terms of growth due to its increasing worldwide popularity and its expanding diversity of products. However, their companies inherently face more variability in their results than those from other food production industries (Geurin and Geurin, 1994; Flaten et al., 2011).

Despite this fact, the field of risk in aquaculture is still understudied and subject to discourse. On the one hand, the scientific literature on the risk field in aquaculture is limited and very unbalanced as most contributions are focused on some specific risks. On the other hand, the industry lags behind comparable industries in implementing systematic risk management and only a small fraction of the industry is insured for losses (Holmen and Thorvaldsen, 2015). In this context, the scientific community and the industry have to work together to address some basic research questions on the fundamentals of risk in its broadest sense, before focusing again on the operative "how-to".

For these reasons, the main objective of this study is to provide a comprehensive risk framework for the aquaculture industry with regard to all those risks that could adversely affect the companies' economic or financial situation.

Materials and methods
The development of a comprehensive risk model for the aquaculture industry requires to identify and classify the risks faced by companies in practice, and to define them in detail.

To do this, the literature providing empirical evidence on aquaculture producers' risk perceptions has been reviewed and consolidated, , which is formed by eight empirical studies (Bergfjord, 2009; Le and Cheong, 2010; Ahsan and Roth, 2010; Ahsan, 2011; Le Bihan et al., 2013; Lebel et al., 2016; Alam and Guttormsen, 2019; Rahman et al., 2021). Furthermore, other studies on risk assessment and management have also been examined in order to properly define each type of risk.

After that, a panel of independent experts - consisting of researchers, distributors and policymakers – have been asked to revise the model, seeking to go beyond the producers' perceptions.

Results and conclusions
The process carried out allowed us to cover a wide range of periods, species, and countries, which is crucial for the development of a consolidated and comprehensive risk model as risk perceptions are usually influenced by different socio-economic aspects. In this way, we aggregated the perceptions of more than 1500 producers from 8 publications, resulting in a model with 7 risk categories comprised of 40 risk sources (Table 1). Moreover, the producers' valuations on the importance of each risk source were also collected and processed to make them comparable, which allowed us to estimate an importance ranking.

This showed that Production, Market, and Operational risks gather the most important sources of risk, while those belonging to the Strategic, Regulatory, Financial, and Reputational risks are slightly behind. With regard to the main specific sources of risk, diseases, price volatility, and quality control have been ranked as the most worrying aspects for producers. On the contrary, they see the uncertainty around technological and HR as not very significant. Lastly, the independent evaluation of the model, based on the opinion of a panel of experts from industry and academia, allowed us to validate the model.

This work responds to the current need for a standardized approach to risk analysis that takes into account the different dimensions of risk, which has been stressed several times. This will help both the scientific community and the industry to standardize and improve risk assessment and management practices. Furthermore, as this model is based on those applied in the financial sector, it could also be useful for other stakeholders, such as financial agents and policymakers, improving the access of the industry to external funds.

Introduction

The Pacific oyster *Crassostrea gigas* (Thunberg, 1793) originates in South-East Asia, but has been extensively translocated for aquaculture purposes and is now one of the main cultured bivalve species. Norovirus (NoV) is one of the most common causes of gastroenteritis globally and outbreaks are often linked to bivalves, including the Pacific oyster (Bellou et al., 2013; Hardstaff et al., 2018). Two main challenge in assuring NoV absence in food is the lack of cultivation based methods for detection and high number of false positive results from RNA in non-infective NoV with damaged capsid. Thus, to improve food safety in raw oysters, temperature treatment prior to consumption has been suggested to inactivate pathogens, including NoV. This study describes temperature development in oyster tissue during several commonly applied thermal treatments (steaming, broiling, baking, barbecuing, boiling water, hot broth). In addition, changes in the sensory quality during heating were evaluated.

Materials and methods

Sixty Pacific oysters of an average weight of 100 g and harvested from a wild population on the South-Eastern Norwegian coast, were included. Oyster heat treatment regimens (time-temperature) were chosen from CDC guidelines (Centre for Disease Control and Prevention, 2019a; 2019b) as well as in accordance with the most common recipe suggestions in both printed and online sources. The following heat treatments were examined:

Steaming: The steaming was done in a steel pot with tap water. Live closed oysters were positioned in a steamer basket and placed into the pot containing boiling water without touching the water surface. Temperature probes were placed in the oyster digestive tissue through a drilled and sealed hole in the flat shell half. The pot was covered with a lid and oysters were steamed for 8 min.

Broiling and baking: During broiling and baking oysters were opened, the upper shell removed, and placed on a metal baking sheet. Thermometer probes were positioned inside the digestive tissue and a tablespoon of butter placed on top. For broiling, the sheet was put into a pre-heated oven set to the grill heater at 250°C, ~8 cm below the heat source at the top of the oven. For baking, the sheet was put into a pre-heated oven at 225°C (top and bottom heat). Oysters were left in the oven for 8 min (broiling) or 10 min (baking).

Barbecue: During the barbecue treatment, the temperature sensors were placed in the digestive tissue of opened oysters. The oysters were put on a small 30x25 cm disposable charcoal barbecue lit 20 min before the trial and temperature was measured for 8 min. Ambient temperature was 20°C.

Broth trial: Oysters were opened, and the soft parts removed from the shell. Thermometer probes were placed in the digestive tissue and the oyster soft parts put into porcelain cups of 250 mL capacity, at room temperature. Broth was brought to a boil and 100 mL were poured into the cups holding the oyster soft tissue. Temperature was monitored for 5 min.

Boiling water: Oysters were opened, and the soft parts removed from the shell. Thermometer probes were placed as above, and the soft parts placed in a steamer basket. Salted water (1 L) was brought to a boil in a metal pot and the heat was turned down so that water was slightly simmering throughout the experiment. The steamer basket holding the oysters was lowered into the simmering broth and the temperature was measured for 5 min.

Temperature development was measured by two digital thermometers each with two K temperature sensors (Thermocouple ET-959). The thermometer displays were filmed throughout each experiment. At least eight replicates prepared in separate batches were analysed per heat treatment, except for baked and boiled oysters with only six replicates.

(Continued on next page)

Results

The highest temperatures were recorded during steaming, broiling and submersion in boiling water. Steamed and boiled oysters were at >90°C after 6 and 4.5 min, respectively. Broiling at 250°C, lead to 78°C when oysters were visually considered ready. Lowest temperatures were observed in oysters on a small disposable barbecue or covered with broth. Temperatures in broth peaked at 56°C and barbecued oysters reached 37°C-68°C, depending on placement on the barbecue. Consequently, both barbecuing and broth-heating would not lead to norovirus inactivation. Virus may be inactivated only in steamed oysters or in boiling water, while baking and broiling shucked oysters in the oven for ≥10 min should increase food safety as well. Steaming for >8 min or broiling and baking at 250°C for ≥10 min is suggested to reduce the number of infectious norovirus, even though this might lead to a less sensory acceptable product with a decline in taste and texture after prolonged heating.

Conclusion

As the highest temperatures were recorded during steaming, broiling and submersion in boiling water, these heating methods would give the best reduction of NoV infectivity, if present. Of all the heating methods boiling water lead to the most rapid temperature increase. Lowest maximal temperatures were observed in oysters on a small disposable barbecue or covered with broth, and both heating methods would not lead to norovirus inactivation. Future analysis of contaminated oysters for assessing infectivity of norovirus would be preferable for more accurate temperature recommendations.

Introduction

The production of farmed Atlantic halibut has stagnated with an average production of 1686 tons/year since 2007 (Statistics Norway, 2020). One of the major bottlenecks hindering the expansion of the industry is the slow growth rates of halibut above 1kg (grow-out phase), linked to the low feed intake rates observed. Ingestion of feed requires appetite stimulating signals such as visual, olfactory, and physiological sensation of hunger. The amount of feed ingested is eventually limited by the filling capacity of the stomach and generally appetite decreases during feeding as satiation (fullness of the stomach) increases (Brett, 1971; Grove et al., 1978). After ingestion of a meal, the food in the stomach is mechanically and chemically digested before it is gradually evacuated from the stomach and enter the intestine for further digestion, followed by absorption, and assimilation of nutrients. The effectiveness of digestive processes is affected by several parameters, including fish size (Flowerdew and Grove, 1979), water temperature (Brett and Higgs, 1970), meal size and type of food. Halibut appetite varies on a day-to-day basis, and it has been observed that it prefers to eat a small meal the day after a large meal (Tuene and Nortvedt, 1995). This suggests that halibut may have a relatively slow gastric evacuation time, negatively affecting the time to next meal. In this study we investigated the gastric evacuation time for 3 different Atlantic halibut sizes using different pellet sizes.

Material and methods

Three size groups (1, 2 and 3 kg) of Atlantic halibut in duplicates were randomly allocated to 12 tanks with a bottom surface of 4.9 m^2 supplied with fresh seawater with a mean temperature of 8.9 °C and 91 % O_2. After the acclimatization period of 14 days, where the fish were hand fed every day using a commercial diet (Hippo Express, Skretting, Norway), the halibut were deprived of food for 120 hours to ensure no feed residuals were present in the gastrointestinal tract (Davenport et al., 1990)Hippoglossus hippoglossus L., eat larger satiation meals (mean 11.7% body weight. The fish groups were then fed a single meal *ad libitum* with respective pellets sizes (7, 9, 13 and 17 mm), and 3 fish were sampled from each tank at 1, 3, 6, 10, 23, 32, 48, 71, 96 and 120 hours after feeding. The content of stomach, pyloric caeca, midgut and hindgut were collected as well as information regarding the round weight, fork length, sex and weight of gonads, liver and heart. Content of the gastrointestinal tract compartments were dried for 48 h at 105 °C and the dry weight normalised to the fish weight.

Results and discussion

The maximal meal ingested by any fish was 1.1 % of body weight. However, there was a large variability, and some fish did not ingest any feed despite 120 hours of fasting. Preliminary analysis of the data indicates a negative relationship between pellet size and feed intake (measured at 1h). To determine the optimal feeding frequency for Atlantic halibut, gastric evacuation time should be accounted for, since satiation is mainly affected by the fullness of the stomach (Brett, 1971; Grove et al., 1978). In our study, the dry weight of the stomach content was reduced to 50 % at 14 hours after feeding and 25 % after 23 hours (Figure 1). This result might explain the variable day-to-day feed ingestion levels observed in commercial halibut farms and the results obtained by Tuene and Nortvedt (1995). The content of the pyloric caeca and midgut reached the highest dry weight at 23 hours, and hindgut at 71 hours. No feed residuals were observed in the gut at 120 hours which corresponds with previous observations (Davenport et al., 1990). This study provides valuable information to design optimal timed feeding regimes for grow-out Atlantic halibut.

MODELLING THE RESILIENCE OF THE UK SEAFOOD SYSTEM

Alan MacDonald* and Sofia C. Franco

Scottish Association for Marine Science, Scottish Marine Institute, Oban, Argyll, Scotland, United Kingdom
Email: alan.macdonald@sams.ac.uk

COVID-19 and the corresponding human response have tested the resilience of seafood supply chains (SC) (Ivanov, 2020) and the wider supply network (SN) where they sit in. The changes to global markets and trade triggered by the pandemic, coupled with factors such as national public health measures (e.g., lockdowns, COVID-secure restriction to operations) or behaviour changes (e.g., to consumer purchase patterns, workforce mobility) have forced business to quickly adapt how they operate and have placed strain on many UK seafood businesses. At the same time, businesses have been responding to systemic changes associated with the withdrawal of the UK from the EU (BREXIT). Changes following COVID-19, meant that UK shellfish and finfish aquaculture producers, for example, have had to cope with risks such as fluctuating demand and supplies due to collapsing export markets, while trying to maintain ongoing production and ensure animal welfare standards. Our ongoing work, as part of the RiseUp project, is brought to light that, to limit disruption, aquaculture businesses have employed a range of in-farm and out-of-farm strategies, from re-routing products, changing export markets, to delaying harvest time to prolong grow-out periods, amongst others. These knock-off effects highlight the relevance of considering impacts and resilience of specific industries, such as aquaculture, in the context of the wider complex SN in which it operates, and which consists of interdependencies to multiple suppliers and customers and whose long-term viability is dependent on how individual and food system resilience interact.

This study, part of the RiseUp project (www.sams.ac.uk/science/projects/riseup/), collected evidence of context of COVID-19 impacts on businesses across the UK seafood industry and the responses that were put in place to limit disruption. The aim of the work herein presented is to develop approaches that can serve to inform how to increase the resilience of the UK seafood businesses and seafood supply network to current and future disruption, by combining expert knowledge from seafood industry stakeholders, collected through interviews and a survey, with resilience modelling using Bayesian networks.

Bayesian networks (BN), directed acyclic graphs encoding conditional probabilistic relationships among variables through feedback, are powerful tools for risk analysis and decision support in real-world problems. Probabilities are set based on expert knowledge and can be updated by Bayesian inference. An advantage of using BNs are that variables can be discrete, continuous or Boolean making it easy to incorporate different data from survey and questionnaires. A new area of research has been the application of BNs to model SC resilience (Hosseini et al., 2019; Yodo and Wang, 2016), however, to our knowledge this has not been done for food SCs and SN in general. Further, we extend the resilience modelling framework by linking risks to SC businesses with mitigation/prevention strategies and concepts of resilience. Defined in Zavala-Alcívar et al. (2020), several resilience concepts (e.g., business innovation, visibility, trust, leadership etc.) help negate the impact of disruptive events. That is, improving resilience should minimise negative impacts of risks such as changes in non-tariffs barriers to trade (i.e., a BREXIT related risk) or market demand (i.e., a COVID-19 related risk). Resilience concepts are dependent on pro-active or reactive strategies. For example, visibility (resilience concept), defined as the ability to respond rapidly to disruptive events by efficiently distributing your critical resources, is likely dependent on having competent staff (mitigation/prevention strategy).

A challenge in the use of BNs to model SN is the proper identification of risks that can impact the different supply chains and the possible mitigation/prevention strategies to resist potentially disruptive events (e.g., COVID-19, BREXIT, climate change, future trade deals) (Lockamy and McCormack, 2012). To overcome this challenge, we combine findings from semi-structured interviews with results from a follow-up online survey, which asked respondents on business characteristics, business risks during times of disruption and 'business-as-usual' operating conditions, impacts of different ongoing disruptive events (e.g., COVID-19, BREXIT), their business responses and attributes and actions that they perceive to have contributed to a successful (or not) response to these shocks. First, data contextualising COVID-19 impacts and business responses, collected from interviews conducted with stakeholders across the UK seafood industry (between October 2020 and February 2021; see Franco et al. AE21 abstract for details), was used to identify business risks, corresponding attributes and actions that may buffer their impacts. Next, a different pool of industry stakeholders was asked to assess the importance of these risks and actions/attributes in an online survey. Following the methodology of Nepal and Yadav (2015) interviewees were asked to rank the detectability, occurrence and severity of risks (e.g., changes in market demand) on a 6-point Likert scale. Interviewees were also asked to rank the importance of several mitigation and prevention strategies to their business response to COVID-19 (e.g., planning and preparedness, situational awareness, capacity to innovate), as well as change in demand, costs, capacity, workforce and turnover before and after the pandemic, further to BREXIT impacts.

(Continued on next page)

We will present our ongoing work on BN development, through a schematic of the conceptual framework for modelling the resilience of the UK seafood industry at the conference and preliminary analysis of connections between risks and resilience of seafood businesses. To facilitate the analysis, risks are divided into environmental, social, economic, external and internal categories. Mitigation and presentation strategies tied to concepts of resilience are then linked to broader resilience categories. A unique property of BNs is the ability to carry out forward and backward propagation analysis, that is, model the overall resilience of a particular business sector e.g., aquaculture business or seafood importer (forward propagation), or determine the best mitigation/prevention strategies given a completely resilient SC (backward propagation). With these different views of the network, such models can provide a useful risk management tool for industries such as aquaculture to build their resilience, as well as a practical approach to inform government policy, for instance to identify unintended consequences of new policy and to support food system resilience in context of change.

Acknowledgments

The RiseUp project 'Resilience of the UK Seafood industry to COVID-19' is supported by the Economic and Social Research Council grant ref.ES/V009907/1 to Franco. The project website is accessible at www.sams.ac.uk/science/projects/riseup/ . The authors would like to extend their recognition to Seafish (www.seafish.org) and are grateful to the businesses that took part in the interviews and online surveys.

EFFLUENT-GROWN ULVA AS A FUNCTIONAL INGREDIENT FOR FARMED ABALONE: IMPACTS ON GROWTH, PHYSIOLOGY AND MICROBIOME

Introduction

Integrated Multi-Trophic Aquaculture (IMTA) represents a sustainable production method that can reduce the environmental impacts of aquaculture, facilitate diversification and increase production. Several large-scale commercial abalone farms in South Africa practice IMTA, growing *Haliotis midae* in land-based raceway tanks, interconnected with *Ulva* **in** adjacent paddle raceways using abalone effluent. *Ulva* **serves as a biofilter**, allowing water from the *Ulva* **systems to be re-circulated back to abalone tanks**, and *Ulva* is used as supplementary feed for abalone. Dietary *Ulva* supplementation has conveyed benefits to a variety of cultured animals, enhancing feed consumption, growth, product quality and health, with some of the improvements to abalone culture believed to be linked to the carbohydrate fraction of *Ulva* (Naidoo et al., 2006; Mulvaney et al., 2013; Kemp et al. 2015; Bansemer et al., 2016). The aim was to investigate the effects of (1) *Ulva* as a partial or complete replacement of formulated feed, and (2) the inclusion of *Ulva,* or specific components of *Ulva*, on feed consumption, growth, physiology and the gut microbiome of cultured *H. midae* to gain a better understanding of the functional potential of *Ulva* as an aquafeed ingredient.

Materials and Methods

To test the effects of *Ulva* as a partial or complete replacement of a local formulated feed Abfeed®S34 (diet AB) on total feed consumption, abalone (67.30±5.49g; n=10 per basket) were fed for 28 days with AB at a rate of 1.27% BW.day^{-1} or with graded levels of AB (75, 50, 25 & 0% of AB); with the balance of the feed constituting of fresh IMTA grown *Ulva* (FU). A separate one-year on farm growth trial was conducted under farm conditions to assess the extent to which AB can be replaced by FU. Abalone (51.10±3.09g; n=200 per basket) were fed AB at a rate of 0.27% BW.day^{-1} or graded levels of AB (100, 80, 70, 60 & 40% of AB) supplemented with *Ulva* (0.21% BW.day^{-1}, dry weight approximation). All treatments were offered in triplicate and growth and condition were assessed on days 112, 223 and 366.

A controlled laboratory trial was conducted to test the effects of specific components of *Ulva* on abalone (20-30g) growth, physiology and gut microbiome. Isonitrogenous diets consisting of dried *Ulva* (10% w/w; AB10U), Ulvan (1% w/w; AB1U), and glucuronic acid (0.1% w/w; AB0.1U) were formulated. Feed conversion ratio (FCR), specific growth rate (SGR), tissue glycogen, and gut microbiome was assessed around day 0, 105 and 215 and compared to abalone fed diets AB, FU, or a combination of the latter (ABFU). The bacterial microbiome was characterised by sequencing the V3-4 hyper-variable region of the 16S rRNA gene. NGS was performed on an Illumina MiSeq sequencing platform, sequence data assessed using QIIME2 (Boylen et al., 2019), reads mapped against the SILVA 16S rRNA database (Quast et al., 2013) and summarized taxonomic abundance at different hierarchical levels were assessed.

Results and Discussion

Incorporation of small amounts of fresh IMTA grown *Ulva* (25%; diet 75A25U) were shown to significantly improve total feed consumption by ca. 90%, compared with abalone fed diets AB and FU (**Error! Reference source not found.** 1). No significant differences in SGR, CF and tissue glycogen content were recorded between treatments in the 1 year growth trial, suggesting as much as 60% of a formulated feed can be substituted with FU without negatively affecting growth and condition of abalone.

The controlled laboratory trial, showed that abalone maintained on ABFU and AB0.1U had the highest SGR, significantly higher than abalone fed AB, AB10U, and FU (Fig. 2). Abalone maintained on FU alone grew at a rate not statistically different to abalone maintained on AB, suggesting farmed abalone can be maintained on a diet consisting only of FU during the grow-out phase of production. Abalone fed diets supplemented with 0.1% glucuronic acid not only had improved SGR, but significantly lower FCR than abalone fed AB; suggesting glucuronic acid may be one of the components within *Ulva* contributing towards growth. NMDS analysis of microbiome data revealed that abalone fed FU diets, and its components, produced significant associations in their intestinal bacterial communities, suggesting specific bacterial species are selected for and are associated with the digestive tract of abalone fed components of *Ulva*. Using DESeq2, several differentially abundant OTUs were identified across dietary treatments, with various bacterial genera, including members of the genus *Vibrio* found to be less abundant in the gut of abalone fed FU supplemented diets compared to AB alone. This study has demonstrated that dietary supplementation with IMTA-grown *Ulva* can reduce an abalone producer's reliance on fishmeal-based dry formulated feeds and have several other health benefits.

Introduction

Several commercial abalone farms in South Africa use *Ulva* to bioremediate farm effluent water, allowing for water to be recirculated back to abalone raceways and the *Ulva* is often used as a supplementary feed source. Despite *Ulva*'s versatility in integrated multi-trophic aquaculture (IMTA) systems, there are biosecurity concerns with using effluent grown *Ulva* as abalone feed, preventing wider adoption of this technology. To better understand the potential disease risks, this project aims to characterize the microbial and fungal communities associated with the seawater and *Ulva* obtained from an integrated abalone-*Ulva* systems (with 50% water recirculation). The findings from this study will provide critical information on biosecurity of IMTA systems, species and system health that may promote broader uptake of more sustainable aquaculture production technologies.

Materials and methods

This study was conducted on a commercial abalone farm along the south-western Cape coast of South Africa. *Ulva* and seawater samples were collected from two separate *Ulva* raceway systems. One system consisted of tanks that received seawater directly from the adjacent coastline, hereafter referred to as the seawater (SW) raceway. The other system comprised raceways receiving abalone effluent water, with 50% recirculation between the abalone and *Ulva* raceways, referred to as abalone effluent water (AEW) raceways. *Ulva* samples were collected from within each raceway, whereas the water samples were collected at the inlet and outlet of each raceway. One SW raceway (only one exists on the farm) and 4 AEW raceways were sampled in winter, summer, and spring. Culture-dependent techniques were used to assess changes in the abundance of specific bacteria on *Ulva* and in seawater using three selective media, namely Tryptic Soy Agar (TSA; a general media routinely used for isolation of marine bacteria), Thiosulfate-Citrate-Bile-Sucrose (TCBS) agar (vibrio selective), and Ulvan agar plates, where the primary carbohydrate of *Ulva* was utilized as the main carbohydrate source. The non-culture-based approach used next generation sequencing (NGS) and downstream bioinformatics analysis to describe the microbiome. The bacterial microbiome was characterised by sequencing the V4 hyper-variable region of the 16S rRNA gene, while fungi and oomycetes were identified by sequencing the ITS2 region of rRNA genes. NGS was performed on an Illumina MiSeq sequencing platform, sequence data assessed using QIIME2 (Boylen et al., 2019), reads mapped against the SILVA 16S rRNA database (Quast et al., 2013) and summarized taxonomic abundance at different hierarchical levels were assessed using MicrobiomeAnalyst (Dhariwal et al., 2017).

Results and discussion

Culturable bacterial numbers on all media types were significantly higher ($P < 0.05$) in the *Ulva* raceway systems receiving AEW when compared with *Ulva* raceways receiving seawater. Bacterial abundance on all three selective media types was also higher on *Ulva* blades sampled from AEW systems. *Ulva* appeared to have an inhibitory effect on the number of culturable bacteria in the water column, as indicated by the general reduction in bacteria recovered from seawater from the inlets to the outlets of each raceway. A total of 15 917 078 individual bacterial amplicon sequence variants (ASVs) were identified in MicrobiomeAnalyst, belonging to 203 family-, 305 genus-, and 154 species level ASV groups. The most abundant phyla detected was Proteobacteria (58%), followed by Bacteroidata (23%) and Campilobacterota (4%). The most abundant genus detected was *Vibrio* (11%), followed by *Pseudoalteromonas* (8%) and *Leucothrix* (5%). The three most prevalent ASVs at genus level in each group consisted of bacteria such as *Rhodobacteriaceae, Saprospiraceae,* and *Vibrio* (Fig.1). Various *Vibrio* sp. and *Psuedoalteromonas* were more prevalent in the water systems (inlet and outlet), whereas *Granulosicoccus*, and *Glaciecola* were more prevalent on *Ulva.* General taxa, such as *Leucothrix*, *Psychrilyobacter*, and Psychromonas were present in both the seawater as well as on the *Ulva* itself. Bacteria inhabiting the *Ulva*, or the *Ulva* itself, can release antimicrobial compounds capable of inhibiting *Vibrio* spp. and other bacteria (Long et al., 2005). This was supported in the current study (Fig. 1) as *Vibrio* spp. were prevalent in the water systems (Inlet and Outlet), but less prevalent on *Ulva*, indicating that *Ulva* is effective at wastewater treatment.

(Continued on next page)

Conclusion

This study describes the diversity and functional roles of microbial communities in an aquaculture system using next-generation sequencing. The use of advanced molecular techniques will promote a better understanding of the complex microbial communities that exist within IMTA systems, and their contribution to the health of the systems and the animals cultivated in these systems..

Introduction:
Halophyte plants such as *Salicornia ramosissima* have the ability to grown in saline soils (marginal land) and/or be irrigated with seawater. Despite the green tips of Salicornia are sold as food, the woody part is still considered a residue. However, this residue biomass is rich in valuable bio-active molecules that can be extracted using simple and affordable processing[1,2]. These compounds include hydroxycinnamic acids that may present strong antinflammatory and antioxidant effects. The present study aimed to assess the effects of *Salicornia ramosissima* biomass inclusion in diets for European seabass *Dicentrarchus labrax*. Fish immune condition during the feeding trial and the inflammatory response to inactivated *Photobacterium damselae* subsp. *piscicida* (*Phdp*) were evaluated.

Material and methods:
European seabass juveniles (mean initial weight: 7.26 ± 0.06 g) were reared at Riasearch Lda. facilities (Murtosa, Portugal). Fish were randomly distributed by 12 tanks of 350 L with 80 individuals allocated to each tank. Four diets were tested in triplicates. A commercial like diet was used as control (CTRL) whereas three experimental diets including *S. ramosissima* biomasses were formulated to have similar proximal compositions to CTRL. In the experimental diets, whole plant biomasses of *S. ramosissima* were included at three different levels: 2.5, 5 and 10% of feed (ST2.5, ST5 and ST10, respectively) and fish were given 3 meals per day, by hand until visual satiety for 62 days. To evaluate seabass immune condition, blood, plasma and head-kidney were collected from 5 fish per tank on day 34 and 62 for haematological and immune condition assessment and gene expression analysis. At the end of the feeding trial, fish were subjected to an inflammatory challenge by intraperitoneal injection with an inactivated *Phdp* (strain PP3). Blood, plasma, peritoneal cells and head-kidney samples were collected from 3 fish per tank at 4, 24, 48 and 72 hours after injection. The sampling point 62 days was used as time 0 h during the time-course study, as they represent unstimulated animals prior to inflammation.

Results and discussion:
No changes were observed among dietary treatments after both 34 and 62 days of feeding on the haematological profile. Similarly, no changes were observed among dietary treatments after both 34 and 62 days on the plasma humoral immune parameters analysed (peroxidase, anti-protease and bactericidal activities and lysozyme). However, in response to inflammation, fish fed ST5 showed a decrease of hematocrit and mean corpuscular values compared to those fed CTRL and ST10, respectively. Also, 4 hours after the inflammatory stimulus, seabass fed ST10 presented a higher concentration of leucocytes found in the peritoneal cavity in response to local inflammation (Figure 1) compared to fish fed CTRL. Head-kidney gene expression is being performed in fish sampled for all treatments and sampled times.

In conclusion, the results obtained in this trial demonstrate that the inclusion of *Salicornia ramosissima* biomasses of up to 10% can be performed successfully in diets for juvenile European seabass with no compromises to fish hematological and innate immune status. In fact, the highest inclusion level showed to improve leucocyte recruitment to the inflammatory focus (peritoneal cavity), what could be key in response to infection.

DIFFERENCES IN IMMUNE RESPONSE TO KOI HERPESVIRUS INFECTION BETWEEN KOI CARP AND AMUR WILD CARP

R. Machat, L. Pojezdal, N. Hodkovicova, H. Minarova, and M. Faldyna

Veterinary Research Institute, Hudcova 296/70, 621 00 Brno (Czech Republic)
Email: machat@vri.cz

Introduction

Koi herpesvirus (KHV) is infective agent causing emerging KHV disease (KHVD), which affecting exclusively breeds of common carp (*Cyprinus carpio*) and carp hybrids with other cyprinids (Bergmann *et al*., 2010; Hedrick *et al*., 2006). KHVD is seasonal disease, which manifests itself in temperatures of 18-28°C (Pokorova *et al*., 2005)several cases have been confirmed all over the world. At present, this viral disease is considered to be one of the most risky factors affecting populations of common carp and koi carp. Affected fish become disoriented and swim erratically with high breathing frequency, swollen gills and partially local skin lesions. The virus was isolated from the tissues of fish showing signs of the disease and subsequently cultured on koi fin (KF-1 and it is typical with high morbidity and mortality. As no treatment or vaccine has been approved in EU so far, all that remains is complete eradication of affected fish farm. KHVD causes significant economic losses, which increase need for understanding nature of the host immune reaction against it. Significant difference in susceptibility among carp breeds was observed (Piačková *et al*., 2013). In this research, we focused on differences in antiviral immune response of two common carp breeds with significantly different susceptibility to KHVD.

Material and methods

Two breeds of common carp were chosen as experimental organisms, highly KHV resistant breed- Amur wild carp (AS), and KHV susceptible breed- koi. 26 fish from both carp breeds were divided into two groups: control (10 fish) and infected (16 fish). Carps from control groups were injected intraperitoneally with virus free media. Carps from infected groups were injected intraperitoneally with dosage 10^4 TCID50/ml of KHV suspension. Both groups were kept in separated water tanks with the same temperature 23°C for 7 days. Samples of gills, spleen, and head kidney were taken at 3 and at 7 dpi (days post infection). Relative expression levels of selected genes were measured using qRT-PCR. RNA for analysis of gene expression were isolated from gills, spleen and head kidney using commercial kit (Qiagen, Germany) according to manufacturer's instructions. Further, cDNA was obtained using LunaScript RT SuperMix Kit (New England Biolabs, USA). Target cDNA was labelled by intercalating dye SYBR Green (Qiagen, Germany) and gene expression was measured at LightCycler 480 (Roche, Switzerland).

Results and discussion

Relative gene expression of several genes participating in immune response to KHV disease infection was measured in this research (Tab. 1). According our not yet published data following genes were chosen: *c9* and *b/c2* genes participating in complement cascade, genes *mx* and *vig1,* as class I interferon signalling pathway (IFN-I) products and gene encoding Fas ligand (*faslg*) activating cytotoxic reaction of cytotoxic cells like NK cells. Following data were obtained by comparison of corresponding groups of infected koi and AS and results were related to the controls.

Infected group	Gills	Spleen	Head kidney
Koi carp 3 dpi	*faslg*, c9***	-	*b/c2**
Koi carp 7 dpi	-	*faslg****	*c9*, b/c2***
Amur wild carp 3 dpi	*vig1**	*mx****	*mx**
Amur wild carp 7 dpi	-	*mx**	*mx**

Tab.1: Significant differences between relative mRNA expressions of targeted genes in gills, spleen and head kidney of fish from infected groups. This data was obtained by comparing 3 dpi koi with 3 dpi AS and 7 dpi koi with 7 dpi AS. *p<0,05, **p<0,01, ***p<0,001

(Continued on next page)

Significantly increased levels of expressions of *faslg* and *c9* genes were detected in koi gills at 3 dpi as well as overexpression of *b/c2* gene was observed in head kidney of koi at 3 dpi. Further, higher expression of *faslg* was revealed in koi spleen and upper expression of *c9* and *b/c2* was observed in head kidney of koi carp. Superior expression of products of IFN-I pathway was detected in AS. Concretely higher expression of *vig1* was observed in AS gills at 3 dpi and *mx* at 3 dpi and 7 dpi time points in spleen and head kidney of AS.

According to obtained data it seems that AS immune response to KHV infection was stronger at 3 dpi than at 7 dpi, which at least partially support data obtained by Adamek *et al*., 2019. On the contrary immune reaction in koi is, at least in spleen and head kidney stronger later during infection in the monitored factors. Moreover it seems that immune response to KHV infection of koi is based on complement cascade and cytotoxic cells in contrary of AS immune response is based at overexpression of IFN-I effectors.

Conclusion

Data acquired in this study showed interesting clue in case of the origin of Amur wild carp resistance. Nevertheless, further research is recommended to understand actual influence of possible different immune response strategy after KHV infection.

Introduction
Presently, the utilization of plant feedstuffs and oils in commercial aquafeeds arise the necessity to evaluate the effects of dietary essential fatty acids (EFA), such as arachidonic acid (ARA) and docosahexaenoic acid (DHA), and carbohydrate levels, and possible interactions between them in marine fish welfare. For that purpose, the effects of dietary ARA/DHA ratio and carbohydrate level on liver and intestine oxidative stress status, liver histology, and intestinal microbiota were evaluated in gilthead sea bream juveniles.

Material and methods
Four isoproteic (47% crude protein) and isolipidic (18% crude lipids) diets were formulated to include 18% or 0% gelatinized starch (HS and LS diets) and dietary ARA/DHA ratios of 2.3/0.3 or 0/2.6 (ARA and DHA diets). Triplicate groups of fish (initial body weight = 47.5 g) were fed each diet to satiety for 84 days. At the end of the trial, the liver and intestine of 3 fish from each tank were collected for the determination of oxidative stress parameters and liver histology. Two other fish per tank were sampled under aseptic conditions for autochthonous (mucosa) microbiota characterization.

Results
No differences in growth performance were observed between dietary treatments, but HS diets increased feed efficiency and protein efficiency ratio. The ARA diets reduced liver and intestine lipidic peroxidation (LPO), and improved liver glutathione redox status (total, reduced (GSH) and oxidized glutathione (GSSG)) when combined with HS (Table 1). In the intestine, ARA diets reduced GSSG content and oxidative stress index (OSI). DHA diets increased hepatic SOD and GR activities but in the intestine, antioxidant enzymatic activity was not affected by the dietary EFA ratios (Table 2). HS diets increased liver OSI and reduced intestinal GSSG. HS also decreased LPO values, but only in DHA diets (Table 1). HS increased liver G6PDH, GR, and GPX (only in the DHA diets) activities but in the intestine, it decreased GR and SOD activities (Table 2). Neither dietary EFA nor carbohydrates induced major histomorphology alterations in the distal intestine but HS, when combined with DHA, promoted hepatocyte hypertrophy and alterations in nuclei position (Fig. 1). Dietary ARA modified mucosa bacterial profile by reducing the number of operational taxonomic units, richness, and diversity, and promoted similarity between bacterial communities. In conclusion, a high dietary ARA/DHA ratio reduced oxidative stress (LPO) and hepatocyte histomorphological alterations.

IMPROVED GROWTH PERFORMANCE OF WHITELEG SHRIMP (*Penaeus vannamei*) USING A PHYTOGENIC FEED ADDITIVE

Alex Makol*, Tobias Aumiller and Karola R. Wendler

Delacon Biotechnik GmbH, Langwiesen 24, 4209 Engerwitzdorf, Austria
Email: alex.makol@delacon.com

Introduction

Crustacean production in 2018 reached 9.4 million tonnes, being marine shrimps dominating the production of crustaceans typically farmed in coastal aquaculture. Besides, they are an important source of earnings for a number of developing countries in Asia and Latin America. Whiteleg shrimp (*Penaeus vannamei*) is the largest produced species with 4.9 million tonnes, accounting for the 52.9% of total crusteans produced. Optimizing shrimp production performance is crucial to the success of the sector. Efficient diet formulation together with successful health and welfare management determines higher production output. As part of a proactive approach to production health and performance, the use of functional and sustainable additives, such as phytogenics, has demonstrated to be an effective tool to boost shrimp performance.

Materials and Methods

Two different studies were conducted to determine the efficacy of a new phytogenic feed additive (PFA) mixture (saponins, spices and essential oils) on whiteleg shrimp growth performance and feed efficiency. In the first one, six hundred SPF shrimps of average initial weight of 1.9±0.26 g were allocated into three groups using with four replications for each treatment in 350 L tanks. In the second one, two hundred and forty shrimps of average initial weight of 1±0.01 g were randomly allocated into three groups with four replications for each treatment in 20 L baskets. In both studies, shrimps were fed for 6 weeks the different treatments: one control group (basal diet) and two groups receiving Syrena® Boost included at 200 & 400 mg/kg of feed, respectively.

Results

After 6 weeks of feeding, results in the first study showed that shrimp survival did not differ between treatments being above 80%. In terms of growth performance, shrimps fed Syrena® Boost at both inclusion rates showed an increase of weight gain of 12.5% and 13.3%, respectively, with an increase in average daily growth (ADG) of 12.9% and 13.5%, respectively. Feed conversion ratio (FCR) was similar between treatments. In the second study, again shrimp survival did not differ between treatments being above 94% in all treatments. Shrimps fed Syrena® Boost at both inclusion rates showed again an increase of weight gain of 10.1% and 7.9%, respectively, being statistically significant ($p \leq 0.1$) at the lowest dose. ADG was also improved by 9.7% and 7.9%, respectively, again being statistically significant ($p \leq 0.1$) at the lowest dose. FCR was reduced by 3.7% and 1.7%, respectively.

In summary, these studies indicate the benefits of supplementing Syrena® Boost, a specific formulation of selected phytogenics, being efficient to promote whiteleg shrimp growth performance and to optimize feed conversion ratio. All this supporting Syrena® Boost as an ideal phytogenic product to enhance the profitability production in a cost-effective way.

OXYGENATION OF SEA CAGES AND MONITORING OF OXYGEN FLUCTUATIONS IN TWO FISH FARMS IN GREECE

P. Makridis*, A. Grimpampi, E. Kakaridi, I.E. Papadakis, and A. Bergheim

University of Patras, Department of Biology, Rio Achaias, 26504, Greece
Email: makridis@upatras.gr

Introduction

Renewal of the water in sea cages is based on sea currents. During summer and early autumn, there is a critical phase for cultured populations as temperature may rise close to the tolerance level of the fish species cultured, and there is a consequent increase of fish metabolism and the need for an increased amount of oxygen. At the same time, the available amount of dissolved oxygen in seawater is lower (Makridis et al., 2018). An additional problem is that during this period of the year, fish pens exhibit increased fouling due to epiphytic organisms, which in its turn may decrease the renewal of the water inside a fish cage.

The aim of this study was to: i) monitor the effect of aeration of the water inside two cages (with and without aeration) by measuring the oxygen concentration every 30 min inside the cages throughout the experiment, ii) take samples before, in the middle, and at the end of the experimental period and measure the expression of important digestive enzymes in liver, intestine and pyloric ceca, iii) evaluate the state of the digestive system at the same sampling points through histological examination in liver, intestine and pyloric ceca, and iv) monitor the oxygen fluctuations in four cages at Galaxidi Marine Farms A/S during one year in four cages, two with seabass and two with gilthead seabream.

Materials and Methods

A population of seabass of approximately 14 tons was split into two cages in a fish farm in Greece (Zervas Kyriazis A/S) which was situated in the Vorios Evoikos Gulf (38°39′1.26″N, 23°6′13.34″E). The cages had a circumference of 40 m and a depth of 8 m. One optical oxygen and temperature sensor was used in each cage and a third one was used as a reference outside the cages. The probes were placed at a depth of 3.5 m and took a measurement every 30 min. The air was injected to the cage through a ring of AirX (Oxyvision A/S Norway) hose. The injection of air took place in one cage in two periods per day from 13th of August to 15th of September 2014, 9-12 a.m., and 9-12 p.m. Tissue samples were taken twice from liver, gut, and pyloric ceca of fish from both cages for histology analysis fixed in 4% formaldehyde and for enzyme gene expression stored in RNA later at -80ºC. Tissues were analyzed using histological methods (embedded in Technovit 7100, cut in sections of 5 μm, stained with methylene blue/azure II and basic fuchsin). The sections were then observed through light microscopy and photographed. Lipid deposition in liver was quantified by use of ImageJ software. The expression of two genes related to lipid metabolism was studied, phospholipase A2 (PLA2) and Hormone Sensitive Lipase (HSL). Phospholipase A2 catalyzes the hydrolysis of phospholipids and serves for the initial digestion of phospholipid compounds in dietary fat, while lipase hydrolyzes stored triglycerides to free fatty acids. Real-time qPCR was performed with housekeeping genes ACTb, L17 and EF1a.

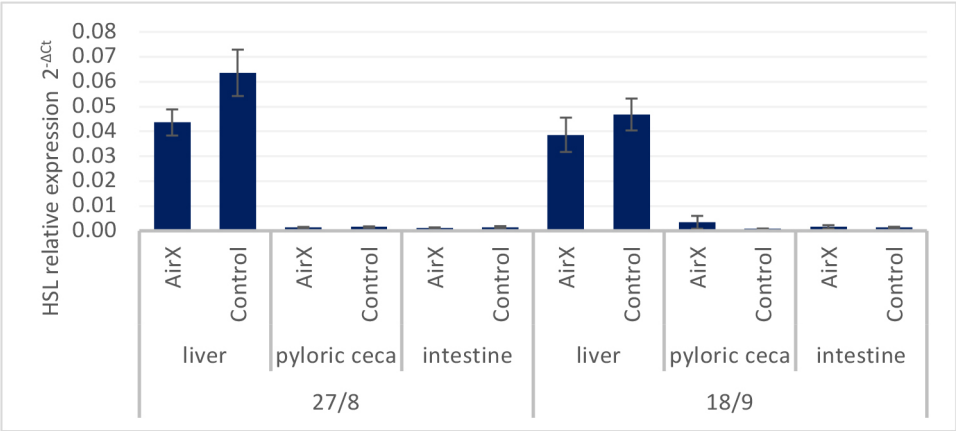

Fig. 1. Relative expression of hormone sensitive lipase in different tissues of seabass sampled during the first trial.

(Continued on next page)

In a second trial performed at Galaxidi Marine Farms A/S, four Guardian xO2 sensors (Meox A/S) for monitoring of oxygen and temperature were placed in two cages with seabass (*Dicentrarchus labrax*) and two cages with gilthead seabream (*Sparus aurata*). Data were recorded and transmitted in real-time through MEOX cloud for an 11-month period from April 2020 to February 2021.

Results and Discussion

In the first trial, the aerated cage showed a higher average oxygen saturation level and a lower FCR compared with the control cage. A higher percentage of lipid deposition was observed in liver of seabass in aerated cage compared with the control cage ($P<0.05$).

The expression of PLA2 increased in pyloric caeca samples from the aerated cage, suggesting that aeration improved the absorption rate of dietary phospholipids. Expression of HSL increased significantly in liver samples from the control cage, in comparison with the aerated cage (Fig. 1). Reduced oxygen levels induced lipolysis and mobilization of the stored triglycerides, to produce energy. The increased energy demand had negative impact on the growth rate of sea bass. A previous histological examination of the same sea bass samples revealed an increased fat accumulation in hepatocytes of fish in the aerated cage. The results of the present study confirm the lipolytic effect induced by low DO levels in farmed sea bass and induced by HSL, as has been shown in other fish species (Li et al., 2018).

In the second trial, oxygen saturation level reached 15% at different periods of the summer and early autumn indicating that there is a important problem with hypoxia in cages in the sea during the most productive period of the year.

Introduction

In aquaculture industry, among other production challenges, is the inconsistency of fish skin coloration between different batches produced. This pitfall, although in a less extend compared with more colorful fish species, can be considered for gilthead seabream (*Sparus aurata*). Pigmentation biology, species characteristics and, defects have been extensively reviewed, for gilthead seabream and Sparidae in general, by Pavlidis and Mylonas (2011). Many factors may affect seabream skin pigmentation in aquaculture, such as feed ingredients (Gouveia et al., 2002, Pulcini et al., 2020) and genetics (Bertolini et al., 2020). Moreover, in intensively reared fish species, stressors or other environmental factors substantially affect skin coloration (Pavlidis et al., 2008). Therefore, the aim of the present study was to find a proper way to analyze skin pigmentation patterns of gilthead seabream, with a view to standardize optimal coloration patterns.

Materials and methods

Gilthead seabream individuals (>350g) produced from different production sources, were purchased from the fish market. Fish were weighted and both total and standard length were measured. Twenty-five (25) spots were measured on each side of the fish (50 in total for each fish) as presented in Figure 1, with a Konica Minolta CM-600d Spectrophotometer at an 8mm target spot. CIELAB coordinates were determined for each spot. Each fish was photographed in the left lateral and frontal sides with a high-resolution digital camera mounted on a tripod in a photo box with two LED lamps (2x1890LM - 5600K). The distance between the camera and the fish was 50cm and color calibration was carried out with a Colour Checker. RGB color values were determined by randomly selecting six pixels for three images per spot and per fish, in characteristic areas of gilthead seabream (both frontal and lateral).

In order to check the integrity of testing correlation analysis was applied between both sides of each fish and the differences among different batches were tested with ANOVA at a 0.05 significance level.

Figure 1 Skin spots tested with the chromatometer

(Continued on next page)

Results

Significant positive correlation patterns between both sides were reported only for the lightness value (L) with high correlation coefficients (R^2>0.85). On the other hand, the parameters a and b (red-green, blue-yellow), correlations between both sides were weak. In general, the application of the spectrophotometer exhibited high inconsistency. RGB values, exported from the digital photographs, exhibited higher consistency and, in some cases, they could discriminate fish between batches.

Discussion

Skin pigmentation in fish is usually measured in specific body areas with a colorimeter. Digital image analysis has the advantages of examining the pigmentation of the whole body or selecting specific areas and applying uniform photography conditions. Digital photography was considered as a more accurate technique to discriminate among fish batches. The heterogeneity of the skin renders the use of the chromatometer difficult to apply, since the specific circular area of 8mm diameter includes many different colours and tones. Therefore, digital photography of the skin is an appropriate tool to study pigmentation patterns, create prototype colours and apply them in nutritional trials and selective breeding.

Introduction

The longfin yellowtail *Seriola rivoliana* has been recognized as a potential species for aquaculture diversification and as relevant for commercial farming (Sicuro and Luzzana, 2016). However, optimal culture conditions and reproduction protocols for this species are scare. Survival past the larval stage has been up until now a bottleneck in the larvae early development process and is extremely variable between reports depending on the rearing conditions (Pacheco-Carlón *et al*., 2021). The temperature has been determined as the main physicochemical factor that performs a fundamental role in producing high-quality fish larvae (Burt, Hinch and Patterson, 2011). Water temperature exerted a direct influence on the accumulation of yolk in the eggs and consequently affected the larval development events by stimulating the growth of various organs, mouth opening, initial inflation of the swim bladder and eye pigmentation of *L. peru* (Moreno Figueroa, 2011). Therefore, the accurate timing of each step of physiological development becomes critical for the fish larvae to receive their first feeding, and finally govern optimal hatchability, the highest survival rates and successive growth (Neuheimer, MacKenzie and Payne, 2018).

Consequently, the purpose of this research was to find out the optimal temperature for hatching time, survival rate, growth performance, biochemical quality and early development (eye pigmentation and mouth opening) of the Longfin yellowtail *Seriola rivoliana* larvae.

Materials and Methods

Breeders are wild-sourced fish that have been maintained in captivity for 4 years by the Mexican company King Kampachi, inside the facilities of CIBNOR, La Paz, Mexico. Fertilized eggs were obtained by natural spawning from a batch of 20 *S. rivoliana* breeders (1:1 female:male). The selected spawning (1.1 L) was obtained in August 2018 (concentration: 1821 ± 74 eggs/ml; diameter: 1.1 ± 0.002 mm).

The effect of fourteen temperatures was evaluated on the larval development of *S. rivoliana*: 16, 18, 20, 21, 22, 23, 24, 25, 26, 27, 28, 30, 32, and 34°C, all with a ± 0.3°C variation. The experiment was carried out in 100-L containers, used as temperature incubators, filled with filtered seawater. Inside each 100 L tank, 100 fertilized eggs were deposited inside six 1-L containers (to determine hatching rate and survival time) and 1 ml of eggs in six 4-L containers (to determine notochord length, growth rate, yolk sac and oil droplet volumes, mouth opening, eye pigmentation and larvae proximal composition), all filled with filtered seawater. Larvae were unfed during the experiment.

Results

The 23°C comfort temperature that showed the significantly highest hatching rate (75.5%) of *S. rivoliana* fertilized eggs. The longer survival times were observed for the larvae hatched in the 22, 24, 26, and 28°C containers, which varied from 90 hours after hatching (hah), up to 120 hah. (Figure 1).

Larvae hatched at 23°C revealed the significantly highest initial notochordal length (2.97 ± 0.02 mm). At 96 hah, only 24°C (72 CTU) larvae presented notochord sizes (2.72 ± 0.09 mm) statistically indifferent compared to the initial length (2.65 ± 0.06 mm).

(Continued on next page)

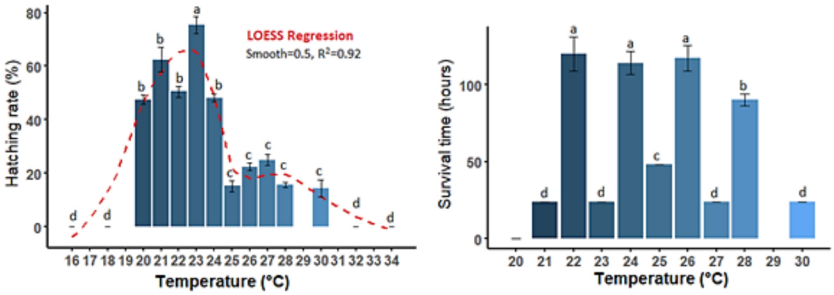

Figure 1. Hatching rate and survival time of *Seriola rivoliana* larvae cultured at different temperatures (°C). Values are given as mean ± standard error (n = 100). Different superscripts indicate a significant difference between treatments. The red dashed line represents the growth rate curve as a function of temperature, generated using LOESS regression.

The higher the incubation temperature, the faster the larvae yolk sac and oil droplet was consumed. Larvae incubated at 22°C and 24°C had a significantly higher amount of protein and lipid than larvae hatched at upper temperatures (26 and 28°C).

Larvae hatched at 24°C started to show pigmentation in the ocular area at 24 hah, while larvae hatched at 22°C presented their first eye pigmentation at 48 hah. By the end of the experiment (96 hah) larvae hatched at 24°C reached an eye pigmentation area of 76.3 ± 2.4 $\times 10^3$ μm^2 and larvae hatched at 22°C, an eye pigmentation area of 54.6 ± 1.2 $\times 10^3$ μm^2. Finally, at 96 hah, larvae hatched at 22°C (88 CTU), had significant wider lateral jaw and a larger mouth opening compared to larvae hatched at 24°C (96 CTU).

Conclusion

Thanks to this study, it can be concluded that modest changes in hatching and larvae rearing temperature can lead to large changes in the survival, growth and larval development for further feeding. According to the results obtained, we recommend incubating the eggs at 23°C to obtain the highest hatching rate. Then, increasing the temperature to 24°C (0.5°C·h^{-1}) to increase the survival rate of larvae during the first 48 hours (48 CTU) and finally reducing incubating temperature to 22°C (0.5°C·h^{-1}) in order to allow larvae to reach an optimal mouth formation for the further endogenous food intake and simultaneously, a sufficient eye pigmentation. The present results could be used for the management of this specie in the aquaculture industry, as well as provide information that would help to acknowledge the effect of temperature on the use of energy reserves at larval development of *S. rivoliana* in captivity.

A POLICY DEFINITION OF INTEGRATED MULTITROPHIC AQUACULTURE (IMTA) AS A MEANS TO STIMULATE ITS UPTAKE IN THE EUROPEAN ATLANTIC AREA

Introduction

Integrated Multitrophic Aquaculture (IMTA) is an innovative and sustainable aquaculture practice combining cultivation of species at two or more different and complementary trophic levels that ultimately minimizes waste and optimizes resources. Although application of this concept has a history of centuries in various parts of the world, commercial uptake of the concept in western aquaculture is still limited. As part of the Integrate project, we attempted to identify the bottlenecks hampering the implementation of the IMTA concept in the European Atlantic Area (Spain, Portugal, France, Ireland and the UK). In round table discussions with the main stakeholders, a common problem appeared: although the conceptual definition of IMTA was clear, a more utilitarian definition making some of the details explicit was necessary, for instance for regulatory purposes. In addition, by doing this, it would also help preventing administrations from inventing their own definitions and interpretations, something that is already happening at least at regional levels and that in the long run could easily lead to confusion and "dilution" of the original meaning of the concept. Here we explain the process we used to come to this definition and discuss its main results.

Methods

The infographic (Fig. 1) summarizes both the methods and the main results. In short, expert opinions of stakeholders (aquaculture, administration, environmental NGOs, consumers, academic, etc.) from the European Atlantic Area were recollected in three steps:

- Thematic national workshops were organised in the participating countries on the technical, economic, social/legislative and environmental aspects of IMTA.
- A questionnaire was sent out to experts from academics, industry and administration sectors.
- The organisation of an international expert workshop. Here, the results were discussed both in separate groups (one for land-based IMTA and one for sea-based IMTA) and in a plenary session.

Results

Reports with the results from the thematic workshops, questionnaire and the final workshop are all available on the project's webpage (http://integrate-imta.eu/category/downloads/).

There are widely contrasting opinions on the desirability of defining the IMTA concept, nevertheless, there was clear consensus that it is an essential step in furthering the development of the industry.

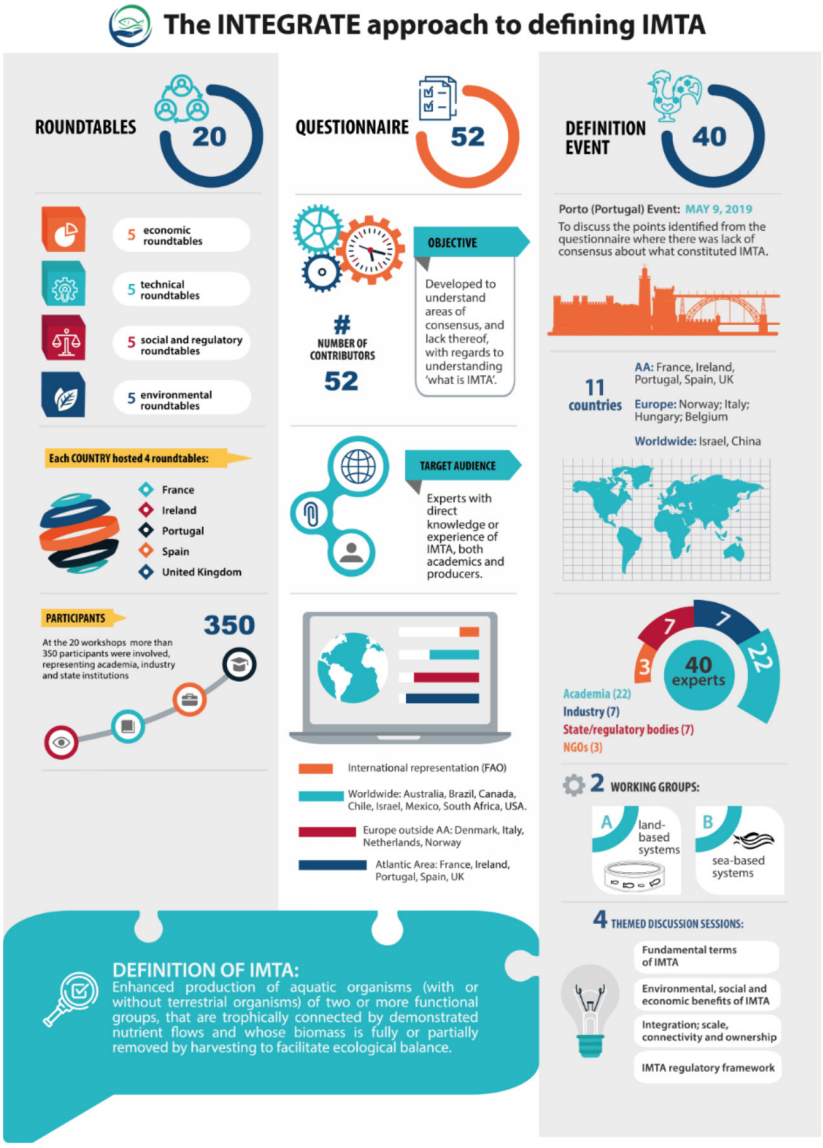
It was concluded that the definition should contain reference to the following components:

- IMTA should be principally aquatic
- Demonstrated flow of nutrients
- Between 2 (or more), managed, functional groups
- The secondary (tertiary etc.) species must be harvested

Furthermore, it was also widely felt that the definition should NOT go into details as degree of connectivity, number of species, etc. or include social or economic performance markers. Taking the above in considerations, the following consensus definition was reached:

IMTA = Enhanced production of aquatic organisms (with or without terrestrial organisms) of two or more functional groups, that are trophically connected by demonstrated nutrient flows and whose biomass is fully or partially removed by harvesting to facilitate ecological balance.

(Continued on next page)



Discussion

We are aware that defining the concept of IMTA is a topic that is not without controversy. It should be stressed that the definition has not been made for the mere sake of defining, nor that it should be interpreted as a fundamental textbook definition. Rather the aim is for it to be useful in policy terms, to facilitate funding and also to enable national governments to be better able to direct licensing among others. We will discuss the further steps that can be taken based on this definition to stimulate the commercial uptake of this concept, for instance in improving consumer acceptance of aquaculture (for instance by means of an ecolabel) and the uses it can have in integrated coastal zone management and spatial planning, topics that are currently being implemented by the Interreg AQUA&AMBI project.

GROWING SEAWEEDS FOR POLYSACCHARIDES EXTRACTS AS POTENTIAL IMMUNOSTIMULANTS IN FISH AQUACULTURE

Introduction

Research on the use of seaweeds in aquaculture feeds has been growing exponentially over the last few years. We have been building a literature database over the last few years. First publications date from the 1980s, with a total of only eight references in the past century, 19 in the first decade of this century and no less than 116 in the period 2011-2020. Moreover, 99 of these are from the last five years. Of this total of 143 references, 85 are studies on the use of seaweeds in fish aquaculture, indicating that this a topic of high scientific interest. The majority of the studies focus on the use of whole seaweed meal, mainly as a source of protein and carbohydrates substituting basically wheat, soy and to a lesser extent, fish meal, in artificial diets for aquaculture. Only in the last five years, studies started concentrating on the use of seaweed extracts as potential functional feed components, where the sulphated polysaccharides appear to be of particular interest (e.g. Coste et al., 2015).

At CTAQUA, we started the IMMUNO&ALGAE project in January 2019 with the aim to further explore the use of seaweeds in fish aquaculture as a source of functional feed compounds, in particular that can have immunostimulating effects. Objectives of the project are to optimize and upscale the cultivation of three pre-selected seaweed species from the southwest of Spain, to optimize the extraction of sulphated polysaccharides and to evaluate their use as potential immunostimulating compounds in finfish aquaculture. Seaweeds were selected based on their commonness in the area, prior experience with cultivation and their apparent potential for upscaling cultivation. In addition, the ambition was to test at least one species of each of the major seaweed groups. This led to the selection of the chlorohyte alga *Ulva ohnoi*, the rhodophyte *Gracilaria gracilis* and the phaeophyte *Dictyota dichotoma*.

The first phase of the project was dedicated to the optimization of the cultivation, to experiment with different cultivation conditions and to obtain biomass, either from culture or from harvest of wild populations, to obtain a sufficient amount of polysaccharide extract for inclusion in experimental diets. This phase is nearing completion and we here present the first results of these efforts and the next steps planned in the project.

Material and Methods

Ulva ohnoi was isolated from an earthen pond extensive aquaculture system in the SW of Spain in 2017 and maintained in culture at CTAQUA since then. The majority of the biomass (90%) used for polysaccharide extraction was grown at CTAQUA, 10% is from harvest from wild populations. Its taxonomic status has been confirmed by DNA sequence analysis. *Gracilaria gracilis* was isolated from the same earthen pond and brought to CTAQUA for cultivation trials. Additional biomass was harvested at the end of 2020 and beginning of 2021 (delay due to pandemic) for extraction. *Dictyota dichotoma* biomass was harvested from the La Caleta beach, city of Cádiz. Unfortunately, no sufficient biomass could be harvested for nutritional trials, also due to the lower percentage of polysaccharides in the algae and the potential confusion with the exotic seaweed *Rugulopteryx okumurae* that recently invaded the area.

As a first step towards cultivation, algal fronds were grown in filtered (1 µm) natural seawater under constant temperature, light and nutritional conditions in an attempt to obtain unialgal cultures. To increase the amount of clean biomass, cultivation volumes were increased stepwise from 250 mL to 5 L bottles. In the next step, algae were grown indoor in photobioreactors under LED lighting at controlled temperature, following a specific nutrient addition regime. Finally, for larger scale cultivation, outdoor tanks were deployed and cultivation was followed through an annual cycle with weekly harvests and weekly nutrient addition.

Polysaccharide extraction was carried out on dried algal biomass by the research group "Photobiology and Biotechnology of Aquatic Organisms" of the University of Málaga (Spain) using repetitive cycles of hot water extraction followed by selective precipitation, purification, flocculation and dialysis. Finally, dry extracts were obtained by lyophilization (see Abdala Díaz et al. 2019 for details).

(Continued on next page)

Results and Discussion

Clean cultivation for *U. ohnoi* was obtained at the first attempt and clean, fast-growing fronds were obtained. For *G. gracilis*, despite various attempts, including cultivation of the youngest growth tips only, cleaning with diatom sand, etc., completely unialgal cultures could not be obtained. Nevertheless, epiphyte growth could be maintained at low levels using a specific pulsed nutrient addition regime. For *D. dichotoma*, no successful cultures could be obtained and more studies are required for this species.

For both *U. ohnoi* and *G. gracilis*, steady growth was obtained in photobioreactors with growth rates ranging between 10 – 13 % d^{-1} and stable weekly biomass yields, although occasional collapses occurred in *U. ohnoi*. In a separate project, the potential relation with the algae microbiome is studied. *U. ohnoi* could be successfully cultivated in outdoor tanks all year long, with maximum biomass yields in spring (May – June) and minimum in winter (Jan – Feb). The annual cycle is still not completed for *G. gracilis*, provisional results also indicate that spring is the most favourable period, whereas in late summer growth rates decreased to close to zero, most likely due to high temperatures (≥ 30 ° degrees daily maximum temperature).

As a next step for the optimization of growth in photobioreactors and maximization of useful compounds, experimental trials are being carried out using diffent LED colours.

Polysaccharides could be successfully extracted from all algae, with the highest yields for *G. gracilis*, followed by *U. ohnoi* and *D. dichotoma*. Carbohydrate contents were considerably lower for the latter. Extracts are currently being tested for antibacterial activity. Subsequently, their potential immunostimulating effect will be tested *in vitro*, using cell line cultures and *in vivo* in a nutritional trial with sea bass. The most promising polysaccharide will finally be tested at different addition levels in a second nutritional trial, followed by a challenge study.

THE EFFECT OF DIFFERENT LIVE FEED ORGANISMS ON LARVAL BALLAN WRASSE (*Labrus bergylta)*

Introduction:
The use of cleaner fish is one important tool in the tool-box to combat the sea lice problem in salmon farming. The major proportion of wrasse used as cleaner fish by the Norwegian salmon industry is coming from capture-based activities, depleting wild stocks. Amongst the four wrasse species used, ballan wrasse (*Labrus bergylta*) is the only species which is also cultivated, though only about 30% of the approx. 3 million fish used per year is produced in aquaculture (Fiskeridirektoratet 2021). The major obstacle in wrasse cultivation preventing large scale production is the difficult first feeding phase and a lack of functional feeding protocols.

Like most marine fish larvae ballan wrasse do not accept inert diets as feed. The current solution to this problem is the use of rotifers as the first feed with a transition to artemia nauplii after about 2 weeks. The initiation of formulated diets usually takes place around 4 weeks into the life of a ballan wrasse larvae. Feeding regimes based on rotifers and artemia usually produce mixed results and are way from being optimal for the larvae (Øie, Galloway et al. 2017), and there is good evidence that effects implanted into any animal during early life history have lasting effects (Winick and Noble 1966).

Material & Methods:
In a 48-day start feeding experiment with ballan wrasse, we studied the feasibility of replacing (Phase 1) rotifers by an experimental cirriped diet or copepod nauplii (*Acartia tonsa*), and (Phase 2) replacing artemia by nauplii of the cirriped *Semibalanus balanoides*. During phase 3 all treatments received the same commercially available formulated diets. Four different treatments were studied: (1) Control: Rotifers-Artemia-Dry diets; (2) Copepods-Artemia-Dry diets; (3) Copepods-Large cirripedia-Dry diets; and (4) Small experimental cirriped diet- Large cirripeds-Dry diets. We sampled at each feed transition for a suite of different response variables such as growth, morphometry, gene expression, lipidomics, histology, and microbiology.

Results:
We found significant differences in mortality rates. Larvae started with copepods died at significantly lower rates than larvae started on either rotifers or small experimental cirripeds (Figure 1 A). The experimental cirripede diet comprised a mix of small and large cirripede nauplii at a ratio of 1:1, whereof the larger nauplii were too large for the larvae to ingest.

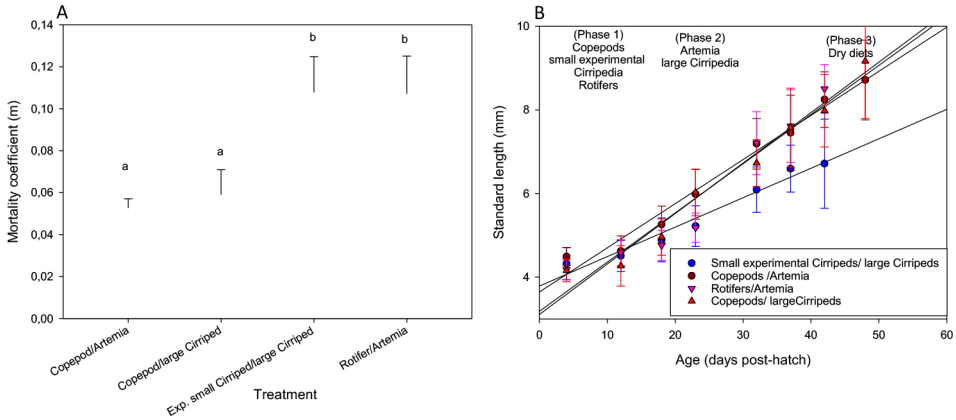

Figure 1 (A) Mortality coefficient of larval ballan wrasse (L. bergylta) fed different diets. (B) Growth in length of ballan wrasse (L. bergylta) larvae fed on different diets.

(Continued on next page)

This pattern was also reflected in early growth (Figure 1 B), copepods fed larvae grew faster than the other two groups. However, once the rotifer-started larvae were fed artemia, they picked up growth rates which were then comparable to larvae receiving copepods in the beginning. There was no pronounced difference between copepod started larvae feeding on artemia or large cirripeds during phase 2 of the experiment.

Gene expression studies at day 42 post-hatch revealed pronounced differences between the rotifer started group and the other three treatments which received natural, unenriched diets. Here, genes involved in fatty acid elongation, terpenoid biosynthesis and purine/pyrimidin metabolism were significantly higher expressed in the rotifer started group. Pronounced differences were also observed in amino acid metabolism. Within the three unenriched groups differences in gene expression were very small. Lipidomics revealed that a group of phosphatidylethanolamines (PE) correlated negative with larval growth rates, while a group of triacylglycerids (TAG) correlated positive with growth. Contrary, a group of monoacylglycerids (MAG) correlated positive with mortality rates.

Discussion & Conclusion:

The first diets in the life of the of the larvae clearly had effects on growth and mortality, but more important, clear effects of the first feed were still visible in both, gene expression pattern and lipidomics data at the end of the experiment. At this time, the larvae received other live feed organisms and the same formulated diets for three weeks. This clearly points towards a nutritional programming in larval fish, as described e.g. in mammals (Hou and Fuiman 2019). This concept opens unique opportunities to not only increase our knowledge on the importance of early life history nutrition in larval fish, but also to use this knowledge to program metabolic pathways early in the life of a fish to increase fish welfare throughout the whole lifespan.

Introduction

Temperature plays a key role in fish physiology as they cannot regulate their body temperature. As consequence, environmental thermal shifts trigger complex adaptive responses that include a wide range of physiological, metabolic and behavioral changes depending on the magnitude and time of such challenges. Gilthead sea bream, is one of the most important aquaculture species in Mediterranean basin. This species is produced under different systems such as inshore and off-shore cages, open flow land facilities and estuarine ponds. In this latter system, fish is highly exposed to severe thermal fluctuations between seasons with a special sensitivity to low temperatures in winter that triggers a specific pathological process named as "winter syndrome". Animals become lethargic and anorexic when water temperature drops close to 8ºC and lethality appears when these values are below 5ºC (Ibarz et al. 2010). Genetic breeding programs have been proven a useful approach to select animals with a better tolerance to extreme temperatures. This approach is highly sustainable to mitigate mortalities and losses in growth during winter (Charo-Karisa et al. 2005; Ma et al. 2007). The aim of this study was to evaluate the genetic estimates associated with cold tolerance of a F3-growth selected broodstock of gilthead sea bream. Heritabilities for survival at four times after an acute cold challenge were estimated. Data are relevant for genetic selection schemes to support aquaculture industry.

Materials and methods

Broodstock (males n = 32; females n = 38) used to generate families was a third generation (F3) from the PROGENSA® breeding program selected for weight at harvest. To generate families, mass spawning was induced by photoperiod modulation and eggs were pooled for four consecutive days. Hatched larvae were cultivated as previously described (Carballo et al. 2020). Animals cohabited in the same tank from larvae until performing the cold shock challenge at 248 days post-hatch. A total of 1 350 animals were randomly selected and distributed into four replicate tanks (0.640 m^3) connected to a recirculating system (RAS) equipped with a cooling, mechanical filter, skimmer, ultraviolet lights and biofilter. The number of individuals (mean weight 42.0 ± 16.1g) per tank ranged between 316 and 362. Animals were kept at 15.7±0.3 ºC (t_0) for 48 h before the challenge. Thereafter, temperature was decreased by 1.7°C per hour by setting the RAS cooler at 4ºC and adding ice made from seawater to the RAS water reservoir until reaching 8.2°C (threshold) in 4.2 h. To assess cold tolerance, more ice was added to rapidly reduce temperature below the threshold and loss of equilibrium (LOE) was set as sampling endpoint at three times: 0.5h (t_1) at 6.5º±0.3 ºC, 1.5h (t_2) 7.0º±0.2 ºC and 3.0h (t_3) at 6.5º±0.3 ºC. As temperature between t_2 and t_3 increased higher than 8ºC (LOE threshold), ice was newly added to the system between such two times. After t_3 sampling, cooler was set to 15ºC and animals were allowed for recovering and sampled 24 h (t_4) after starting the challenge. All alive fish in t_4 were considered as cold tolerant. Temperature was continuously recorded using a temperature data logger. Oxygen was always higher than 6 ppm and salinity was 37 ppt.

Weight was individually recorded in each sampling and caudal fin samples were taken for genotyping. DNA isolation, microsatellite analysis and parentage assignment were carried out as previously reported (Carballo et al. 2020). Genetic estimates were calculated using animal models fitted by REML in WOMBAT. Tank replicates were used as fixed factors. Cold tolerance was treated as a binary trait for cumulative LOE vs non-affected fish at each sampling point (t_1, t_2, t_3, t_4). Weight was added as covariate. Heritability (h^2) was transformed to the underlying liability scale according to Dempster and Lerner (1950).

Results and discussion

No mortality or disease signs were evident before the challenge. Animals displayed a normal swimming behavior at temperatures higher than 8ºC. The LOE was observed at temperatures lower than 7.2. Cumulative LOE ranged between 13.2 and 18.2% at t_1, 28.2-43.6% at t_2 and 50.6-60.4% at t_3. No additional mortality or behavior alterations were registered between t_3 and t_4 and hence the last sampling time was discarded for genetic estimates. Mean weight of sampled fish for LOE at each time point increased progressively from 33.6±15.2 g at t_1 to 40.6±15.1g at t_3. Mean weight of tolerant fish sampled at t_4 was 48.3±15.4 g. Genotyping assigned 85% individuals (n = 1 156) to a unique parent pair comprising 130 families that contained between 3 and 22 individuals. Familial variability for cold tolerance (t_3) ranged between 31 and 79%.

(Continued on next page)

Heritability estimate for weight was low (0.159±0.049). A similar heritability was observed in a study of our group four young seabream juveniles (Carballo et al. 2020), however, higher values (0.32) were obtained by Navarro et al. (2009) for a similar age. Our broodstock was a F3-growth selected generation for weight at harvest with a lower genetic variability explaining such differences. With respect to cold tolerance after an acute challenge, heritability on the liability scale ranged between 0.204±0.070 for t_3 and 0.225±0.092 for t_1. Previous genetic studies that evaluated tolerance as survival by cooling-degree-hours in long experiments found a wide range of heritabilities from 0.08 to 0.32 (Charo-Karisa et al. 2005; Ma et al. 2007). Interestingly, genetic correlations between weight and cold tolerance were positive and ranged between 0.230±0.244 for t_1 and 0.391±0.205 for t_3. Moderate-high positive correlations between cold tolerance and body weight or length are consistently observed in fish supporting that selective breeding for growth in sea bream could also improve on cold tolerance in the selected broodstocks.

Introduction

Senegalese sole is one of the most important aquaculture species in Southern Europe. However, its production is not yet sustainable since F1 broodstocks, unlike wild breeders, has no reproduction success. Artificial fertilization has been identified as a potential solution although currently it is limited by the low volume of sperm produced and the high individual variability in sperm quantity and quality (Beirao et al. 2009). Thus, more knowledge is required about the role of temperature and hormonal therapies. Physical factors such as temperature (García-López et al. 2009) and hormonal therapies such as the dopamine inhibitors (DIs) combined or not with gonadotropin-released hormone (GnRHa) (Guzman et al. 2011) have been reported as modulators of spermatogenesis and milt production . In this study, the effects of two DIs, metoclopramide and sulpiride, and the interaction with GnRHa were assessed in soles cultivated under weekly thermocycles. Sperm production and quality parameters were evaluated using Computer Assisted Sperm Analysis (CASA). Results are highly relevant to standardize artificial fertilization in sole.

Material and methods

A total of 27 male F1 breeders (mean weight = 684.6 ± 243.3 g) were randomly selected from genetic breeding program of CUPIMAR company. These animals were cultivated in open flow at constant temperature (20ºC) and moved to a 12 m^3 tank attached to a recirculation system (RAS) to apply the thermocycles. A total of 18 females (mean weight 1242.5 ± 436.6 g) were also added to simulate a functional broodstock unit. Before handling, fish were anesthetized with 2-phenoxyethanol (300 ppm) and males were evaluated for sperm production. In the RAS, initial temperature was set at 20 °C and then decreased 1ºC d^{-1} until 15 °C. Thereafter, four thermocycles ranging from 15 to 18ºC were applied as follows: 2 d at 15ºC, 2 d increasing 1.5 ºC d^{-1} until 18ºC, 1 d at 18ºC and 2 d decreasing 1.5 ºC d^{-1} until 15ºC. Hormonal treatments with DIs were applied in the thermophase of each cycle (always on wednesday). Three groups were established: 1) control (CTRL) injected with the carrier PBS (n = 9); 2) sulpiride, SUL (n = 9; 20 mg kg^{-1}); and 3) metoclopramide, MET (n = 9; 2 mg kg^{-1}). In the last thermocycle, five males of each group (CTRL, SUL and MET) were also injected GnRHa (25 μg/kg) remaining four animals as negative control. Sperm was collected in the fourth thermocycle at 48 h after hormone injection and immediately diluted 1:3 in Marine freeze®. Sperm evaluation was carried out at 3 h using IVOS II™ CASA system at 15 s after activation. In addition, sperm quality was also evaluated at 24 h for the motility parameters using the ISAS-CASA software. Statistical differences were examined using a GLM with DI groups and GnRHa stimulation as fixed factors in SPSS v25.

Results and Discussion

No mortality or sign of stress were observed during the trial. Before trial, only three out of 27 males (11.1%) were fluent. After four thermocycles and hormonal treatments, 70.4% of fish (nineteen out of 27 males) were spermiating. Statistical analysis did not show significant differences in the number of spermiating fish between DI and GnRH injected fish with respect to the PBS-injected CTRL indicating that thermocycles had a major role in the activation of sperm production in sole.

The volume of sperm collected for each animal ranged between 5 and 50 µl (average 16.2 ± 13.2 μl) without significant differences among DI- or GnRHa-treated groups. With respect to cell concentration and total spermatozoa production, no significant differences associated with DI treatments were found. However, GnRHa injection modified both traits with a significant interaction DI □ GnRHa. Soles from SUL group and injected with GnRHa increased significantly cell concentration (3.3-fold) and total spermatozoa (7.6-fold) with respect to non-GnRHa injected fish. In contrast, soles from the CTRL or MET groups injected with GnRHa remained as unresponsive and they did not modify or even reduced cell concentration (1.9-fold in the MET group) or total spermatozoa (2.8-fold in CTRL group) with respect to those non-GnRHa injected fish.

(Continued on next page)

Effects of hormones on sperm motility were similar to those obtained for sperm quantity parameters. While no significant differences associated with DI treatments were found, GnRHa injection increased values of total motility (TM) and progressive motility (PM) traits with a significant interaction DI GnRHa. GnRHa-injected fish from SUL group increased significantly TM (3.0-fold) and PM (4.0-fold) with respect to non-GnRHa injected fish. Moreover, GnRHa increased PM in fish from the MET group (1.5-fold) with respect to non-GnRHa injected fish. The CTRL group remained as unresponsive to GnRHa injection. With respect sperm velocities, GnRHa injection increased VCL and VSL in fish from MET and SUL groups (between 1.3- and1.6-fold) but not in CTRL with respect to non-GnRHa injected fish. All these data indicate the important role of DIs to modulate the response of GnRHa to enhance sperm production and quality.

When the effects of hormonal treatments on sperm quality were evaluated 24h after sperm collection, all parameters drastically dropped with an average loss of 72.1% and 65.7% for TM and PM, respectively and 27.6% and 16.4% for VCL and VSL respectively. It should be noted that PM and VSL reduction in fish from the SUL group (85 and 33.8 %, respectively) was significantly higher than CTRL group (58.3 % and 0.8 %, respectively). Nevertheless, the differences in such parameters associated with GnRH-injection in SUL and MET for were still observable after 24h.

In conclusion, thermoperiod increased the rates of fluent males. Moreover, SUL treatments improved the responses of GnRH to enhance spermatogenesis and improve sperm quality. The extender or did not preserve the sperm of hormonal treatments quality after 24h.

THE INTERNATIONAL AQUACULTURE FEED FORMULATION DATABASE (IAFFD): NUTRIENT FORMULATION TARGETS FOR DIFFERENT PRODUCTION SYSTEMS

Lukas Manomaitis*, Dominique P. Bureau, Neda Nemati, Sirri Kayhan

United States Soybean Export Council (USSEC)
541 Orchard Road , #11-03 Liat Towers, Singapore 238881
LManomaitis@ct.ussec.org

The United States Soybean Export Council (USSEC) has worked for over 35 years with the aquaculture industry worldwide to promote a profitable, responsible, feed-based aquaculture industry while specifically promoting the use of United States soy products in aquaculture feeds. One of the primary targets for USSEC are aquaculture feedmills, as this is where soy enters aquaculture production value chain. USSEC identified a critical weakness in the aquaculture industry that generally does not exist in the terrestrial livestock industry, namely the availability of a standardized feed formulation database. Since 2014 USSEC has partnered with others in the aquaculture nutrition space to create the first known standardized aquaculture feed formulation database, now known as the International Aquaculture Feed Formulation Database (IAFFD).

Now entering v7.0, the IAFFD contains almost 700 feed ingredients in the Feed Ingredient Composition (sub) Database (FICD), and the Aquaculture Species Nutritional Specifications (ASNS) (sub) database has information on 31 species at different age groups (typically six for fish and four for crustaceans). This database has been made freely available to the public to help improve aquaculture feed formulation approaches and is available at www.IAFFD.com. It was envisioned that this database would be used for training purposes, and as a reference, but increasingly we are seeing the database being adopted, in full or in part, as an actual database by commercial industry

There are many novel characteristics to the IAFFD, but one of importance is that an attempt is being made to link target nutrient levels in the ASNS to specific production systems. Similar to how different species and different life stages may require different nutrient levels, it is anticipated that different production systems, from extensive to highly intensive (such as Recirculating Aquaculture systems, or RAS) may require different nutrient targets for optimal performance. As this approach is developed it will be important to get input from industry for what important parameters need to be considered to allow more targeted nutrient levels and what additional ingredient information may be needed. For example, in RAS it may be important to target faster growth and a different energy/protein level due to the cost of the production system and desired body conformation, and to add information on ingredients that quantifies their impact on water quality.

AN OPTIMISED NON-ACTIVATING MEDIUM FOR SHORT TERM STORAGE OF BARRAMUNDI *Lates calcarifer* MILT

Introduction

A reliable milt storage procedure is a critical requirement for the use of advanced reproductive techniques for farmed barramundi (*Lates calcarifer*). Specifically, integrating artificial fertilization within current barramundi selective breeding programs would eliminate challenges to efficient family production seen with the current mass-spawning approach (e.g. skewed parental contribution and uncontrolled pairings; Robinson et al., 2010). The success of artificial fertilization lies in an ability to store and handle gametes effectively, while also ensuring that the functional and structural integrity of gametes is maintained (Beirao et al., 2019). A previous study successfully stored spermatozoa collected from wild barramundi using marine Ringer's solution as a non-activating medium (NAM; Palmer et al., 1993). However, the outcome could not be replicated when using spermatozoa collected from captive-bred individuals; the use of marine Ringer's solution leads to major cell lysis within 30 minutes of incubation. As such, the cause of cell lysis was investigated, and the NAM composition was optimized to suit the cellular requirements of spermatozoa collected from captive-bred barramundi.

Materials and methods

The ionic and metabolite composition of seminal plasma from captive-bred barramundi (n = 10) were characterized to refine the non-activating medium (NAM) composition. The effect of NAM osmolality, pH, and Na^+ and K^+ concentrations on sperm quality were then examined using methods described in Marc et al. (2021). Milt samples were collected through testicular cannulation. Sperm motility parameters were evaluated by a computer-assisted sperm analyzer (CASA; AndroVision®, Germany). Sperm viability was assessed using a dual staining method Hoechst 33342/Propidium Iodine by flow cytometry (CyanADP, Beckman Coulter, USA). To assess the effect of NAM osmolality on spermatozoa, sperm samples (n = 5) were initially diluted 1:10 in NAMs adjusted to 260, 300, 350, 400, and 450 mOsm/kg and incubated at 4 °C for 1 h. Sperm motility and sperm viability were then assessed. After determining the optimal osmolality, sperm samples (n = 10) were used to assess the effect of NAM pH (i.e. 6.5, 7.4, 7.8, 8.1, and 8.5) on sperm motility. This trial was repeated with sperm samples (n = 7) using HEPES as a replacement for $NaHCO_3$ buffering agent and sperm motility was assessed after 1 h and 24 h incubation at 4 °C. Finally, sperm samples (n = 6) were used to investigate the effect of NAM NaCl/KCl ratio (i.e. 0/190, 140/50, 160/30, 185/5, and 190/0 mM) on sperm motility. Sperm motility was assessed after 1, 24, 48, 72, and 96 h incubation at 4 °C.

Results

The viability of barramundi spermatozoa was significantly higher after 1 h incubation in NAM adjusted to 400 mOsm/kg (78.2 ± 2.9%) when compared to the original NAM at 260 mOsm/kg (44.8 ± 3.3%; $P < 0.05$). However, sperm motility did not differ significantly between NAMs and remained low (23.5 ± 2.1%). After determining the optimal NAM osmolality, the effect of NAM pH was investigated. After 1 h incubation, sperm motility was negatively affected by the increase in pH, and was only observed at pH 6.5 after 24 h incubation (11.2 ± 2.4%). Biochemical analysis of the NAMs revealed the presence and an incremental increase of pCO_2 in NAMs with a pH between 7.4 and 8.5. Therefore, to determine the intrinsic effect of pH on sperm motility, the organic buffering agent $NaHCO_3$ was replaced by HEPES. After 24 h incubation in NAM buffered HEPES, sperm motility was at the highest at pH 7.4 (35.1 ± 3.3%), followed by 7.8 (29.7 ± 3.4%). Finally, the effect of NaCl/KCl ratio was tested. After 1 h incubation in NAM buffered HEPES adjusted at 7.4, spermatozoa stored in the 185/5 mM (56.8 ± 5.0%) and 190/0 mM (56.5 ± 4.3%) showed the highest sperm motility, while sperm motility was inhibited in the Na^+ free NAM. After 24 h incubation, 185/5 mM NAM had the highest sperm motility (47.7 ± 7.2%), and was able to maintain motility for up to 72 h.

(Continued on next page)

Discussion and conclusion

The characterization of the ionic composition and osmolality of seminal plasma provided valuable insight into the potential cause of damage to spermatozoa stored in MRS (Palmer et al., 1993). The original MRS had a total osmolality of 260 mOsm/kg, which was lower than the seminal plasma osmolality (mean: 396.1 ± 13.4 mOsm/kg) of captive-bred barramundi. This difference in osmolality caused the cell lysis as sperm viability was restored when the NAM osmolality was adjusted to 400 mOsm/kg. It is therefore possible that the osmolality of seminal plasma might fluctuate according to the environment and that MRS may be isotonically balanced with spermatozoa collected from wild barramundi inhabiting brackish environments. In this study, it was found that the presence of $NaHCO_3$ in the NAM was at the origin of the sperm motility inhibition. While the sperm motility mechanism in barramundi remained to be elucidated, this finding suggest that barramundi spermatozoa might be sensitive (1) to HCO_3^- as $NaHCO_3$ dissociates into HCO_3^- and H^+ at pH 7.4 and above or (2) to Ca^{2+} as HCO_3^- ionized at high pH into CO_3^{2-}, causing Ca^{2+} to precipitate in the form of $CaCO_3$, and rendered Ca^{2+} bio-unavailable for sperm activation. Furthermore, barramundi spermatozoa appeared to require Na^+ but not K^+ in the NAM to maintain activation potential as sperm motility was rapidly inhibited in Na^+ but not in K^+ free medium. Finally, the optimized NAM containing 185 mM NaCl, 5 mM KCl, and 10 mM HEPES at pH 7.4 allowed for the first time to reliably stored barramundi spermatozoa for 2 – 3 days at 4 °C, thereby facilitating the further development of advanced reproductive technologies for the species. These results lay the foundation for further studies looking at the regulatory role played by different ions in barramundi sperm motility to further improve medium composition.

Introduction
The rapid development of aquaculture, in last decade, has made this sector one of the most important both at economic and social level gaining a main role in human nutrition (FAO, 2018). Meanwhile, the future development of aquaculture will be severely limited by the lack of proteins intended for animal feed (as a competitor of human nutrition). Fishery and aquaculture by-products can be considered as promising alternative feed ingredients for fish farming in terms of nutritional quality and availability; however these products are still underused resulting in economic and environmental issues (Gasco et al., 2020). At the same time, the need for limit the use of soy in fish diets has become necessary for the sustainability of aquaculture production. The effects of total replacement of wild fish meal, (FM) fishoil (FO) and soy product (SP) by using fishery and aquaculture by-products were tested on the growth, health and fish quality parameters of European seabass.

Materials and Method
Five experimental diets (control C, 0FM100FO, 0FMFO, 0FMFO-50SP, 0FMFO-0SP) were formulated to contain increasing levels of fisheries and aquaculture by-product, up to a total replacement of wild FM and FO and SP. Diets were administered to triplicated fish groups of 50 seabass individuals (initial weight: 75.96±19.03g). Animals were reared in RAS for 119 days until triplicate their initial weight. Specific growth rate (SGR), feed intake (FI), feed conversion rate (FCR), somatic indexes and blood plasma biochemistry were detected. Also, 30 fish fillets per diet were sampled and then stored at -80 °C. A perchloric acid extraction was performed and a high resolution 600 MHz 1H Nuclear magnetic resonance (NMR) spectrum was recorded. The assignment of all major NMR signals of the perchloric extracts was performed and a multivariate classification analysis was applied on the entire dataset to reveal metabolites important for characterizing samples according to the diets (Picone et al., 2011). Differences among treatments were considered significant at $P < 0.05$

Results
At the end of the trial, final body weight (FBW) was significant higher in fish fed C diet then 0FM100FO, 0FMFO and 0FMFO-50SP diets while in 0FMFO-0SP was the lowest. SGR was significant higher in fish fed C diet than 0FMFO, 0FMFO-50SP and 0FMFO-0SP. No significant differences in FI were detected between C and the other diets, while it was higher in 0FMFO than 0FMFO-0SP. FCR was significant lower in C diet then 0FMFO and 0FMFO-50SP diets. Viscerosomatic index and hepatosomatic index were both significant higher in fish fed 0FMFO-0SP than the other treatments while in C diet were the lowest.

Discussion
This study highlighted the possibility to total replace wild FM and FO using by-product from fisheries and aquaculture with only a marginal reduction of the overall performance and considering the positive implication on the economic and environmental impact at industrial level. In particular, when only wild FM was totally replaced by fisheries by-product no differences were recorded, while the combine replacement of wild FM and FO resulted in a performance reduction. Interestingly, the further replacement of soy products by alternative plant proteins in the free wild fish diet did not result in a decline of performance. As the fish quality is a broad and complex concept embracing many components, the metabolomics study applied in this work will provide a comprehensive descriptor consisting of a pattern of molecular components undergoing metabolic changes related to the different diets.

Introduction

Intra- or interspecific transplantation of germline stem cells (GSCs) such as spermatogonial and oogonial stem cells (SSCs and OSCs) has been recognized as an efficient tool for the conservation of genetic resources in fish (Yoshizaki et al., 2011). This methodology allows surrogate production of donor-derived gametes by the recipient individuals where the type of produced gametes (sperm or eggs) depends on the sex of the recipient fish. In our previous study, we tested the plausibility of transplanting brown trout and grayling GSCs into diploid rainbow trout recipients as a proof-of-concept which could be used for the conservation of many endangered Balkan trout species (Lujić et al., 2018)additional ex situ strategies such as surrogate production are needed. Steps required for transplantation such as isolation of high number of viable germ cells and fluorescent labeling of germ cells which are to be transplanted have been optimized. Isolated and labeled brown trout and grayling germ cells were intraperitoneally transplanted into 3 to 5 days post hatch rainbow trout larvae. Survival of the injected larvae was comparable to the controls. Sixty days after transplantation, fluorescently labeled donor cells were detected within the recipient gonads indicating successful incorporation of germ cells (brown trout spermatogonia and oogonia—27%; grayling spermatogonia—28%; grayling oogonia—23%. In the present study, we tested the plausibility of utilizing triploid rainbow trout as a surrogate for obtaining brown trout gametes, as triploid fish are generally sterile and would enable production of only donor-derived gametes after reaching maturity.

Material and methods

Three trials were conducted in order to test the plausibility of surrogate production of brown trout gametes from rainbow trout recipients. In the first trial, isolated GSCs were transplanted into all-female recipients, while in the second and third trial, GSCs were transplanted into mix-sex recipients. Donor fish in all trials were euthanized by an overdose of 2-phenoxyethanol. Gonads were removed, placed in a dissociation solution comprised of L-15, 10% FBS, 2 mg/ml collagenase I and 30 µg/ml DNase I, they were minced, and incubated for 1 h (ovaries) or 1.5 h (testes) at room temperature (RT; 23 □) on a shaking plate. The dissociation was terminated by adding an equal volume of L-15 supplemented with 10% FBS. Samples were filtered through 50 µm filters and centrifuged at 200 ×g for 10 min at 10 □. Viability was assessed by trypan blue exclusion staining.

Transplantation of brown trout GSCs into 3n rainbow trout larvae was conducted as described in Lujić et al. (2018) additional ex situ strategies such as surrogate production are needed. Steps required for transplantation such as isolation of high number of viable germ cells and fluorescent labeling of germ cells which are to be transplanted have been optimized. Isolated and labeled brown trout and grayling germ cells were intraperitoneally transplanted into 3 to 5 days post hatch rainbow trout larvae. Survival of the injected larvae was comparable to the controls. Sixty days after transplantation, fluorescently labeled donor cells were detected within the recipient gonads indicating successful incorporation of germ cells (brown trout spermatogonia and oogonia—27%; grayling spermatogonia—28%; grayling oogonia—23%. In short, three- to five-day post-hatch 3n rainbow trout larvae (approximately 33 - 36 dpf) were used as recipients. Approximately 15000 GSCs were injected into the abdominal cavity of each recipient, and the larvae were transported to the hatchery the following day where they were reared until further work. In the first trial, isolated GSCs were stained by the fluorescent linker dye PKH-26, and after 60 days, some of the recipients were dissected to visualize the incorporation of donor GSCs into recipient gonads. Further, in all trials, recipients were reared until the age of three years when their gonads were excised, and the fate of transplanted cells was determined by histological observation of gonad morphology and species-specific PCR amplification of mtDNA control region.

(Continued on next page)

For histological verification, gonad pieces of recipient fish were fixed in 10% neutral-buffered formalin, processed through standard histological procedure and embedded into paraffin. Subsequently, 5-µm thick sections were cut and stained with hematoxylin and eosin staining. For molecular analyses, gonadal pieces of recipient fish were placed in RNA later and were stored at -20 °C. DNA from each sample was isolated using First-DNA all tissue kit (Genial) according to the manufacturer's instructions and the amplification of mtDNA control region (mtDNA CR) was conducted as described in Lujić et al. (2018) additional ex situ strategies such as surrogate production are needed. Steps required for transplantation such as isolation of high number of viable germ cells and fluorescent labeling of germ cells which are to be transplanted have been optimized. Isolated and labeled brown trout and grayling germ cells were intraperitoneally transplanted into 3 to 5 days post hatch rainbow trout larvae. Survival of the injected larvae was comparable to the controls. Sixty days after transplantation, fluorescently labeled donor cells were detected within the recipient gonads indicating successful incorporation of germ cells (brown trout spermatogonia and oogonia—27%; grayling spermatogonia—28%; grayling oogonia—23%.

Results and discussion

Fluorescently-labelled GSCs transplanted into 3n recipients in the first trial were observed within the recipient gonads at 60 days post-transplantation. Incorporation rate of OSCs was 50% (5/10 individuals), while the incorporation rate of SSCs was 66.7% (4/6 individuals). These results indicate successful incorporation of both brown trout SSCs and OSCs in recipient gonads.

Histological analyses of gonads dissected from mature, three years old transplanted rainbow trout demonstrated that female recipients in all trials did not display signs of gonadal development, and that the ovaries appeared immature with dominant germ cell nests containing OSCs. Primary oocytes were not observed, while single vitellogenic oocytes were scarce. In the first two trials, brown trout-specific mtDNA CR was amplified in only one female recipient, while in the third trial it was amplified in four female recipients. These results indicate that in some cases donor GSCs were present within recipient gonads, however, they did not differentiate into functional gametes. As for testes, all males of the second trial displayed well developed spermiating testes, while in the third trial, all testes were immature, and did not display significant gonadal development. Brown trout-specific mtDNA CR was not amplified in any recipient males in any of the trials indicating that donor GSCs were not present within recipient testes.

Conclusions

In this study, we demonstrated that both SSCs and OSCs are able to incorporate into 3n rainbow trout larvae. However, after rearing the recipients for three years, we did not observe significant gonadal development indicating that the donor cells were not able to differentiate into functional gametes, even though presence of donor-derived cells was observed in ovaries of some female individuals. Therefore, based on the current study, 3n rainbow trout are not suitable recipients for brown trout surrogate production.

Introduction
For many consumers, aquaculture is not a well-known sector of food production (Fernández-Polanco & Luna 2012). In EU, the consumers who consume fish and seafood less frequently are those who have no understanding of the information accompanying the products (Cantillo et al., 2021). Hence, increased awareness of consumers on fish farming practices and their sustainability can be one potential way to increase farmed fish consumption. To study the potential ways to increase the awareness, we assessed consumers' perceptions on the quality and quantity of current information on fish farming, and wishes for information.

Material and methods
A subcontracted market research agency conducted online cross-cultural surveys in three countries (Finland n=412 people, France n=417, Spain n= 413). The master questionnaire, developed in English and translated into national languages, included items about the participants' fish consumption, objective knowledge, information received today and wishes for more information, and socio-demographic characteristics (e.g. country, gender, age, education level). The development of the questionnaire was based on the qualitative results of focus-groups done in the earlier phase of the project (Mariojouls et al., 2021). SPSS Statistics (version 26) was used for the analysis of correlations between the frequency of fish consumption, knowledge on aquaculture and respondent's nationality.

Results and discussion
Results show that there is a relatively weak knowledge of fish farming in the three countries, as only 14% to 24% of total respondents indicated they know aquaculture 'well' or 'very well', and 33% stated that they do not know fish farming at all. Spanish population confirms having better knowledge about fish farming than Finnish or French respondents.

We asked how the consumers qualify the received information, and most respondents stated that information given is 'neutral', but much more frequently in Finland (59%), and less in France (34%), Spain being in an intermediate situation with 46%. The second qualification is "mostly positive" in Spain (23%) and Finland (18%), while it is "mostly negative" in France (25%). Interestingly, the opinion of 'sufficient information' is expressed by a larger share in Finland (23%) and Spain (20%) than in France (10%), and among males (22%) compared with women (16%). The answer 'no opinion' was chosen by 24% of respondents in both Finland and France, and 20% in Spain.

Results show a clear interest of respondents for receiving information about fish farming and most respondents consider it as useful. Spanish respondents are the most interested (84% for the total 'very useful' and 'useful'), followed by Finnish respondents (70%), and French respondents (67%).

While in the three countries the available information about fish farming is considered insufficient by most of the respondents, the starting point for communication is not the same:

France has the strongest share of consumers expressing they have no knowledge about fish farming (40%) and that information about fish farming is insufficient (61%). The overall profile is characterized by low knowledge and an opinion on available information as neutral or negative.

Spain has the largest share of consumers having some knowledge about fish farming (only 24% knowing 'not at all'), but they also mostly consider that available information is insufficient (60%) while 20% say it is sufficient. The overall profile is a relatively high level of knowledge, and an opinion of a rather good quality of available information.

(Continued on next page)

Finland is an intermediate situation: the respondents with no knowledge about fish farming represent 34% of total population, there is the highest share of total respondents saying the available information is sufficient (23%). The overall profile is characterized by a relatively low knowledge about fish farming and an opinion about available information being neutral or positive, while the need for receiving information is less high than in Spain and France.

Conclusions

There is a rather low consumer awareness about aquaculture and the specific production system practices. Understanding of the knowledge gaps and consumer perceptions will benefit to design actions to increase awareness about aquaculture. Informed consumers could be more positive towards the emergence of new and sustainable production approaches, without being misled by the negative information that may follow when new technological advantages in food production are adopted.

SUSTAINABLE RECIRCULATING AQUACULTURE SYSTEMS: FROM PREDICTIVE ANALYTICS TO INTELLIGENT PHOTONIC PLATFORM

Carlos Marques, et al

i3N & Physics Department, University of Aveiro, Portugal

In the last decade, aquaculture production in intensive systems have been rising rapidly, often using RAS with limited water exchange. The benefits of RAS are the reduced fresh and saltwater usage, reduced land requirement due to the high stocking density, reduced wastewater effluent volume, increased biosecurity by effectively treating disease outbreaks, and independence from weather and variable environmental conditions. RAS satisfy the objectives of European Union for sustainable aquaculture by producing food while sustaining natural resources with a minimum ecological impact [1]. However, RAS are complex systems where fish biomass and water chemistry/quality interact and small variations may result in sub-optimal conditions, inducing stress, reduced feed intake and may result in reduced growth performance or mortalities [2]. This is a major concern for the industry which needs to be addressed by scientific community.

In order to produce quality fish and promote their wellbeing, the effective and POC monitoring of fishes' stress and water quality is key. Even though there have been remarkable developments in aquaculture, the quality assessment of the water and the fishes' welfare is still based on water and fish sample analysis, and its management is still empiric. The industry is now appealing for technology for POC, real-time monitoring, as well as artificial intelligence and machine learning (ML) tools to prevent catastrophic events (i.e. fish death, diseases prediction).

When analyzing the pros and cons of the available technologies applied to real-time aquatic media monitoring, photonics, and more specifically optical fibers, add great advantages to the equation. Naming just a few, fiber optics offer: immunity to electromagnetic interference, very small size, lightweight, light path control, remote sensor deployment, high transmission rate, multiple sensors working in different wavelength regions just on a single fiber, the use of biocompatible and biofunctionalized materials, inert nature enabling them to have minimal impact on the environment.

Sharp increases of cortisol can indicate that the fishes are under stress. Therefore, the aquaculture industry wants to quantify real time cortisol content in the water, so far this has not been incorporated on any type of POC solution. Cortisol measurements are still based on blood sampling and analyses of plasma cortisol after fish capture and termination, an invasive method where the results may be doubtful from the stress caused by the sampling method. In addition, the analytic method (via chromatographic techniques - laborious and expensive alternative) is time consuming and the results normally are only available long after the sampling of the fish. A successful technology for real time sensing of cortisol in water will represent a significant contribution to fish welfare and management, which has both an ethical (welfare) and economical rational (via the way stress influences mortality and growth). Such technology is particularly important in RAS farms. RAS are particularly suitable farming environments for such sensors, due to low water exchange causing higher accumulation and easier sensing of cortisol compared to flow through systems.

In parallel, the monitoring and control of ammonia levels has high priority in intensive land-based fish farms, since ammonia is toxic to fish at very low concentrations. The toxicity varies with other water quality parameters and accumulation of ammonia is the limiting factor for producing fish in RAS. This parameter is also an indicator of the biological filters performance to ensure good water quality. Hence, better control of ammonia is crucial to reduce risk, improve fish welfare and increase production and revenue from intensive farming. The existing sensors for ammonia are generally used in sewage treatment plants and do not give consistent values in saltwater systems. Also, analytical lab techniques are available such as spectrophotometry methodologies but these are time consuming and require organic solvents. Moreover, there is a lack of available technology to add sensor elements directly in water tanks and to have real time measurements.

Those are the reasons for the choice of these substances as wellbeing indicators. It is crucial to be able to control and regulate the intricate water chemistry, to maintain optimal equilibrium, which is so sensitive in RAS, due to high fish biomass, high growth rate and low water use.

(Continued on next page)

As regards data collection and processing, a wireless technical platform will be developed to be flexible and easy to adapt to different tank environments and setups and minimize interference with daily fish and tank management. A cloud-based data handling, processing and storing platform, via a user-friendly graphic interface on e.g. mobile phone and PC, will secure a unique overview of critical parameters, and give quick time response and high probability event predictions and allow for consequent corrective actions and regulation. Moreover, this type of continuous logging and accumulation of a broad set of environmental data (ammonia and cortisol) may be linked together with other environmental parameters (e.g. O2, pH, CO2, Redox, temperature collected by aquaculture industry) and production data (growth, mortality, % feeding, feed conversion ratio, stocking density, etc.) to develop strong management and planning tools based on multi-modal data analyses and artificial intelligence.

As is well known by the aquaculture industry, large databases are increasingly common and are often difficult to interpret. However, in data sets with many variables, there may be the possibility to create subgroups of these that have a common effect. This is possible as there may be more than one variable that may be measuring the same driving principle that governs the behavior of the entire system. A proper investigation should not aim to only identify these driving forces but also detect redundancy of information and simplify data analysis by replacing a group of variables by just one [3].

Currently, the absence of such POC sensors or the use of unsuitable sensors, preventing accurate visualization and treatment of data in real time, make it difficult to construct predictive models. This can be done with the implementation of the smart POC in-water non-invasive solutions, which will follow the global evolution associated with Internet of Things (IoT), allowing real time and wireless data communication from the tanks to the control center and online platforms.

In this paper we will review the state-of-the-art done in this matter to have the first smart multi-modal sensing platform (cortisol, ammonia and new progress in bacteria and nano-plastics detection) [4-8] for monitoring the wellbeing and quality of farmed fish in tanks in a noninvasive/nonintrusive way allied with predictive analytics tool.

E-mail: catia.marques@ipma.pt

Introduction

Meagre (*Argyrosomus regius*) has been considered, in last decade, as one of the most promising fish species for aquaculture, in Mediterranean countries, and has even been described as the "Southern salmon" by some, due to its fast growing and processing potentials[1,2]"ISSN":"00448486","abstract":"A performance trial (88days.

Since 2009 several research projects have been developed, at the Aquaculture Research Station of Olhão (EPPO), to address questions related to meagre rearing, including the capture in the wild, adaptation to captivity, breeding procedures, larval feeding protocol development and larval and juvenile rearing [1,3–6]"ISSN":"00448486","abstract":"A performance trial (88days. One of the most important questions raised along the years was the optimal rearing temperature for this species, and although the normal spawning temperature rounds the 20ºC, the optimal rearing temperature, for larvae and juvenile, seems to be situated a couple degrees above, which makes meagre a suitable species to rear in recirculation systems (RAS), at higher and controlled temperatures. Another relevant question that has been addressed in trials conducted over the last years, was the optimisation of protein requirements for meagre farming.

In this work we present an overview of the trials conducted on meagre, tackling optimal protein and temperature requirements for this species.

Materials and methods

Meagre breeders were kept in 10m^3 or 50m^3 tanks in a flow through water system with controlled temperature, constant aeration, under a regime of 10 h light:14 h dark. Fish were manually fed *ad libitum*, with a commercial feed (SPAROS) and supplemented every two days with frozen seafood (mackerel and squid). Larval trial: eggs were distributed immediately after hatching in 250L tanks, with a density of 1 larvae/L. Temperatures were kept at 18, 21 and 24 ºC. Fish were fed *ad libitum*, with a commercial diet (Caviar®, BernAqua) until they reach 12mm. Growth and survival parameters were taken daily and samples for larval ontogeny, IGF1 expression and digestive enzymes were collected; Post-larval trial: fish were distributed at the density of 1 fish/L in 300 L tanks. Temperatures were kept at 20 and 24ºC and fish were fed *ad libitum* with a commercial diet (SPAROS). Biometric samplings took place every five days and density was adjusted to 1.5 Kg/m^3, except for the final sampling, that occurred when the fish reach the density of 5 Kg/m^3. Fish size dispersion was accessed and samples for IGF1 gene expression, histology and microbiology were collected. For the juvenile trials fish were distributed in homogenous groups (triplicates) in tanks of 1500L: 1) temperature of the tanks were kept at 20 (LT) and 24ºC (HT) and fish from the two groups were fed, *ad libitum* 3x a day, with isolipidic diets containing either 48 (LP) or 52% (HP) of protein (SPAROS) until doubling their initial weight; 2) temperature of the tanks were kept at 22 (LT) and 26ºC (HT) and fed, *ad libitum* 3x a day, with isolipidic diets with different protein content and origin: CP50 (24.5% fish meal – FM – and 25.5% vegetable origin proteins – VP), CP55 (28% FM and 27% VP) and CP55 ALT (7% FM, 21% VP and 27% poultry meal – PM) (SPAROS), combined in 4 treatments (LTCP55, HTCP50, HTCP55 and HTCP55 ALT). Both juvenile trials were conducted until fish doubled their initial weight. Growth parameters, survival and feed conversion rate were calculated and samples for fatty acids, gene expression, skeletal development and histology, were collected.

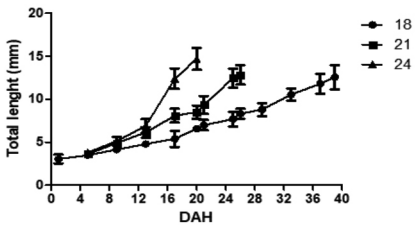

Figure 1 -Growth rate of meagre larvae reared at 18 (*circle*), 21 (*square*) and 24ºC (*triangle*). DAH, *days after hatching*.

	Treatments		ANOVA (*p-value*)[1]
	LT CP55	HT CP55	T[a]

(Continued on next page)

Results and Discussion

For both larvae and juveniles, it was shown that the optimal rearing temperature for meagre is around the 24ºC with fish presenting a fast growth at this temperature (Figure 1). Additionally, a higher rearing temperature had no negative impact on the normal development, with fish presenting a proper external morphology and organ development.

Specific growth rate (SGR) and protein efficiency ratio (PER) were significantly higher in the HPHT treatment with the higher temperature (24ºC) promoting feeding ingestion (Table I). The protein increase in the diet showed a tendency for fish protein retention with that not being affected by a lower temperature. Fatty acids content in the liver was not affected by the temperature nor the protein, however there is a decrease on muscle lipid content in the LTHP treatment. These results showed that growth and feeding efficiency were maximized at higher temperatures and that temperature is prevalent over the source and protein content in the diet, as fish growth performance was not affected by these factors when reared at higher temperatures (Table I).

CAROTENOID TISSUE DISTRIBUTION IN MALE AND FEMALE SEA URCHIN, *Paracentrotus lividus,* FED EXTRUDED DIETS WITH INCREASING LEVELS OF β-CAROTENE

Introduction

Gonads of sea urchins are considered a delicacy due to their organoleptic characteristics. The demand for this product has been rising, mostly in Europe, and consequently increasing fisheries. Aquaculture can minimise the overexploitation of natural populations, whilst assuring its availability during the whole year. Baião et al. (2019) reported high gonad yield by feeding a formulated extruded diet to *P. lividus* in captivity. Since colour is the first stimuli presented to a consumer, and a major marketability influencing factor, this characteristic is a relevant quality trait in sea urchin gonads. Echinenone is the most abundant carotenoid in the gonads and depends on availability, uptake and bioconversion of β-carotene from dietary sources. When ingested, β-carotene is transformed into echinenone, however, its metabolisation site is still controversial; Symonds et al. (2007) hypothesised a β-carotene metabolisation into echinenone in the gut wall, and then mobilisation to the gonads. Echinenone is reported as being responsible for the intense colouration in the gonads of the sea urchin (Shpigel et al. 2005). The present study aimed to investigate the response of *P. lividus* to increasing dietary levels of natural sources of β-carotene. Carotenoid distribution was hence evaluated in gut and gonads of both female and male.

Materials and methods

A control diet (CTRL) was formulated and compared with four isonitrogeneous and isoenergetic experimental diets containing two levels of *Dunaliella salina* (0.75% or 1.5%, in diets D1 and D2, respectively) as a natural rich source of β-carotene. In two of these *D. salina* supplemented diets, the commercially available macroalgae mix was totally replaced by *Porphyra* (D1P and D2P). All diets were cold extruded (<30 °C) and softly dried (<45ºC), distributed every 48h, for 8 weeks, to quadruplicate groups of sea urchins, placed in plastic mesh cages in a saltwater recirculation aquaculture system with a stocking density of 3.5 $kg.m^{-2}$; temperature 18 ºC, salinity 35‰, and a 10h L/14h D photoperiod. At the end of the growth trial gut and gonads of 8 animals per tank were sampled for carotenoid quantification by high performance liquid chromatography (HPLC).

Results and Discussion

Carotenoid content in *P. lividus*' gut differed significantly between sexes and diets. The gut content of β-carotene and echinenone increased proportionally to β-carotene dietary inclusion levels, in both sexes, but was always higher in males (**fig.1 A, B**). The gut echinenone content increased linearly with gut β-carotene content in both sexes (**fig.1 C**). Sea urchins fed diets D2, D1P and D2P resulted in significantly higher concentrations of β-carotene and echinenone in the gut than those fed D1 and CTRL. Contrarily to the gut, the dietary treatments did not affect carotenoid content in gonads, but males had always higher levels than females. Comparing both tissues, the gut had higher levels of β-carotene than gonads (10-38 μg/g *vs* 1.7-4.7 μg/g*),* irrespectively of the sex. In males, echinenone levels in gonads were higher than those detected in the gut; female echinenone levels were similar between gonads and gut, and consistently lower than males in both tissues. Echinenone gonad content presented a positive correlation with gonad's β-carotene, and in female a very significant linear relationship could be established (**fig.1 D**).

(Continued on next page)

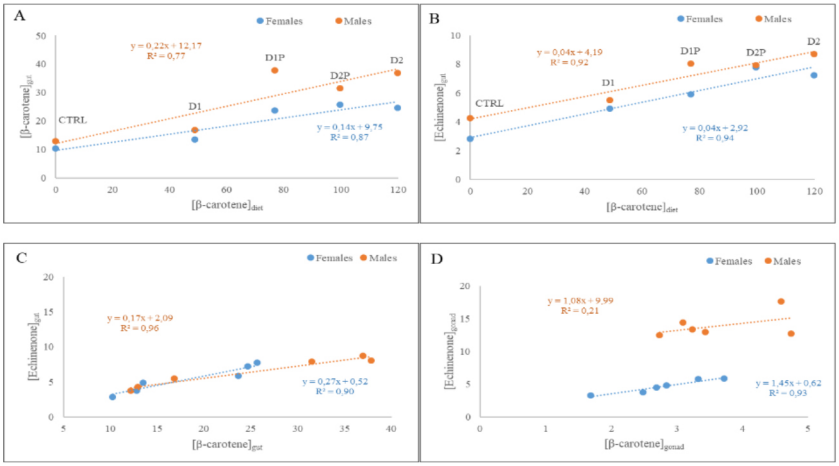

Figure 1 – Regression line between pigment concentration in diets and/or tissues in *P. lividus*. **A** – diet β-carotene vs. gut β-carotene. **B** – diet β-carotene vs. gut echinenone. **C** - gut β-carotene vs. gut echinenone. **D** – gonad β-carotene vs. gonad echinenone.

Conclusion

The inclusion of increasing levels of β-carotene in diets for *P. lividus* resulted in an effective accumulation of β-carotene in the gut, and of echinenone in a lesser extent. The deposition of echinenone in gonads was not affected by the dietary treatments and may depend on the ability of sea urchin to either mobilise pigments from the gut, or to synthesise them in the gonads from β-carotene. So the ability of sea urchins to either mobilise or synthesise those pigments in the gonads will have an important role in defining gonad quality.

HOW TO SELECT THE CORRECT GENOMICS TEST FOR YOUR BREEDING PROGRAM

E. Marques*, J. Stannard, D. Plouffe, J. Buchanan

Center for Aquaculture Technologies. 8395 Camino Santa Fe, Suite E. San Diego, California, United States, 92129. E-mail: emarques@aquatechcenter.com

Introduction

The aquaculture industry is ripe for the uptake of DNA-based technologies also known as genomics. The sector has observed and, therefore, learned lessons from the livestock industry where DNA tools are heavily applied, and genetic gains are no longer simulations on a computer screen.

Many aquaculture producers have questions and are seeking guidance to improve their genetics and implement new tools in their breeding programs. Before making recommendations, it is important to emphasize that the use of genomics will not make the need for collecting phenotypes or the need to improve a management system go away.

Economically important traits are complex in nature, which means that part of their outcome originates from improvements in genetics - through the observation of measurable traits and other breeding records - and part from improvements in management (i.e., health, nutrition), so investing in one while ignoring the other will not solve all your problems.

Genomics is just one tool in the box and does not replace good husbandry practices and a commitment at all levels of an organization to supporting the genetic improvement program.

Below are the top 3 tools (genomics and bioinformatics) that any aquaculture producer should consider investing in:

The top 3 AquaArray genomics tools:

1- Low Density (LD): for those dipping their toes in genomics without any knowledge of which populations they have (i.e., species or strains), we recommend a panel with less than 200 SNPs. It provides insights into the genetic architecture of the population and a basis for relatedness and inbreeding. This panel also allows for parentage testing, an important step in the calculation of EBVs (estimated breeding values), which is another way of saying genetic merit. Each species has its own LD panel.

2- Medium-Density (MD): If you have been investing in high-density (HD) genotyping (see below) for a while and you have a solid knowledge of how your population is structured (i.e. level of linkage disequilibrium), then you should start thinking about a medium-density panel that can be imputed to your HD dataset to save cost while maintaining precision.

3- High-Density (HD): The most powerful tool for a full-throttle, high-speed genetic improvement program. These panels have around 50,000 markers and can be used for parentage testing, genomic selection, marker-assisted selection, etc. Producers that have been, and are committed to, collecting phenotypic data are in the sweet spot for the use of this HD tool.

The top 3 bioinformatics tools:

The bioinformatics tools provide actionable insights needed to move ahead, and without them, the tools I listed above are just a bunch of As, Ts, Cs, and Gs.

Below is a list of analysis and application coming from these genomics tools:

1. A Genetic Overview (GO) Analysis: A powerful analysis that provides insights on the diversity and level of inbreeding between animals of a population. When combined with a strain ID analysis - it enables the differentiation between animals used in different production systems and markets. For example, Tilapia (the Nile vs Mozambique), Largemouth Bass (Florida vs Northern).

(Continued on next page)

2. Parentage Analysis: This analysis defines the pedigree of your animals, and it is - after you have been collecting phenotypic data – the first step for the calculation EBVs (genetic merit). It requires samples from the broodstock and its progeny.

3. Genomic Selection: At this stage, the pedigree information and phenotypic data have been collected over many generations. Here we assign a value (+ or -) for each of the thousands of markers obtained from the HD SNP panel and that information is then added to the genetic evaluation. You may have heard of the term GE-EBVs (genomic-enhanced estimated breeding values). This is a more precise estimate of the genetic merit because of the power added by the DNA information.

What's next?

Once you have decided which genomics tool best fits your needs, or you may also want to email us at info@aquatechcenter.com to discuss more, it is time to collect a biological sample. This step cannot be ignored, and a misstep here can often mean low quality DNA yield and, therefore, no results. Fin clips (for fin fish) or pleopods (for shrimp) are a great source of DNA. We guide our clients throughout sample collection and submission to ensure that we generate usable results.

What's your weakest link?

A genomic tool will only be as good as your weakest link. So, if you have not already done so, there will come a time when you need to upgrade your management program (i.e., invest in better feed, monitor for pathogens, buy bigger or more tanks, modify your layout). To put it into layman's terms, do not expect to reach the finish line by putting Porsche tires (HD tool) on your Volkswagen Beetle.

If your weakest link right now is in pathogen detection and monitoring, the best way is to couple one of the genomic tools above (LD, MD, or HD) with a panel for pathogen detection where you can choose which pathogen to test for. You may not need all of them, so it is important that you have an à al carte option rather than an 'all you can eat' buffet.

And, if you are noticing that you need help in multiple levels of your business (health, nutrition, genetics, genomics), an annual breeding contract that carries custom made recommendations would likely serve you better and qualified professionals are out there to help new entrants wade through all their options!

SUSTAINABLE AND NATURE-BASED PRODUCTS TO POTENTIALLY MITIGATE CILIATE OUTBREAKS IN TURBOT AQUACULTURE

A. Carvalho[1], M. Válega[2], A.M.S. Silva[2], I. Domingues[1], A.M.V.M. Soares[1], C.R. Marques[1,*]

Background:
Philasterides dicentrarchi is a facultative parasite which causes scuticociliatosis, a severe systemic disease leading to high mortality rates in turbot aquaculture (Budiño et al., 2001), ending up in severe economic damages. Hence, the stability of fish production in aquaculture depends on viable prevention and control measures against pathogens (Shankar Murthy and Kiran, 2013). Several measures have been attempted to manage this pathogen, with little success, as its virulence makes this task ascendingly difficult (Shin et al., 2014). Therapeutic agents previously assessed for that purpose (*e.g.*, oxyclozanide, niclosamide, and formaline; Cogliano et al. 2005) can be harmful to fish (Dai et al., 2008) and the surrounding environment, risking the health of fish and humans (Ahilan et al., 2010).

Given the side effects often associated with synthetic drugs, plant extracts have become a focus of research as treatment and prevention agents against microorganisms, due to low associated costs, biodegradability, low environmental impact, low likelihood of resistance, and minimal side effects on fish (Shankar Murthy and Kiran, 2013).

No effective measures have successfully been established to mitigate *P. dicentrarchi* growth and pathogenicity, however, it is urgent to find a mitigation plan against it, most importantly, one which would not harm the fish in aquaculture (Shin et al., 2014).

Aim:
Evaluate the bioactivity of six plant extracts as antiprotozoal agents against *P. dicentrarchi*, with the ultimate objective of verifying their potential feasibility for integrating disease control measures in turbot aquaculture. This work is within the project MAXIAQUA - *MAXimization of the strategies of control of a parasite in aquaculture of turbot*.

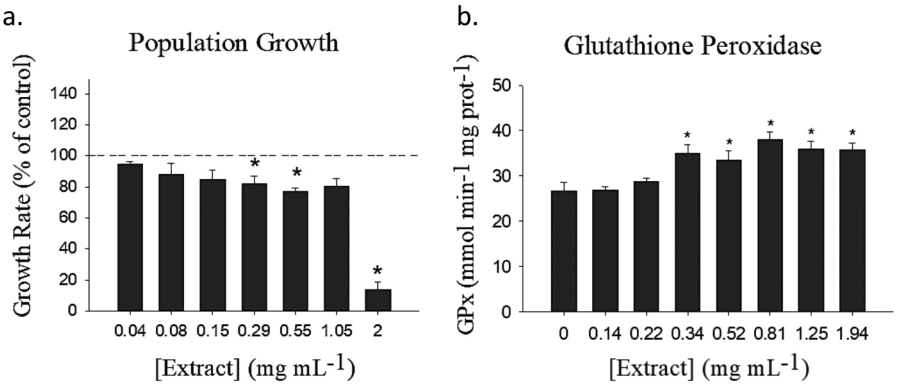

Figure 1 – Graphical representation illustrating the observed effects of one of the plant extracts analysed, on (a.) *P. dicentrarchi* population growth and (b.) glutathione peroxidase enzyme activity. Population growth results are expressed as percentage of control ± standard deviation, with control being 100%, represented by the reference line. Glutathione peroxidase results are expressed as mean ± standard error. * Significantly different from control (One-way ANOVA, Dunnett's test; $p < 0.05$).

(Continued on next page)

Methods:
Plant extracts from six plant species were obtained through the Soxhlet method. The extracts were tested against *P. dicentrarchi* and their effects on parasite populational growth, oxidative stress, and protease activity were assessed. Population growth was assessed by cell counting, the antioxidant enzyme glutathione peroxidase was used as a biomarker for oxidative stress, and protease activity was assessed using FITC-casein. Data analysis involved the application of a one-way ANOVA followed by the *post-hoc* multicomparison Dunnett's test, in order to identify treatments that induced a response significantly different than the control ($\alpha = 0.05$).

Results and Discussion:
All plant extracts, particularly at high concentrations, hindered *P. dicentrarchi* population growth (*e.g.*, Fig. 1a). Glutathione peroxidase activity was significantly affected by all plant extracts, in a non-dose dependent pattern and most extracts caused a decrease in *P. dicentrarchi* protease activity (*e.g.*, Fig. 1b).

Plant extracts affected different sub-lethal responses of the parasite, having hindered its reproduction and virulence, showing their potential as control strategies in turbot aquaculture. These findings further evidence the possible effectiveness of using plant extracts as a prevention strategy against *P. dicentrarchi* growth and pathogenicity, allowing fisheries to avoid antibiotics or such compounds which could have a toxic impact on farmed fish and their environment, which, considering these fish are produced for human consumption, would be detrimental in both health and economic levels (Voon et al., 2012).

Introduction

Worldwide, and particularly in Portugal, the production and capture of bivalve mollusks are both activities with high cultural, commercial, and economic potential (Oliveira et al., 2013; DGAV, 2020). According to FAO (2020), world aquaculture bivalve production was of 17.7 million Ton in 2018. Due to the intensification of anthropogenic activities, it has been observed an increasing abundance of chemical and biological contaminants in the marine environment (Borja *et al*., 2011). Therefore, in the view of its filtering characteristics, bivalve species are highly exposed to harmful agents (Silva & Irineu, 2008). Moreover, since these species are commonly consumed raw or low cooked by humans, they may represent an important via of pathogens exposure to humans, leading to health concerns (Anacleto *et al*., 2014). Considering this, the goal of our work was to detect and/ or identify cultivable pathogenic bacteria associated with two commercially valuable bivalve species, before and after being depurated. This preliminary study has been developed under the project SEEBug – (Development of a sensor for the fast and efficient detection of pathogenic bacteria in Bivalves) funded by MAR2020, and it intendsto identify other relevant bacterial pathogens that should eventually be considered withinbivalves microbiological monitoring programs.

Materials and methods

This study focused on *Cerastoderma* sp. and *Ensis* sp. bivalves, which were collected in Ria de Aveiro during the summer season (in July). In order to detect and isolate pathogenicbacteria two protocols were applied based on: (i) the procedures outlined in International Organization for Standardization (ISO) 16649-3, ISO 6887-1, and ISO 6887-3 standards for *Escherichia coli* detection – Protocol I; and (ii) the use of selective (Salmonella Shigella (SS), MacConkey (MC), and TCBS (Thiosulfate-Citrate-Bile Salts-Sucrose) agar) and universal (Trypticase Soy Agar (TSA)) culture media to isolate and determine the cultivable bacterial diversity colonizing bivalves – Protocol II. In Protocol I the MPN(Most Probable Number) of *E. coli* per 100g of bivalve was computed, whilst in ProtocolII the number of colony forming units (CFUs) per 100g of bivalve was counted. Isolated clones were subjected to molecular identification through sanger sequencing of 16S rRNAgene.

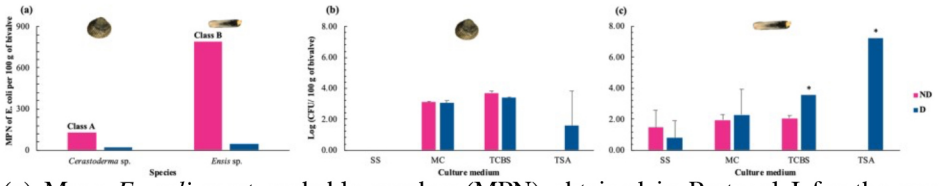

Fig. 1 - (a) Mean *E. coli* most probable number (MPN) obtained in Protocol I for the non-depurated (ND) and depurated (D) *C*erastoderma sp. and *Ensis* sp. bivalves. Logarithm (Log) of colony forming units (CFU) determined by Protocol II for (b) *Cerastoderma* sp. and (c) *Ensis* sp. Error bars represent standard deviation. (*) represent statistically significant differences ($p \leq 0.05$) between ND*vs*. D within each media.

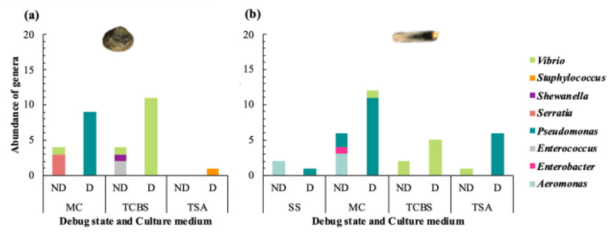

Fig. 2 - Abundance and distribution per genus of the bacterial isolated in different culture media (Protocol II) before and after the depuration process (a) *Cerastoderma* sp., for which there no growth was observed on SS agar and (b) *Ensis* sp.

(Continued on next page)

Results and discussion

Overall, it was possible to detect cultivable bacteria by using the two protocols in both organisms. Through Protocol I, according to EU (2019), the MPN of *E. coli* detected on *Cerastoderma* sp. (Figure 1(a)) before depuration revealed to be within the valuesconsidered acceptable to human consumption (130 MPN/ 100 g – class A areas). The MPNof *E. coli* present *Ensis* sp. non-depurated was within the legal limit set for Class B areas (790 MPN/ 100 g). As expected, after the depuration process a significant decrease of MPN/ 100 g was observed (Figure 1(a)), revealing the efficiency of the depuration method for *E. coli*.

Regarding Protocol II, it was also observed a decrease of CFUs after bivalves' depuration,except for *Ensis* sp., where it was verified a significant increase of CFUs in TCBS and TSA media (Figure 1(b, c)). Moreover, it was isolated other bacteria genera (Figure 2), some of them indicated as human pathogens (*e.g.*, *Pseudomonas* and *Vibrio*), which mayrepresent a public health problem. Hence, our results revealed that, although the depuration process seems to be efficient to reduce *E. coli* MPN, to other bacteria genera itmay not be the best method. Therefore, further studies are needed to detect and characterize in detail pathogenic bacteria present in bivalve mollusks.

Introduction

Pelagic fish such as sardines (*Sardina pilchardus*) is the main target of the Iberian fisheries reaching more than ten times the amount of gilthead seabream (*Sparus aurata*) or seabass (*Dicentrarchus labrax*) catches. In Portugal, there has been a decrease of the sardine stock due to prolonged low recruitment and high catch levels (Monteiro, 2017) and the impact in the economy is very serious. Thus, it is very important to find solutions to preserve and maintain the renewal of this valuable resource and the aquaculture production is one of them. Due to being one of the most commercially important species in the canning industry (INE, 2020) the interest in sardine aquaculture is growing (Bandarra, 2018) and the recent publications allows a better understanding of its physiological and ecological requirements (Silva, 2019). The increase of marine aquaculture production allows the frequent report of diseases outbreaks due to different parasites. Under aquaculture conditions, endoparasites such as the myxosporea class, are a potential harmful for marine fishes being present in several tissues (Alvarez-Pellitero, 1993). Little parasitological studies have focused on sardine and there is a lack of information about the problems that can result from a myxosporean infestation. The present study aims to report and characterize for the first time the presence of a myxosporean specie parasitizing the gall bladder of European sardine, *S. pilchardus*, maintained in captivity at the Aquaculture Research Station of Olhão (EPPO).

Material and Methods

One stock of *S. pilchardus* was obtained from commercial purse seiners and adapted to captivity at EPPO facilities. After a quarantine period, sardines were maintained in an open-system water circulation and kept under a natural light regime. After 1 year in captivity, the gall bladder of 56 sardine with an average weight of 43.8 ± 6.8 g and length of 16.6 ± 0.6 cm, was thoroughly examined for the presence of myxosporean infection in a cleaned slide by light microscopy. Free fresh spores were observed at 400x and photographed using a light microscope equipped with a digital camera. Morphometric analysis was performed from the observation of mature spores in 10 microscope fields per slide and the infestation was classified by ranks: 0 – no parasites; I – 1 to 10; II - 11 to 20; III – 21 to 100; IV – 101 to 500; V – more than 500 (parasites per slide). Infected gall bladders were preserved in 96% ethanol and stored at -20ºC for molecular analysis. The genomic DNA was extracted using a Qiagen® QIAamp DNA micro kit, following the manufacturer's instructions. The PCR was carried out in using the extracted genomic DNA and three set of primers, to amplify distinct rRNA regions. The resulting PCR product were excised from gel, purified, and sequenced.

Results and Discussion

Some mature myxospores were ellipsoidal with a length between 25-100μm and the two pyriform polar caps were oriented towards the center of the myxospore (Figure 1).

Myxospores prevalence in the sampled fish was 80%, with an infection level of II. Detection of the myxospores species DNA by PCR can be more effective than microscopic examination. Using 3 set of primers, it was possible to identify 3 distinct regions of the SSU rDNA (Figure 2). With the DNA sequence of the amplified regions, it can be possible to compare the molecular identity of the observed parasite with other myxosporean sequences, resulting in the positioning in a phylogenetic tree.

The infestation level of mature myxospores can be ranked and this classification will provide a better understanding of the pathogenic effects of this type of parasites.

Introduction

The current work focuses on an unexpected observation during the execution of a long-term experiment in which the effects of probiotic supplementation on *Solea senegalensis* culture was being tested. The initial main goal of the experimental design was to evaluate the long-term effects of prolonged intake of probiotics from the first stages of larval development to the juvenile stage. In a periodic routine sampling of the culture on day 45 after hatching, the presence of tail-rotting in some sampled animals was observed. Here, we present the results of the evaluation carried out at this experimental point after this observation, focusing on the potential beneficial effect of the tested probiotic on Senegalese sole early culture to prevent tail rot.

Material and methods

All protocols involving animals were approved (authorization number 2021-02) by the Spanish and institutional bioethical guidelines of the Animal Welfare Service following European Union Directive 2010/63/EU for the protection of animals for experimental uses and Spanish regulations (RD/2013). The initial batch of embryos for the experiment was obtained by in vitro fertilization (IVF) from F1 broodstock following the protocol described by Rasines (Rasines et al, 2013). To ensure the genetic origin of the larvae, maximizing uniformity of the experimental replicates, gametes from only one female and one male were used for IVF. The progeny was split at 1 day post hatching (dph) into six 200 L round tanks (3 per experimental condition) at a 50 larvae/L density. General culture protocol and feeding regime were based on Cañavate and Fernández-Díaz, 1999 with some modifications. Two experimental groups were created: the control group (CTRL) in which live food was enriched with a commercial product (Easy Dry SELCO®, Inve Aquaculture) and the experimental group (PROBIO) in which live food was enriched (10^{11} CFU/mL) with *Pediococcus acidilactici* MA 15/5M (Bactocell®, Lallemand). Immediately after the observation of tail rot in the 45 dph sampling, a prophylactic treatment with hydrogen peroxide was provided to all tanks to avoid deterioration of the specimens.

Cumulative mortality was evaluated daily along the experiment. Thirty fish per experimental group (10 fish/replicate) were sampled for weight at 45 dph. SGR $((\ln W_f - \ln W_0)*100/T_f-T_o)$ was used as parameter to monitor growth. After biometrical analysis, each animal was placed under a stereomicroscope and dorsal images focusing on the tail were captured. Tail areas were measured using Adobe Photoshop CC 2020. In addition to the quantitative approach, the tails were evaluated subjectively by five different people. Evaluators were given an illustrated scale with examples of severity of tail rot starting from 0 (no lesion), 1 (low; a reduction of 25% of fin tissue), 2 (moderate; 50% of tissue reduction) to 3 (high incidence, practically absence of tail fin rays). The evaluators blindly assigned each image a level of affection based on the scale with a margin of 0.5 points for each of the 60 images. The mean of the five data for each image was considered as the tail rot incidence value for the specimen.

In order to analyse the immune response generated in the fish, total RNA was extracted from 9 fish of each group (3 per tank). Each fish body was homogenized (T25 Ultra Turrax ®, IKA) in an initial volume of 1 mL of TRI Reagent® (Merck). After cDNA synthesis (2 µg; High-Capacity RNA-to-cDNA™ Kit, Applied Biosystems), the following genes were evaluated by qPCR using SYBR green master mix (Applied Biosystems): hepcidin (HAMP1), complement c3 (C3), leucocyte cell-derived chemotaxin 2 (LECT2), non-specific cytotoxic cell receptor (NCCRP1), tumor necrosis factor a (TNFA) and interleukin 1 beta (IL1B). Three technical replicates were used in the qPCR analysis. The levels of the expression of these genes were normalized to eukaryotic elongation factor 1 alpha (eEF1A) levels using the formula $2^{-(\Delta\Delta Ct)}$ (Livak and Schmittgen, 2001).

Statistical analysis was performed using SPSS 21.0. Non-parametric variables were analyzed using Mann-Whitney test. Normally distributed variables were analyzed using the student's t-test. Values with $p < 0.05$ were considered to be statistically significant. Data are expressed as mean ± SEM.

(Continued on next page)

Results and Discussion

Mortality data were globally very low at 45 dph. In both experimental groups for this time point, survival was similar and above 98%. Taking into account specific growth rate values, the statistical analysis revealed significant difference in SGR ($p = 0.0161$) indicating a slightly higher growth rate in PROBIO group. Regarding the tails, the statistical analysis showed a strong significant difference ($p < 0.0001$) between the fin area of both groups. While the CTRL group presented a mean area of 0.1893 ± 0.0518 cm^2, the PROBIO group showed a mean value of 0.3240 ± 0.0090 cm^2. These quantitative values were in line with the severity differences ($p < 0.0001$) issued by the evaluators. While in the CTRL group, the mean value of the incidence was scored with 1.8530 ± 0.0993 a.u.; in the PROBIO group the mean was 0.2500 ± 0.0528 a.u., since almost any fish showed signs of tissue reduction. Gene expression analysis corroborated that the animals in the CTRL group were undergoing an activation of their immune system with an overexpression of C3 ($p = 0.0034$) and LECT2 ($p = 0.0012$). Taking these data together, the observations recorded in this experiment indicate that the bioencapsulation of the probiotic strain *Pediococcus acidilactici* MA 15/5M in rotifers and artemia metanauplii may be a useful biotechnological tool to prevent the appearance of tail rot in the early culture of Senegalese sole.

Introduction

Mussel farming has been identified as one of the most promising food sectors that can help to meet the nutritional requirements of a growing human population while providing other ecosystem functions and services [1]. Italy, with 92,564 t in 2018, contributed to the 15% of the EU mussel production [2]. This makes Italy the third most important European producer of mussel, after Spain and France.

Mussels are filter-feeders of naturally occurring phytoplankton. As such, mussels represent the functional and trophic connection between pelagic and benthic processes, contribute to the fundamental nutrient storage and cycles, and play a key role in regulating incipient eutrophication phenomena through the top-down control on phytoplankton biomass [3].

Recently, several authors have investigated the possible contribution of farmed bivalves in mitigating the effects of climate change (i.e., increased carbon stock in seawater, CO_2) [4]traditionally considered a waste of aquaculture activities, have recently acquired an interest under the current framework of zero waste circular economy. Shell CaCO3 is a sustainable biomaterial that could partly replace the presently dominating non-renewable mineral sources in some applications. Although the carbon footprint of powdered CaCO3 production from biological or mineral sources are about the same, the environmental impact is notably different. Furthermore, bivalve CaCO3 contributes to sequester anthropogenic carbon dioxide (CO2. Mussels build their shells through the biocalcification process, incorporating chemical carbon species, i.e., hydrogen carbonate (HCO_3^-), in the form of calcium carbonate (CaCO3-) while, at the same time, releasing CO_2, according to the following equation: Ca_2^{2+} $2HCO_3^-$ $\rightleftharpoons$ $CaCO_3 + CO_2 + H_2O$. However, the role of mussel farming as a carbon sink is controversial and a scientific consensus on this topic is far from being achieved due to an open-ended debate about the definition of the criteria for the estimation of the biogenic carbon flux (e.g. mussel respiration) [5], [6]Italy. Yet, according to the Kyoto Protocol, CO_2 fluxes resulting from photosynthesis and animal respiration should not be taken into account when calculating greenhouse gasses (GHG) emissions, as they are part of the short C cycle and are balanced.

In this study, the Life Cycle Assessment (LCA) methodology has been applied to three case studies of mussel farming in the north Adriatic Sea, Italy. This study examines all the relevant fluxes of materials and energy across the systems and explores the potential role of biocalcification processes in sequestering carbon from the seawater during shell formation.

Materials and methods

The case studies investigated in this work are referred to as Class_A1 and Class_A2, and Class_B (one case study). Class_A case studies document the environmental performance of mussel farms located in Class A rearing areas, Class_B case study concerns the evaluation of a mussel farm located in Class B rearing area. Unlike mussels reared in Class A areas, those reared in Class B areas must undergo a depuration process before being placed on the market (Reg. EU 2017/625). The LCA approach follows the guidelines of [7]. *Goal and scope*: the objective of this study is to assess the environmental performance of two mussel supply chains, through the analysis of material and energy flows of the only production phase for Class_A mussels, and through both the production and treatment plant phases of Class_B mussels. In the analysis of the CO_2 flows through the systems, the flows of biogenic CO_2 resulting from the biocalcification process are also considered and computed. For this calculation, data on the shell:meat ratio, specific for each site, have been provided by the farmers. Environmental data are according to the literature [8]. A cradle-to-gate analysis has been carried out, considering the following processes: 1) mussel seeding and growing, 2) mussel harvesting and transport to land, and, only for Class_B, 3) mussel depuration in Italy and 4) in France. For all case studies, the system boundaries include the above processes and all material and energy inputs and outputs to and from the systems. The functional unit chosen is 1 kilogram of fresh mussels, including shell, suitable for sale. The *Life Cycle Inventory* is based on data provided by farmers through questionnaires and interviews (foreground data). Ecoinvent 3 database has been used to gather data about production of electricity, fuel, raw materials and transport (background data). The *Life Cycle Impact Assessment* has been carried out using the software SimaPro 9.1.0.7 (PRé Consultants), adopting the ReCiPe 2016 (H) method.

(Continued on next page)

Results and conclusions

Carbon footprint (CF, i.e., global warming impact category) of Class_A farms amounts to 0.07 and 0.13 kg CO_2 eq (case studies Class_A1 and Class_A 2, respectively). CF of Class_B farm is 0.53 kg CO_2 eq. These values do not consider the carbon sequestration potential of biocalcification. The difference between Class_A and Class_B results can be attributed to the depuration process required for the sale of Class_B mussels. For all three case studies, the factor contributing most to the environmental impacts is fuel consumption.

When considering biogenic carbon fluxes, the CO_2 sequestration associated with shell formation, net of the CO_2 released, contributes to lowering the CF. This contribution is approximately equal to the overall GHG emissions produced by Class_A farms (CF corrected for the biocalcification process = 0.01 and 0.06 kg CO_2 eq, Class_A1 and Class_A2, respectively), while it reduces the emissions of Class_B mussel production by 25% (CF corrected = 0.43 kg CO_2 eq).

The CF (including the biocalcification process) associated with the production of 1 kilogram of protein is 1.06 and 1.92 kg CO_2 eq for Class_A1 and Class_A2, respectively, and 9.87 kg CO_2 eq for Class_B. These values are much lower than those for beef production (45-210 kg CO_2 eq/kg protein) [9]aquaculture and fishery have major impacts on the environment. In order to identify the range of impacts and the most important factors thereof, as well as to identify what are the main causes of the differences between products, we analysed 52 life cycle assessment studies (LCAs, and comparable or slightly higher than those of vegetable meat substitutes (6-17 kg CO_2 eq/kg protein), potatoes (11.2 kg CO_2 eq/kg protein) and soybean (1.9 kg CO_2 eq/kg protein) [10].

In conclusion, mussel farming proves to be a sector with low environmental impacts. The positive effect of the biocalcification in incorporating CO_2 within the shell allows for an annulment (Class_A) or a substantial reduction (Class_B) of farms' GHG emissions. Given the tight correlation of shell CO_2 sequestration with the ratio of shell to meat, when this ratio increases, the overall CF potential may even assume negative values.

Moreover, since the ratio between CO_2 emitted and sequestered during the biocalcification process depends on both environmental (pH, salinity, temperature and partial pressure of CO_2) and trophic conditions, further studies could clarify whether the choice of farming site can contribute to making this ecosystem service, typical of shellfish farming, more efficient, thus improving the sustainability of the sector.

Introduction
Regulation of feed intake (FI) and reducing fat deposition, namely visceral fat deposition, is of extreme relevance in fish aquaculture, from an economic, environmental, and consumer perspective. Indeed, feeding represents more than 50% of operating costs in intensive fish farming. Thus, reducing FI without affecting growth performance may have a significant economic impact and contribute to reducing the environmental impact associated with feeding. Modifying fillet fatty-acid profile will also have a considerable implication on fish flesh quality to consumers.

Oleic acid (OA) is a monounsaturated fatty acid that has been receiving special attention as a functional ingredient in mammal diets, due to the beneficial effects in weight gain and fat deposition control by interfering with FI. Recent research in fish also provided evidence that FI is affected by OA (Librán-Pérez et al., 2014).

OA is abundant in some vegetable oils that are becoming used as an alternative to fish oil in aquafeeds. Therefore, novel aquafeeds may have altered OA levels compared to traditional aquafeeds.

However, up to now, the interplay between dietary OA and FI, fat deposition, and metabolism regulation in fish was not explored. Thus, the present study aimed to evaluate the effect of dietary OA supplementation on FI and lipid metabolism of European seabass (*Dicentrarchus labrax*) fed high-fat aquafeeds.

Material and methods
Six isoproteic diets (45% crude protein) with two different dietary lipids levels (16 and 22%) were formulated with fishmeal and cod liver oil as protein and lipid sources and supplemented with 0, 1, or 2% of OA (diets 16L:0OA; 16L:1OA; 16L:2OA and 22L:0OA; 22L:1OA; 22L:2OA). Triplicate groups of 22 European seabass (initial body weight: 21.4g) were fed with these diets twice a day to apparent visual satiation, six days a week, for 10 weeks. At the end of the growth trial, fish were bulk weighed following one day of feed deprivation. Fish continued to be fed for 3 more days, then hypothalamus and liver from 3 fish per tank were collected 3 hours after the morning meal and stored until analysis. Visceral fat and liver from another 3 fish per tank, were collected to evaluated fat deposition mechanisms.

Results
The growth of European seabass was not affected by dietary treatments. However, regardless of dietary lipid levels, OA supplementation enhanced feed efficiency by decreasing feed intake (Table 1).

Regarding lipid metabolism, dietary OA supplementation increased the hepatic G6PDH and decreased malic enzyme activity (Table 2). However, no effects on other key enzymes of fatty acid anabolism or catabolism were noticed. In the hypothalamus, the activity of lipid metabolism enzymes was not affected either by dietary OA supplementation or dietary lipid levels (data not shown).

Conclusions
Our data showed that supplementation of 1-2% DM of OA to fishmeal and fish oil-based diets lead to a reduction of feed intake by 12% in fish fed 2%OA diets and to an improvement of feed efficiency around 8%, without major impacts on the growth performance of the European seabass. Nevertheless, further analyses are needed to better understand the effect of OA in the mechanisms involved in feed intake regulation of European seabass.

Despite the crucial ecological and economic roles of mollusk bivalves, little is known about their associated microbiota members. In this context, high-throughput 16S rRNA gene amplicon sequencing was applied to assess the microbial community diversity among three tissues (intestine, hepatopancreas and gills) of shellfish species living in sympatry at Ria de Aveiro lagoon. This lagoon is one of the major shellfish harvesting sites in Portugal. The study comprehended five different bivalve species with economic value, namely the clams *Ruditapes philippinarum*, *Ruditapes decussatus*, *Venerupis corrugata* and *Solen marginatus* (razor clam), the cockle *Cerastoderma edule* and the mussel *Mytilus edulis*.

Preliminary results show that microbiota structure differed among tissues, with intestine harboring the highest number of microbial ASVs for all bivalve species. Both Chao1 richness estimates and Shannon diversity levels for gut microbiota were significantly higher in comparison with the other tissues for almost all species, with exception of *C. edule*. No significant differences in species richness were found between bivalves for hepatopancreas and gills. On the other hand, results show significantly lower Shannon diversity levels for *V. corrugata* in these organs. Gut microbiota β-diversity for the five bivalves is not only distinct compared to the other organs, but also among the mollusks themselves. Results also show a clear microbial community distinction between gills tissues of *V. corrugata* and *S. marginatus* compared to the other bivalve species. A small set of core ASVs was identified in different tissues - gills (1 ASV), hepatopancreas (2 ASVs) and intestine (43 ASVs)- suggesting a possible role of the core taxa for the ecological fitness of the hosts. Concerning exclusive genera observed, the highest numbers are presented by *M. edulis* in intestine (50), *S. marginatus* (14) and *C. edule* (12) in hepatopancreas and again *C. edule* (51) in gills. Overall, our results indicate that bivalve-associated microbes are host- and tissue-specific among sympatric bivalve species. The resulting data contribute to the deep characterization of the taxonomic diversity of the bivalves' microbial communities which is essential for the understanding of host-microbe association and its impact on bivalve physiology.

GROWTH PERFORMANCE, FEED UTILIZATION, AND TAURINE SYNTHESIS OF COMMON CARP FED DIFFERENT LEVELS AND SOURCES OF DIETARY METHIONINE

Karthik Masagounder[a*], Yuanyuan Zhou[b], Sarah He[c], and Chaoxia Ye[b]

Introduction

Methionine is involved mainly in the body protein synthesis and is a precursor for various metabolites which are essential for DNA methylation (e.g., S-Adenosylmethionine) and antioxidant defense (glutathioine, taurine). Commercially common carp feed is formulated primary with plant ingredients where methionine is often the first limiting amino acid. DL-methionine (DL-Met) and methionine hydroxy analogue (DL-2-hydroxy-4-methylthiobutyrate or DL-HMTBA and its calcium salt) are the two commonly used supplemental methionine sources in the feed production. However, their biological efficiency as a source of methionine is not the same and therefore, the correct nutritional value needs to be considered in the feed formulation to avoid any production loss. The objective of the study was to evaluate the effects of DL-methionine (DL-Met) and a methionine hydroxy analogue (MHA-Ca) on the growth performance, feed utilization and the expression of genes related to taurine and protein synthesis in juvenile common carp.

Material and methods

The experiment involved 9 diets. A basal diet was formulated to meet amino acid requirements for juvenile common carp according to NRC (2011) and Evonik recommendations, except for Met (0.49%) and Met+Cys (0.94%). For diet 2 to 4, the basal diet was supplemented with increasing levels of DL-Met at 0.1% increments (0.1-0.4%), and for Diet 6 to 9, the basal diet was supplemented with 0.1% increment levels of MHA-Ca (0.1-0.4%). The analyzed content of total and supplement Met levels were close to the planned values in all the diets. Each diet was randomly assigned to 5 replicate tanks. Each tank contained 30 fish with an average initial body weight of 3.7g. Fish were fed twice daily to apparent satiation for 8 weeks. Growth performance, feed conversion ratio (FCR), and muscle taurine content of fish were evaluated. In addition, at the end of the trial, fish liver samples (n = 6 fish per tank; 5 tanks) were analyzed for the expression of genes of enzymes (cysteine dioxygenase, CDO; cysteinesulfinate decarboxylase, CSD) involved taurine synthesis and genes of protein involved in the mTOR pathway.

Results and Discussion

Basal diet deficient in Met (0.49%) and M+C (0.94%) showed significantly lower growth rate, final body weight, FCR, protein efficiency ratio, and muscle taurine content ($P < 0.01$, one-way ANOVA). Increasing methionine supplementation significantly improved performance for both the methionine sources. Two-ANOVA test revealed the main effects due to methionine levels and sources on the performance parameters without any interaction effect between the two. Results showed that DL-Met produces better growth, body weight, FCR, protein efficiency and muscle taurine content than does MHA-Ca ($P < 0.01$). Between the two methionine sources, DL-Met fed fish exhibited higher expression genes of enzymes (CDO, CSD) responsible for taurine synthesis in the liver compared to the MHA-Ca fed group, corroborating the taurine levels found in the plasma and muscle tissue. We also found higher expression of mTOR related genes (S6 and eIF4E) by DL-Met vs MHA-Ca in the liver of fish, supporting the better growth and protein efficiency observed with the DL-Met fed fish than with the MHA-Ca fed fish.

Finally, we used multiple exponential or linear regression analysis, depending on the response of the performance parameter (body weight, growth, FCR and muscle taurine content), to compare the biological efficiency of the two methionine sources. Based on the analysis, biological efficiency of MHA-Ca was found to be only 43-52% relative to DL-Met on weight-for-weight basis (51-62% on an equimolar basis), depending on the parameters (Table 2). Overall, results demonstrate that DL-Met is a more efficient Met source compared to MHA-Ca in common carp.

Introduction

Cost of shrimp feed is largely dictated by dietary protein levels and sources. Commercial shrimp feed typically contains 35-40% crude protein (CP), depending on feed type. Shrimp, like other farm animals, don't have a true requirement for protein, but for a well-balanced dietary amino acid level. In the commercial feeds, the bulk of shrimp requirements for essential amino acids (EAA) are met through intact sources. Following ideal protein concept in formulating shrimp diets for EAA requirements using supplemental sources is slowly gaining momentum in shrimp feeds due to its potential to spare the dietary protein sources such as fish meal and thus, the dietary protein content and feed cost. The objective of this study was to evaluate the performance of whiteleg shrimp to varying levels of dietary protein balanced for amino acid profile using supplemental amino acids.

Material and methods

A positive control diet containing high dietary protein level (40%), mimicking the industry standard diet with 14% fish meal level, was formulated (D40). A set of treatment diets containing 38% (D38), 36% (D36), 34% (D34) and 32% (D32) crude protein levels was formulated by reducing the inclusion of intact protein sources such as fish meal and wheat gluten meal, while meeting our recommended amino acid levels using supplemental sources including AQUAVI® Met-Met, L-Lys and L-Thr. With this approach, the formulation cost of feed was gradually reduced with the increasing protein reduction, up to 20% between D40 and D32. All the diets were produced by a commercial feed mill in Vietnam. Analyzed crude protein and amino acid levels were close to the planned values for the diets. Four tanks (800 L water volume) were randomly allotted to each dietary treatment. Each tank was stocked with 80 shrimp (2.5 ± 0.04 g, mean ± SD). A water temperature of ~30 °C and a salinity of ~15 ppt were maintained throughout the experiment. Shrimp were fed with the respective diets to apparent satiation, 4 times daily over 56 days. Mortality was daily recorded and accounted for survival. All the shrimp were bulk weighed at the beginning and end of the experiment, and the mean weight was calculated based on the counts of shrimp. At the end, four shrimp per tank were pooled and used for body composition analysis. From the initial population, 20 shrimp were pooled and used for initial body composition.

Results and Discussion

After 56 days, survival varied from 95% to 97% with no significant differences detected among treatments. Final body weight, growth rate, feed intake, and FCR did not differ among dietary treatments (Table 1). Net protein utilization (protein gain x 100 / protein intake) showed significant improvement in shrimp fed with the diet containing 34%CP versus those fed with the diets containing 36-40% CP, showing the benefits of feeding shrimp with the amino acid balanced reduced protein diets. Diets did not affect body composition of shrimp (Table 2). We also examined intestinal morphology (n = 3 shrimp per tank) of shrimp. Villus height, villus width (D40 > others), crypt depth (D36> others) and the ratio of villus height to crypt depth (D36>D38) showed significant differences, with no clear trend to the dietary CP levels. Our study results overall demonstrate the opportunity to reduce dietary protein levels in commercial shrimp feed using supplemental amino acids.

Introduction

One of the bottlenecks in multitrophic recirculation culture systems (IMTA-RAS) of fish and macroalgae is to increase the productivity and reduce the land surface required for seaweed production. The knowledge of the effect of the fluctuations in the irradiance received by the algae along their trajectory inside the tanks on the processes of photoinhibition and growth, will contribute to increase the productivity and the elimination of nutrients by surface unit in fish-seaweed multitrophic systems.

In tanks with opaque walls, where light received by the seaweed comes from the incident light in the water surface, light attenuation along a vertical axis depends on algal biomass. The incident irradiance to the water surface (E_0) attenuates through the water columns and declines exponentially with depth. According to Lambert-Beer law the irradiance at a depth Z (E_Z) below the surface will be: $\mathbf{E_Z=E_0 \cdot exp^{(-K'Z)}}$. K' ($\mathbf{K'=K_0+K_a \cdot B_V}$) is the light attenuation constant (m^{-1}), which will be determined by the water light extinction coefficient (K_0 in m^{-1}), the seaweed biomass per unit volume (B_V in g/m^3) and the seaweed light extinction coefficient (K_a in m^2/g). In tanks with seaweed K_0 has a small relative contribution to the K' value.

The aim of this work was to determine the effect of the *Ulva* biomass and chlorophyll content on the light extinction cofficients in seaweed tanks with opaque walls.

Material and methods

Three circular tanks (64 cm diameter, 30 cm height) with bottom air injection (6 l min^{-1}) and opaque walls that received the irradiance through the water free surface were used. A height of water equal to the radius of the tank was always maintained to ensure the formation of two rotating flow cells placed, in the vertical section of the tank, at both sides of the aeration inlet. The incident irradiances in the surface of the tanks were: 1090, 476 and 183 μmol m^{-2} s^{-1} in tanks 1, 2 an 3.

Experiments were carried out with three *Ulva ohnoi* biomass (256, 512 and 768 g, which correspond to stocking densities SD 0.8, 1.6 and 2.4 kg m^{-2}). For each biomass, five PAR measurements were made every 5 cm from the surface to the deepest point of the tank (30 cm). K_0 was calculated without seaweed at different days in the tanks, and the relation between turbidity and K_0 was established (Fig. 1).

The seaweed used in each tank was acclimated during 1 week at SD 2.4. kg m^{-2}, before the experiments were made. Chlorophyll content was determined after the period of acclimation in 10 fronds of each tank with a portable chlorophyll optical meter using the method described by Masaló and Oca (2020). To carry out the PAR measurements the biomass was extracted, centrifuged and consecutively the biomass was increased from 256 to 768 g. With each biomass the PAR along the vertical axis was measured (5 measures at each depth) in the three tanks.

The chlorophyll content in Tanks 1, 2 and 3 were 102.2, 119.8 and 120.1 μmol m^{-2}, respectively (Table 1).

K' increased (Fig. 1), as it was expected, with seaweed biomass. Calculated K_a (from K_0 and K') where higher in Tanks 2 and 3 and was highly correlated with chlorophyll content (Table 1).

Results presented show that light extinction coefficients decreased with a decrease in chlorophyll concentration, indicating that tanks with a low chlorophyll concentration received more irradiation than the ones with higher chlorophyll concentration and could be photoinhibited and productivity would be negatively affected.

The knowledge of K_a for specific seaweed condition will allow to determine the light extinction coefficient in funcition of *Ulva* biomass and to estimate the PAR received by the alga fragments in each position of the tank.

THE GONADAL SOMA-DERIVED FACTOR (GSDF1) AS MARKER OF PRECOCIOUS PUBERTY IN MALE EUROPEAN SEA BASS (*Dicentrarchus labrax*)

Alessia. Mascoli *, Berta. Crespo, Joan Pizarro, Felipe Espigares, Cinta Zapater, Silvia Zanuy, Ana Gómez.

Department of Fish Physiology and Biotechnology, Instituto de Acuicultura Torre de la Sal (CSIC) 12595 Ribera de Cabanes, Castellón, Spain.

Introduction

In nature, European sea bass males reach puberty by their second year of life; however, under intensive culture conditions, the sex ratio male:female increases (3:1), males generally are smaller than females and the precocious puberty occurs as a phenotypic response to enhanced growth conditions and feed availability (Espigares *et al*., 2015). Around 20-30% of farmed male European sea bass enter puberty at one year of age (Carrillo *et al*., 1995). Puberty is associated with a progressive reduction of the growth rate with age (Taranger *et al*. 2010), that is even more marked in precocious males compared to their non-precocious counterparts during the second year (Felip *et al*., 2006), resulting in considerable economic losses in fish farms.

The gonadal soma-derived factor (Gsdf), which belongs to the transforming growth factor beta (TGFβ) superfamily, is exclusively found in teleosts and it is apparently involved in the proliferation of type A spermatogonia, with expression levels decreasing as spermatogenesis progresses (Schulz *et al*., 2010; Skaar *et al*., 2011). Therefore, it could be considered a decisive player in the onset of puberty and a possible marker for the early detection of precocious males.

Materials and methods

All the animals used for experiments were kept under natural photoperiod and temperature conditions at the Instituto de Acuicultura Torre de la Sal (IATS) facilities. Juvenile (9-months-old) European sea bass males were subjected to hemigonadectomy in September, the period when spermatogonial proliferation towards differentiation may occur in precocious males (Molés *et al*., 2011). The left testicle was extracted from each animal, frozen in liquid nitrogen and stored at -80 °C until molecular analysis. Hemigonadectomized animals were kept until the spermiation period (February), when they were sacrificed and the right gonad collected for histological analysis.

One-year-old male European sea bass kept in natural conditions were sampled every two weeks from August to November. In each sampling only the smallest 15% (Small group) and the largest 25% (Large group) fish were selected for analysis. Gonads were sampled for histological analysis or frozen in liquid nitrogen and stored at -80 °C to perform gene expression assays.

Adult specimens of male sea bass (5-years-old) kept in natural conditions were sampled monthly during an entire annual reproductive cycle.

Testes from all fish (9-months-old hemigonadectomized, 1-year-old and adult animals) were staged, according to Begtashi *et al*. (2004). Total RNA was extracted from whole testes and reverse-transcribed, and cDNAs were used as templates for quantitative real-time RT-PCR (qPCR) assays.

Results

The hemigonadectomized 9-months-old animals were classified as “non-precocious” or “precocious” when right testes remained in stage I, or reached stage IV, respectively. The *gsdf1* gene was found to be significantly downregulated in the left testes of precocious animals in September ($p < 0.05$) (Crespo *et al*., 2013).

One-year-old males from the Small group did not arrive to full spermiation and showed higher *gsdf1* expression than the ones of the Large group during all the experiment time, with significant differences in August and October. Most of the animals of the Large group spermiated the next winter.

During the annual cycle of adult sea bass, *gsdf1* showed maximum expression levels in premeiotic (immature) testis, that decreased as spermatogenesis progressed, with a slight increase in stage VI (post-spawning) in preparation for the next reproductive cycle.

(Continued on next page)

Discussion

In juvenile 9-months-old sea bass males, precocious puberty is negatively correlated with *gsdf1* expression. According to Begtashi *et al*. (2004), during their first year of life, precocious males are significantly larger than non-precocious one. Thus, in the group of 1-year-old large fish there are significantly more precocious animals than in the group of small specimens. In accordance with these results, small males (supposed not precocious) showed higher *gsdf1* expression than the large ones.

In adult males, high expression levels of the gene are only detected in premeiotic stages, suggesting a role for *gsdf1* in spermatogonial stem cells, or in proliferation of undifferentiated type A spermatogonia. Once spermatogenesis starts, a number of undifferentiated type A spermatogonia halt the self-renewal process and enter the differentiation pathway toward meiosis, which would explain the lower expression levels of *gsdf1* in adult males after premeiotic stages and in juvenile precocious animals (Crespo *et al*., 2013).

In summary, this study confirms *gsdf1* as marker of precocious puberty and as a potential target for puberty manipulation.

OCEANOGRAPHIC AND ECOLOGICAL INTERACTIONS WITH AN OFFSHORE, LONG-LINE MUSSEL FARM

Llucia Mascorda Cabre1*, Phil Hosegood1, Martin Attrill1, Emma Sheehan1

School of Biological and Marine Sciences, Faculty of Science and Engineering, University of Plymouth, Plymouth, UK
E-mail: llucia.mascordacabre@plymouth.ac.uk

Introduction

Bivalve aquaculture has traditionally been established in shallow, sheltered waters in inshore areas generating notable negative environmental impacts due to the accumulation of waste products. However, the recent global expansion of the offshore industry is perceived to have a lower environmental impact coupled with a higher growth potential. Mussels can positively contribute to marine ecology as carbon storage, nutrient remediation and coastal defence. Hence, the development of offshore aquaculture has the potential to provide the most sustainable source of protein to feed our growing population.

In 2013, the University of Plymouth commenced a robust annual monitoring study of the UK's 1st large scale offshore mussel farm in Lyme Bay, south west UK. Using a range of underwater survey vehicles and sampling techniques, the study has been valuable in showing ecological interactions such as the potential to increase habitat value and increase commercially valuable mobile species (Figure 1).

Aims

This PhD aims to assess the overall footprint of this offshore mussel farm, focusing on the effects that the farm has on the oceanography and plankton, while maintaining the long-term ecological surveys during three more survey seasons. The study will focus on how currents and waves are modified by the structure and the consequent impact on the surrounding ecology. The focus is specifically on sediment transport and plankton depletion as well as the functional change of benthic and commercially targeted species.

Methodology

For the oceanographic study, current velocity data was collected with a boat mounted Acoustic Doppler Current Profiler (ADCP) through an entire tidal cycle during spring tides. A fixed bedframe ADCP will also be placed on the farm to further study water column profiles. For the ecological study, benthic epifauna is being quantified through Towed HD video array, ROV and Baited Remote Underwater Video (BRUV) while pelagic epifauna is being quantified using Non-baited Midwater Video rigs (NMV). Sediment and infauna communities are being quantified by sediment grabs and laboratory analysis whereas plankton communities have been sampled using a plankton mesh throughout the entire water column and identified to species level at the laboratory.

Results

Oceanographic and ecological data is being analyse and will be shown during the oral presentation. Preliminary observation of results show that the presence of the mussel farm is having an effect on the speed and direction of the flow, both at ebb and flood tides (Figure 2) as well as the abundance and type of zooplankton (Figure 3).

Introduction

Ocean based sources account for 20 % of the plastic pollution such as overboard discharges from ships and abandoned, lost or otherwise discarded fishing and aquaculture gear (ALDFG). Considering that ALDFG is estimated to compose less than 10 percent of total marine debris by volume at a global scale, and even though the overall contribution to ALDFG from aquaculture is probably limited due to its static nature; intensive aquaculture still has the potential for lost cages, longlines, poles and other floating and fixed items to escape the system, being transformed in sources of plastic debris.

Considering that Aquaculture is the fastest growing food-producing sector, accounting already for 50 percent of the world's fish that is used for food, and with an European goal of doubling its production by 2030, AQUA-LIT's goal is to avoid that an increase in aquaculture production imply an increase in marine litter input. Thus, the project main objective was to provide the aquaculture sector with a Toolbox that can provide existing, upcoming and already implemented tools, case studies, best practices, a database and links between stakeholders for addressing the 3 main components of marine littering from aquaculture activities: prevention & reduction, monitoring & quantification, and removal & recycling.

Metholodgy

The AQUA-LIT Toolbox is the result of the compilation of available literature and litter databases (e.g. OSPAR, HELCOM, Marine Litter Watch), the information provided by the stakeholders in the frame of the project, the state of play regarding the aquaculture marine litter management in 2019 and 2020 and the input of the experts that have been part of or have work closely together with the AQUA-LIT team. The assessment is based on the proposed tools and governance approaches developed during the AQUA-LIT Learning Labs in the Mediterranean Sea, North Sea and Baltic Sea regions, and at the same time built on AQUA-LIT's comprehensive review including: D2.2 Knowledge Wave on Marine Litter from Aquaculture Sources, D2.3 Available Tools and Measures, D2.4 Potential Future Impacts and D3.5 Learning Labs outcomes (portfolio of best practice fact sheets).

Results

The toolbox accessible online and as an App, provides more than 400 of ideas and solutions to tackle marine litter that can be filtered by stage (prevention and reduction, monitoring and quantification, removal and recycling), by type of aquaculture (shellfish, finfish, seaweed), by sea basin (Baltic Sea, Mediterranean Sea, North Sea), and by category of measure (support, knowledge, responsibility, legislation).

Furthermore, the toolbox also includes information on which ports have the facilities to receive waste, a database of funding opportunities to create a project on marine litter, as well as a marine litter inventory that provides an overview of the available knowledge on marine litter originating from the aquaculture sector, a set of policy recommendations for the EU and lastly, specific action plans for outermost regions.

(Continued on next page)

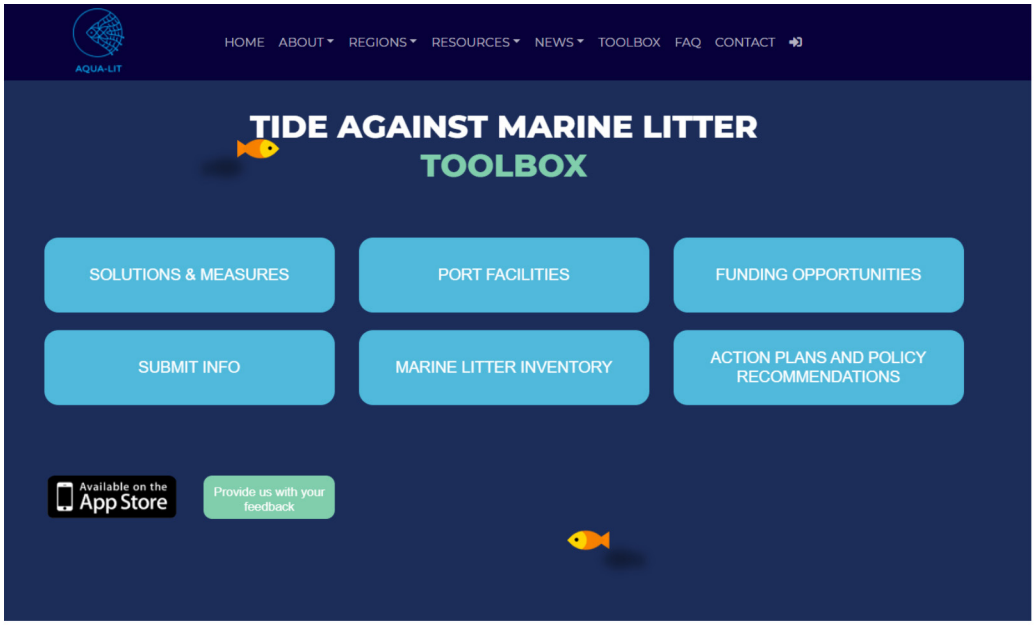

Figure 1. AQUA-LIT toolbox platform

Conclusions

The AQUA-LIT toolbox aims to be considered the most important knowledge repository for aquaculture-mairne litter related information across Europe and the starting point for the development of new European policies regarding the marine litter coming from aquaculture.

This Toolbox can be used as a guidance for the management of the marine litter that comes from aquaculture in the European context. The targeted audience includes aquaculture farmers; professional clusters, associations and platform representatives; policy makers; port authorities; aquaculture gear and equipment producers; engineering, system design and construction companies; plastic manufacturers; waste managers; researchers; environmental and social consultancies; NGOs; classification and certification bodies; communicators and any other interested person.

COLLABORATIVE LAND-SEA INTEGRATION PLATFORM

M. Mata-Lara*[1]

*[1] Geonardo Environmental Technologies Ltd., Zahony utca 7, Budapest, 1031 (Hungary)
Email: mariana.mata.lara@geonardo.com

Introduction

More than 90 % of the EU territory is covered by rural areas, where roughly half the EU population[1] lives and works. Rural development in the EU faces major, highly-dynamic challenges including global competition, decreasing population densities, lack of employment, desertification, land abandonment, and climate change. These significant challenges are addressed by the EU Strategic Guidelines for Rural Development (2006/114/EC), which aim is to improve the competitiveness of the agriculture and forestry sector in these areas, taking into consideration the natural environment, quality of life and simultaneously ensuring a diversity of the rural economy. At the same time, though, in the EU alone, the coastal regions contain half the population as well as half the GDP, and 23 of 28 EU countries have a coastline. Aquaculture, being part of the Blue economy, creates jobs and economic development opportunities in the EU's coastal and rural communities. This sector can also help: decarbonise the economy; fight climate change and mitigate its impact; reduce pollution; contribute to better preserving ecosystems (in line with the objectives of the Biodiversity strategy and the Zero-pollution ambition for a toxic-free environment); and be part of a more circular management of resources[2].

We argue that coastal and rural regions and their related economic activities operate as a coupled system. Economic development in coastal areas can contribute to rural development as addressed by the Guidelines for Rural Development, providing ecosystem goods and services and business opportunities applicable in the hinterland as well[2]. Thus, COASTAL aims to improve the rural-coastal synergies in strategic business and policy decision making and collaboration between coastal and rural actors. This will be achieved by developing, demonstrating, and applying a generic toolset and performance indicators by combining a multi-actor approach with system dynamics modelling. Specific attention is given to aquaculture and to understand the interactions with market, demographic, environmental and climate forecasts, and quantify the positive and negative externalities.

Methodology

COASTAL is a unique collaboration of coastal and rural business entrepreneurs, administrations, stakeholders, and natural and social science experts. Local and scientific knowledge are combined to identify problems and develop practical and robust business road maps and strategic policy guidelines, aimed at improving land-sea synergy. A multi-actor approach is followed to analyse the social-environmental and economic land-sea interactions in a collaborative System Dynamics (SD) framework, taking into consideration the short-, mid- and long-term impacts of decision making and feedback mechanisms on coastal and rural development. The project is organised around interacting Multi-Actor Labs (MALs), combining tools and expertise for six case studies representing the major coastal regions in the EU territory. Most of the case studies have the presence or link with aquaculture. In each MAL local actors and experts participate in collaborative exercises to analyse problems, analyse the causes, propose and discuss solutions, and validate and interpret the impacts of simulated business and policy decisions. The MALs are connected into a durable platform for collaborative knowledge exchange – COASTAL – which is underpinned by a generic set of tools and performance indicators. The COASTAL platform and synergistic tool set will be further exploited and developed beyond the project lifetime.

Results

A total of fourteen system models have been developed for themes ranging from coastal tourism, eutrophication, eco farming and decommissioning of offshore wind parks to shellfish farming. The quantification of systemic interactions is based on peer-reviewed published and reported data and modelling approaches, expert judgement and field samples obtained as part of the project. All models address land-sea interactions and capture socio-environmental interactions which were identified earlier in the project by coastal and rural stakeholders. In this project two specific case studies are dealing in depth with aquaculture as a regional spearhead. In the French case-study the long-established oyster culture in the Charente region is being studied. While in the Romanian case study models are made concerning the freshwater aquaculture in the Danube delta as well as for the potential upcoming marine aquaculture in the Black Sea.

Conclusions

Results from the project could lead to policy adjustment in these coastal-rural zone, enabling aquaculture to develop as a sustainable blue economy in those regional zones and contributing to the EU Green deal objectives. The methodology could be transferred to other regions where aquaculture can also play an important role in a sustainable regional development.

PROSPECTS OF AQUACULTURE GROWTH IN RUSSIA

G.G. Matishov* and E.N. Ponomareva

Federal Research Centre The Southern Scientific Centre of the Russian Academy of Sciences (SSC RAS),
41 Chekhov Street, 344006 Rostov-on-Don, Russian Federation
E-mail: icd@ssc-ras.ru

The strategy for scientific and technological development of the Russian Federation, approved by Decree No. 642 of the President of the Russian Federation of 1 December 2016, defines (as priorities for the scientific and technological development of Russia for the next period of 10 to 15 years) directions, which will allow to obtain scientific and scientific and technical results and create technologies that are the basis for the innovative development of the domestic market for products and services and Russia's stable position in the foreign market. Such directions should ensure the transition to a highly productive and environmentally-friendly agriculture and aquaculture, the production of safe and high-qualitative, as well as functional, food.

According to FAO, the pace of aquaculture development, as before, is ahead of other sectors of the fishing industry in the world (FAO, 2018). Aquaculture is the future of agriculture. The volume of aquaculture production in the world over the past 10 years has doubled and almost equaled the volume of traditional fisheries.

Russia's share in the world aquaculture production is currently only 0.25%. This situation is due to the fact that both in Russia and the Soviet Union the main fisheries forces were aimed at developing and increasing the volume of fish catches. The total volume of aquaculture production (including aquatic plants) reached 328.6 thousand tons in 2020.

The main limiting factor in the development of aquaculture in Russia and in the world is the lack of inexpensive, effective biotechnologies, technical equipment and means, and environmentally-friendly feeds. The pace and scale of development of commercial fish farming in Russia lags far behind the global ones and much lower than the pace of the leading aquaculture countries (China, Norway, Vietnam, etc.). However, aquaculture production in Russia increased from 90.4 thousand tons in 2001 to 328.6 thousand tons in 2020 (increased by 3.6) of which more than 50% is produced in the South of Russia (Krasnodar and Stavropol Territories, Rostov, Astrakhan and Volgograd Regions).

Meanwhile, the total area of only marine areas in the Russian Federation suitable for mariculture is estimated at 0.38 million km². According to expert estimates, the effective use of existing potential in our country allows to increase the volume of aquaculture production by 25 times. In the Far East alone, natural conditions make it possible to cultivate up to three million tons of aquatic biological resources annually. The intensive development of aquaculture, especially in the southern regions of Russia, is possible only if it is industrialized with scientific and technological solutions being integrated into it – both in terms of reproduction, feeding and maintenance, and in terms of processing. The transition to new technologies and an increase in aquaculture production at least by 10% annually will also allow the development of the production of new technical equipment and means both within aquaculture and related industries.

There is an increase of industrial farms for growing aquaculture objects every year in Russia: there were 27% of them in 2019; however, according to forecasts, the growth of industrial (commercial) aquaculture by 2020 is expected to be up to 35%, and up to 40% by 2022.

On the whole, positive trends are observed in the fishing industry in Russia, the volumes of aquaculture are increasing, and fish farming indicators are growing at a significant pace. It was the sanctions that had a positive effect on this very sub-segment of the agro-industrial complex of the national economy. Since 2015, significant changes have taken place when it comes to the increase of the output of aquaculture products and the development of its (aquaculture's) industrial part. Over the past 30 years, the volume of consumption of fish and fish products per person in Russia has increased, on average accounting for 21.5 kg of fish per year.

INSECT MEALS AS INNOVATIVE FEED COMPONENTS IN JUVENILE IDE *Leuciscus idus* NUTRITION

Jan Mazurkiewicz[1,2*], Marcin Wiśniewski[3], Mateusz Rawski[2], Natalia Homska[1,2], Grzegorz Kujawa[3]

E-mail: jan.mazurkiewicz@up.poznan.pl

Introduction

The ide (*Leuciscus idus*) is native European species of rheophilic cyprinid fish, which wild populations are dependent on conservation efforts, in particular regular restocking. For this reason, it is necessary to develop effective methods of rearing for stocking material. One of the important elements of this process is the nutrition of juvenile stages in controlled conditions, requiring the optimization of diet composition in terms of specific nutritional and behavioral requirements. At the moment restocking facilities raising ide juveniles are using commercial feeds for carps which are not balanced in terms of specific needs of ide. The aim of the experiment was to evaluate the effects of insect meal inclusion into the ide diet on fish growth performance and feed utilization in comparison with fishmeal based diet.

Material and Methods

For the production of feeds three insect species larvae meals were used. Four diets were formulated: HI – diet with 20% *Hermetia illucens* meal inclusion, TM – diet with 20% *Tenebrio molitor* meal inclusion, ZM – diet with 20% *Zophobas morio* meal inclusion. The control group (CON) was a diet based on fishmeal with no insect meals. The growth trial lasted 60 days and 200 individuals of ide with an average body mass of 30 grams were randomly assigned to four experimental groups, five replicates each (10 fish/tank). The fish were kept in a recirculation aquaculture system with controlled conditions (water temperature 22˚C, photoperiod 14h light, 10h darkness). The effects of the diets on the efficiency of rearing of ide juveniles were assessed based on fish growth parameters such as: mean individual body weight gain (BWG), specific growth rate (SGR), percent weight gain (PWG); and feed utilization parameters including: feed conversion ratio (FCR), protein efficiency ratio (PER); and somatic indices: Fulton's condition index (CI), viscerosomatic index (VSI) and gastrointestinal tract to fish total length ratio (GIT:FTL).

Results

The highest values of BWG, SGR, and PWG were observed in the HI and TM groups and they were nearly 30% better than the control group. The decrease of FCR was observed in HI (by 0.62) and TM (by 0.63) groups in comparison to CON. There were no statistically significant differences in terms of PER, CI and GIT:FTL. No mortality of the fish occurred during the experiment. In case of VSI it was highest in the control group and lowest in ZM group.

Conclusions

The results indicated that the use of black soldier fly and mealworm insect larvae meals in the diets for ide juveniles has a positive effects on their growth performance and feed utilization, with no adverse effects on fish condition and gastrointestinal track development. Up to date, there is a very little knowledge regarding ide juveniles nutrition and still further studies are needed to correctly define proper feeding strategy and diet requirements of cyprinid rheophilic fish.

This study was carried out as part of the project entitled: "Innovative feed components in the nutrition of rheophilic fish – optimizing and increasing the efficiency of rearing juvenile stages", no. 00001-6521.1-OR1500001/17/19, Task 2.1 "Innovations" according to EU Regulation No. 508/2014, Priority 2 – "Supporting environmentally sustainable, resource-efficient, innovative, competitive and knowledge-based aquaculture" realized in the Operational Program "Fisheries and Sea".

USING A BLOW-UP TARPAULIN FOR REVERSE OSMOSIS FRESHWATER TREATMENT OF AGD AND SEA LICE IN ATLANTIC SALMON (*Salmo salar*)

Introduction

Amoebic gill disease (*Parameoba perurans)* and salmon louse (*Lepeophtheirus salmonis*) infestations of Atlantic salmon are both susceptible to freshwater treatment (Mc Dermott et al., 2021[1]). The attraction of non-medicinal use and the organic status of farmed salmon in a period of climate change has led to an increased use of hyposaline water from the sea through reverse osmosis (R.O.) or nanofiltration (Mc Dermott et al., 2021[2]). In trials, soft freshwater produced on site from an R.O. plant was used to treat amoebic gill disease (AGD) and reduce sea lice numbers using a blow-up tarpaulin placed within the pen to be treated in an effort to eliminate the practice of second pumping. Water chemistry and efficacy of treatment were determined to assess if this adaptation had the potential to reduce handling and workload.

Materials and methods

Lehanagh Pool is a Marine Institute research site, located 0.25 km from the shore in Bertraghboy Bay, on the West Coast of Ireland. The site is a licensed 23-hectare multi species research site. The location is relatively sheltered with a tidal range approximately 5m, where salinity is typically >32 ppt but can range from 24 to 35 ppt. A floating R.O. plant produced 50m³ low salinity (<2ppt) water that was pumped in 25 minutes to a blow-up tarp deployed within the pen to be treated. The pen was split by raising the net in the middle with all 5,000 post smolts in one side and the blow-up tarp in the other. The fish were then pumped and dewatered into the blow-up tarp and after the last fish was transferred the trials commenced. In Trial 1 the fish were retained for 3h and in Trial 2 for 4.5h. When treatment was complete the fish were simply spilled into their original pen. During treatment the water chemistry was carefully monitored. A full appraisal of the sea lice and AGD status before and after treatment was undertaken by the Marine Institute.

Results

The use of the blow-up tarp reduced the handling and time involved in treating both AGD and sea lice by removing the need to pump fish twice. The fall in pH using low buffered R.O. (~1ppt) water was significant, yet the pH remained above the critical level of 5.7, having reached a plateau just above this level midway through the treatment. Water temperature in the blow-up tarp remained constant and was the same as the ambient sea water in the pen. AGD control using R.O. in Trial 1 and Trial 2 was effective and for both time periods. Reinfection of AGD was observed within 8 days and highlighted the importance of continuous freshwater treatments and the need for a constant supply of suitable soft water. Sea lice levels were low at the site, so treatment efficacy was difficult to determine yet the results show that a 3h freshwater treatment was not sufficient to remove adult ovigerous females and adult males. By increasing the treatment time to 4.5h efficacy improved. Biosecurity and the removal of harmful biological or biochemical substances by R.O. were also important considerations for fish welfare in undertaking these trials.

The BIM project of providing freshwater from reverse osmosis for tarpaulin treatments was co-funded by the Government of Ireland and the European Union, under Ireland's European Maritime & Fisheries Fund Operational Programme for the seafood sector.

Introduction

The Scottish farmed salmon industry continues to expand and there is a requirement to reduce the level of finite marine origin raw materials used in traditional feed formulations. One alternative is to produce feeds with higher proportions of plant-derived oils and proteins, but these diets can lead to reduced feed utilization and also have lower levels of essential omega-3 long-chain polyunsaturated fatty acids (n-3 LC-PUFA), eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3). A novel solution to this problem is applying an early nutritional intervention or "stimulus" where fish are fed a predominantly vegetable-based diet for a short period, to induce more efficient uptake and utilization of nutrients from a similar diet when fed later in development, a concept referred to as "nutritional programming". Previously, it was demonstrated that Atlantic salmon (*Salmo salar*) fed such diets during a three-week stimulus phase from first exogenous feeding, resulted in significantly greater growth and nutrient retention efficiency during freshwater grow out (Clarkson et al. 2017). Associated with the improved growth and feed efficiency, key pathways of intermediary metabolism were upregulated (Vera et al. 2017). The current study aims to elucidate whether the effects of nutritional programming are sustained during post-smolt rearing in seawater.

Materials and methods

Four experimental dietary groups were established in triplicated treatment tanks (Figure 1). Two treatments were fed an experimental vegetable-based diet for a three-week "stimulus" period from first feeding, while remaining tanks were fed a standard marine-based diet (Figure 1). Following stimulus, all groups were then fed a standard marine ingredient diet until week 36. Thereafter, two treatment groups were re-fed a vegetable-based diet for four weeks prior to sea transfer, while remaining tanks remained on marine-based feeds. At week 40, smolts were transferred to sea based tank rearing facilities. Following a two-week acclimatization post- transfer, when fish were fed a standard marine based diet, all fish were transferred to a vegetable-based diet for a 14-week period. Samples were collected at key phases for biometrics, body & tissue composition, and nutrient retention efficiency and utilization.

Results & Discussion

Our hypothesis was that fish subjected to a vegetable-based stimulus diet would better utilize dietary nutrients in later development. The study presents results indicating whether there is evidence to support this theory based on growth, feed intake and body composition. Specifically, attributes of digestibility and retention of essential nutrients will be discussed, with primary focus on levels of n-3 LC-PUFA, DHA and EPA. Greater positive retention and/or a net increase of DHA and EPA accumulation and deposition during seawater challenge, by treatment fish fed a vegetable-based stimulus, is one key indicator of successful and sustained nutritional programming. A net increase of EPA and DHA demonstrates endogenous biosynthesis of these essential fatty acids from precursor α-linolenic acid (ALA; 18:3n-3), which is abundant in the vegetable-based feed. Empirical evidence of nutritional programming upregulating fatty acid biosynthesis to trigger endogenous production of essential EPA and DHA could determine how we formulate more resource-efficient feeding strategies and aquafeeds for Atlantic salmon in the future.

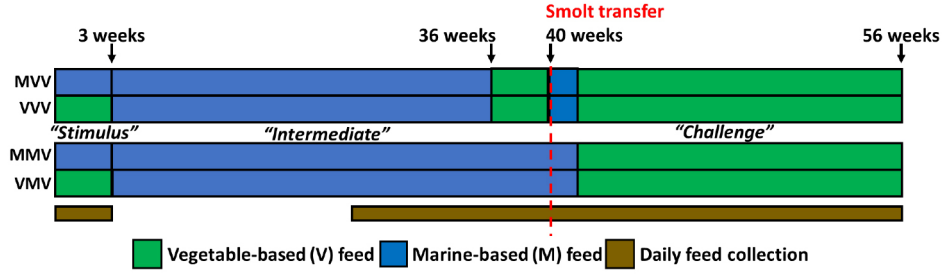

Figure 1. Schematic of trial showing when specific diets were fed and periods when excess feed was collected. All timepoints are cumulative.

ANTIGEN PERSISTENCE AND ANTIBODY RESPONSE THROUGHOUT A COMMERCIAL PRODUCTION CYCLE OF ATLANTIC SALMON (*Salmo salar* L.) FOLLOWING INTRAPERITONEAL INJECTION WITH A MULTIVALENT VACCINE

Marwa. Mechlaoui*, Endre Nordstrand, Ingvill Jensen and Tore Seternes

Norwegian College of Fishery Science, UiT The Arctic University of Norway, Tromsø, Norway
E-mail : Marwa.mechlaoui@uit.no

Introduction

Global salmonid production continues to grow annually and Atlantic salmon (*Salmo salar* L.) is one of the most economically valuable species. However, infectious diseases is a major challenge affecting both fish welfare and economy in a negative manner. 10% of all cultured aquatic animals are estimated to be lost due to infectious diseases. *Vibrio anguillarum* is within the genus vibrio, and it is the etiological agent of classical vibriosis, a deadly haemorrhagic septicaemia disease in marine and freshwater fish species. Disease prophylaxis through vaccination has been found to be the best approach for prevention of infectious diseases. In aquaculture today, oil-adjuvanted multivalent vaccines containing six to seven antigens are routinely used; however, limited information is available regarding the duration of the vaccine-induced immune response in a commercial aquaculture setting.

In the present field study, we have investigated the immune response against the bacterial antigen *V.anguillarum* in Atlantic salmon throughout a commercial production cycle. After intraperitoneal vaccination with a multivalent commercial vaccine, analysis focused on granuloma development, the localization of *V.anguillarum* vaccine antigen at the injection site and the serum antibody response.

Materials and methods

Atlantic salmon were vaccinated with an oil-adjuvanted multivalent vaccine containing six antigens including *V. anguillarum (*Alpha Ject micro 6, Pharmaq). Five weeks after intraperitoneal vaccination, fish were transferred to the sea site at Skogshamn, production area 10, Troms, Norway, and sampling (blood and organs) took place every six weeks from 20 randomly selected individuals counting 14 samplings in total until final slaughtering (87 weeks after vaccination). Serum antibody response against *V. anguillarum* was measured by an ELISA. Vaccine antigen persistence was microscopically evaluated by immunohistochemistry using a polyclonal antibody that recognize *V. anguillarum* O1. Inflammation and granuloma development were assessed using standard histological methods.

Results and conclusion

Vaccine granulomas were located in the adipose tissue surrounding the injection site of the vaccine up to 44 weeks after immunization. *V. anguillarum* bacterial fragments were identified as red immuno-labelling in the vaccine granulomas either in association with oil droplets or in the periphery.

The serum antibody response to *V. anguillarum* was detected and persisted at a high level at all samplings from week 11 to 56 post-vaccination. Following that, there was a major decrease in specific antibody levels, which remained at low throughout the rest of the production cycle. At week 56 post-vaccination, a slight increase in antibody response was found correlated to an increase in seawater temperature as well as the fish specific growth rate. The given commercial vaccine has proved to induce a good immune response of Atlantic salmon to *V. anguillarum*, but further investigations needs to be done to study more the vaccine efficiency.

EFFECT OF PESTICIDES ON EMBRYONAL DEVELOPMENT OF AQUATIC BIOTA

Introduction

Pesticides, industrial chemicals, and many other types of contaminants have been constantly entering the aquatic environment. Pesticides, which are commonly used in agriculture, can have a negative impact on non-target species as well as human health. In few past decades, water pollution caused by pesticides has become a commonly discussed issue. Pesticides after entering water environment are persistent in the aquatic environment and they have bioaccumulation potential. These properties can have a negative effect on aquatic biota, fish and even their consumers. We tested the toxicity of commonly used pesticides of MCPA in its clear form and as a part of Bofix commercial herbicide on *Danio rerio* and *Xenopus laevis* embryos. In acute tests toxicity, embryos were exposed to environmental concentration (0.1 µg/L) and to relatively high concentration (10; 100; 1 000; 10 000 and 100 000 µg/L) for 96 hours.

Materials and methods

The experiment was performed according to the Guideline for Test No. 236: Fish Embryo Acute Toxicity (FET) (OECD 2013) for the period of 96 hours with six different concentrations (0.1; 10; 100; 1 000; 10 000 and 100 000 µg/L) and the control group. Fertilized eggs of *Danio rerio* and *Xenopus laevis* were selected using binocular microscope and distributed into 24 microwell. For each concentration plus control, 24 embryos were used. Bofix was soluble in ISO 7346 (ISO, 1996) and MCPA was soluble in ISO 7346 with ethanol. During the test the temperature was 26 °C for *Danio rerio* and 23 °C for *Xenopus laevis*, photoperiod was 12 hours light/12 hours dark. The solutions were changed every 24 hours and indicators of the toxicity were observed. We observed mortality, malformation, hatching and the hearbeat. Statistical analysis was conducted using Unistat 5.6 (Czech Republic).

Results and discussion

Bofix had a negative effect on *Danio rerio* and *Xenopus laevis* mortality, where mortality of *Danio rerio* at the concentration 10 000 and 100 000 µg/L reached 100%, at the concentration 1 000 µg/L was mortality 38% after 24 hours post fertilization (hpf). At 24 hpf mortality of *Xenopus laevis* at the concentration 100 000 µg/L reached also 100% and at 48 hpf at the concentration 10 000 µg/L mortality was 100%. Johansson et al. (2006) reported LC50 for fish 100 mg/L and for amphibians 3,6 g/L. A 96hours exposure to Bofix at the concentration of 1 000 µg/L revealed increased malformation (100% of *Danio rerio* specimen, 40% of *Xenopus laevis* specimen) and at the concentration of 100 µg/L were observed 36% malformation of *Xenopus laevis*. Bofix did not have effect on hatching. MCPA had a negative effect on *Xenopus laevis* mortality, where mortality was 100% at the highest tested concentration, but did not have any effects on hatching or malformation rate. In case of *Danio rerio* the negative effect on hatching rate and malformation were observed after 96 hpf, where only 23% embryos were hatched at the highest tested concentration. Moreover, these embryos showed significant malformation rate (84%). The most common malformation caused by Bofix and MCPA were heart oedema, blood clot and deformation of spine. Lutnicka et al. (2018) tested the effect of MCPA at the concentration of 100 µg/L on juvenile common carp, changes in the blood differential and morphologic changes in the kidney were observed.

Conclusion

The results of the study show that the commercial preparation Bofix is more toxic than pure MCPA due to the content of additives. Bofix caused a high percentage of mortality and malformation at the concentration 1 000; 10 000 and 100 000 µg/L. But also, negative effect on development of the embryos were observed with MCPA in clear form, where malformations were observed at the highest tested concentration on *Danio rerio.*

THE USE OF A NUTRIENT-BASED MODEL AS A DECISION TOOL TO SUPPORT THE DESIGN OF NUTRITIONAL EXPERIMENTS

Introduction

In aquaculture research fish performance is often evaluated through *in vivo* trials. This allows the assessment of the impact of factors of interest (change between treatments) on fish reared under the same context (constant conditions between treatments). Although this type of approach is effective in theory, in practical terms it may be difficult to implement when several factors and/or multiple levels are of interest, due to constraints such as space available in the experimental facilities and budget. Consequently, when designing an experiment, aquaculture researchers are often confronted with the decision of what set of treatments to include, to meet existing limitations and not to compromise the effectiveness of the research. This means that usually some prior knowledge must be put on the table to support the design of an experiment.

Nutrient-based mathematical models can be great tools to be used in this regard in the framework of fish nutrition research. On one hand, they are developed and calibrated based on large datasets generated in distinct scientific contexts, which enables to encapsulate the knowledge that has been generated by science in different studies into a single tool. On the other hand, since they consider in detail a wide range of factors, such as feed properties (e.g., proximate composition, digestibility, amino acid and fatty acid profile), feeding quantities and temperature, their application has the potential to provide accurate predictions in distinct scenarios and, as such, they can support a more effective design of a wide variety of *in vivo* trials.

In this work, we illustrate how a specific nutrient-based model (FEEDNETICS™) was used in the context of the H2020 project AquaIMPACT (www.luke.fi/aquaimpact/) to support the design of a research experiment. The main objective of this model application was to select two dietary treatments that show *in silico* relative differences within the range of 5-10%, in terms of final body weight and feed conversion ratio, to later test them in an *in vivo* trial to be carried out with two seabass populations (selected vs unselected).

Methods

The dynamic nutrient-based model FEEDNETICS™ (Soares et al., 2018) was used to run predictions for European seabass (*Dicentrarchus labrax*). In general, data inputs (e.g., rearing conditions and feeding regimes) for the model were defined based on the parameters under which the *in vivo* nutritional trial was expected to be carried out. In terms of rearing conditions, an initial fish bodyweight of 20g, a constant temperature of 20ºC and a production period of 180 days, were defined. Regarding the feeding regimes, four dietary treatments (A, B, C and D), composed of two diets with different pellet sizes (2 mm and 4 mm), were considered, being the main difference between them in terms of crude protein (from 45.5% (2 mm) and 39.5% (4 mm) to 50% (2 mm) and 44% (4 mm), in diets A and D, respectively) and gross energy contents (from 17.36 MJ/Kg (2 mm) and 17.56 MJ/Kg (4 mm) to 18.38 MJ/Kg (2 mm) and 18.57 MJ/Kg (4 mm), in diets A and D, respectively). Moreover, three feeding tables (FiT) were applied (80%, 100%, 120% of a reference FiT). Therefore, a total of twelve feeding regimes (four dietary treatments × three feeding levels) were composed. The relative difference (d_r) between the pairs of results was calculated as:

the pairs of results was calculated as: $d_r = \frac{|x-y|}{max(|x|,|y|)}$.

Results

FEEDNETICS™ predicted that diet D presented the best fish performance in terms of final body weight (FBW) and feed conversion ratio (FCR), followed by diet C, B and A, in this order (Table 1).

The treatments to be used in the *in vivo* trial were the ones with d_r within the range of 5-10%, in terms of FBW and FCR. In this sense, only two combinations of dietary treatments, A-C and B-D, matched the pre-defined screening criteria (Figure 1). Since the proximate composition of diet B, was the one more similar to the protein and energy contents used by the industry for European seabass, the combination B-D was selected to be used in the *in vivo* trial.

(Continued on next page)

Table 1 – Final body weight (FBW), feed conversion ratio (FCR), protein efficiency ratio (PER), nitrogen (N) and phosphorus (P) waste estimated by FEEDNETICS™ in each dietary treatment, grouped by feeding table.

	A			B			C			D		
	80%	*100%*	*120%*	*80%*	*100%*	*120%*	*80%*	*100%*	*120%*	*80%*	*100%*	*120%*

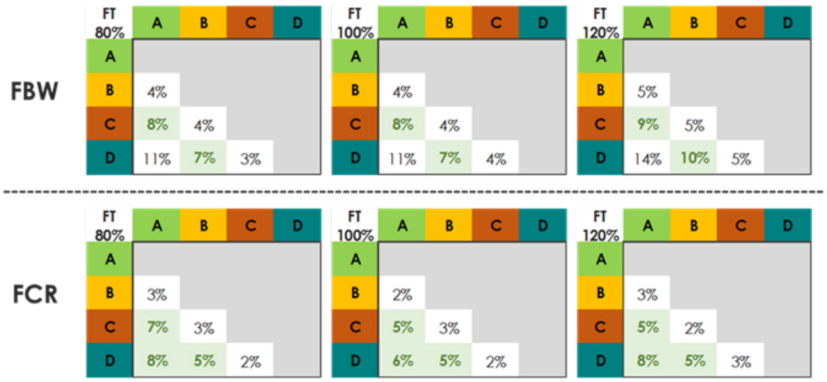

Figure 1 – Relative differences between dietary treatments, grouped by feeding table, in terms of final body weight (FBW) and feed conversion ratio (FCR). The cells highlighted in green show the values where the d_r is between the range of 5-10%.

Conclusions

Nutrient-based models, such as FEEDNETICS™, can be used by aquaculture researchers to support informed decisions in the design of an *in vivo* trial. Screening beforehand the impact of multiple treatments on fish performance with a model, ensures that the experimental design to be adopted is adequate to meet the outlined research objectives and, in addition, it may also contribute significantly to reduce the overall costs of the experiment.

Introduction

Phosphorus is an essential nutrient for skeletal physiology, ionic homeostasis, and energy metabolism in fish. Unlike other minerals, the phosphorus content in water is insufficient to meet fish requirements and therefore the diet is the main external source of phosphorus. In aquaculture, commercial diets commonly have higher phosphorus concentration than the basal requirements in most fish species to ensure growth and prevent skeletal disorders. This practice poses a serious environmental problem as excess phosphorus in water from non-eaten food and urinary/fecal excretions produces eutrophication of aquatic ecosystems. Our previous studies with acellular-boned fish (Suarez-Bregua *et al*., 2021) revealed that a lower phosphorous concentration diet is possible without affecting the fish health and growth. In this study, we wondered if this is also applicable to cellular-boned fish species. Thus, the objective of this study was to analyze the effect of dietary phosphorus concentrations (low, standard, and high phosphorus diets) on bone mineralization of zebrafish (*Danio rerio*), a popular model organism and a cellular-boned teleost species.

Material and Methods

One hundred and eighty zebrafish (30 dpf) were randomly distributed in six plastic tanks of 10 L (30 fish per tank) connected to a recirculation system. Fish from duplicate tanks were fed three times a day with three different diets: low phosphorus diet (LP, 0.47%), standard phosphorus diet (SP, 1.30%), and high phosphorus diet (HP, 3.15%). Dietary trials were conducted at ambient temperature (27ºC) and natural photoperiod (14 h light/10 h dark) for 10 weeks. After this period, 100 dpf zebrafish were randomly sampled, euthanized, weight and length measurements were recorded and fixed for subsequent analysis. Following the fixation, the volumetric bone mineral density (vBMD) was determined by micro computed tomography (CT) scanning. Whole-body mineral content was analyzed by using inductively coupled plasma optical emission spectrophotometry and quantitative real time PCR (qPCR) analysis were also performed to determine the expression of bone mineralization and Pi homeostasis markers (*entpd5*, *sparc* and *pth4*).

Table 1. Growth measurements of zebrafish fed low (LD), standard (SP), and high (HP) phosphorus diet for 10 weeks.

Zebrafish	LP	SP	HP
Length increase (%)	61.18 ± 0.35 [a b]	64.24 ± 0.65 [a]	50.97 ± 2.87 [b]
Weight increase (%)	93.54 ± 0.29 [a b]	94.69 ± 0.26 [a]	81.94 ± 4.13 [b]
Condition factor (K)	0.91 ± 0.02 [a]	0.86 ± 0.02 [a]	0.81 ± 0.06 [a]

Data are presented as means ± SEM (n = 10). Different lower-case letters denote significant differences (Kruskal-Wallis and Dunn's post-hoc test, $p < 0.0005$).

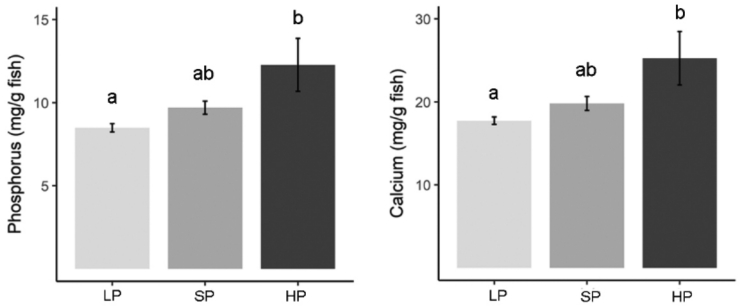

Figure 1. Whole-body phosphorus and calcium concentration determination in zebrafish fed LP, SP, and HP diets.

(Continued on next page)

Results

As shown in Table 1, zebrafish fed the high phosphorus diet were significantly smaller than those fed the standard (SP) or low (LP) phosphorus diet. The whole-body mineral content analysis (fig. 1) showed a significant increase of whole-body phosphorus and calcium contents after HP feeding compared with LP dietary treatment. This suggests that in zebrafish a positive relationship between the dietary phosphorus concentration and whole-body mineral levels exists.

Zebrafish fed the LP diet also exhibited a significantly reduced vBMD in the skull and vertebrae samples compared with fish under SP feeding. This changes in vBMD are supported by the down-regulation of *pth4* and *sparc* gene expression in fish fed the LP.

Conclusion

The dietary phosphorus concentration significantly affects the mineralization of the cellular zebrafish bone in contrast with previous studies with acellular-boned fish (Suarez-Bregua *et al*., 2021). Therefore, a possible differential regulation of phosphate homeostasis depending on the type of bone that a certain fish species has may exist. These results could be taken into account when designing new feed formulations depending on the type of bone of each specific fish species. Nevertheless, further studies with different cellular-boned fish species with commercial relevance should be carried out.

GILL-ASSOCIATED NITROGEN CYCLE BACTERIA CONVERT AMMONIA TO NITROGEN GAS IN COMMON CARP (*Cyprinus carpio*) AND ZEBRAFISH (*Danio rerio*)

Wouter Mes*[1,2], Mike S.M. Jetten[1], Henk Siepel[2], Sebastian Lücker[1], Marnix Gorissen[2], Maartje A.H.J. van Kessel[1]

Introduction

Ammonia is the main nitrogenous waste produced by teleost fish and its accumulation can lead to toxicity in aquaculture settings where fish are kept at high fish density and are fed protein-rich diets. Controlling ammonia levels is therefore key in recirculating aquaculture systems (RAS). Most ammonia is excreted via the gills of teleost fish, which makes this organ a prime habitat for colonization by nitrogen-cycle bacteria.

Recently, it was shown that excreted ammonia can be converted into dinitrogen gas (N_2) in carp and zebrafish gills through the combined activity of ammonia-oxidizing and denitrifying bacteria, which interestingly seem to reside *inside* gill cells of carp (van Kessel et al., 2016). The role of these bacteria in nitrogenous waste removal by fish is largely unknown. Our project aims to investigate the fundamental characteristics of this novel symbiosis and determine whether it can be used in aquaculture to decrease ammonia excretion of teleost fish. We identified the presence of ammonia-oxidizing bacteria in common carp and zebrafish gills and measured activity of these bacteria *in vivo* in common carp. We additionally examined 16S rRNA sequencing datasets for presence of nitrogen cycle bacteria in other species than carp and zebrafish.

Materials and methods

Common carp (*Cyprinus carpio*) and zebrafish (*Danio rerio*) were grown under control conditions in recirculating systems with nitrifying biofilters. Fish were euthanized and gills were aseptically removed for microbiome analysis.

The gill microbiome of common carp and zebrafish was investigated through molecular methods. Bacterial DNA was isolated from fish gill and PCRs were performed for the ammonia monooxygenase subunit A gene (a functional marker for ammonia oxidizing bacteria) and nitrite reductase (a functional marker for denitrifying bacteria). Additionally, 16S rRNA amplicon sequencing was performed to obtain an overview of bacteria present in fish gill samples. We analyzed and compared the results with publicly available 16S rRNA sequencing datasets from teleost fish that included gill samples using the DADA2 pipeline and amplicon sequencing variants (ASVs) of nitrogen cycle bacteria (ammonia oxidizers, nitrite oxidizers and denitrifiers) were identified using the SILVA database. Phylogenetic relationships were examined, as well as differential abundances of nitrogen cycle bacteria between gill samples and other samples (water, sediment etc.).

Histological analysis was also performed on gills of common carp and zebrafish. Bacteria were localized in gill tissue through fluorescent *in situ* hybridization and electron microscopy.

Common carp (±50-100g) were used for individual nitrogen gas measurements. Carp were placed in 5L tanks that were closed off from the surrounding air. The atmosphere above the water in the tank was replaced by a mixture of argon and oxygen, after which the accumulation of dinitrogen gas in the headspace was regularly measured with gas chromatography/mass spectrometry for 2.5 hours.

Results

Using on molecular methods, we confirmed the presence of *Nitrosomonas*-like ammonia oxidizers in carp and zebrafish gills (fig. 1). Additionally, microscopy indicated that these bacteria seem to be located intracellularly in carp gills.

In our 16S rRNA amplicon sequencing dataset, 2 *Nitrosomonadaceae* ASVs were found in carp and zebrafish gills. These ASVs were different from the *Nitrosomonadaceae* species in the water and biofilter. Analysis of other teleost gill microbiomes revealed the presence of 53 *Nitrosomonas*-affiliated ASVs in gill samples from 6 datasets, indicating that presence of ammonia oxidizers in gills is a widespread phenomenon.

(Continued on next page)

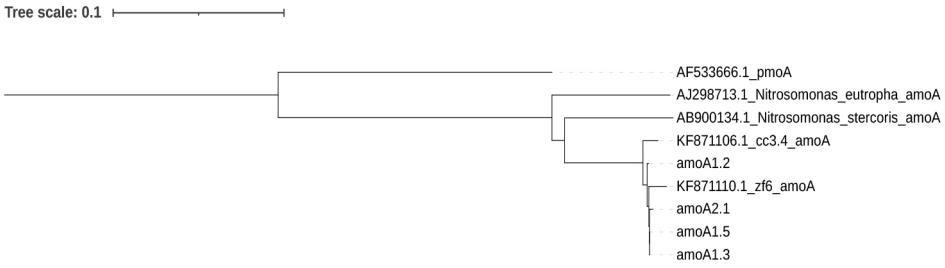

Fig. 1: Phylogenetic tree of the ammonia monooxygenase subunit A genes identified in zebrafish and carp gill tissue.

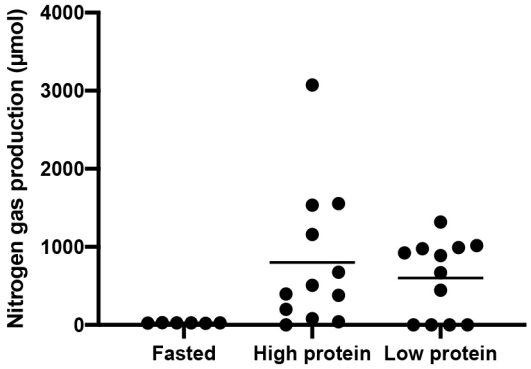

Fig. 2: Production of dinitrogen gas by carp fasted, fed by hand or ad libitum through a pendulum feeder. Mean ± SD, n= 30

Carp that were kept individually in closed tanks produced measurable amounts of dinitrogen gas within 2.5 hours and the amount of dinitrogen gas produced was higher when these fish were fed (fig. 2). This suggests a correlation between the amount of ammonia produced by fish as a waste product and the resulting production of nitrogen gas by the symbiotic bacteria.

Conclusion

Nitrogen cycle bacteria were present and active in fish gills and present a novel symbiosis between vertebrate animals and bacteria. In future experiments, we will study how these bacteria are transmitted, as well as the timepoint of colonization of the gills using germ-free zebrafish.

EFFECT OF FRESHWATER RAS ENVIRONMENT ON OSMOREGULATION, GROWTH PERFORMANCE AND ANTIVIRAL RESPONSE IN ATLANTIC SALMON (*Salmo salar*) POST-SMOLTS

Herve Migaud*, Mikey Clarkson, Lynn Chalmers, Chessor Matthew, Pedro Munoz, Ahmed M. Ahmed, Simon MacKenzie, John F. Taylor

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, UK
E-mail: Herve.migaud@stir.ac.uk

Introduction

Within the Atlantic salmon farming sector there is a growing adoption of Recirculation Aquaculture Systems (RAS) for the manipulation and production of smolts. While offering many advantages (e.g. biosecurity, water and waste management, manipulation of physiological windows), RAS systems are operated under relatively intensive and constant conditions (e.g. 24hr light, high temperature) compared to conventional ambient open water/flow through production systems and fish also experience markedly different water chemistry. Under RAS, it has been suggested that de-synchrony between photoperiod and temperature may occur (e.g. "winter" short-day at high temperature) leading to inconsistent smoltification success and suboptimal performance at sea. Osmotic ionic balance & efficiency may also be affected by interactions with rearing water chemistry. Given that the single most critical element of smoltification is the development of hypo-osmoregulatory ability to maintain hydro-mineral balance via excretion of ions, then it is imperative to understand how water chemistry variation between systems (RAS vs FT) interacts with the process of smoltification, and subsequent seawater performance (Kolarevic et al., 2014; van Rijn et al., 2020). In addition, freshwater history is likely to impact immune function and disease resistance at later sea water (SW) stages given immune suppression has been reported in smolt transferred to SW (Johansson et al., 2016), but the potential effects of RAS environment remain to be documented. Therefore, a large collaborative project was launched in 2019, ROBUSTMOLT, to test the hypothesis that environmental conditions experienced in RAS during the freshwater phase (e.g. water chemistry and microbiology, nutrition, temperature and photoperiod) may influence early life history traits of salmon that will subsequently impact the microbiomes, immune barriers, ion regulatory capacity, and ultimately robustness at sea. This communication will present results from several studies which compared growth and osmoregulation in parr reared in either FW RAS and open loch cage and performances following SW transfer including feeding, growth and disease resistance tested through an immune challenge.

Material and Methods

Analyses were done from two main studies using fish from a commercial salmon production company in Scotland reared in either a RAS or loch site during the freshwater phase and transferred to seawater either in the company marine production sites (study 1 – smoltification) or the Machrihanish Marine Environmental Research Laboratory (MERL) at the Institute of Aquaculture (study 2 – SW performance). Sampling in study 1 was performed in RAS between -500 degree.days (DD, June 2019) and 400 DD (late July 2019) from the onset of the spring photoperiod and consisted in water and blood samples for mineral analyses, gill samples for Na+ K+ ATPase (NKA including enzyme activity and gene expression by qPCR), and histological analyses, and physiological assessment (weight/length, condition and smolt index) at regular intervals from parr to smolt. Two different smoltification regimes were compared in RAS using two different identical streams, either photoperiod (RAS-P) or diet manipulations (RAS-D). Loch reared smolt were sampled similarly however SW transfer occurred later in 2019. Additional samples were collected at 1 and 4 weeks post SW transfer. In study 2, smolts produced commercially in either freshwater RAS or open loch cages were transferred to MERL between mid-February and early March 2020 (2 weeks window) with an initial weight of 92.2 g and 101.2 g, respectively. Smolts (480 from each origin) were stocked into 12 x 1.5m^3 (n = 6; 80/tank) and reared for 5 months. Fish were assessed for seawater adaptation (including ATPase, chloride, survival), growth (weight/length, SGR, FCR), feed intake (daily waste feed collection) and immune parameters following an artificial viral challenge using Polyinosinic:polycytidylic acid (poly I:C) I.P. injection (1.25 mg of poly(I:C) tested against PBS and control, n=3, 6 fish/treatment/tank) at two time points post SW transfer (2 and 6 weeks). Fish were marked with panjet (alcian blue, Sigma-Aldrich, UK) to differentiate between treatments. Sections of head kidney, liver and spleen were dissected and preserved in RNA later for gene expression analysis by qPCR of innate immunity gene markers.

(Continued on next page)

Results and Discussion

Results of study 1 showed similar growth profiles between cohorts (RAS-P/D and loch). However, differences were found in the temporal changes in smolt index and NKA in FW and blood ion balance post SW transfer. Gill NKA remained relatively stable in RAS-P fish while diet clearly promoted smoltification with a sharp rise between -500 and 150 DD and a more classic profile was observed in the loch fish. Post SW transfer, RAS fish appeared to be under osmotic stress within the first 4 weeks. Water mineral levels increased in RAS throughout the FW phase and reached levels much higher than in the loch. Further data on gill (and gut) NKA gene expression will be presented.

Study 2 showed clear differences between the RAS and loch cohorts in SW. Thermal growth coefficient was significantly higher in loch fish compared to RAS fish for the first 8 weeks post transfer. Loch fish feed intake (expressed as g/metabolic body weight/day) was significantly higher from the time to transfer indicating a better capacity of loch fish to cope with SW. Mortality remained low however was higher in RAS fish during the first 4 weeks post SW transfer further supporting the challenge experienced by RAS fish. Complement increased sharply in the RAS immuno challenged fish 2 weeks post SW transfer but not in the loch fish. The PolyI:C challenge worked effectively and elicited a strong immune response in fish. In the 6-week post-SW, a greater complement activity response was observed in the loch fish than RAS-reared salmon following the PolyI:C challenge. Expression of anti-viral genes showed significant differences between RAS and loch fish especially for LGP2, a modulator of cellular anti-viral response, in the head kidney and Mx, LGP2 in the spleen.

Conclusions

This study provides new scientific data on the impact of RAS compared to loch on osmoregulation and smoltification in FW and growth, feeding and immune response following SW transfer. Data supported anectodal reports from the industry and recently published data (van Rijn et al., 2020) with regards to RAS fish performance in the weeks following SW transfer. However, given the multifactorial differences between RAS and loch rearing conditions, further studies are needed to identify factors explaining the apparent reduced coping ability of smolts reared in RAS and develop mitigation strategies.
This work was funded by UK Research Council (UKRI), the Scottish Aquaculture Innovation Centre (SAIC) and industry partners.

Introduction

EU-CONEXUS is a transnational European higher education and research institution that covers the theme of Smart Urban Coastal Sustainability (SUCS) from a global point of view. It was created in the framework of the European universities' initiative (2019), led by the European Commission, with the aim to strengthen strategic partnerships across Europe. EU-CONEXUS is focused on urban and semi-urban coastlines that are very important, for inter alia, aquaculture and fisheries, trade, energy, tourism but at the same time, most vulnerable, to the consequences of climate change. The EU-CONEXUS Alliance includes six Partners: La Rochelle Université (FR), Universidad Católica de Valencia (ES), University of Zadar (HR), Agricultural University of Athens (GR), Technical University of Civil Engineering of Bucharest (RO) and the University of Klaipeda (LT) and 3 Associated Partners: Waterford Institute of Technology (IE), Rostock University (GE) and Frederick University (CY). The partners, from all European geographical regions, develop teaching, research and innovation programmes that include the totality of social, economic, technical and environmental problems and opportunities that the coastlines are facing today. The recent HORIZON 2020 project RESEARCH FOR SOCIETY (2021) will strengthen the EU-CONEXUS research approach into a fully-fledged university service equally covering research, education and societal needs.

Materials and Methods

The Alliance implements a student-centred service, which relies on the active engagement of students in all activities of this European University, orchestrated by the Student Board. Joint actions have been developed by creating two joint Minor course programmes, by designing joint study programmes for the Master and PhD cycle, launching a joint action for secondary schools to raise awareness on SUCS, and by developing a joint learning platform and a smart campus. A personalised approach and study track system has been chosen by EU-CONEXUS as a guiding principle of its university services in a multilingual and multicultural environment. Virtual mobility options facilitate further the selection of the appropriate course offer for special study interests by benefitting from the best available expertise wherever it is located on the inter-university campus. Several tools and activities have been developed for promoting EU-CONEXUS Joint Research Area and submitting joint projects to international calls for proposals.

Results

The EU-CONEXUS European University, launched (2021) its first joint educational offer: the "Minor in Coastal Development and Sustainable Maritime Tourism" and the "Minor in Blue Economy and Growth". In the course catalogues, students have a detailed insight into the curriculum and the opportunities/industries/jobs in the labour market where the knowledge and skills acquired in these courses can be applied. The first graduates were awarded a Minor Certificate and graduation ceremonies have been organized by the partner universities. A Skills Map for SUCS relevant employment was created, aiming to engage with the socio-economic environment. EU-CONEXUS has developed a list of stakeholders from public and private sectors, active in the fields of SUCS. A 2-year transnationally integrated multi- and interdisciplinary joint Master programme in Marine Biotechnology (JMPMB) will be initiated in 2022. The programme has been designed to entirely cover the marine biotechnology pipeline from biodiscovery to market product launch, enabling the student to integrate in a variety of professional careers. The 1st PhD summer school was held in Zadar (July 2021). Students

(Continued on next page)

gained experience working in interdisciplinary research teams, conducted by recognised experts and received a certificate and transcript of records. EU-CONEXUS Joint Research Institutes (JRIs) and research teams represent a multicultural, multilingual and multidisciplinary environment for conducting innovative research and projects, sharing common equipment, research outputs and methodology. An online Research Portal has been developed, based on a comprehensive scientific mapping, which enables the users to look up scientific interests, projects and contacts. Researchers have already benefited from the broad EU-CONEXUS network by submitting joint proposals to the HORIZON 2020 calls, COST Actions and others. Joint Standard Operating Procedures (JSOPs) have been developed, harmonising research protocols and processes between laboratories. A common Multilingual Manual of General Laboratory Safety Procedures is applied in EU-CONEXUS laboratories. In addition, educational material that encompasses audio and visual guidance was produced, to enhance laboratory training. All methodology and educational materials are available at the Protocol Portal, where researchers and students are invited to apply them in their research activities. Accreditation of certain EU-CONEXUS laboratories according to ISO/IEC 17025 validate the status of excellence and also the possibility of external services. To support the EU-CONEXUS Joint Research Area, a Call for Research Staff Mobility among the Alliance has been launched, giving researchers the opportunity for scientific knowledge exchange, life-long training and job shadowing on SUCS topics. EU-CONEXUS supports the development of joint research projects by offering a Project Development Fund supporting partners in the preparation of projects to international calls for proposals. “Research hours” are organized every month, aiming to create teams with common research interests, to identify topics for joint projects, to facilitate partnerships, to inform on upcoming calls, and eventually (?) to advice researchers on writing a good proposal. Schools, teachers and pupils participated in the school contest “Think smart, create green” and were exposed to SUCS problems and developed creative thinking by searching for solutions through scientific methodologies. The Buddy System, an initiative of the EU-CONEXUS Student Board, aims at connecting students within the alliance.

Conclusions

EU-CONEXUS partners are united around common values: sustainability, expertise, bravery and novelty. The EU-CONEXUS study programmes give students of EU-CONEXUS universities the opportunity to participate in flexible, international, multidisciplinary curricula and to acquire up-to-date competences that are in high demand on the labour market. The EU-CONEXUS Joint Research Area aims to brings together researchers and students from the different partner institutions around common fields of interest, developing science and innovation into a hub of excellence on SUCS and creating an attractive career environment for EU-CONEXUS students. Researchers actively invite partnerships with coastal industries, businesses and society actors to ensure the transfer of knowledge and the improvement of quality in and around coastal areas.

Acknowledgments

The European University EU-CONEXUS is funded by ERASMUS+ “Cooperation for innovation and the exchange of good practices” EAC-A03-2018. EU-CONEXUS RESEARCH FOR SOCIETY project is funded by the European Union’s Horizon 2020 research and innovation Programme.

DEEPER *IN VITRO* INVESTIGATION INTO THE POSSIBLE ROLES FOR FOUR MAJOR CORTICOSTEROIDS IN FOM IN RELATION TO THEIR PLASMA KINETICS ALONG THE WHOLE REPRODUCTIVE CYCLE OF FEMALE EURASIAN PERCH *Perca fluviatilis* L

Introduction

Eurasian perch, *Perca fluviatilis* L. is a promising candidate for the freshwater aquaculture and is mainly cultivated in intensive monoculture in recirculating aquaculture systems (RAS) (Fontaine and Teletchea, 2019)pikeperch Sander lucioperca. Such systems depend on the artificial control of both photoperiod and temperature to induce synchronous spawning. However, the production of eggs with optimal quality under such artificial conditions proved to be challenging (Rocha de Almeida et al., 2020; Żarski et al., 2011)regardless of the mechanism. The maternal mRNA in fish eggs is crucial for the proper embryogenesis. Our working hypothesis is that modifications of maternal mRNAs may reflect potential genetic and/or epigenetic modifications occurring during domestication and could have consequences during embryogenesis. Consequently, we investigated the trancriptomic profile of unfertilized eggs from two populations of Eurasian perch. These two populations differed by their domestication histories (F1 vs. F7+–at least seven generations of reproduction in captivity. Such deterioration in reproduction might be accredited to four major corticosteroids (11-deoxycorticosterone, 11-deoxycortisol, corticosterone and cortisol). Up to date, neither the basic roles nor the kinetics of these four corticosteroids during the whole reproductive cycle of female perch has been well defined. In previous reports on yellow perch, the involvement of the four main corticosteroids in Final Oocyte Maturation (FOM) as maturation inducing hormones (MIH) had been suggested following some *in vitro* assays (Goetz and Bergman, 1978; Theofan and Goetz, 1983). However, we recently eliminated their involvement in FOM as MIHs using *in vitro* culture assays. In fact, we confirmed using both *in vitro* and *in vivo* injection assays that 17α,20β-dihydroxy-4-pregnen-3-one (DHP) is the MIH in female perch (El Mohajer et al., 2021). The latter finding still cannot entirely eliminate their involvement in FOM mechanisms. In this study, we therefore further investigated other possibilities for their involvement in FOM using *in vitro* assays as well. Additionally, we used *in vivo* assays to better spot their involvement and monitor their kinetics during the whole reproductive cycle. Through both assays, we anticipate to better define the role of the four corticosteroids in female perch as an attempt to better understand the reproductive drawbacks in RAS systems.

Materials and Methods

In vitro assay: the activity of the four corticosteroids, at three different doses, was tested during FOM in combination with the recently realized MIH (DHP) at two different doses. The hormonal combinations were dissolved in Cortland culture medium into which mature female Eurasian perch follicles, at the start of the FOM, were added. The follicles were subjected to the treatment for a 62hrs incubation period.

In vivo assay: domesticated female Eurasian perch were kept in RAS system under strictly controlled photothermal conditions used to initiate and derive the reproductive cycle until spawning. The fish were blood sampled periodically and the plasma levels of corticosteroids were measured for each sampling time.

Results

The results of our *in vitro* combination experiment revealed that we cannot eliminate the possibility of an effect for corticosteroids during FOM where most of corticosteroids revealed a slight inhibitory effect of the MIH activity of DHP suggesting a negative effect for these steroids on the FOM achievement. Additionally, the *in vivo* plasma kinetics for most of the corticosteroids revealed some elevations in their plasma levels around ovulation and spawning. It also revealed some high levels at the initiation of the reproductive cycle. Therefore, our results are in favor of the possibility for the involvement of corticosteroids in FOM and the initial stages of the reproductive cycle. Through becoming closer to defining the roles of these corticosteroids, we believe we would better combat the reproductive drawbacks in perch maintained in RAS systems.

DIETARY FUMONISINS AFFECT THE IMMUNE RESPONSE OF RAINBOW TROUT (*Oncorhynchus mykiss*)

H. Minarova[1,2*], L. Pojezdal[1], M. Palikova[2,3], J. Mares[3], K. Hlavova[1], K. Stastny[1], M. Faldyna[1], H. Modra[3]

Introduction

Mycotoxins and their effects have been examined in different animal species; however, more information about their impact on the fish immune response is still required. Fumonisins, produced by several *Fusarium* species, represent the most common mycotoxins in plant meals, which have been more frequently used in fish feed production in recent years. These toxins can cause major health problems in fish (Oliveira & Vasconcelos 2020), including both immunostimulation and immunosuppression (Riley et al. 1996; Pestka et al. 2004). Their effects need to be investigated more, especially in the main aquaculture species.

Materials and Methods

Rainbow trout (*Oncorhynchus mykiss*) kept in recirculating systems were fed fumonisins for a period of 10 weeks. Some of the fish from the fumonisin group and from the control group were vaccinated against *Yersinia ruckeri* at week 6. At weeks 3 and 10, samples of the head kidney were taken after euthanasia of the fish (6–10 fish from each group).

Non-specific mitogen-driven (100 μg/ml phytohaemagglutinin) as well as specific antigen-driven lymphocyte proliferation assay was performed, with leukocytes isolated by density gradient centrifugation. The test was evaluated by an ELISA-based assay using bromodeoxyuridine. Levels of specific antibodies were also determined by an in-house ELISA at weeks 9 and 10.

Results

Non-specific stimulation showed a significant increase in proliferative activity after vaccination against *Y. ruckeri* in the fish from both fumonisin groups (vaccinated and non-vaccinated), indicating a pro-inflammatory immune reaction. Similar results were obtained in the non-vaccinated control. The vaccinated compared to the non-vaccinated fish from the control group showed significantly lower proliferation levels. With specific stimulation, significantly higher values were detected in the vaccinated fish from the fumonisin group compared to the vaccinated control.

Levels of specific antibodies were significantly increased in the vaccinated fumonisin group compared to the non-vaccinated fish at week 9. However, at week 10, the control fish showed similar results with even higher values. The enhanced immune reaction, which occurred very quickly in the vaccinated fish from the fumonisin group, may be indicative of pro-inflammatory changes (Ellis 1999).

Conclusions

Dietary fumonisins caused an activation of the immune system of rainbow trout after vaccination against *Y. ruckeri*, indicating a pro-inflammatory immune reaction. Alterations in lymphocyte proliferative activity and in the production of specific antibodies confirm a negative impact of these toxins on the fish immune response.

IMPROVED FERTILIZER MANAGEMENT FOR SMALL TO MEDIUM SIZED COMMERCIAL DECOUPLED AQUAPONIC SYSTEMS

Hendrik Monsees[a], Rebecca John[a], Gösta Baganz[a], Georg Staaks[a], Werner Kloas[a], Daniela Baganz[a],

a Leibniz-Institute of Freshwater Biology and Inland Fisheries, Müggelseedamm 310, 12587 Berlin, Germany

Introduction

The potential of becoming one of the most effective sustainable production systems for the combined production of animal protein and plant crops is attributed to decoupled aquaponic systems (Kloas et al. 2015, Monsees et al. 2017). Here, recirculating aquaculture systems for fish production are combined with hydroponic systems for soilless plant production allowing individual management of each single compartment thereby recycling dissolved nutrients derived from metabolism of the fish. Nevertheless, professional adjustment of selective micro- and macro-nutrients can be very expensive, especially for small to medium aquaponic operations (e.g. complete lab analysis of RAS-derived water). Therefore, (i) one of the aims of this study is to provide cost effective strategies for nutrient management in aquaponics systems. In order to meet specific plant requirements, the knowledge on nutrient concentrations as well as predictable patterns and trends in the RAS water is pertinent for correct fertilizer addition. Consequently, further aims are to (ii) identify the origins of macro- and micro-nutrient and to find accumulation patters, as well as the attempt to predict their general trends, and nutrient dynamics (N,P,K), (iii) to meet plant needs as close as possible according to a professional fertilizer management in hydroponic production units.

Material & methods

Literature values from RAS and aquaponic applications were collected with regard to predefined boundary conditions. Additionally, water samples were collected from different research or commercial RAS or corresponding aquaponic facilities. Micro- and macro-nutrients were analyzed using continuous flow analysis (CFA) and inductively coupled plasma-optical emission spectrometry (ICP-OES). Models were tested in a first trial with two different treatments against a hydroponic control (n = 3, 10 lettuce plants per replicate).

Results

General nutrient patters for RAS and aquaponic facilities were identified and used for the development of models. The first results of the model testing in a hydroponic setup revealed that lettuce can be effectively produced in an aquaponic setup without the need for detailed nutrient analyses. The lettuce growth was comparable between both aquaponic applications, but significantly reduced by 10 % compared to the hydroponic control (Fig. 1).

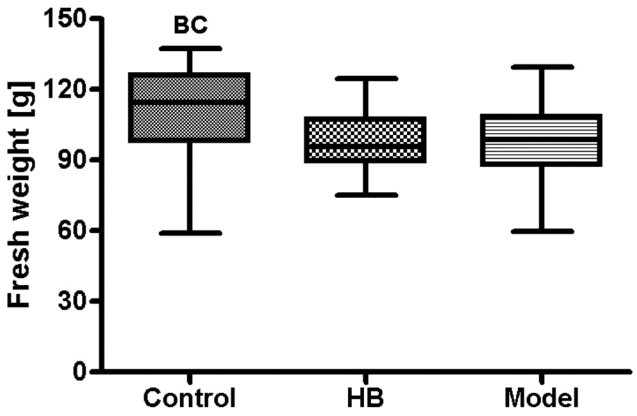

Fig. 1. Lettuce growth in three different hydroponic treatments. C = control, tab water based nutrient solution; HB - aquaponics, fish water based nutrient solution with supplemented nutrients after detailed nutrient analyses; Model - like HB, but without detailed nutrient analyses prior to nutrient supplementation. The three different treatments were applied in triplicates, each with ten individual lettuce plants.

(Continued on next page)

Discussion

The potential of identifying and using nutrient patterns in RAS and aquaponics for a combined production of fish and plants in a decoupled aquaponic approach were clearly shown in this study. By applying this easy approach, professional nutrient management can be simplified for small and medium aquaponic producers. The first results are very promising, showing that overall aquaponic yield is not affected with respect to the type of nutrient management. The post adjustment of the nutrient profile using fish water for professional hydroponic application was more challenging as in conventional hydroponics (with rain water or tap water) but it was demonstrated that for most nutrients the set points were reasonably close to the recommended nutrient concentrations as it was also shown in other studies (Suhl et al. 2016, Monsees et al 2019).

Additionally, the authors are very optimistic that with ongoing professionalization and standardization of practices in decoupled aquaponic technology, more farmers will adapt towards professional management approaches and that comparable yields to conventional hydroponic production can be expected, as it was already show e.g. in Monsees et al. 2019.

Introduction

A proper development of the aquaculture sector implies: (a) an effective replacement of marine raw ingredients (fish meal, FM; fish oil, FO) by sustainable raw materials and (b) a successful breeding program addressed to improve growth, feed utilization and fish health. Thus, the formulation of diets for genetically selected European sea bass (*Dicentrarchus labrax*) to determine how the interaction of breeding programs and nutrition together determines fish performance and diet utilization is needed, being the aim of the present study.

Materials and methods

During a production cycle a sea bass selected genotype (GS) and an unselected (wild) genotype (NGS) (15 ± 0.5 g initial mean weight), were fed a control diet with a low content of FM/FO based in nowadays commercial formulations and a "future" diet based on low FM/FO contents but formulated to cover the predictable sea bass requirements of the GS and enable them to completely express their growth and feed utilization potential. Fish were fed for nine months in triplicate (3 replicates/diet/genotype). Growth performance and feed utilization were monitored along the feeding trial. Additionally, at the beginning (t=0) and at the end of the feeding trial (t=9 months), fish were sampled for fillet biochemical composition and fatty acid profiles (15 fish/diet/genotype), morphological evaluation of the intestine (9 fish/diet/genotype), microbiota (6 fish/diet/genotype) and gene expression analyses (6 fish/diet/genotype).

Results

Sea bass genotype markedly affected fish performance. After 8 weeks of feeding GS sea bass presented higher weight gain than NGS, regardless of the diet fed (Fig. 1). This marked effect was maintained to the end of the experiment. Fillet biochemical composition results indicated that GS fish present higher ($p<0.05$) lipid and lower ash ($p<0.05$) percentages than NGS fish. Fish fed Future diet presented higher ($p<0.05$) lipid content than fish fed control diet. Besides, a significant interaction ($p<0.05$) between genotype*diet was detected for ash and protein content. Fish fed future diet presented higher ($p<0.05$) liver lipid content in expenses of protein, ash and protein percentages. A significant interaction ($p<0.05$) between genotype*diet was detected for moisture liver content. Fillet and liver fatty acid profiles will be also discussed.

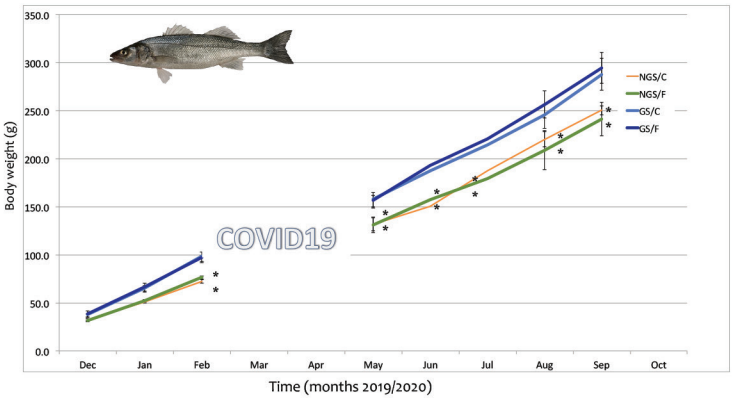

Fig. 1. Sea bass growth in terms of body weight. NGS: unselected genotype; GS: Selected genotype. C: control. F: future diet. *denotes significant differences among groups in a specific month ($p<0.05$)

(Continued on next page)

In terms of intestine gene expression, responsiveness to the feeding trial was more relevant in posterior section, where a significant interaction ($p<0.05$) between strain*genotype was found in the expression of *cd4, il-1β, il-10, mhc ii,* and *tnf-α* genes. Specifically, *il-1β* was up regulated in distal intestine of NGS fish compared to GS Europen sea bass, while *tnf-α* expression was up regulated ($p<0.05$) in GS fish fed future diet compared to fish fed the control diet. The expression of *il-10* was up regulated ($p<0.05$) in GS fish compared to NGS fish. These results were correlated with the morphology patterns observed in both intestinal regions.

The reduction of gut microbiome biodiversity was more evident in GS than in NGS fish.

Concerning gut microbiome analysis, a reduced biodiversity and species richness were found in fish fed experimental diets compared to their T0, but not among them.

At family level, Lactobacillaceae, Streptococcaceae, Staphylococcaceae, and Peptostreptococcales-Tissierellales were significantly less abundant in GS fish than in NGS fish, regardless of the diet. Accordingly, *Lactobacillus* and *Streptococcus* genera were absent in the same fish. In contrast, in NGS fish the presence of *Acinetobacter, Staphylococcus*, and *Pseudomonas* was detected.

In summary, our data indicated a higher influence of the genotype on *D. labrax* growth performance, than the diet formula fed. However, the diet formula influenced the composition of the fillet and the liver as well as their fatty acid profile. On the other hand, the genotype had a slight influence in modulating the resident intestinal microbiota composition compared to the GS strain, but NGS fish showed the presence of opportunistic pathogenic bacteria in their intestine. The NGS strain revealed a trend to show a like-chronic inflammatory status, that was more evident in fish fed future diet.

Cyberlindnera jadinii YEAST INDUCES SYSTEMIC IMMUNOMODULATORY EFFECTS IN THE SPLEEN OF ATLANTIC SALMON EXPOSED TO A DIETARY SOYBEAN MEAL INDUCED CHALLENGE

B. Morales-Lange*, J. Agboola, J. Hansen, O. Øyås, L. Mydland, M. Øverland

Department of Animal and Aquaculture Sciences, Faculty of Biosciences, Norwegian University of Life Sciences, Ås, Norway
E-mail: byron.maximiliano.morales.lange@nmbu.no

Introduction

Future growth in aquaculture depends on feed ingredients that can meet nutritional needs and improve overall health of the fish (Agboola et al., 2021). To face this problem, dietary composition of salmon feed has shifted from marine ingredients towards increased use of plant ingredients. Nevertheless, these ingredients can have negative effects such as soybean meal induced enteritis (SBMIE) and changes in gut-microbiome that affect the mucosal immunity. The effects of plant ingredients are not limited only to local targets such as the intestine, but also to systemic effects on active immune organs, since immunity has a wide range of cellular and molecular components that can act in an integrated and systemic way. Based on this, our study evaluates the immunomodulatory potential of novel microbial ingredients (heat-inactivated or autolyzed *Cyberlindnera jadinii yeast*) to control the inflammatory profile on Atlantic salmon exposed to a dietary soybean meal challenge. To achieve this, we propose the spleen as a target organ to characterize the immune response of the fish, as this organ plays a key role in the activation and coordination of the local and systemic immunity, regulating components associated with both innate and adaptive responses, through the antigen presentation process.

Materials and Methods

In this study, four diets were used (previously reported in Agboola et al., 2021), a fish meal based control (FM), a challenging diet with 40% soybean meal (SBM), and two diets containing 40% SBM and 5% of *C. jadinii* yeast exposed to different down-stream processing conditions: heat-inactivated (ICJ) or autolysation (ACJ). Then, using RNA-seq and indirect ELISA, the immunomodulatory effects of the diets were analyzed in the spleen of 10 Atlantic salmon per dietary group (from duplicated tanks) after 37 days of feeding.

Results

The results showed that SBM (compared to FM-group) induced a down-regulation of pathways related to ion binding and transport (Fig. 1), along with an increase at the protein level of CD83 and pro-inflammatory cytokines such as TNFα and IFNγ and (Fig. 2). On the other hand, the inclusion of *C. jadinii* induced an increase in MHC II and a reduction in ZBTB46, compared to both control diets (Fig. 2). However, while ICJ (compared to FM-group) maintain the inflammatory response associated with SBM, with higher levels of TNFα and IFNγ (Fig. 2), and with an upregulation of creatine kinase activity and phosphagen metabolic process (Fig. 1), the inclusion of ACJ modulated the inflammatory response compared to SBM group by the activation of biological pathways related to transporter and ion binding activity (Fig. 1). ACJ also controlled the pro-inflammatory profile of SBM, by increasing IL-10 levels and decreasing TNFα levels, triggering an immune response similar to that of FM (Fig. 2).

Conclusions

Our data suggest that the spleen is a good target to evaluate the immunomodulatory effects of functional ingredients in fish. Moreover, *C. jadinii*, after a down-stream process by autolysis, can serve as a an alternative protein sources with health beneficial effects when formulating sustainable feeds for salmonids, due to its favorable amino acid composition and its ability to control the inflammatory profile in Atlantic salmon fed challenging plant-based diets.

Introduction

The novel mechanical, thermal, optical, and antimicrobial properties of nanomaterials (NMs) make them valuable tools in many sectors such as the food industry and also in the aquaculture activity. However, there is great concern regarding the impacts of engineered NMs, mainly metallic nanoparticles (NPs), on environmental and human health. NPs are present in the marine environment, and background levels of TiO_2 and Ag NPs have been reported in molluscs [1,2]. Therefore, studies regarding controlled exposition of NPs to cultured molluscs and fish are important for elucidating the bioaccumulation rate of these new emerging pollutants and the impact on the aquaculture sector.

Transmission electronic microscopy (TEM) and single particle-inductively coupled plasma – mass spectrometry (sp-ICP-MS) has been for studying and quantifying the presence of TiO_2 and Ag NPs in mussels (*Mytilus sp*) and turbot (*Scophthalmus maximus*) after controlled exposure in an aquaculture facility. This communication summarises the preliminary results regarding the bioaccumulation rate of these new pollutants in tissues from mussels (digestive gland, mantel and gill) and turbot (muscle, kidney, intestine and liver).

Methods and results

Mussel and turbot tissues were subjected to microwave assisted acid digestion followed by ICP-MS for assessing total Ti and Ag contents; whereas, an assisted enzymatic hydrolysis procedure and sp-ICP-MS was used for TiO_2 and Ag NPs quantification/characterization. The collected tissues follow a standard procedure for TEM analysis. Shortly, fixation with Karnovsky fixative, post-fixation with osmium tetroxide and finally embed and include on resin.

ICP-MS have shown low bioaccumulation of TiO_2 NPs when exposing mussels to P25 TiO_2 (25 nm) at 0.1 mg L^{-1} [total Ti increase from 0.03 (day 0) to 0.27 µg g^{-1} (day 28)] and at 1.0 mg L^{-1} [total Ti increase from 0.03 (day 0) to 9.0 µg g^{-1} (day 28)]. The presence of TiO_2 NPs were not detected by sp-ICP-MS since the low NPs size (25 nm) but the measurement of dissolved Ti plus TiO_2 NPs (sp-ICP-MS) and total Ti (ICP-MS) were in good agreement.

Regarding Ag NPs (PVP-15 nm Ag), exposes at 0.1 mg L^{-1} showed an increase on the total Ag from 0.003 µg g^{-1} (time 0) to 1.5 µg g^{-1}, value which reached a plateau at sampling day 21st. Low bioaccumulation was also observed for experiments at 1.0 mg L^{-1} (the maximum total Ag concentration was closed to 1.5 µg g^{-1}, value which was obtained after sampling day 7th, being then constant until the end of the experiment). Ag bioaccumulation in mussels appears to be independent on the dose at longer exposure times since the maximum Ag concentrations measured in the tissues has been the same for both Ag NPs concentrations. This finding could be related with the dark scum observed in some tanks after long exposure times and/or high Ag NPs concentrations (the analysis of the dark scum revealed the presence of silver). Similar findings have been found when assessing Ag NPs instead of total Ag: Ag NPs are accumulated at a maximum concentration of 2.37×10^8 Ag NPs g^{-1} after 28 days (0.1 mg L^{-1} Ag NPs) and 2.56×10^8 Ag NPs g^{-1} after 28 days (1.0 mg L^{-1}).

Digestive gland, mantel and gill from mussels were analysed by TEM after 0, and 28 days of exposure. Neither Ag NPs nor TiO2 NPs were observed in any tissue.

(Continued on next page)

Regarding turbot, both TiO_2 and Ag NPs were found to be poorly accumulated and negligible total Ti and Ag concentrations were detected in the muscle. Most of Ti was detected in the faeces, which concentrations ranging from 1.6 (equivalent dose 0) to 40 μg g^{-1} (equivalent dose 1.5 mg Kg^{-1} per fish and day). It seems that Ti is eliminated in faeces. An analysis of the faeces by energy dispersive X-ray spectrometry (EDX)-scanning electron microscopy (SEM) confirmed the massive elimination of the TiO2 NPs by this route. However, liver was found to be a target organ for TiO_2 and Ag NPs, and little bioaccumulation rates were observed: total Ti concentration up to 0.25 μg g^{-1} (dose of 1.5 mg kg^{-1}, day 90) and total Ag concentration up to 6.0 μg g^{-1} (dose of 1.5 mg kg^{-1}, days 30, 45 and 90). Ag was also found to be accumulated in kidney [Ag concentration up to 0.25 μg g^{-1} (dose of 1.5 mg kg^{-1}, days 30, 45 and 90)]. Because of the low concentrations of total Ti and Ag in turbot tissues, the levels of TiO_2 and Ag NPs in were found un-detected in cultured turbot by sp-ICP-MS. TEM analysis of muscle, liver, kidney and intestine after 0 and 90 days of exposure showed that there was not significant bioaccumulation because no NPs were visualized in any tissue, which is in agreement with the sp-ICP-MS results. However, some ultrastructural changes were observed in some of the tissues (e.g. kidney) indicating some damaged that is currently being investigated.

Introduction

The wide spread use of metallic nanoparticles, mainly silver nanoparticles (Ag NPs) and titanium dioxide nanoparticles (TiO_2 NPs) is a current concern due to their increasing presence in the environment and the current doubts about its potential toxicity to living beings. This communication deals with controlled exposure assays of clams (*Ruditapes philippinarum*) to Ag NPs and TiO_2 NPs in order to test the potential bioaccumulation rate of these nanomaterials in species of aquaculture interest. Single particle-inductively coupled plasma – mass spectrometry (sp-ICP-MS) has been used for studying and quantifying the presence of Ag NPs and TiO_2 NPs in enzymatic extracts from exposed and unexposed clams. In addition, we have also studied the effect of exposure of these nanoparticles on the growth and mortality of clams.

Methods and results

Bioaccumulation assays consisted of exposing clams to Ag NPs (PVP Ag, 15 nm) and TiO_2 NPs (P25 TiO_2, 25 nm) at equivalent doses of 0.1 and 1.0 mg L^{-1} for twenty-eight days.

In both assays, 360 clams were distributed in 9 tanks of 50L each (40 clams / tank). Each equivalent dose was tested in triplicate. The water was renewed 3 times a week. Once a week the clams were fed with a microalgae suspension (T-iso) together with the corresponding NPs concentration. During the tests the mean temperature of the water was 18.9 ± 0.7 and 19.9± 0.8 ºC for AgNPs and TiO_2NPs assays, respectively. At days 0, 7, 14, 21 and 28, weight and length of clams shell were measured. Then, 3 clams from each tank were slaughtered (9 clams / dose) and their meat was frozen at -20ºC until analysis. Initial clams weights were 23.3 ± 3.4 and 19.9 ± 2.3 g for AgNPs and TiO_2NPs assays, respectively.

Total Ag and Ti assessment was performed by ICP-MS after a microwave assisted acid digestion sample pre-treatment. The determination/characterization of Ag NPs and TiO_2 NPs was carried out by sp-ICP-MS and an assisted enzymatic hydrolysis procedure with pancreatine and lipase was required for NPs isolation from the fresh clam tissues.

Negligible total Ag contents were assessed in clams at the initial time of the experiment (time 0) and also in the control tanks along a twenty-eight days period. Exposure at 0.1 mg L^{-1} led to a little increase on total Ag concentration in clams which was found to remain constant along the assay [from 322±66 ng g^{-1} (sampling day 7^{th}) to 310±103 ng g^{-1} (sampling day 28^{th})]. A similar result has been obtained when using an equivalent dose of 1.0 mg L^{-1} [similar total Ag concentrations at all sampling days, from 313±18 ng g^{-1} (sampling day 7^{th}) to 352±76 ng g^{-1} (sampling day 28^{th})]. It must be noticed that the increase on the equivalent dose does not imply a higher bioaccumulation rate.

Further analysis by sp-ICP-MS has revealed that the bioaccumulation rate of Ag NPs is dependent on the equivalent dose. Therefore, Ag NPs concentration were found to remain constant along the experiment [from $7.20\times10^{8}\pm4.28\times10^{8}$ Ag NPs g^{-1} (sampling day 7^{th}) to $2.66\times10^{8}\pm7.78\times10^{7}$ Ag NPs g^{-1} (sampling day 28^{th})] when exposing clams to an equivalent dose of 0.1 mg L^{-1}. However, bioaccumulation rates at an equivalent dose of 1.0 mg L^{-1} were found to increase from $1.20\times10^{9}\pm6.32\times10^{7}$ Ag NPs g^{-1} (sampling day 7^{th}) to $1.24\times10^{10}\pm1.68\times10^{10}$ Ag NPs g^{-1} (sampling day 14^{th}), remaining constant until the end of the experiment [$1.03\times10^{10}\pm1.19\times10^{10}$ Ag NPs g^{-1} (sampling day 21^{st}), and $2.57\times10^{10}\pm2.65\times10^{10}$ Ag NPs g^{-1} (sampling day 28^{th})]. During this assay, an increase in the fragility of the shells was observed, correlated with the higher the dose and the longer the exposure time. However, no significant differences were observed in weight and length between the different groups. Neither mortalities associated with the administration of AgNPs were observed.

(Continued on next page)

Regarding TiO_2 NPs, higher bioaccumulation rates than those observed for Ag NPs were obtained. Low total Ti contents in clams were assessed at the beginning of the experiment (time 0), and the total Ti concentration was found to slightly increase in the control (unexposed clams) tanks [from 109±93 ng g^{-1} (sampling day 7th) to 707±156 ng g^{-1} (sampling day 28th)]. Exposure to an equivalent dose of 0.1 mg L^{-1} led to a gradual increase of total Ti concentration from 386±124 ng g^{-1} (sampling day 7th) to 2123±479 ng g^{-1} (sampling day 21st), remaining constant at sampling day 28th (1989±596 ng g^{-1}). A similar trend was observed when using the equivalent dose of 1.0 mg L^{-1}, but the total Ti concentration was found to increase from sampling day 7th (996±392 ng g^{-1}) to sampling days 14th (2974±529 ng g^{-1}) and 21st (2866±856 ng g^{-1}), followed by a fast increase at sampling day 28th (5892±1582 ng g^{-1}).

The assessment of TiO_2 NPs at both equivalent doses has shown a little increase until the sampling day 14th, followed by a decrease on the TiO_2 NPs at the end of the experiment. Therefore, concentrations from $7.18\times10^5\pm7.28\times10^4$ TiO_2 NPs g^{-1} (equivalent dose of 0.1 mg L^{-1}) and $1.51\times10^6\pm3.46\times10^5$ TiO_2 NPs g^{-1} (equivalent dose of 1.0 mg L^{-1}) at sampling day 7th increased to $3.12\times10^6\pm2.35\times10^6$ TiO_2 NPs g^{-1} (equivalent dose of 0.1 mg L^{-1}) and $8.23\times10^6\pm2.73\times10^6$ TiO_2 NPs g^{-1} (equivalent dose of 1.0 mg L^{-1}) at sampling day 14th. Then, TiO_2 NPs concentration decreased at $1.79\times10^6\pm4.95\times10^5$ TiO_2 NPs g^{-1} (equivalent dose of 1.0 mg L^{-1}) and $2.95\times10^6\pm1.21\times10^6$ TiO_2 NPs g^{-1} (equivalent dose of 1.0 mg L^{-1}) at sampling day 21st. TiO_2 NPs concentration at the end of the experiment (sampling day 28th) were $8.66\times10^5\pm3.63\times10^5$ TiO_2 NPs g^{-1} (equivalent dose of 0.1 mg L^{-1}) and $8.17\times10^6\pm5.09\times10^6$ TiO_2 NPs g^{-1} (equivalent dose of 1.0 mg L^{-1}). The slight accumulation of TiO_2 NPs at short times affected the weight gain of the clams, although this effect disappeared when the concentrations of TiO_2Nps were reduced. The mean weight of the clams that received the 0.1mg L^{-1}dose was significantly lower with respect to the control on day 14; while in those that received the higher dose (1.0 mg L^{-1}) the weight increase was significantly less on days 7 and 14. However, no significant differences in shell length growth were detected. Furthermore, as in the AgNPs bioaccumulation test, no significant differences were obtained between the mortality of the control clams and those that received the different doses of TiO_2 NPs.

Abstract
It has been reported that the wild oyster populations provide several ecosystem services such as the water quality improvement, thanks to their high filtration capacity. To know the real filtration capacity in natural populations is initially necessary to study the individual filtration at laboratory scale. Therefore the objective of this work was to study the influence of water microalgae concentration and flow on the clearance and ingestion rates in the Pacific oyster (*Crassostrea gigas*). Oysters were collected from the wild, acclimated to captivity and kept in 1 L flow through individual tanks. Several culture conditions were tested: inlet water microalgae concentration (100, 200, 300, 400 and 500 cel/mL) and flow rate (25 and 50 mL/min). Clearance and ingestion rates were calculated every hour for 8 hours, and referred to the dry meat weight (mL/min·g, and cel/min·g, respectively). Both phytoplankton concentration and flow rate affected significantly the clearance and ingestion rates. At higher phytoplankton concentrations, the efforts for collecting feed were lower due to an elevated availability. However the concentrations between 100-200 cel/mL favored the clearance rate.

Introduction
Recently, the study of the ecosystem services in coastal and marine environments is gaining attention. It has been reported that the wild oyster populations provide several ecosystem services as the water quality improvement, seashore stabilization and habitat for fish and invertebrates (Grabowski et al., 2012).

The role of the oyster reefs on the water quality is based on their high filtration capacity. For instance, it is known that, in the late 19th century, oysters in the Chesapeake Bay probably filtered a water volume equivalent to the entire volume of the bay in less than a week (Newell, 1988). In this sense, small scale experiments are necessary to study the individual filtration for extrapolating to natural populations and determining its efficacy as natural depurators (one of their ecosystem services).

Therefore the objective of this work was to study the influence of water microalgae concentration and flow on the clearance and ingestion rates in the Pacific oyster (*Crassostrea gigas*).

Material and methods
Oysters were collected from the El Rompido shore (Spanish South-western coast), and acclimated to captivity during 14 days before starting the experiment. The mean size and wet total weight were 111.15±0.48 cm and 139.67±1,51g, respectively. The essay was carried in individual 1 L-tanks, with a continuous water and phytoplankton supply through peristaltic bombs. Animals were kept in vertical position into the tanks through a specific structure, with the valve aperture at the top. Several flow rates and phytoplankton concentrations were assayed: 25 and 50 mL/min, and 100, 200, 300, 400 and 500 cel/mL. Monospecific cultures of *Isochrysis galbana* were used for reaching those concentrations in the supplied water. *Isochrysis* cell concentration was measured at every tank water inlet (the same for all tanks) and outlet every 60 min during 8 hours for every oyster (8 per treatment). After every trial (8 hours) every oyster was sacrificed and calculated the dry meat weight. Clearance and ingestion rates were calculated every hour, and referred to the dry meat weight (mL/min·g, and cel/min·g, respectively). Data are expressed as mean±SE. A 2-way ANOVA was performed in both variables to study the effects of flow rate and phytoplankton concentration on them ($p<0.05$).

Results and conclusions
The p values obtained after the 2-way ANOVA performance are shown in Table 1. Both phytoplankton concentration and flow rate affected significantly the clearance and ingestion rates. The mean clearance and ingestion rates obtained for every trial is shown in Fig.1.

The best results for clearance rate were obtained for the *Isochrysis* concentration of 200 cel/mL, and it grew as well as the flow rate. The ingestion rate was directly related to the phytoplankton concentration for every flow rate. Therefore, at higher concentrations, the efforts for collecting feed were lower due to an elevated availability. However the concentrations between 100-200 cel/mL favored the clearance rate. This can be due to this range is similar to that found in wild conditions, and this rate can increase if flow rate grow.

(Continued on next page)

Table 1. Results (p values, ns=no significant) coming from the two-way ANOVA (phytoplankton concentration and flow rate as factors) performed on the clearance and ingestion rates.

Factor	Clearance rate	Ingestion rate
Concentration	0.00	0.00
Flow	0.00	0.00
Concentration*flow	ns	0,41

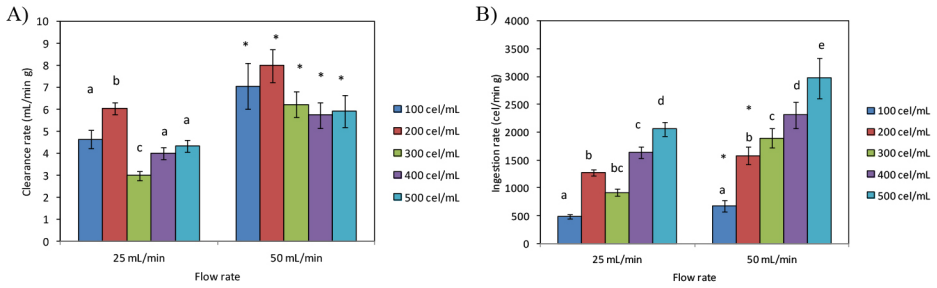

Fig 1. A) Clearance rate (mean±SE) for every treatment. B) Ingestion rate (mean±SE) for every treatment. Different letters indicate significant differences within every flow rate, and asterisks indicate significant differences between flow rates for every concentration.

Introduction

In aquaculture a great number of bacterial species are used as probiotics (Newaj-Fyzul et al., 2014). The use of these microorganisms is mostly related to the need to decrease or avoid the use of antibiotics, increasing the sustainability of the aquaculture industry. Probiotics can reduce pathogenic bacteria due to direct competition dynamics, producing inhibitory molecules and enhancing the host immune system (Balcázar et al., 2007). In cultured fish, probiotics improve fish growth and feed conversion rates, due to an increase in feed digestibility and absorption of nutrients (Merrifield et al., 2010; Martínez Cruz et al., 2012). Furthermore, the use of probiotics can restore the eubiotic state of the intestinal microbiota or can help maintain gut microbiota homeostasis (Borch et al., 2015; Ringø et al., 2016). Accordingly, the aim of the present research was to evaluate, in gilthead sea bream (*Sparus aurata*), the effects of the administration of the probiotic *Lactococcus lactis* subsp. *lactis* SL242, on growth performance, feed utilization, intestinal morphology, transcriptional response, and gut microbiota.

Materials and Methods

The trial was conducted with sea bream juveniles (70-90 g), individually tagged and reared in nine 500-L tanks with 40 fish/tank. Fish were divided into 3 groups and were fed with a control (diet A) or experimental diets (diets B and C), supplemented with 2.0 E+09 CFU/kg and 5.0 E+09 CFU/kg dose of probiotic, respectively. At the end of the feeding trial, all the animals were weighed, in order to calculate the growth index, and four fish per replicate were sacrificed to collect intestinal samples for morpho-histological evaluation, gene expression and microbiota analysis. The latter performed using Illumina MiSeq platform and a metagenomics pipeline based on VSEARCH and RDP databases.

Results and Discussion

The final biomass of fish fed diet C was significantly higher than the control group (diet A), with intermediate values for fish fed diet B. Indeed, even if without significant differences, the best growth performance tended to be achieved by the animals that have received the higher dose of probiotic. Histological analysis, performed using a quantitative metric system, confirmed that probiotic did not alter the macroscopic morphology of the intestine and did not cause inflammation. In addition, the microscopic evaluation detected an amelioration of the intestine structure, through the increase of the height of the mucosal folds and the number of goblet cells, in fish fed probiotic. These results suggest that *L.lactis* SL242 played an important role improving the potential capacity of digest and absorb nutrients. A customized PCR array was designed to study the transcriptomic response. As discussed by numerous authors (Nayak, 2010), probiotics enhance the piscine immune system. The present results confirmed these effects, as significant changes were found in the expression of key genes involved in innate and acquired immunity (il10, il12 and tlr2), that resulted upregulated in fish fed diet C as compared to the control group. The composition analysis of the gut microbiota showed a higher Firmicutes/Bacteroidetes and Proteobacteria/Firmicutes ratios in the sea bream fed diets containing probiotic compared to control fish. Despite the physiological effects on the host are difficult to assess from genomic data alone, these results could be correlated to their better growth performances (Magne et al., 2020; Rimoldi et al., 2020). Accordingly, although the microbial gut-adherent analysis reveal a lack of colonization of the probiotic in the host's intestinal mucosa, the functional prediction showed that the microbiota of fish that received probiotic was more involved in the digestion and absorption of protein. This confirms that positive modulation of fish gut microbiota can occur without probiotics colonization in the intestinal environment.

Conclusion

Our results highlight the interactions between diet and fish microbiota, suggesting that manipulating fish microbiome, through the use of well-designed probiotics, may represent a promising intervention to improve fish growth performances and digestive capacity.

Introduction

Image analysis has proven to be a powerful phenotyping tool in breeding programs. It allows an objective and numerical measures of color and shape, improving the accuracy of phenotyping these traits when compared to human-based evaluation. In aquaculture, several methods have been used to describe animal shape. Procruste based methods used morphological points of interest on the animal whereas Fourier analysis use a whole contour-based analysis. More recently, machine learning algorithms have been implemented. For shellfish, defining easily identifiable points of interests for Procruste approach is not obvious. Elliptic Fourier transformation has been shown to be more suitable in organism with shapes resembling shellfish, such as seeds or tree leaves (Costa *et al.* 2011). In our poster, we describe the development of an analysis pipeline using standardized photography, automated image analysis for colorimetric evaluation, contour-tracing and elliptic Fourier analysis for multivariate approach to shape.

Material and Methods

1249 photos of 2.5 years old shucked Pacific oyster *Crassostrea gigas*, from Vendée Naissain hatchery (Bouin, France) were taken using a Canon EOS 2000D camera, fixed and under standardized light. Upper face of the upper shell as well as animal in its lower shell were photographed. Luminosity and white balance were standardized using an internal control using Fiji software (Schindelin *et al.* 2012). Mean upper shell color in the L*a*b* color space were measured. Shell positions on images were defined, and contour of the upper shell was reconstructed using package Momocs in R (Bonhomme *et al.* 2014). Contours for all shells were then aligned, centered, and scaled, to remove position and size effects on shape. Shape was then reconstructed by using elliptic Fourier analysis for up to 15 harmonics. Variance of the Fourier descriptors was then analyzed using a principal component analysis.

Results and discussion

Color in le L*a*b* color space was found moderately variable, with coefficient of variation varying from 13 to 53%. However, the analyzed oysters were not representative of all possible color variation that can be found in the Pacific oyster – they were white to slightly orange. We expect this methodology to perform accurately even with different colored oysters such as black or stripped oysters, and more testing is currently being done.

Six harmonics described 95% of shell shape variance, and 12 harmonics described 99% of shell shape variance. We limited the number of harmonics to 6, as adding more help only to described unwanted details like the knife scar made during oysters shucking (figure 1).

The PCA of Fourier descriptors revealed that the two first axes explained 35.9 and 24.1% of variance (Figure 2). Axis one seemed to be driven by the overall roundness of shell, when axis 2 was mainly driven by shell symmetry (or asymmetry).

Conclusion

The pipeline presented here is useful for objective quantification of shape and color variance in any given population of mollusks. The method could be useful for a wide range of application: breeding and genetic improvement, rearing methods impact evaluation, or grow-out site characterization. The pipeline was developed using only open-source software for easier transferability.

Introduction

Aquaculture has an increasingly important role in providing global food security. To support the predicted growth of intensive aquaculture production it is crucial to find alternative ingredients to fishmeal (FM). Insect meals arise as a sustainable alternative to FM since insects are efficient converters of biowaste, require almost no land and water for their production, and possess high amounts of protein, lipids, vitamins, and minerals. Chitin, which is present in the exoskeleton of insects, has also been indicated to possess antioxidant boosting proprieties, indicating that insect meals can also be used as functional ingredients in aquafeeds (1). Therefore, this study aimed to evaluate the effects of dietary FM replacement with increasing levels of defatted black soldier fly, *Hermetia illucens,* prepupae larvae meal (HM), up to 100%, on growth performance and liver oxidate stress response of gilthead seabream juveniles.

Materials and methods

Four isoproteic (43% CP) and isolipidic (18% CL) diets were formulated to include HM (61.8% CP, 6.8% CL, 11.9% ash, 21.6 kJ g^{-1} gross energy, 6.20% chitin) at 0 (HM0), 15 (HM15), 30 (HM30), and 45% (HM45), replacing 0, 22, 60, and 100% of FM protein, respectively. A feeding trial was conducted with triplicate groups of gilthead seabream juveniles (initial body weight of 32 g). Fish were hand-fed twice a day, 6 days a week, for 67 days. At the of the trial, feed consumption was recorded, and fish were bulk weighted for estimation of growth performance. The liver of 3 fish per tank was also sampled for the determination of oxidative stress parameters.

Results and discussion

Present results indicate that HM is well tolerated by gilthead seabream juveniles and can replace all FM protein (corresponding to 79% of the protein in the control diet) without compromising growth performance and feed efficiency (Table 1).

Compared to the control, the dietary inclusion of 15% and 30% HM led to a decrease in the activity of superoxide dismutase (SOD) and glutathione reductase (GR), respectively, while a 45% inclusion of HM decreased the activity of glutathione peroxidase (GPX) and glucose-6-phosphate dehydrogenase (G6PDH) (Figure 1). On the other hand, catalase (CAT) activity and lipid peroxidation (LPO) were not significantly affected by diet composition (Figure 1). These results seem to indicate that dietary HM induced some responses in the hepatic oxidative enzyme response, while not affecting liver oxidative stress.

Introduction

Fresh fish can easily deteriorate after being captured due to the endogenous enzyme activity and rapid microbial growth naturally present in fish. What is more, changes in composition during fish decay leads to protein degradation and lipid oxidation, as well as changes in fish odor, flavor, and texture. Therefore, it has become imperative to develop effective treatment methods in order to extend the shelf life of fish (Campos et al., 2012). Application of organic acids on fish surfaces, mainly through dipping or spraying, is a widely used and well-known practice due to their antimicrobial properties (Mei et al., 2019). The objective of the present study was to investigate the effect of minimal processing methods, i.e. surface decontamination of fish with organic acids, on the quality and shelf life of farmed European sea bass (*Dicentrarchus labrax*) under controlled isothermal conditions (0°C).

Materials and methods

Whole farmed European sea bass were treated using organic acids. Samples were stored isothermally at 0°C for 6 days after harvesting to evaluate the effect of organic acids on the initial microbial load. Fish was gutted manually and immersed in water for 0-10 min. The incorporation of natural organic acids (0-200 ppm, 0-10 min - lactic acid, citric acid and peracetic acid) at different concentrations in the washing water during gutting was also tested for its efficacy to reduce the initial microbial load and prolong the shelf life. Control (treated with water) and organic acid treated samples were afterwards stored under controlled isothermal conditions (0°C) for shelf-life testing. Microbial enumeration included several spoilage microorganisms, such as total viable count (TVC), *Pseudomonas* spp., *Enterobacteriaceae* spp. and H_2S-producing bacteria (mainly *Shewanella putrefaciens*). Quality evaluation included evaluation of pH, colour and texture measurement and sensory parameters (1-9 scale). A sensory score of 5 was taken as the average score for minimum acceptability.

The activity of major proteases, namely Calpain, Collagenase, Cathepsin B and L responsible for white muscle degradation was also measured; a piece of white muscle was extracted from the treated fillet on day 0, 2, 3, 6, 7, 10, 12 post-treatment, snap-frozen in liquid nitrogen and stored at -80 °C until enzyme extraction. Enzymes were extracted and the activity of these enzymes was assayed as described in Ntzimani et al. (2021). Activity was expressed as fluorescence units (FU) change per minute per mg protein.

Results

Higher washing solution concentrations and longer treatment, led to increased microbial load reduction. Initial surface decontamination in the range of 1.0-2.0 log cfu/g (for total viable count, *Pseudomonas spp. and Enterobacteriaceae spp.*) by the addition of organic acids in the washing water, resulted in 3-4 days shelf-life extension of fish stored at 0°C. Higher reduction of the initial microbial load was observed after treatment with citric acid for TVC, *Pseudomonas* spp. and H_2S-producing bacteria, and with lactic acid for *Enterobacteriaceae* spp. Microbial growth during subsequent refrigerated storage of untreated (Control) and treated fish was modeled using the Baranyi Growth Model. The limit of sensory shelf life of gutted fish (score 5 by the sensory panel for overall impression) coincided with a level of 10^7 cfu/g of *Pseudomonas* spp. for gutted samples, stored at 0° C (Tsironi et al., 2019).

(Continued on next page)

Amongst the treatments all four proteolytic enzymes recorded the lowest activities post-treatment with 200ppm peracetic acid (P200). In contrast, the lower concentration of 150ppm peracetic acid (P150) could not delay an early activation of calpain and collagenase. P200 and P150 groups differed significantly in all four enzymes (p-value<0.05). Following the citric acid treatment, calpain and collagenase shared a similar activation pattern having an early high peak two days after the citric acid was applied. Cathepsins are acid proteases located in the lysosomes. They may be liberated into both the cytoplasm and the intracellular spaces as a consequence of lysosomal disruption occurring after cell death due to a pH fall (Cheret et al., 2007). Cathepsins B & L are two cysteine proteases with an optimal activity pH of 5-7.5 (Larsen et al., 2004). Applying citric acid (200ppm) appeared to influence their activities recording lower activities compared with the control group even 12 days post-treatment (p-value<0.05).

Discussion and conclusion

The results of the study indicated that the application of organic acids, as alternative disinfection approaches to the conventional post-harvest fish processing methods, led to improved stability of flesh quality during subsequent refrigerated storage and significant shelf-life extension, in terms of microbial growth, physicochemical and organoleptic degradation of the fillets. Regarding the endogenous enzymatic activity, applying peracetic acid in the highest, according to the FDA, concentration resulted in a late and low activation on all four enzymes, in favour of the flesh quality. Similarly, the suppression of cathepsin activity following the citric acid treatment (200ppm) is expected to delay the fillet degradation during storage. The results encourage the application of minimal processing of fish to extend shelf life and penetrate new distant markets currently inaccessible to fresh fish products.

Introduction

Temperature is a high impact factor for the performance and wellbeing of poikilothermic organisms and it is gaining importance as climate change and disturbance of seasonal temperatures are expected to impact on organismal fitness. Each animal is adapted to perform within a thermoneutral zone of temperatures and within that range, optimal temperatures for survival, development, and growth are recorded. An important biological function that is implicated in growth and development and is influenced by changes in environmental temperatures is the oxidative phosphorylation (OXPHOS), which produces enough energy to cover up to 90% of the cellular energy needs. Here, we investigate how different rearing temperatures at early development may influence the response of OXPHOS genes to exercise in metamorphosing larvae of gilthead seabream (*Sparus aurata*).

Materials and methods

Gilthead seabream eggs from a spontaneous spawn of captive breeders were subjected to 17, 20 and 23°C, from the onset of the epiboly to the end of yolk-sac larval stage and the beginning of exogenous feeding; subsequently all groups were kept under identical rearing conditions and constant rearing temperature (20°C) up to the end of the trial (18–19 mm TL). Swimming performance was assessed by estimating the relative critical swimming speed at the middle of metamorphosis. Both rearing and swimming test conditions are described in detail by Kourkouta and colleagues [1]. A total of 68 samples of the caudal region were collected and stored in methanol at -20°C until RNA extraction. Samples represented the three rearing temperatures while for each case, control (not exercised) and exercised individuals were sampled. RNA was isolated and cDNA synthesis was performed. The expression of nine (9) genes of interest was quantified by real-time PCR and it was normalized against two reference genes (rps18, rpl13a). Eight of the target genes are the paralogues coding for subunits of OXPHOS complex III (*uqcrfs1a, uqcrfs1b, uqcrha, uqcrhb, uqcrc2a, uqcrc2b, uqcr11a, uqcr11b*); the ninth one is PPRAG-coactivator-1a (*pprgcg1a*), a marker of mitochondria biogenesis. Significant differences between the expression level of each gene at different temperatures and exercise level were analyzed using Wilcoxon signed-rank test.

Results

Developmental temperature (DT) alone (control samples) affected the expression of neither of the OXPHOS genes nor *pprgc1a* with only exception *uqcr11a* that was significantly lower at 17°C than at 20°C reared fish. Interestingly, DT governed differential responses to swimming in four genes implicated in mitochondrial biogenesis and function (*pprgc1a, uqcrfs1a, uqcrfs1b, uqcrhb*) as compared with the control fish. These increases were common in fish reared at 23°C, while such an increase was also observed in *uqcrfs1a* of fish reared at 17°C. Exercised fish reared at 20°C or/and 23°C exhibited significantly higher expression levels than exercised fish reared at 17°C.

Discussion

The effect of exercise on mitochondrial biogenesis and on OXPHOS regulation and efficiency are well studied in different animals including fish [2]. While the impact of exercise on those procedures is obvious, the way that different factors including the kind and length of the exercise [3], the nutrition uptake [4] and the general state of the exercised individual, the needs of specific tissues [5] and or developmental stages along with environmental factors such as temperature [6] or oxygen availability [7] affect those procedures may vary. In this study we show that while the different DT appeared to have no impact on the mitochondrial bioenergetics of metamorphosing fish under normal circumstances, the exercise challenge revealed a differential capacity to respond as shaped by early DT. Our results suggest that DT changes in a short time window at the beginning of development is sufficient to influence plasticity in OXPHOS gene response later on, under highly energetic demanding processes such as acute exercise. For each gene examined, only one of the gene paralogues was highly affected by DT, indicative of the subfunctionalization occurred following teleost-specific whole genome duplication. The results render further investigation in a fast changing climate and aquatic environment.

Introduction

The reliance of European aquaculture on marine feed ingredients continues to be high and the dependence on wild caught fish cannot support the aim for sustainable doubling in production by 2030(Leduc et al., 2018).In the quest for highly nutritive and functional raw materials to efficiently replace fish meal, plant proteins represent a suitable protein alternative to fish meal and are increasingly being used in fish feed (Morais, 2011). However, plant-based diets have also been reported to impact fish metabolism by regulating the expression of genes involved in amino acid metabolism, lipid metabolism, carbohydrate metabolism, and immune function (Xu et al., 2018). In gilthead seabream (*Sparus aurata)* aquaculture, genetic selection has been applied to improve several key features such as growth and to allow the adoption of plant ingredients with minimal impact on growth and health (Perera et al., 2019). In this study, we examine the response of erythrocyte transcriptome to an experimental plant-rich across different genetic backgrounds in gilthead seabream, as shaped during a commercial breeding programme.

Materials and methods

Sampling took place in a commercial fish farm of Nireus Aquaculture SA (member of AVRAMAR Group), in Paleros, Greece. Fish originated from six full-sib families were tagged with an intraperitoneal chip and randomly divided into two sea cages, which were fed on different diets; a high plant-protein containing 85% plant proteins and a high animal-protein containing 30% of marine animal protein. Two samplings were performed at 15 and 30 days after the initiation of feeding trial. Blood was sampled by caudal puncture, transferred into sterile tubes, centrifuged to separate the plasma from erythrocytes, which were stored in RNAlater until RNA extraction.

Total RNA from erythrocytes of selected samples was extracted using the E.Z.N.A.® Total RNA Kit I. Samples were pooled in full-sib families and sent to Novogene Europe for RNA sequencing. In total 24 samples (6 families x 2 Feeds x 2 sampling days) were sent for creating sequencing libraries. The indexed libraries were sequenced on HiSeq 2000 platform (Illumina, USA) employing 150bp paired end reads. Quality control, assembly and annotation of the transcriptome was performed from Novogene Europe. For the validation of a number of differentially expressed genes a real time quantitive PCR was performed individually on the samples used for the transcriptome analysis.

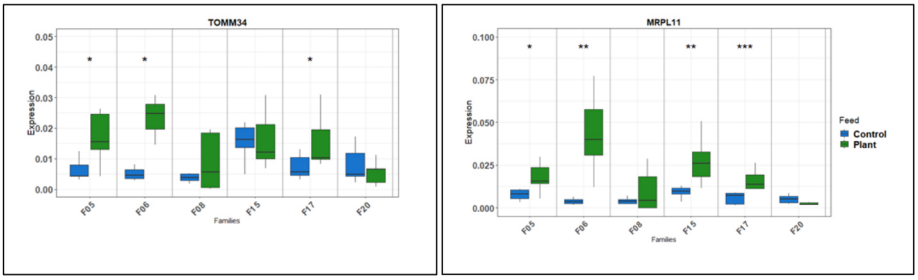

Figure 1. *Family-specific response of mitochondrial ribosomal protein 11 (MRPL11) and translocase of the outer mitochondrial membrane (TOMM34) in erythrocytes 15 days from feeding initiation.*

(Continued on next page)

Results and Discussion

A high number of differentially expressed genes were identified at all pairwise comparisons performed. Specifically, 2618 genes were upregulated, and 1312 genes were downregulated in all families fed on the plant-based diet. Genes with elevate transcription level were participating in biological processes as oxidative phosphorylation, proteasome, ribosomal proteins, and the supplement. On the contrary, a decreased gene transcription was observed on phospholipid synthesis and membrane cytoskeleton. Also, a high number of genes involved in immune responses were detected suggesting inflammatory response.

A differential expression analysis was also performed within each family. In total, 118 genes continued to emerge amongst the comparisons. A selection of genes with the higher p-value and the biggest log-foldchange was made for evaluating their expression through real time quantitative PCR. The detailed expression patterns revealed significant family-specific response of erythrocyte transcriptome to the plant-rich diet (Figure 1). In addition, the expression patterns differentiated between day 15 and day 30 after initiation of feeding, adding an extra dimension to the family-specific response.

Conclusion

Erythrocyte transcriptome offers a non-invasive way to explore the physiological consequences of novel raw materials in aquaculture towards increased sustainability. Moreover, the results of the study verify the potential of genetic selection towards the sustainability of aquaculture production.

Introduction
Progressive loss of fish freshness post-mortem is attributed to complex combinations of biochemical and structural changes along with muscle spoilage caused by microbial activity (Tavares et al. 2021). Proteases that hydrolyze the collagen of the connective tissue (collagenases), and the muscle fibril proteins, predominantly cathepsins and calpains, hold a key role in this process (Sriket, 2014). The objective of this study was to evaluate the effect of electrostunning as an effective alternative harvest technique on the flesh quality of gilthead seabream (*Sparus aurata)*. How this effect differentiates with seasonal water temperature was also explored.

Materials and methods
Whole gilthead seabream (*Sparus aurata*) was harvested from net cages in Nireus Aquaculture SA (member of AVRAMAR Group) facilities and stored immediately in ice. Two different electrostunning settings were compared with the conventional harvest method (**CS**) of ice water; **HC**, high electric field 2V/cm and flow 1.6m/sec; **LC**, low electric field 1.8V/cm and flow 1.6m/sec. Sampling was performed in the same fish farm in Astakos (Aitoloakarnania, Greece) in August 2020 and February 2021.

The activity of major proteases, namely Calpain, Collagenase, Cathepsin B and L responsible for white muscle degradation was measured; a piece of white muscle was extracted from the fillet at slaughter (day 0) and on days 1, 2, 5, 7 and 13 post slaughter, snap-frozen in liquid nitrogen and stored at -80 °C until enzyme extraction. Crude enzyme extract was extracted according to Lakshmanan et al. (2005) with slight modifications. The activity of these enzymes was assayed by the Barrett and Kirschke (1981) method with minor refinements. Protein content in enzyme extracts was quantified with the Bradford (1976) method using bovine serum albumin as standard. Activity was expressed as fluorescence units (FU) change per minute per mg protein.

Results
At sampling, the average water temperature was 25°C in August 2020 (Hot) and 15.5°C in February 2021 (Cold). Calpain exhibited the highest levels of activity of all the proteolytic enzymes measured in both seasonal periods. In Cold period, HC group exhibited the lowest enzymatic activity amongst all proteolytic enzymes, whereas LC elicited an early activation. These differences between LC and HC groups were statistically significant (Cathepsin L p-value<0.05 Cathepsin B, Collagenase and Calpain with p-value<0.001). On the contrary, in Hot period a mixed activation pattern was observed. Calpain and Collagenase activity in HC group recorded an early high activation pattern in comparison with the LC group (p-value<0.05). Although, a late peak in enzymatic activity of both cathepsins was observed in HC group in comparison with the LC group, statistically significant differences were observed only in cathepsin B activities (p-value<0.05) A significant correlation amongst enzymatic activities was observed across slaughter methods and water temperatures.

Discussion and conclusion
In both seasonal periods, calpain and collagenase activities showed an early activation post-mortem in accordance with previous studies (Ntzimani et al. 2021; Bao et al. 2020). Significant temporal differences in all enzyme activities were recorded in either water temperature, and different harvest methods. Fish being poikilothermic animals, cannot maintain stable temperature and its physiology is directly affected by water temperature changes. This may be a decisive factor in deciding which electrostunning settings will be used in each temporal period.

Introduction

Fish behavior activity is complex activity, which is traditionally determined by human experts, telemetric tags, flow through chamber of by tracking of the individual fish using computer vision. Several methods of fish behavior monitoring have been developed for different reasons. The most promising and cheap method is computer vision fish tracking. It provides an automated, non-invasive, and cost-effective methods of recording behavioral parameters. Single camera or multi-camera 3D machine vision has been used in behavior analysis or trail tracking (Saberioon and Cisar, 2016). The visible or near infrared light is used for fish monitoring (Farokhi et al., 2016, Pautsina et al., 2015). The output of the monitoring systems is the 3D trajectory of the fish which represent the fish swimming during the given period. The main issue of the monitoring systems is the tracking of the fish in the tanks with high fish density. The fish overlapping enables to monitor individual fish behavior just for very limited time. Therefore, some studies focus on the parametrization of the behavior of the fish school instead of the individuals.

Application of the modern deep learning methods (Nichols et al., 2019) could solve the problem of fish behavior parametrization without the need to detect and track individual fish. To be able to optimize the feeding we have to distinguish (classify) different states of the fish based on the analysis of the behavior. The deep learning concept will be used to automatically parametrize fish behavior and classify it into predefined classes. The research is focused on the feeding optimization in intensive aquaculture and specially on the recirculation aquaculture systems (RAS) represented by the fish cultivation tanks. This focus is given by the possibility to control all conditions of the fish cultivation and precise control of fish feeding and feed distribution in the tank.

Materials and methods

The initial experiments were focused on the classification of Sea bass behavior into 3 classes: normal, stress (caused by knocking on the tanks) and feeding, Fig. 1. The video records of fish swimming in the standard cultivation tanks (3 tanks) were collected. The short videos (4 minutes) of all three types of behavior were collected using 45 fish. Video data were cut into 3 seconds clips and resized to 228 by 228 pixels. Only the inner area of fish tank was used for processing. Totally 210 sequencies were obtained for each class and 100 randomly selected sequencies were used for classification validation. for The GoogleNet feature extractor (Szegedy, 2015) was used for data processing.

Each frame of video was transformed into 1024 features and stored in vectors in sequence of 45 rows (3 second of 15 fps video). After preprocessing, feature vectors sequencies were feed to Long Short-Term Memory (LSTM) network to process the sequential data and perform the classification.

Results

The classification accuracy after 30 epochs of training was 99%, such high accuracy shows that classes are significantly different and easily distinguishable by the network. On validation dataset accuracy was 99% that also show that our network was not overfeed.

Discussion

In this study we proved that we could distinguish between different types of fish behavior using the concept based on deep learning. The concept avoids the detection and tracking of individual fish in the tank. The disadvantage of the approach is generalization of the solution. The system is specific for the fish species and for the cultivation tanks used for network training. The similarity of cultivation tanks (mainly circular shape) and possibility to make specific models for fish species will enable to use the concept for general fish behavior monitoring. We started new experiments for common carp with more classes of fish behavior to study the possibility of feeding optimization and fish welfare determination.

(Continued on next page)

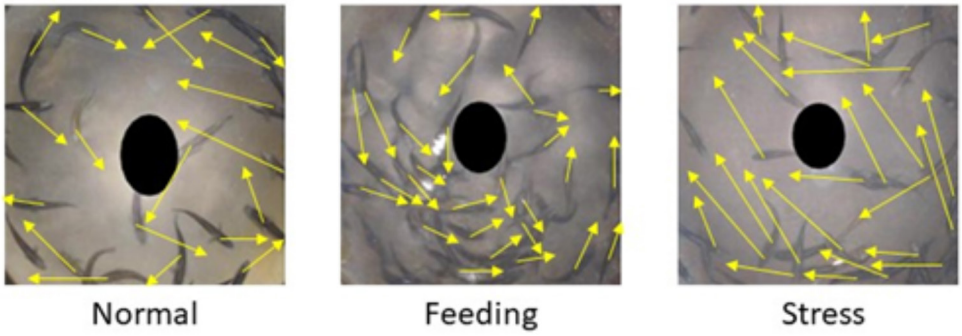

Fig. 1 Example of tree behavior classes: left – normal behavior where the fish swim all directions, middle – feeding behavior where the fish search for the food, right - stress behavior where the fish swim out of the noisy place.

Introduction

Due to its rapid reaction time with organics and potent efficacy as an oxidative disinfectant, the usefulness of peracetic acid (PAA; chemical formula $C_2H_4O_3$) has been demonstrated in a range of industrial applications. Previously, the antimicrobial, bactericidal, virucidal, fungicidal, and sporicidal properties of PAA have been exploited for highly effective wastewater treatment (Kitis, 2004). More recently, PAA has been used to improve water quality in recirculation aquaculture systems (RAS) without disturbing the microbial composition and nitrification function of biofilters (Suurnäkki et al., 2020). While PAA has not yet been approved by the U.S. Food and Drug Administration for use in aquaculture in the United States, PAA has been approved in Europe for use in aquaculture systems and by the U.S. Environmental Protection Agency (EPA) for use as an aquaculture surface disinfectant (e.g. tanks and pipes) when food fish are not present (DiCocco et al., 2021). With increasing use of PAA as an alternative to other therapeutants and disinfectants, having a rapid and accurate method for PAA concentration analysis is very useful. This comparison includes two methods: (i) CHEMetrics Peracetic Acid Test Kit — Vacu-vials Instrumental Kit and (ii) Hach Total Chlorine Method 8167. The CHEMetrics Peracetic Acid Test Kit features self-filling ampoules for the colorimetric analysis of PAA, 0-5.00 ppm. The kit employs DPD (N,N-diethyl-p-phenylenediamine) chemistry. The sample is treated with an excess of potassium iodide, PAA oxidizes the iodide to iodine, then iodine oxidizes DPD to form a pink coloured species in direct proportion to the PAA concentration. Hach Total Chlorine Method 8167 uses the same DPD chemistry process. This method features a powder pillow reagent added to a glass vial along with the option of self-filling ampoules. For this comparison, the power pillow variation was used. Results through this method are given as 0.02-2.00 mg/L Cl_2 and used to calculate mg/L PAA with a multiplier of 1.07. Both methods require use of a colorimeter or spectrophotometer.

Materials and methods

This comparison was conducted by reviewing and analyzing multiple factors of each method. To analyze the accuracy of both methods, four different standard solutions of PAA were created using a commercial product containing 15% PAA and 10% H_2O_2. Each standard was then tested in triplicate using both methods. Results were compared to the target standard solution for accuracy. Standard solutions were neutralized using sodium thiosulfate before disposal. Other factors taken into consideration for comparison include time and effort required, cost, and disposal.

Results & Conclusions

After comparison of accuracy, time and effort required, cost, and disposal, the CHEMetrics vacu-vials were superior only in the time and effort required by the method. The vacu-vials had a reaction time of only one minute, where the Hach Total Chlorine Method 8167 reaction time was three minutes. The steps required for the vacu-vials were also less, making the process more streamlined and easier to accomplish in a shorter time than the Hach Total Chlorine Method 8167. The vacu-vials covered a wider range of PAA concentration, eliminating any need for dilution for a concentration less than 5.0 mg/L of PAA. Otherwise, the two methods were comparable in terms of accuracy and disposal requirements. The average accuracy of the CHEMetrics vacu-vials being 97% and the Hach Total Chlorine Method 8167 being 95%. The Hach Total Chlorine Method 8167 was more economical in the upfront cost with $0.23 per powder pillow, while the CHEMetrics test was $1.06 per vacu-vial.

OPTIMIZATION OF PRODUCTIVITY, FATTY ACID AND FUCOXANTHIN CONTENT OF *Chaetoceros muelleri* AND *Thalassiosira pseudonana* IN THE PROVIAPT FLAT-PANEL PHOTOBIOREACTOR

Introduction

The production of microalgae with a stable and high nutritional quality within hatcheries and nurseries of crustaceans and bivalves is still a major bottleneck. Culture conditions are often suboptimal, reducing culture density, productivity and resulting in lower and unstable nutritional microalgae quality. Furthermore, contamination often spoils the product and culture crashes reduce hatchery yields, all increasing the operational costs. Finally, regular photobioreactors are often unsuitable for the cultivation of sensitive microalgae species such as *Chaetoceros* sp., because of induced shear stress, again resulting in low productivities and a reduced nutritional quality.

Proviron (Hemiksem, Belgium) has developed, engineered and patented a closed photobioreactor system for indoor cultivation of microalgae, named ProviAPT (Proviron Advanced Photobioreactor Technology), which is particularly suited for the mass production of high quality algae biomass for aquaculture purposes. One ProviAPT production reactor features a total of 35 vertical flat panels and a volume of 220 Liters, made out of a feed-grade plastic film material, illuminated artificially by means of LED lights. The vertical stacked reactor configuration allows high areal productivities and the specific reactor geometry allows operation both at low pressure gradients and at reduced airflows. Other than resulting in major cuts in energy cost for aeration, this geometry provides gentle cultivation conditions allowing the system to host sensitive, recalcitrant species. Rigorous control and standardization of the operational parameters results in a product of constant and high quality.

The presented work includes: (1) the optimization of productivity, lipid content, fatty acid profile and fucoxanthin (bioactive carotenoid) content in a lab-scale proviAPT reactor by means of light conditions (wavelength mixing ratios) and dilution rate; and (2) the validation of these laboratory scale observations at full production scale.

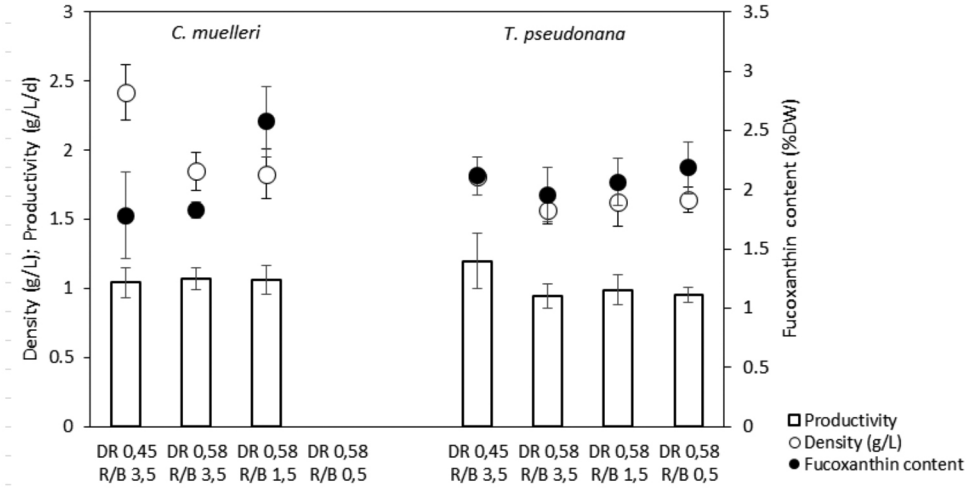

Figure 1. Influence of light conditions (R/B: wavelength ratio red-to-blue) and dilution rate (DR: dilution rate) on the productivity and fucoxanthin content (%DW) of *C. muelleri* and *T. pseudonana* (data at DR 0.58 R/B 0.5 for *C. muelleri* to be determined).

(Continued on next page)

Materials and methods

Chaetoceros muelleri (CCAP 1010/3) and *Thalassiosira pseudonana* (CCAP 1085/12), two diatoms with importance in larval feeds, were cultivated in 6.4 Liter lab-scale ProviAPT photobioreactors in semi-continuous operation mode, with a feed cycle of 12 hours. A temperature of 20.5 ± 1°C, CO_2 concentration of 0.5 %(v/v) and a salinity of 25 ppm was applied, while light intensity was kept at 473 μmol photons/m^2/s in a 20:4h day-night regime. Tested operational conditions are presented in figure 1. Temperature, pH, salinity and cell density were logged daily. After a minimum of 7 days in equilibrium conditions, microalgae biomass was harvested and stored at -20°C upon freeze-drying and analysis for ash fraction, total lipids, fatty acid profile and fucoxanthin content. Subsequently, lab-scale observations were validated at industrial scale in one reactor battery counting 6 production units, each composed out of 16 proviAPT reactors of 220 Liter, containing 21 m^3 of microalgae culture. Hereby, the laboratory scale

ProviAPT reactor of 6.4 Liters is an exact copy of 1 of the 35 flat panels of a full-scale reactor with a volume of 220 Liters.

Results and discussion

For both, *C. muelleri* (CM) and *T. pseudonana* (TP), enriching the light in the blue spectrum over a red-to-blue ratio (R/B) from 3.5 to 0.5 or increasing the dilution rate (DR) from 0.45 to 0.58, did not influence the average growth rate significantly with a value of 1.06 ± 0.02 g/L/d for CM, compared to 1.02 ± 0.12 g/L/d for TP (Figure 1). In contrast, for CM, fucoxanthin content increased significantly with 44% (from 1.8 ± 0.4 to 2.6 ± 0.3 %DW) when the light was enriched with blue wavelengths (R/B from 3.5 to 1.5). Fucoxanthin content of TP was not influenced by the color of light, presenting a stable value of 2.1 ± 0.1 %DW. An increase in dilution rate, resulting in a decrease in biomass density, was not observed to influence fucoxanthin content.

Enriching the light in the blue spectrum (from a red-to-blue ratio of 3.5 to 1.5) resulted in an increase in total fatty acid content from 55 to 68 mg FAME/g AFDW for TP, with a significant increase in eicosapentaenoic acid (EPA; C20:5n-3) from 1.3 to 2.0%AFDW. Similarly, docosahexaenoic acid (DHA; C22:6n-3) increased from 0.19 to 0.27%AFDW.

The full fatty acid profile and total lipid content for both microalgae species will also be presented, as well as the validation of laboratory scale observations in production scale proviAPT photobioreactors.

Conclusion

The presented findings indicate that light conditions (e.g. decreasing the mixing ratio red-to-blue) can be tuned at industrial scale microalgae production facilities to increase the fatty acid, EPA and DHA content of the diatom *T. pseudonana* and fucoxanthin content, a promising bioactive compound in larval feeds, of *C. muelleri*. Furthermore, the suitability of the proviAPT laboratory scale photobioreactor was verified to maintain a constant microalgae productivity with a stable nutritional value over time under fixed operational conditions, while it was found that optimized growth conditions at laboratory scale can be applied at industrial scale.

THE APPLICATION OF NACL IN PIKE-PERCH AQUACULTURE TAKING INTO ACCOUNT ONTOGENY

Christopher Naas * [ab], Werner Kloas [b], Andreas Müller-Belecke [a]

a Institute of Inland Fisheries in Potsdam-Sacrow, Im Königswald 2, 14469 Potsdam

E-Mail: christopher.naas@ifb-potsdam.de

The optimal salinity for rearing juvenile pike-perch (*Sander lucioperca*) in recirculating aquaculture systems (RAS) is 3g NaCl L^{-1}. Hereby, an increased biomass gain and feed utilization can be expected. However, throughout pike-perch's development from egg to yearling, fundamental morphological and physiological but also major nutritional changes take place. These alterations are likely to affect the optimal salinity of this species when reared in RAS.

In a set of different experiments, we investigated the performance of five different life stages of pike-perch exposed to different NaCl concentrations - and where possible - under RAS or RAS-like conditions, respectively. First, a standardized fish egg test was conducted in order to investigate the embryonic development of pike-perch considering NaCl (0 to 12g NaCl L^{-1}). Free-swimming and feeding larvae (0.8mg body weight (bw)) and dry-feed adapted pike-perch (0.4 g bw) were exposed to NaCl (0 to 9g NaCl L^{-1}) in static exposures. Furthermore, pike-perch fingerlings (30g bw) and yearlings (100g bw) were reared in RAS under different saline conditions (0 to 12g NaCl L^{-1}). Based on aquaculture performance parameters (growth, feed efficiency), as well as further welfare indicators an optimal NaCl concentration for every life stage was determined.

Pike-perch's embryonic development was not affected at concentrations up to 6g NaCl L^{-1}. Beneficially, the exposure to NaCl significantly reduced fungal infections during the incubation. Free-swimming and artemia-feeding larvae grew best under 6g NaCl L^{-1}, but did not tolerate 9g NaCl L^{-1}. Dry-feed adapted pike-perch showed best growth at 3g NaCl L^{-1} with a clear decrease in performance when NaCl concentrations increased. Also, pike-perch fingerlings showed best performance under 3g NaCl L^{-1}, but displayed growth depression at 6 and 9g NaCl L^{-1} and did not tolerate 12g NaCl L^{-1} at all. Pike-perch yearlings can be reared up to 6g NaCl L^{-1} without negative effects on their growth performance.

Consequently, the optimal NaCl concentration varies with the ontogenetic development of pike-perch. Depending on the life stage, 3 to 6g NaCl L^{-1} is optimal for pike-perch in RAS and can thus safely be applied by fish farmers. In the context of available literature, an increase of tolerance towards salts with an increase in biomass can be derived.

THE COMPARISON OF SPERM MOTILITY AND DENSITY IN FOUR DIFFERENT GOLDFISH (*Carassius auratus*) TYPES

Introduction

Different goldfish types play an important role both in ornamental fish farming and science (Ahmadmoradi et al. 2012). Considering its historical background the goldfish is a suitable model animal for the study of artificial selection as well as for developmental biological studies (Li et al. 2019). Chilled storage of sperm can contribute to the genetic research, artificial reproduction, and shipping or trade of valuable samples (Glenn et al. 2011). Sperm motility and cell density is an important parameter in determining sperm quality. Both parameters can directly affect the fertilization rate in fish (Fauvel et al. 2010). Difference was observed in case of the chilled sperm storage of three goldfish variants in the previous study of Bernáth et al. 2017.

Materials and methods

The aim of our study was to examine the effects of different goldfish types on the sperm quality. The males were kept in a recirculating system at 22 °C. The spermiation was hormonally induced using 2 mg bodyweight kg^{-1} of carp pituitary 24 hours prior to sampling. Sperm motility of four different goldfish types (Common goldfish-"wild type" *N*=5, Shubunkin *N*=4, Black Moor *N*=4, Oranda *N*=5) was compared during 60 hours (at 12-hour intervals) of refrigerated storage (4 °C). In our experiments, progressive motility (pMOT, %), curvilinear velocity (VCL, μm/s), linearity (LIN, %), amplitude lateral Head Displacement (ALH, μm), Beat Cross Frequency (BCF, Hz), straight line velocity (VSL, %) in various types were analysed using a CASA (Computer-assisted Sperm Analysis) system. Sperm cells were activated in an activating solution for cyprinids by adding 0.01 g ml^{-1} bovine serum albumin (BSA). In addition, sperm density in the four variants was also investigated. Sperm samples of the goldfish types were diluted in a sugar-based extender at a ratio of 1:999 and were loaded into a Bürker-type haemocytometer.

Results

Based on the examined CASA parameters, significant difference was not observed between the variants, as well as significant decrease was not recorded during 60 hours of storage in neither of them. Furthermore, a similar cell concentration was determined among the variants (Common goldfish $2{,}01x10^{10} \pm 3{,}46x10^{9}$; Shubunkin $1{,}71x10^{10} \pm 3{,}25x10^{9}$; Black Moor $1{,}66x10^{10} \pm 3{,}02x10^{9}$; Oranda $1{,}56x10^{10} \pm 5{,}83x10^{9}$).

Discussion and conclusion

According to our results the chilled storage for few days is applicable in the case of the four investigated goldfish types. Although statistically significant difference in cell density was not observed, a variability among the types was observable. Our results can contribute to the improvement of the common hatchery propagation and the investigation of the possible effects of the artificial selection on the reproductive biology in different goldfish types.

Background

Blue-mussels from the Mytilus species-complex (*M. edulis* x *M. trossulus* x *M. galloprovincialis*) are an abundant component of the benthos community, found in the high latitude habitats. Aside from their ecological value (Norling & Kautsky, 2007), these foundation species are of extreme relevance to the aquaculture industry, with 2 149 534 tonnes produced globally in 2019 (FAO, 2021).

Blue mussels are able to withstand a wide range of environmental conditions and significant effort has been made to understand the physiological consequences of environmental stress in this species (e.g Lesser, 2016; Melzner, 2011; Riisgard, 2013). Our understanding on the genomic mechanisms underlying species distribution, hybridisation and local adaptation remains incomplete, as the development of genetic resources began to be emphasized in recent years. To help overcome this, we developed a novel genomic tool, a medium-density SNP array, for rapid, high-throughput genotyping of individuals in the *Mytilus* species complex. The array contains globally polymorphic SNPs, which capture the genetic diversity present in mussel populations thriving across a gradient of diverse environmental conditions (e.g. temperature, salinity and CO_2), and showing high population divergence in response to habitat, facilitating the investigation of genomic structure in this species complex. Whilst genetics and breeding technologies have yet to be widely applied to improve blue mussel aquaculture production. This multipurpose tool can also benefit shellfish aquaculture, facilitating genome wide association studies (GWAS) for key production traits, and testing genomic selection approaches.

Material and Methods

For the creation of the array, 23 *Mytilus* spp populations were sampled from across their global distribution, incorporating 4 species in this complex (*M. edulis*, *M trossulus M. galloprovincialis* and *M. chilensis*), as well as hybrids. Populations were selected based on prevailing environmental conditions to capture habitat diversity (e.g. upwelling regions, low salinity regions; Figure 1), and subsequently genetic diversity associated with local adaptation. Samples were sequenced using a low coverage (4-6x) whole-genome resequencing approach, with sequences aligned to the *Mytilus galloprovincialis* genome prior to filtering and calling of SNPs. In addition, existing sets of published and validated SNPs were included on the array as informative for speciation, as well as diagnosis of transmissible cancer. The final SNP set was selected and incorporated on the in medium-density SNP-array, developed in collaboration with Affymetrix.

Results and future perspectives

In this study, we have identified SNPs representative of global and within species diversity and explored levels of introgression in *Mytilus* spp populations distributed worldwide. A subset of 60K SNPs was used to develop a SNP array the *Mytilus* species complex. This tool will allow the consistent, fast and affordable genotyping of individuals, facilitating the investigation of ecological and evolutionary processes in these taxa. Unravelling global genetic diversity in *Mytilus* spp populations will contribute to our understanding on ecological and biological processes ongoing in these taxa. The applications of this array extends to shellfish aquaculture, contributing to the optimisation of this industry via (a) genomic selection of blue mussels,; (b) parentage assignment; (c) inbreeding level assessment and (d) species/product identification and provenance.

Subsequently, we will undertake analyses to assess to the heritability and mechanisms of stress tolerant phenotypes, as well as conserved mechanisms of adaptation/divergence among populations inhabiting challenging environments. By combining ‘omic approaches with physiology, we can investigate the genetic basis of phenotype and characterise animals resilient to environmental stress. Such research is especially relevant to safeguard aquaculture production under climate change.

Introduction

Infectious disease represents the most pressing biological threat to modern aquaculture at a global scale. Control of disease outbreaks is essential for maintaining fish health and welfare, which is crucial for sustainable and profitable aquaculture production. The work presented here is part of the EU Horizon 2020 project, AQUA-FAANG, which aims to improve understanding of genome functional regions and genotype-to-phenotype pathways in the six most commercially important European aquaculture fish species, with a major focus on dissecting immune responses and the basis for disease resistance. The outcomes of this project will contribute towards sustainability and competitiveness in European aquaculture in addition to cross-national food security.

Our focus within AQUA-FAANG is Atlantic salmon, which represents a major food production species globally and an excellent source of protein, omega 3 oils and micronutrients. One of the goals of our research is to examine immune transcriptomic responses using both *in vivo* and *in vitro* models that mimic viral (poly I:C) and bacterial (formalin killed *Vibrio)* infections. RNA-Seq was thus performed on head kidney tissue (*in vivo*) as the primary lymphoid organ and from primary cell cultures of head kidney leucocytes.

Material and Methods

Juvenile freshwater Atlantic salmon with an average weight of 50g were used. For *in vivo* stimulation, fish were stimulated intraperitoneally with *Vibrio* extract (n=6), poly I:C (n=6), or PBS (n=6, control) and sampled 24hr later. For the *in vitro* experiment, head kidney leukocytes were extracted by percoll gradient separation, then incubated for 24 hr with the same three immune treatments (n=6 each).

For transcriptomic analysis paired end 150bp sequencing was performed using an Illumina NovaSeq 6000. The Nf-core (Ewels, *et al*., 2020) RNA-seq pipeline was used for analysis. Following trimming and removal of low quality reads the sequences were mapped to the new Atlantic salmon reference genome (Ssal_v3.1 (GCA_905237065.2)) using STAR. FeatureCounts was used to generate read count for the annotated genes before DESeq2 (Love *et al*., 2014) was used to identify differentially expressed transcripts.

Results

36 RNA-seq libraries were sequenced (~30M paired end 150bp reads per sample) and the resulting transcriptomes showed a strong clustering of samples by treatment (Figure 1). The number of differentially expressed genes (adjusted $P<0.05$) per treatment is shown in Table 1. We are currently comparing the responses of the leukocytes to the *in vivo* head kidney responses, where other cell types are present. When both *in vivo* and *in vitro* responses to the stimulants are examined we find many common responses for each stimulant, along with some unique responses (Table 1). Further downstream analysis of the data will be presented in this poster.

(Continued on next page)

Table 1: Differential gene analysis between different immune stimulants in Atlantic salmon. Genes differentially expressed in common between in vivo and in vitro for each stimulant Poly I:C and vibrio extract) are shown. Adjusted p-value cut-off was set at 0.05.

	Up regulated	**Down regulated**
Poly I:C vs control	1302	233
Vibrio vs control	4459	4392

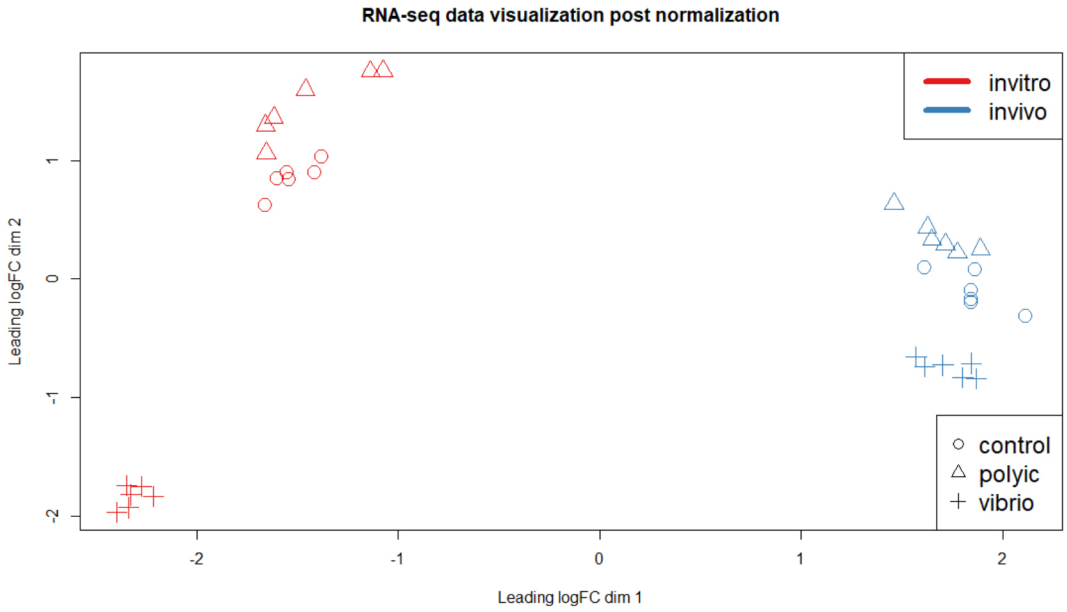

*Figure 1: **MDS plot of RNA-seq counts generated using featureCount and normalised using DESeq2**. Different clustering patterns can be seen between two conditions (in vitro vs in vivo) and different treatment groups (control, poly I:C and Vibrio).*

Aquaculture is one of the most relevant sources of protein to fulfil a constant growing human population. However, it is urgent to overcome the lack of sustainability of protein production sources, since the demand for high-quality protein, and the depletion of wild fishstocks are forecast to increase aquacultural fish demand by 37% between 2016-2030[1]. One of the most promising protein biomass sources for aquafeeds is microalgae, due to its high nutritional quality and high production sustainability[1]. Nevertheless, microalgae industrial production still requires optimizations to improve the sustainability of its production. For that purpose, an integrated strategic plan is essential, considering the most relevant bottlenecks of this area such as the energetic use, water supply and nutrient sources. PROFUTURE is a H2020 research project focused on improving productivity, sustainability and marketability of microalgae protein for innovative foods and feeds. It counts with 31 partners, 21 of which industrial, from 13 different European countries. Currently under the scope of PROFUTURE project, several biotechnological optimization steps in the protein production pipeline are being performed, including microalgae cultivation, drying, and processing. The ultimate objective is to develop novel foods and feeds from different protein sources. Necton's tasks are focused in microalgae production and reduction of its costs, testing a novel drying method, and leading industrial-level protein production pipeline. Microalgae production costs is being tackled by the installation of a highly efficient and low energy consuming, off-the-grid, tubular photobioreactor. Solar panels were installed in the facilities to reduce grid energy consumption for microalgae production. The drying behaviour of several microalgae species are being evaluated in a hybrid solar drier assisted by an algorithm that controls internal heat and humidity for improved drying. This work shows the recent advances in sustainable solar drying of *Nannochloropsis oceanica* and *Tetraselmis chui*, two widely used species in aquaculture, being the latter recently approved as novel food. Drying results will be compared with other innovative dryers from partners to select the one that provides best biomass quality, sustainability and cost-effectiveness. Finally, with all the improvements chosen and in place, industrial partners led by Necton will produce sustainable microalgae protein and innovative foods and feeds at industrial scale, including feeds for shrimp, catfish and carp.

CHARACTERIZATION OF DIGESTIVE ENZYMES IN THE GREATER AMBERJACK (*Seriola dumerili*) REARED AT DIFFERENT TEMPERATURES

C. Navarro-Guillén*, E. Perera, M. Yúfera

Instituto de Ciencias Marinas de Andalucía (ICMAN-CSIC), Campus Universitario Rio San Pedro, 11519 Puerto Real, Spain
Email: carmen.navarro@csic.es

Introduction

Temperature is one of the most important factors regulating the rate of many biological processes, especially in poikilotherms. In fish, water temperature has a significant effect on digestion efficiency through the modulation of feed intake, gut transit time and enzymatic activity. The study of fish digestive biochemistry is essential to obtain valuable information on factors that affect the net efficiency of food transformation and growth, and therefore aquaculture profitability. In this context, the evaluation of types and functional features of the digestive enzymes involved in the hydrolysis of the main nutrients is one of the most important aspects to understand digestive capacities of species of interest.

The greater amberjack, *Seriola dumerili*, is a fast-growing pelagic teleost with great interest for the diversification of marine fish aquaculture in the Mediterranean region. The seeding of fry in cages for on-growing will face seawater temperatures which, in the case of the Mediterranean Sea, range between 15-28 ºC, approximately. The aim of the present study was to assess the activity and functional characteristics of key digestive enzymes in juveniles of greater amberjack, as well as of the possible modulation of their relative importance by water temperature.

Materials and methods

Juveniles of greater amberjack (initial body weight 56.2 ± 19.6 g) were randomly distributed in three independent RAS systems with water temperature set to 18, 22 and 26ºC, respectively. Fish were fed *ad libitum* five times daily for 17 days. At sampling, fish were dissected (n = 8, per temperature) and each digestive tract was separated into stomach and pyloric ceca for preparation of enzyme extracts. Extracts were used for the assay of pepsin in the stomach, and trypsin, chymotrypsin, lipase and leucine aminopeptidase activities in the pyloric ceca following the protocols described by Perera et al. (2017) and Yúfera et al. (2019). Optimal pH for enzymes were determined by measuring the activities at different pHs. Optimal temperature was determined in a range from 10 to 90°C. Classes of proteases in the pyloric ceca were determined by the use of specific protease inhibitors according to Perera et al. (2008).

Results

Fish body weight at the end of the experiment was 61.4 ± 21.5, 101.5 ± 27.5 and 145.9 ± 41.5 for fish reared at 18, 22 and 26ºC, respectively. Optimal pH and temperature for the different enzymes are resumed in Table 1. The use of the specific inhibitor for serine proteases SBTI resulted in inhibition ranging from 37 to 47%, for fish reared at 18 and 26ºC, respectively. In fish reared at 18ºC, higher inhibition was obtained with the specific inhibitor for chymotrypsin TPCK (27.83%) while higher inhibition was recorded with the specific inhibitor for trypsin TLCK in fish reared at 26ºC (38.15%).

Discussion

The present study presents for the first time a partial characterization of the main digestive enzymes from *S. dumerili*, being the optimal pH obtained for the different enzymes similar to those reported by others authors for closely related species (Kishimura et al., 2006). By contrast, optimal temperature for trypsin and chymotrypsin was higher to those usually reported for fish, ranging from 50 to 70ºC, suggesting the presence of thermally robust proteases. Lipase activity was more sensitive to heat and alkaline pH than proteases, suggesting a different and maybe more complex three-dimensional structure of the active enzyme.

Enzyme activity	Optimal pH	Optimal T (ºC)
Pepsin	2.5	60 – 70
Trypsin	10	90
Chymotrypsin	9	90
Lipase	7.5 – 8	50 – 60
Leucine aminopeptidase	11	65 – 75

Table 1. Optimal pH and temperature (T) for digestive enzymes in the greater amberjack *Seriola dumerili*.

(Continued on next page)

The inhibition assay showed the importance of the activity of serine proteases in the digestive tract of the greater amberjack, as expected for a carnivorous species. The incubation of intestinal extracts with the specific inhibitor SBTI caused, on average, a reduction of 42% in overall casein digestion, being this inhibition 10% higher in fish reared at 26 than fish reared at 18ºC, probably due to changes in the relative contribution of different serine proteases and their different susceptibility to SBTI. Indeed, the use of the specific inhibitors TLPC and TPCK suggested inverse trypsin and chymotrypsin relative activity levels with changes in temperature, with higher trypsin relative contribution in 26ºC-fish while higher chymotrypsin contribution in 18ºC-fish. In Atlantic salmon, an increasement in the relative activity of chymotrypsin related to trypsin in the pyloric ceca was observed when growth was limited (Rungruangsak-Torrisen, 2007). However, in the present study, although the use of specific inhibitors suggested different relative contribution of trypsin and chymotrypsin depending on water temperature in *S. dumerili*, activity levels of both enzymes in the pyloric ceca were similar for the three treatments. These results might be explained by other factors, likely the presence of isoforms.

In conclusion, the results of the present study increased the knowledge on the digest biochemistry of the greater amberjack, and the effects of rearing temperature on its digestive enzymes functional flexibility, aiding in improving management practices for this species industrialization.

WATER TEMPERATURE AFFECTS FEEDING BEHAVIOR AND GUT TRANSIT TIME IN GREATER AMBERJACK JUVENILES (*Seriola dumerili*) FED MULTIPLE DAILY MEALS

C. Navarro-Guillén*, N. Gilannejad†, G. Martínez-Rodríguez, M. Yúfera

Introduction

Water temperature is a primary factor in fish production systems, directly affecting the production efficiency. Specifically for open sea cages, water temperature is poorly controlled and determined by environmental factors, having a special impact the current scenario of global warming.

The efficiency with which the on-growing fish feeds are digested is a key factor determining the feed conversion ratio and, therefore, the profitability and environmental cost of the production process. The efficiency of digestion depends on the time the food is available for hydrolysis within the gut, being food residence time dependent on the feeding frequency and the environmental conditions. In particular, water temperature affects food intake, food transit time and, consequently, growth. However, the estimation of food transit times in fish has usually been performed under unrealistic conditions, from gut filling or evacuation after a single meal.

The greater amberjack (*Seriola dumerili*) stands out as an interesting species to support Mediterranean aquaculture diversification due to its high added commercial value and good adaptation to captivity. Nevertheless, as emerging species, the knowledge on its digestive function is in its infancy. The objective of the present work was to examine the effects of temperature on the feeding behavior and gut transit rate over a daily cycle in greater amberjack juveniles under standard feeding conditions.

Materials and methods

Greater amberjack juveniles with 34.2 ± 15.7 g of body weight (BW) were randomly distributed in three independent RAS systems set to 18, 22 and 26 ºC. Juveniles were reared for 37 days and fed *ad libitum* three times daily with a commercial diet (SPAROS Lda., Portugal). To properly evaluate the transit of each meal, feeds from the different meals were labelled with different inert markers, lanthanum, ytterbium or yttrium. After the experimental period, three fish per temperature were sampled every 4 h during 24 h for feed content and transit determinations. The gastrointestinal tracts (GIT) were dissected in stomach, pyloric ceca, anterior intestine, middle intestine, and distal intestine. Inert markers content was analyzed following the protocol described in Yúfera et al. (1). Transit time for each meal was calculated as the time comprised between feeding and 95% of the ingested meal been evacuated.

Results

Average BW at the end of the experiment was 82.9 ± 35.7, with no statistical differences due to rearing temperature. Voluntary feed intake (VFI) for each meal is summarized in table 1. Globally, 26ºC-fish consumed more feed over the day, mainly supported by a trend of higher feed intake in the first meal of the day compared to 18 and 22ºC-fish.

Overall, food transit time along the GIT was faster in fish reared at 26ºC, with an average of 9h 41min ± 45min for each meal ($P = 0.001$). The specific transit time for each meal is shown in table 2. Transit time of the second meal tended to be slower at 18 and 22ºC, by contrast, at 26ºC the second meal tended to be faster. Moreover, transit time in each segment differed between meals and water temperature (results not shown).

Discussion

The present work evaluated for the first time the transit time throughout the digestive tract of three consecutive daily meals in greater amberjack juveniles reared at three different temperatures. Fish reared at 26 ºC showed both, higher daily feed intake and faster gut transit time compared to 18 and 22 ºC-fish, however, a higher feed consumption was not reflected in higher growth. Gut transit rate defines the duration and physiochemical conditions in which the ingesta is processed by digestive enzymes in the GIT, and consequently influences the utilization of the nutrients (2). Thus, the present results suggested that, in greater amberjack juveniles, slower transit time is correlated with a more favorable nutrients utilization as described for other fish species, such as cobia juveniles (1).

(Continued on next page)

Water temp	VFI for each meal			Daily VFI
	1st meal	2nd meal	3rd meal	
18ºC	0.87±0.14	0.62±0.62	2.12±1.07	3.61±0.33[b]
22ºC	0.99±0.45	0.90±0.58	1.80±0.44	3.69±0.27[b]
26ºC	2.36±0.25	0.83±0.76	2.09±0.87	5.28±0.43[a]

Table 1. VFI (% BW) for each meal and total per day in *S. dumerili* reared at 18, 22, and 26ºC. Results are presented as mean ± SEM. Different letters indicate statistical differences in daily VFI between treatments ($P < 0.05$).

Table 2. Transit time for each meal at the three rearing temperatures. Results are shown as mean ± SEM. Different letters indicate statistical differences in transit time between treatments ($P < 0.05$).

Water temp	Transit time for each meal		
	1st meal	2nd meal	3rd meal
18ºC	12h 56min±1h 36 min	15h 41min±2h 21min[b]	14h 28min±1h 20min
22ºC	13h 11min±1h 22min	17h 7min±1h 21min[b]	13h 8min±1h 20min
26ºC	9h 50min±2h 1min	8h 26min±1h 18min[a]	10h 48min±55min

Transit rate assessment is a challenging task when more than one meal is offered because the ingested feed is mixed up with the feed of the previous and the next meal(s). The present work demonstrated that each meal tended to progress in a different rate along the GIT and not all meals were affected in the same way by the temperature increase. However, meals transit rate between temperatures was only statistically different for the second one. In addition, the progression of the inert markers along the different GIT segments revealed that at 26 °C the meals transited fast enough to progress as clearly three separate batches, while at 18 °C consecutive meals became mixed in the GIT as a consequence of a higher residence time.

In conclusion, the present study analyzed for the first time how successive meals are processed within the GIT of on-growing greater amberjack juveniles. As expected, results confirmed that the passage time of the ingesta throughout the GIT varies among the different daily meals and it is modulated by water temperature, suggesting differences in the digestion efficiency of the meals.

UNRAVELLING THE IMPACT OF INTESTINAL MICROBIOTA ON HOST TRANSCRIPTOMICS IN GILTHEAD SEABREAM JUVENILES FED NON-CONVENTIONAL FEED INGREDIENTS

Introduction

In a sustainable aquafeed scenario, processed animal proteins (PAP), insect, microbial and algae-products appear as suitable replacers of fish meal (FM) in practical fish diets (Glencross et al., 2020; Basto et al., 2021). However, such new and emerging ingredients have been tested one-by-one rather than using different formulation combinations. In this regard, a previous study in gilthead sea bream (*Sparus aurata*) pointed out that graded levels of sustainable PAP- and NoPAP-based feed formulations are able to support optimal growth performance when nutrient requirements are met (Fernandes et al., 2021). However, PAP-based feed formulations caused a slight impairment of feed conversion ratio (FCR) associated with a down-regulation of the hepatic insulin-growth factor-I and the up-regulation in head-kidney of pro-inflammatory cytokines, chemokines and T-cell markers. Here, we focused on gut health indicators to assess the main effects of PAP and NoPAP- based diets on the mucosal adherent microbiota of the anterior intestine (AI) and its impact on changes in the host transcriptomic profile of selected markers of intestinal function and integrity.

Methods

Quadruplicate groups of gilthead seabream were fed *ad libitum* daily with three different diets in a 77 days feeding trial. The control diet (CRTL) followed a commercial type formulation. In both NoPAP and PAP diets, insect meal, fish by-products, microbial and yeast biomasses were used as FM and vegetable protein replacers. The PAP diet also comprised several PAP ingredients such as poultry meal, feather meal hydrolysate, and porcine blood meal. The NoPAP diet included *Spirullina* and *Chlorella* meal as additional protein sources. At the end of the feeding trial, RNA from the AI was collected and run through a PCR-array to profile the expression of a panel of 44 genes, including markers of epithelial integrity, interleukins and immunoglobulins, among others. DNA from the adherent bacteria of the AI was collected and the V3-V4 region of the 16S rRNA of each sample was amplified and sequenced by Illumina MiSeq. Taxonomic assignment was performed against the RDP database. Alpha diversity was calculated using Phyloseq, and beta diversity using partial least-squares discriminant analysis (PLS-DA) models. Metagenome prediction and pathway analysis were performed using Piphillin. Differentially expressed (DE) genes and discriminant OTUs were correlated using the *corrplot* R package.

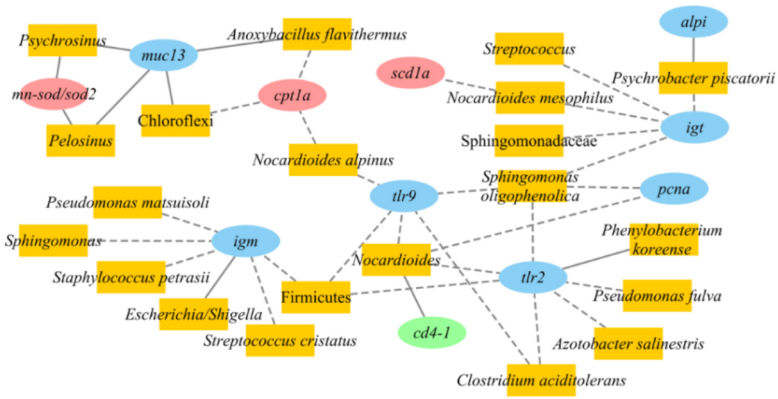

Figure 1: Integrative analysis of discriminant gut intestinal OTUs (orange rectangles) and intestinal (blue ellipses), hepatic (red ellipses) and head-kidney (green ellipses) genes. Edges show positive (solid grey lines) or negative (dashed grey lines) OTU-gene correlations (Spearman correlation test; $P < 0.01$).

(Continued on next page)

Results

The gene expression analysis revealed 13 DE genes (out of 44) ($P < 0.1$) in response to the experimental diets. Markers of epithelial integrity (*pcna*) and pro-inflammatory genes (*alpi*, *il8* and *igm*) were significantly up-regulated in fish fed PAP diet. Fish fed NoPAP diet presented an up-regulation of the anti-inflammatory cytokine *il10*. In the microbiota analysis, Illumina sequencing reads were assigned to 2,180 OTUs and a significantly lower richness and alpha diversity were found in the NoPAP group in comparison to CTRL fish. Detailed differences in microbiota composition were analysed with a statistically validated PLS-DA which clearly separated CTRL fish from fish fed PAP and NoPAP diets, with 135 OTUs mainly driving this separation (VIP ≥ 1). Inferred metagenome results showed a differential regulation of 34 pathways. Both NoPAP and PAP groups showed, among others, the up-regulation of routes tailoring immune response and inflammation (C-type lectin receptor, VEGF, TNF and NFκ-β signalling pathways), with a lower degree of activation in fish fed NoPAP diet. Fish fed PAP and NoPAP diets also displayed an exclusive type of response at this level, with the differential regulation of 14 and 10 inferred pathways, respectively. Correlation tests disclosed a remarkable amount of DE intestinal genes (12) involved in 38 significant ($P < 0.01$) correlations with 29 of the discriminant OTUs (Fig. 1). This highlights the relation between host gene expression and changes in the gut microbiota. In addition, 11 out of the 29 correlated OTUs were also associated with changes in the relative expression of liver and head-kidney genes, retrieved from previous studies performed in the same fish.

Conclusions

Even though growth performance was not affected by the experimental diets, these results disclosed a pro-inflammatory response to PAP-based formulation in terms of gene expression and intestinal microbiota. This inflammatory condition seems to be ameliorating using NoPAP-based feed formulation, which becomes especially interesting as an alternative eco-efficient feed for seabream. At the same time, a remarkable correlation between changes in gut microbial population and gene expression was unravelled at local and systemic levels. This highlights the potential action of the gut microbiome as a "second genome", probably being involved in the regulation of the transcriptomic response of this marine farmed fish when fed innovative diet formulations based on increased circularity and resource utilization principles.

EFFECT OF DIFFERENT TYPES OF SINGLE CELL PROTEIN ON FEED INTAKE, GROWTH, BODY COMPOSITION AND DIGESTIBILITY OF WHITELEG SHRIMP (*Litopenaeus vannamei*).

Marit A.J. Nederlof*[1], Fariz K. Harwinda[1], Remon van Ginkel[1], Johan W. Schrama[1]

[1]Aquaculture and Fisheries Group, Wageningen University, Wageningen, The Netherlands.
*marit.nederlof@wur.nl

Introduction

The aquaculture industry is reliant on land and marine protein sources, and fishmeal is one of the major sources of protein used in the aquaculture sector. Limited supply, resource-use conflicts and environmental concerns force the aquaculture sector to look at alternative sources of protein that can improve the sustainability of aquaculture. To keep up with the increasing demand for high quality shrimp feeds in a growing industry, there is an interest in alternative protein sources that can (partly) replace fishmeal in shrimp diets (e.g. Amaya et al. 2007, Panini et al. 2017, Shao et al. 2019).

Single cell proteins (SCP) have been used as an alternative protein source for aquafeeds (Glencross et al. 2020). SCPs are (dried) cells of micro-organisms and can be of algal, fungal or bacterial origin. Of the three different SCPs sources, bacterial SCPs have in general the highest protein levels (50 – 80% on a dry basis). Nevertheless, compared to micro-algae, SCPs of bacterial origin have been studied less frequently for their potential as fishmeal alternative (Glencross et al. 2020).

The success of alternative protein sources depend among others on their impact on attractability and palatability (i.e. feed intake) and their bioavailability (i.e. digestibility and growth). The way SCPs are processed may affect attractability, palatability or bioavailability (Teuling et al. 2019), which in turn may lead to differences in fish or shrimp performance.

This study aims to assess the potential of four bacterial SCP products (provided by String Bio), which differ in the way they are processed, as a substitute for fishmeal in shrimp diets, by studying their effect on feed intake, growth, body composition and digestibility of whiteleg shrimp (*Litopenaeus vannamei*). This was tested against a basal diet, a diet containing a high-quality fishmeal and a diet containing soy protein concentrate as protein source.

Materials and Methods

The SCP products for this study were provided by String Bio (www.stringbio.com). The products were made using their proprietary fermentation process from Gammaproteobacteria *Methylococcus capsulatus*. The bacteria were grown on methane, either derived from biogas or natural gas. SCP1 was produced by aerobic fermentation of *Methylococcus capsulatus*, SCP2 and SCP3 were produced by optimization of the downstream processing to have varying levels of peptides, SCP4 was formulated to have an additional immunomodulatory function by the inclusion of metabolites naturally expressed by the bacteria.

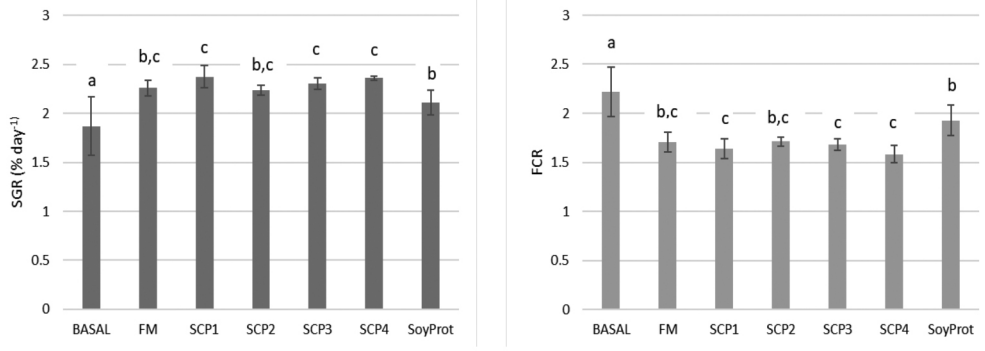

Figure 1. Growth (SGR, % day^{-1}) and FCR of *Litopenaeus vannamei* fed the experimental diets for a period of 10 weeks.
Shrimp were fed to apparent satiation, with one of the seven experimental diets: a basal diet (BASAL), four diets each with one of the SCP products at an inclusion level of 15% (SCP1, SCP2, SCP3 and SCP4), a fishmeal diet (FM, inclusion level of 15%) and a soy protein concentrate diet (SoyProt, inclusion level of 15%). Bars are mean values (n = 4); error bars are standard deviations. Different superscripts indicate significant differences between the diets.

(Continued on next page)

To study the effect of the four bacterial SCP products on feed intake, growth and body composition of *L. vannamei* a growth trial of 10 weeks was performed. During the growth trial, whiteleg shrimp (average initial weight 2.7 ± 0.2 gram) were fed to apparent satiation with one of seven experimental diets; a basal diet (BASAL), four diets each with one of the SCP products at an inclusion level of 15% (SCP1, SCP2, SCP3 and SCP4), a fishmeal diet (FM, inclusion level of 15%) and a soy protein concentrate diet (SoyProt, inclusion level of 15%). Each diet was tested in 4 replicates.

The growth trial was followed by a digestibility trial, during which the same shrimp were fed with the same experimental diets. Shrimp faeces was collected for a period of 7 weeks, to study the effect of the four bacterial SCP products on total N, amino acid and P digestibility.

Results

Growth was affected by diet ($P<0.05$; Figure 1). Post hoc analysis showed that shrimp fed the basal and SoyProt diet had the lowest SGR. Shrimp growth on the diets with SCP did not statistically differ from the diet with fishmeal ($P>0.05$). Numerically, shrimp fed the SCP1 diet had the highest SGR (Figure 1). Patterns in feed intake were comparable to SGR and affected by diet ($P<0.05$), but differences were less pronounced. Feed intake at the basal and SoyProt diets (0.25 g/d) was lowest, while feed intake was higher at the other diets. Feed intake was equal for shrimp fed the SCP diets and the FM diet, ranging between 0.26 and 0.27 g/d. Feed intake was highest for SCP1 and SCP3 diets. FCR was also affected by diet ($P<0.05$). FCR was highest for the basal diet. FCR was lowest for FM and all SCP diets. SCP diets did not differ from the FM diet, but the FCR tended to be lower for SCP1, SCP3 and SCP4 compared to FM (Figure 1). The current results show that bacterial SCP at 15% inclusion give similar results as fishmeal, thus being a potential alternative for fishmeal in shrimp diets. Analysis on nutrient digestibility are in progress and are included in the presentation.

DEVELOPMENT OF AN *IN SILICO* METHOD TO DESIGN NEW SPECIES POLYCULTURE IN AQUACULTURE

Nellya Amoussou*, Thomas Lecocq, Alain Pasquet and Marielle Thomas

University of Lorraine, INRA, UR Animal and Functionality of Animal Products, Team Domestication in Inland Aquaculture, Nancy, France

Among the range of practices that promote aquaculture efficiency and sustainability, polyculture (i.e. production of two or more fish species in the same physical space at the same time, adapted from [1]), is one of the most ancient fish farming practice in the world. In Western Europe, intensive monoculture has been favored during the last decades instead of the traditional extensive pond polyculture production. Nevertheless, the recent theorization of long-standing productions as well as developments of new concepts (agroecology) and practices (integrated multi-trophic aquaculture, aquaponics, and integrated agriculture-aquaculture) reflect a renewed interest in polyculture for future aquaculture developments [2]. Indeed, polyculture is seen as an opportunity to promote aquaculture by mitigating some of the negative impacts and unsustainable development of current aquaculture [3]Sander lucioperca (L.. In order to be efficient, polyculture requires that the involved species are compatible (i.e. species which can live in the same production system without detrimental interactions or competition for resources) and moreover complementary (i.e. species which can use different parts of the available resources or develop commensal/mutualist interactions) [4]. Ensuring compatibility and complementarity requires to promote an optimal use of all resources; trophic (e.g. by combining species with different diets), spatial (by combining species occupying different areas in the living environment), and temporal (by combining species with different periods of activity; e.g., day and night) [4]. Although long-standing polyculture are available, new species combinations are requested to maximize the benefits of polyculture, to address new socio-economic and environmental challenges (e.g. climate change, new technological developments and new consumer demand). For example, considering the context of climate change, new species combinations are needed since some species that were initially compatible in a given environment may no longer be so due to the resistance of some of them to variations in environmental parameters such as temperature and salinity. Moreover, considering a large number of species could maximize the chances to determine the best combination(s) of species to provide to fish farmers.

Problematic and objectives

Designing new species combinations involves considering a large number of possible species combination, which cannot be assessed by empirical methods. Indeed, such methods are based on trial-and-error essays, and are thus time-consuming and costly. They do not maximize the chances of identifying combinations of polyculture that respond to new socio-economic and environmental issues. Such empirical approaches are reasonably unlikely to be feasible for practical and ethical reasons [4]. Moreover, considering only empirical methods cannot be regarded as the most efficient solution to develop new fish polyculture because the most useful species combination(s) for aquaculture purpose could be missed out. To overcome this problem, here we propose an integrative conceptual method to standardize and rationalize the choice of the best species combinations for future polyculture.

Background and steps of the *in silico* method

In order to reach an efficiency and sustainability aquaculture, a polyculture should (i) use optimally all available resources in the aquaculture system, (ii) to maximize fish welfare while addressing regulation, economic and environmental expectations. This implies to consider interspecific interactions to design new combinations, because the functioning of an agro(eco)system depends mainly on the nature of these interactions [5]. Therefore, considering functional approach through species functional traits is necessary to understand how organisms interact with their environment and with other species [6].

(Continued on next page)

Based on a functional approach, we propose the development of a new prospective and integrative method, divided into four successive assessing steps, requiring the intervention of scientists and stakeholders at several levels. The first step consists in theoretically predicting the compatibility of a wide number of fish species using their relevant functional traits (morphological: e.g., size, mass, physiological: e.g., growth rate, phenological: life span, and behavioral: e.g. swimming activity, predation, intra and interspecific relationships), available in different databases. The fish species compatibility is based on the calculation of an index, considering their stage of development, their abiotic requirements, the degree of competition for space/time/trophic resources and the risk of predation. This index is based on a contrasting gradient of compatibility ranging from 0 for incompatible species to 1 for highly compatible species. The second step aims to select one or more (new) species combination considering the stakeholder's advices. The third step assesses species combinations performances from bioassays in Recirculated Aquaculture systems or in ponds. A fourth step corresponds to the transfer of technologies in real aquaculture exploitation conditions. During the conference, the presentation of the *in silico* method will be widely illustrated with examples of species combinations which have been tested in Recirculated Aquaculture systems.

Introduction

The aquaculture sector is in transition. Not only is the sector expected to contribute to global food security, it also needs to comply with increasing societal demands for responsible and sustainable production and adopt the new digitalization opportunities. Enabling technologies provide a new window of opportunities, with the exploration of high-tech solutions as steppingstones towards this paradigm shift. The development of efficient, green and smart production systems requires expertise across a wide range of technology and social science disciplines, whilst setting the farmed species and the production ecosystem in the centre. The Bridgehead Aquaculture 2050 project is developing a toolbox to acquire a strengthening of the innovation capacity across the value chain.

Methodology

The region of Mid-Norway is used as a pilot area for the development of a knowledge exchange and capacity building platform. The county of Trøndelag is ranked high in the top 25 Regional Innovation Leaders in Europe[1]. It also represents about 1/3rd of the total national aquaculture production (amounting to 1,45 million tonnes in 2019[2]), and locates two major aquaculture educational and research centres, i.e. NTNU and SINTEF. Alongside fish, shellfish and algae farming companies, Bridgehead Aquaculture involves mainly businesses supplying technology, services, or feed to the aquaculture sector. Many of them are connected through their membership in a regional cluster[3].

The knowledge and innovation capacity in the aquaculture sector can be considerably strengthened through a more efficient utilisation of existing scientific and practice-based competences.

Applying the toolbox across the aquaculture value chain has an expected impact on three different levels:
1. Education: improved aquaculture relevance of studies, especially in enabling technological education areas and for those with limited knowledge about the sector
2. Research: stronger engagement of industry in the creation of research projects
3. Industry: increased competence level of company employees

Results

The toolbox of Bridgehead Aquaculture 2050 has developed and implemented routines for more and stronger cross-stakeholder interactions at the education and skill development level. More specifically, the presentation wants to highlight four pilot instruments that were developed in 2020/21.

Minor in aquaculture[4] is a set of aquaculture courses and seminars directed to civil engineering students across a variety of specialities, i.e. marine technology, renewable energy, environmental engineering, ICT, cybernetics and robotics, mechanical engineering, electronics systems design. The minor enabled the students to recognise how their specific expertise can be applied to problem-solving in aquaculture planning, operations, and development across the value chain. In addition, they developed biological and cross-disciplinary communication skills and increased their knowledge about the sector's structure and its stakeholders.

At a Bachelor level, a study programme in aquaculture engineering[5] was developed. This is a 3-year's professional education programme within operations and maintenance of aquaculture farming systems, both at sea and on land. The study programme was developed and set off in 2020 because of a clear demand by the sector, emphasising a lack of candidates with this specific set of skills.

(Continued on next page)

Students represent a powerful instrument for change, of which the sector is not adequately aware. In order to lower the threshold for student-industry interactions, an online portal[6] for the aquaculture sector was established at the university. It provides, amongst others, guidelines, agreement templates and examples of past student assignments in aquaculture, an annual wheel for collaborating opportunities and deadlines, and open summer job assignments or internships. Overall, it helps both students and companies with little experience or network to interact.

Additional instruments in the toolbox are existing collaborative mechanisms adapted to the particularities of the aquaculture sector: the industry PhD scheme, continued education courses at bachelor and master level, trainee programmes, and lifelong learning.

Discussion and conclusion

As a response to the need for a more efficient and mutual exchange of theoretical and practical knowledge, the Bridgehead Aquaculture 2050 project developed a regional knowledge platform with a set of new and improved instruments.

It was shown that the instruments stimulated aquaculture stakeholders in the target region to build up trust, competence and experience in collaborating with groups they previously had little knowledge about. Participating students and researchers opened a wide range of expertise within the fields of technology, natural sciences and social sciences. The sharing of knowledge, creation of engagement and general networking across the stakeholder groups using one or several Bridgehead instruments, contributes to the realisation of the paradigm towards a sector-wide acknowledgement of the importance of research-based innovation in the green and digital transformation.

The Bridgehead Aquaculture toolbox is based on strengthening existing assets that have so far been underexploited by the aquaculture sector. Being supported and implemented by strong institutions and networks, the legacy of the instruments is secured. As a next step, the toolbox can possibly be expanded to other regions in Europe with similar needs and area of opportunities.

DEVELOPMENT OF AN EASY TO OPERATE HATCHERY PROTOCOL FOR BLUE MUSSEL (*Mytilus edulis)* SEED PRODUCTION

Pernille Nielsen*[1], Clarie Ng[1], Pascal Barreau[1], Camille Saurel[1], Iarfhlaith Connellan[2], Colin Hannon[3]

E-mail: peniel@aqua.dtu.dk

Introduction
Blue mussel (*Mytilus edulis*) cultivation largely depends both on seed availability and food from the natural environment and is therefore highly impacted by natural variations in seed and feed supply. Currently, the blue mussel production industry has an over reliance on seed provided by wild harvest or use of suspended collectors for natural settlement of spat. Hatchery produced blue mussel seed has been proposed as a solution to ensure sufficient seed supply and provides the opportunities for selective breeding and possibilities of triploid production giving the product increased added value. However, production of hatchery produced blue mussel seed is challenged by the fact that hatchery produced seed can be prohibitively expensive compared to the actual sale value of harvested mussel seed from the wild. Consequently, further development and optimisation of hatchery produced blue mussel seed is required for the further advancement and implementation at an industry scale in an economic timeframe.

Results and discussion
A protocol for blue mussel hatchery reared seed has been developed in Ireland. The protocol has shown to be successful in a traditional shellfish hatchery setting but is not operational for mussel farmers without access to a hatchery facility. The goal of our research is to implement, adapt and optimise this robust and repeatable protocol to other hatchery conditions and to develop in parallel a low-technological protocol that will be implemented at an industry level, operational by mussel farmers and thereby reduce the overall cost of hatchery produced mussel seed. The presentations will focus on the simplified production, the feeding setup for the larvae rearing as well as the settlement success comparison for commonly used spat collectors by farmers in Denmark vs settling material commonly used in hatchery. The results will be discussed in terms of trade-offs of the two different hatchery protocols and if the low-tech method would be transferable to the farmers as an affordable source of mussel seeds and if it can improve the economic feasibility of hatchery produced blue mussel seed.

EFFECTS OF POST OVULATORY AGING ON FERTILISATION, DEVELOPMENT, SURVIVAL AND HATCHING IN ATLANTIC HALIBUT *(Hippoglossus hippoglossus)* EGGS

N. Niepagen*, L. Berg, E. Kjørsvik

Norwegian University of Science and Technology, Brattørkaia, 7010 Trondheim
E-mail: nils.niepagen@ntnu.no

Introduction

While established for decades, aquaculture of Atlantic halibut is challenged by many obstacles one of which is insufficient production of juveniles (Engelsen et al., 2004). One of the problems encountered is a highly variable egg quality, possibly caused by overripening or post ovulatory ageing. Post ovulatory ageing is a process of degeneration on eggs which begins right after ovulation. In rainbow trout, incorrect stripping time can result in very low egg quality, changes in morphology, composition and maternal gene expression due to post ovulatory ageing (Aegerter et al., 2005). Mating of Atlantic halibut in captivity is rarely observed and eggs and milt need to be stripped by hand (Holmefjord, Lein, 1990). Decades ago, wild fish were used for broodstock, but some hatcheries have since bred up to F3 generation fish which are in production today. Wild females were typically closely monitored by hatchery personnel to estimate the optimal stripping time shortly before they would spontaneously release their eggs in the water (Norberg et al., 1991). Farmed broodstock typically obtain lower fertilisation rates than wild fish, higher variability and in many individuals the lack of spontaneous egg release. Today, in three of the four Atlantic halibut hatcheries in Norway, technicians are stripping females based on how much their ovaries are visually built up and on experience. If no eggs are obtained, the fish are checked again after 12-80 hours. Fish that gave eggs are stripped again after a protocol, such as e.g. in 81-84 hour intervals. This study is aimed at understanding the implications of post ovulatory ageing on egg quality of Atlantic halibut during fertilisation, development and hatching.

Materials and methods

Experiments were conducted at Nordic Halibut AS, Midsund, Norway during summer 2020 and spring 2021 spawning seasons. The natural spawning season for Atlantic halibut is spring but spawning in summer is achieved by photomanipulation. All broodstock were stripped by hatchery personnel, and a flexible stripping protocol was implemented to obtain egg batches as close to ovulation as possible. Briefly, based on the fertilisation percentage of a given batch, the fish was stripped again after 60-72 hours. The lower the percentage of the previous batch, the shorter the time for the next stripping. Only gentle pressure was applied to strip the eggs from the females, if no eggs were obtained,the fish were checked later. Six egg batches were obtained this way as shortly after ovulation as possible. Each egg batch was divided into six fractions (50-150 mL each), which were stored in a concealed container filled with eggs to the top at 6°C. To simulate post ovulatory ageing, one egg fraction at a time was fertilised using cryopreserved milt (Cryogenetics AS) at 0, 1, 2, 4, 6 and 12 hours after stripping. For eggs from each fertilization time, between 200-400 eggs were distributed to each of three petri dishes and to nine 800 mL cell culture flasks (three per sampling stage) containing 1 L of seawater with 0.25mL/L solution of terramycin (100mg/mL) and incubated at 6°C. Eggs were sampled for evaluation of fertilisation rates (from petri dishes) and of embryonic development at 14h post fertilisation (hpf) for 8 cell stage, , at 48-50 hpf for blastula stage, at 300 hpf (after blastopore closure) and at 540 hpf for hatching rate (from cell culture flasks).

Results

Data evaluation for spring 2021 is still in progress. However, in summer 2020, fertilisation rates were slightly but not significantly decreasing up to 12 hours past stripping. Survival was constant for four hours after stripping and at 6 hours past stripping it decreased dramatically from 70 % to 30 % in one of the batches. Other observed trends were higher mortality during incubation with longer post ovulatory ageing, a higher percentage of eggs lacking activation during the fertilisation process and higher occurrence of failures in body axis formation after gastrulation. The flexible stripping protocol led to an average increase in fertilisation rate and batches followed according to this protocol were either stripped too early (no eggs obtained) or increased in fertilisation rate compared to the previous batch of the same fish.

(Continued on next page)

Discussion and conclusion

Survival and fertilisation rate in artificially aged Atlantic halibut eggs are correlated over a longer period. We showed however, that post ovulatory ageing had a higher influence on survival than on fertilisation rate. This indicates that previous findings based only on fertilisation rate may have underestimated the problem of overripening in Atlantic halibut broodstock (for example Norberg et al., 1991). Thus, our data is highlighting the importance of a flexible stripping protocol that is suitable to avoid overripening of the eggs as much as possible. In turbot, low egg qualiry leads to reduced ability to cope with environmental stress, abnormal development, deformities and incomplete eye migration (Kjørsvik et al., 2003). It is likely that similar to turbot, fry from low quality batches in Atlantic halibut will suffer higher mortalities and possibly more deformations during development and metamorphosis. Low fertilisation rates and high variability in egg quality in Atlantic halibut can at least to some extents be explained by post ovulatory ageing due to inadequate stripping protocols for farmed broodstock. This study shed light on how to improve halibut egg quality by modifying the established stripping protocols based on the fertilisation rates of previous batches. This not only dramatically increased the quality of successive batches, but it also enables researchers to obtain batches that are less affected by post ovulatory ageing when exploring differences in egg quality between individual broodstock fish and their different egg batches.

PREDICTION OF AQUAFEED PERFORMANCE OVER A FULL PRODUCTION CYCLE

A. Nobre[1]*, S. Cabaleiro[2], F. Soares[1], T. Silva[1], L. Conceição[1]

[1]SPAROS, Lda. Área Empresarial de Marim, Lote C, 8700-221 Olhão, Portugal

Introduction

At the fish farm, with feed costs accounting for 50% to 70% of total production costs, feeding management is a critical activity. An evaluation of the suitability of the commercially available aquafeeds for the particular farming conditions of each farm/site is of paramount importance to address the sustainability challenges raised by fast growth of the aquaculture industry and the increasing expected demand for farmed fish. In this work, we illustrate the application of a nutrient-based model (FEEDNETICS™) to evaluate seabass aquafeeds used by the Mediterranean industry, considering two different temperature profiles. In the FEEDNETICS™ virtual environment, users can compare different production settings, feeds or feeding regimes and analyse which ones have the potential to improve their FCR, reduce the time to harvest, enhance growth, improve their economic conversion, or reduce their waste of N and P, all of this within hours of field implementation for the entire production cycle. This work was carried out in the context of the EU's H2020 PerformFISH project (No. 727610) which aims to contribute to sustainable growth of the Mediterranean Marine Fish Farming industry.

Methods

FEEDNETICS™ is a web-application developed by SPAROS Lda (Olhão, Portugal) that includes a mechanistic nutrient-based model to predict fish growth and composition along time, using information on temperature, feed intake and feed properties. The model has been calibrated with a wide range of datasets and is currently available for gilthead seabream, European seabass, rainbow trout and Nile tilapia, with several applications done at fish farms and for generic conditions (Soares et al., 2020, Nobre et al., 2021).

Long-term term simulations of European seabass growth were carried out with FEEDNETICS™ considering three aquafeeds applied in the Mediterranean farms (Table 1). The feeding rates were defined using a feeding table per feed generated by a protein and energy flux model similar to the FeedEST engine (available at http://performfish.eu/industry-corner). The farming conditions considered a cage with 300,000 fish (initial weight: 50 g), mortality rate of 1% per month, a harvest weight of 450 g and two temperature profiles (Besson et al. 2016):Western Greece (average 19.3 ºC, 14.3 ºC to 24.2 ºC) and Eastern Coast of Spain (average 18 ºC, 11.9 ºC to 24.1 ºC).The simulated conditions included two different scenarios of feed waste, both within the range considered for the industry (Ballester-Molto´ et al., 2016): i) 8% to 10% of feed waste, and ii) 10% to 15% feed waste.

The prediction results were used to evaluate the feed performance concerning FCR, growth rate, time to reach harvestable weight, total feed quantity, N and P waste, and savings on feed.

Results

According to the model results (Table 2) for the Eastern Spain temperature profile, Aquafeed 1 leads to a better fish performance with a shorter production cycle (435 days), lower FCR (2.0), and less N and P waste. However, and considering the simulated conditions, Aquafeed 2 leads to a better economic conversion with savings estimated around less 111 € of feed per ton of fish produced compared with the Aquafeed 1. For this temperature profile, and regarding the economic conversion, Aquafeed 1 is also outcompeted by Aquafeed 3, which is the feed that leads to the worst fish performance.

Table 1 . Feed specifications.

	Aquafeed 1	Aquafeed 2	Aquafeed 3
Proximal composition (as feed basis)			
Digestible Protein (%)	42.3	40.5	38.3
Digestible Lipids (%)	18.4	17.1	16.7
Digestible energy (MJ/kg)	18.7	18.5	18.2
DP/DE (g/MJ)	22.6	21.9	21.0
Amino acid (AA) profile	Assumed default values in accordance with the requirements of the species		
Fatty acid (FA) profile			
Feeding quantity	Feeding table per feed		
Cost of feed (relative to Aquafeed 2)	+10%	ref	-8%

(Continued on next page)

As illustrated in Table 2, the precise evaluation of aquafeeds will depend, among other factors, on the particular temperature profile under which fish are reared. According to the FEEDNETICS™ simulations (Table 2), the more favourable Western Greece temperature profile leads to substantial improvements of the production performance compared with the Eastern Spain and for the same scenario of feed waste (8% to 10% of feed waste). As expected, also in the Western Greece scenario, Aquafeed 1 leads to the best fish performance comparing with both Aquafeed 2 and 3. However, the savings on feed (Table 2) indicate a different trend between the two temperature profiles: under the Western Greece temperature profile, Aquafeed 1 leads to a better economic conversion despite its higher unit cost, with savings estimated around 41 € and 538 € of feed per ton of fish produced, compared with Aquafeed 2 and 3, respectively.

Despite the impact on the production profitability, the feed losses are difficult to estimate with precision over the production cycle. Herein, we illustrate how we can use this tool to build a what-if scenario where, instead of 8%-10% of feed losses, we assume losses in the range of 10%-15%. In Table 2, the impacts related to the increase in feed losses are quantified considering the Western Greece temperature profile, which leads to a substantial increase of days in production, overall, more expenditure of feed, with decreasing growth rates and worst FCRs. It is interesting to highlight that the impacts are non-linear between the 3 aquafeeds. In this case, it was proportionally higher for Aquafeed 2, leading to an increase of the savings on feed for Aquafeed 1 compared to Aquafeed 2 (less 303 € of feed per ton of fish produced).

Final remarks

Nutrient-based models allow farmers to select feeds and plan feeding, towards optimized feeding. As illustrated in this PerformFISH use case, this type of tools can assist farmers in predicting the impact of different feeding strategies on their farm's performance. Mechanistic nutrient-based models include the fish physiological and metabolic processes that are required to predict the effects of feed composition and temperature on fish growth, feed conversion and wastes, among other variables. Farmers can quantify the impact of their actions or build what-if scenarios, such as quantifying the feed cost per ton of fish produced, and estimate time to market size of a given stock based on a certain cage stocking date. Such nutrient-based models will most likely be part of a good precision farming toolset.

Introduction

Historically, jellyfish (JF) products are not new. These gelatinous organisms have been used for centuries as human food in Asian countries, while modern exploitations are applied in medicine and cosmetics. Nevertheless, due to their high water content, JF are often presumed to be a poor food source and a trophic dead end[1]. However, in addition to the vertebrate predators that extensively consume gelatinous species, at least 124 fish species, some of them with economic value like the seabream *Sparus aurata*, the piked dogfish *Squalus acanthias* and the Atlantic saury *Scomberesox saurus*, are reported to prey on JF in natural waters[2].

On a dry-mass basis, JF contain a higher proportion of polar lipids than what is found in standard aquafeed pellets, including n–3 highly unsaturated fatty acids, especially eicosapentaenoic acid, and n–6 HUFAs, such as arachidonic acid[3]. In addition, some jellyfish species are important amino acids, such as glycine and taurine, that dominates the free amino acids (FAAs)[4]. Therefore, several studies have investigated the potential of using JF as feed for aquaculture fish[5,6].

In the framework of the Horizon 2020 'Gojelly' project, three JF species - *A. solida*, *Cotylorhiza tuberculata* and *Catostylus tagi* - were selected for product evaluation as aquafeed, based upon the following criteria: 1) species need to have been recorded in the geographic area to avoid the incidental introduction of non-indigenous species in the ecosystem, in the case of trials with live JF; 2) species need to present biochemical composition potential to be used as feed; 3) biomass availability.

Materials and methods

The first trial, conducted at the facilities of the Mariculture Centre of Calheta, Madeira, evaluated the potential of using live jellyfish to feed juvenile's seabream, using all the life stages benthic polyps (< 1 cm), and the free-swimming ephyrae (≈ 2 m) and medusa (≈ 1cm) of reared *A. solida* (one of the most worldwide distributed jellyfish genera that fulfil the first criteria) *versus* standard seabream aquafeeds. For two days, seabream were fed with the different items for two hours before removal of the remaining food to estimate the ingestion rate.

The second trial aimed to determine the potential of incorporating jellyfish biomass into a compound diet for seabream at the juvenile stage. *C. tuberculata* was collected in Mar Menor, Spain, immediately frozen (-20ºC) and transported to "Sparos Lda." facilities (Portugal). Based on the composition of the jellyfish biomass (dry and fresh forms) determined upon arrival and taking into account the feasibility of its use in industrial feed extrusion processes, the trial comprised six dietary treatments: the control diet (CTRL) that mimicked a commercial feed for gilthead seabream juveniles and four additional diets incorporating at mixing (before extrusion) either dry or fresh jellyfish biomass at 2.5 and 5.0%. A sixth diet contained 2.5% of the fresh JF biomass but incorporated post-extrusion by vacuum coating to potentiate the jellyfish biomass bioactivity role. Seabream juveniles (initial weight of approximately 24g) were fed with the six diets (three replicates per treatment) for two months in a flow-through system. Survival, growth, and biochemical composition were determined at the end of the feeding trial that lasted two months.

Finally, a third trial was conducted to determine the acceptability of freeze-dried JF (*C. tagi*) by the goldfish *Carassius auratus,* one of the most common freshwater fish found in pet shops, *versus* a diet based on commercial fish flakes. Fish were fed four dietary treatments: one exclusively commercial feed and three others with different percentages of JF (25, 50, 75%) plus commercial feed, once a day, for 45 days. The remaining food was weighted, and feeding was video recorded (30 s before feeding, 60 s during feeding and 60 s after feeding). At the end of the trial, biochemical composition and food consumption were analyzed.

(Continued on next page)

Results and Discussion

The first trial showed that seabream displayed predatory activity over benthic (polyps) and pelagic stages (ephyra and medusa). Although standard dry pellets were the most preyed item, within JF, the highest ingestion rates were observed for polyps, followed by ephyrae, and last by medusa. Results of the ingestion rate on polyps and ephyrae highly exceed the values found by Marques et al. (2016), which might be explained by the fact that seabream used in that study were larger (min 70g) and likely less interested in small prey.

Results of the second trial showed no differences in growth, biochemical composition, nor in most immunological parameters, except for peroxidase (p 0.025), showing that inclusion of JF, tended to increase peroxidase levels. Further studies need to investigate the potential of jellyfeeds to increase this enzyme activity, as peroxidase activities in fish erythrocytes suggest the predominant role of this enzyme in the protection of polyunsaturated acids against uncontrolled oxidative processes possibly indicating an important positive role of including jellyfish biomass in aquafeeds.

Results of the goldfish trial indicated that jellyflakes were accepted. As soon as jellyflakes were delivered into the aquaria, fish exhibited a "chasing behavior" (defined as increased swimming speed towards the flakes) and increased biting frequency (refers to the number of times that each fish was seen biting on the flakes deposited at the bottom of the aquarium per meal). Biochemical results indicated that the proximate composition of goldfish fed different percentages of JF had significantly higher protein content and lower lipid content.

Fish generally accepted all JF aquafeeds products in all trials, and no adverse effects were found. Both freeze-dried JF and compound diets with JF as an ingredient present the advantage of availability throughout the year, easier to store and manipulated by users.

Introduction

Egg quality has a powerful influence on reproductive success. It remains a serious problem of largely variable cause(s) in human reproductive medicine (Keefe et al., 2015) and livestock production (Bobe and Labbé, 2010). Recent research in teleosts has focused on differential abundance of maternal mRNA and protein stockpiles deposited in the egg for clues to the origin of the problem (Cheung et al., 2019; Ma et al., 2019; Sullivan et al., 2015). Earlier studies revealed several impaired mechanisms involved in early development related cellular processes in zebrafish (Yilmaz et al., 2021, 2017). The evolutionary conserved stereotypical procedure of cellular events led us to investigate whether these findings are common in marine species of aquaculture interest. An unsteady supply of high quality eggs and fry in Atlantic halibut (Hippoglossus hippoglossus), makes this species a perfect candidate to study egg quality related mechanisms. The objective of our study was to analyze proteomic profiles in good (GQ) versus poor quality (BQ) eggs, to identify proteins that can serve as egg quality markers, and to discover molecular mechanisms determining egg quality.

Material and methods

Eggs from a total of 25 spawns were collected in 2019-2021 reproductive seasons. For each egg batch, aliquots were snap frozen at 1 hour post fertilization (1hpf) for subsequent analyses, while 100 ml was incubated for egg quality assessment, based on survival rates prior to hatching at ≃ 12 dpf. Proteomic profiling between GQ and BQ eggs was performed via tandem mass tags labeling (TMT) based liquid chromatography tandem mass spectrometry (LC-MS/MS). Obtained spectra was searched against an in-house built proteome database originated from Atlantic halibut egg transcriptome. Differentially abundant proteins (DAPs) were determined based on p values resolved from Student's t-test ($p < 0.05$) followed by Benjamini Hochberg correction for multiple testing ($p < 0.05$). Functional annotation of DAPs was performed using the GO, KEGG, and UNIPROT databases. Overrepresentation analyses were done via GESTALT using human proteome as reference database. DAPs were additionally tested for protein-protein interaction networks using the STRING Network search tool. Eight DAPs were selected as candidate markers based on fold differences in abundance and were subjected to parallel reaction monitoring (PRM) based targeted LC-MS/MS. Relative abundance of gene expression for 21 DAPs were also determined via TaqMan based quantitative PCR. Eggs from GQ and BQ spawners were also processed for transmission electron microscopic (TEM) evaluations at 1hpf for analysis of differences in mitochondrial number and structure.

Results

A total of 115 proteins were differentially abundant between GQ and BQ eggs with 64 being down-regulated and 51 being up-regulated in BQ eggs compared to GQ eggs. Frequency distribution of DAPs showed clear differences in proteomic profiles between GQ and BQ eggs ($p < 0.05$). Accordingly, GQ eggs seem to contain significantly higher number of proteins related to protein folding, while BQ eggs seem to be enriched with proteins related to transcription, protein degradation and synthesis inhibition, and mitochondrial biogenesis. Overrepresentation-test-based enrichment analysis ($p < 0.05$) revealed significant biological processes, molecular functions and cellular components which are in close agreement with frequency distribution analysis findings. STRING network analysis of proteins down-regulated in BQ eggs revealed a network of three subclusters of proteins related to cytoskeletal regulation and energy homeostasis, protein homeostasis, and fatty acid degradation. Proteins which were up-regulated in BQ eggs formed a network made of two major subclusters of proteins mainly related to mitochondrial biogenesis, energy and protein homeostasis.

(Continued on next page)

PRM based LC-MS/MS results revealed five out of the eight candidate marker proteins (MT-ND5, DHRS9, GATD3a, FBP1, UQCRFS1) to be significantly different in abundance between GQ and BQ eggs. Accordingly, MT-ND5, DHRS9 and GATD3a are down-regulated while FBP1 and UQCRFS1 are up-regulated in BQ eggs. UQCRFS1 and FBP1 were additionally found to be part of the STRING network cluster which was formed by BQ up-regulated proteins. Relative abundance of expressions of 7 out of the 21 tested genes exhibited an increase with the same tendency pattern ($p > 0.05$) and 6 genes exhibited a converse tendency pattern ($p > 0.05$) to protein abundance, while 8 genes exhibit a similar increasing tendency pattern to protein abundance and significant differences between GQ and BQ eggs ($p < 0.05$). These genes (*cyc1*, *fh*, *gcn1*, *ghitm*, *uqcrb*, *uqcrfs1*, *fbp1a*, and *atp5f1a*) were also found within the STRING network cluster revealed to be significant in BQ up-regulated proteins. The overall findings were additionally supported by TEM observations which revealed clear signs of differences in mitochondrial number and structure between GQ and BQ eggs.

Conclusions

Frequency distribution, enrichment and protein-protein interaction analyses of DAPs between GQ and BQ A. halibut eggs revealed matching results pointing to impairments in mitochondrial structure and functions and protein folding related activities. Additional findings based on TEM imaging fortifies the hypothesis concerning the impairments in mitochondrial structure and functions. The overall findings were found to be corresponding to previous findings in zebrafish and thus there seem to be high similarities in the pattern of impaired molecular mechanisms in BQ eggs of zebrafish, a well-established biomedical model, and Atlantic halibut, a representative of marine flatfishes with aquaculture interest. We expect discoveries of such mechanisms in poor quality eggs to spur development of practical strategies to determine and eliminate the potential causes leading to egg quality problems in Atlantic halibut and other farmed fishes, thereby contributing significantly to development of effective strategies for improving breeding practices and sustainable growth of Norwegian and global aquaculture.

PIGMENT QTL GENOTYPE BY DIET INTERACTION ON GROWTH IN ATLANTIC SALMON (*Salmo salar*)

Introduction

Growth and fillet color are two important traits in farmed Atlantic salmon. The color of the fillet results from an uptake of supplementary astaxanthin - an antioxidant which has a positive effect on growth in early life (Bazyar Lakeh et al., 2010). However, the ability of fish to utilize and retain astaxanthin is limited while astaxanthin in the diet accounts for approximately 2–4% of feed cost. This trait is highly heritable, and in recent years there has been progress in understanding the underlying biological pathways, including identification of a number of QTLs and candidate genes that explain a large portion of the genetic variance (Helgeland et al., 2014). The relationship between astaxanthin deposition and growth is not fully understood but are likely to be connected because of the antioxidant effect of the pigment. Furthermore, such association or interaction may depend on the amount of marine omega-3 in the diet which has a positive effect on fillet color and robustness (Bou et al., 2021). The aim of this study was to examine the pigment QTL genotype by diet interaction in Atlantic salmon in terms of its effect on growth.

Materials and Methods

Data in this study was from AquaIMPACT project (H2020 BG2018-818367). Previously, Mowi Genetics had performed genome-wide association studies for pigment levels in several year classes of fish from the breeding nucleus using a ThermoFisher Axiom genotyping array containing approximately 55,000 single nucleotide polymorphism (**SNP**) markers distributed over the salmon genome. From this data, two major QTLs were mapped, with the locus having the largest effect being subsequently used in this study. In June 2020, 959 Atlantic salmon with known pedigree and pigment QTL genotype from the Mowi breeding nucleus in Norway were distributed across six 5x5m^2 sea pens located in Averøy, Norway. The sea pens were evenly split between two different diets (3 replicates each) from Skretting ARC: a common extruded feed kernel coated with a standard oil mix rich in vegetable oil (standard diet or **K**) or coated with an oil mix (Veramaris®) enriched with omega-3-PUFA from microalgal oil (diet **H**). A bivariate animal mixed model, where body weights from different diets (measured in March 2021) were treated as different traits, was fitted using **REML** in WOMBAT with genomic relationship matrix (**GRM**) generated from 53,186 SNP markers. The genomic based heritability ($\boldsymbol{h^2}$) for growth, genetic correlation ($\boldsymbol{r_g}$) – as a measure of genotype re-ranking and their SE were subsequently estimated.

Results

The genomic based h^2 for growth with diet H (0.40±0.01) was slightly higher than for growth with diet K (0.35±0.01). The r_g was close to unity (0.94±0.09), indicating marginal or no genotype re-ranking of growth between H and K diets. The plot of phenotype-genotype association shows no re-ranking of pigment QTL genotypes across different diets (**Fig 1**). For the K diet, high pigment deposition genotype (**PP**) had higher and significant ($P<0.05$) mean weight (2.80 kg) than low pigment deposition genotype (**pp**; 2.67 kg). The use of H diet resulted in considerably positive effect on growth in both genotypes but the difference in mean weight between PP and pp genotypes became less and statistically non-significant ($P>0.05$). Mean genomic EBVs shows the same pattern.

Discussion and Conclusions

To the best of our knowledge, this is the first report on the association between pigment QTL genotype and growth in Atlantic salmon. The genomic based h^2 for growth is in the upper range with the previous estimates reported in literature. Higher growth in PP than in pp indicates that pigment genotypes may be associated with growth but it may be diet-dependent trait as the difference in growth is less in H than in K. Selection for PP genotype not only increases astaxanthin deposition, leading to less pale fillet and higher level of antioxidant for health benefits, but also higher growth. Further study to confirm this finding should be conducted.

Introduction

In nature, fish regularly have to deal with a lack of food, and subsequently have evolved mechanisms of coping with limited food availability. Compensatory growth, during a specific period of time, is considered significantly faster than the growth rate of fish that have not experienced feed deprivation (Nikki *et al*., 2004). European seabass, *Dicentrarchus labrax*, a widely distributed marine teleost, is considered of great commercial importance, as it exhibits high growth rates, high market demand, and good feed-conversion ratio values. Many interacting environmental and genetic factors play a role in the various physiological pathways of fish growth. Expression levels of specific mRNAs can explain variation in growth rates, and therefore can be used as valid biomarkers for fish selection. The study will present information on identification of target-genes related to the nutritional status during short-term intermittent feeding in European seabass, that can be used as potential biomarkers for breeding programs.

Materials and Methods

After a 4-week acclimatization period to laboratory conditions, 540 graded fish weighing 87.5±16.2 g were randomly distributed into two treatments with three replicate tanks per treatment in a recirculating aquaculture system (RAS). Fish of the first treatment (control) were fed continuously to apparent satiation for 40 days, whereas the second treatment was fed in a feeding-fasting scheme of 80-20% (2 days of fasting followed by 8 days of refeeding to apparent satiation) for 40 days. Water quality parameters were monitored daily.

At the end of the experiment (D40), all fish were graded in two groups according to their final weight (FG-fast growers and SG-slow growers from the fasted treatment and from the control treatment; four treatment-group combinations) and sacrificed with phenoxyethanol overdose (1 ppt). Growth parameters, serum glucose, cholesterol, triglycerides, non-esterified fatty acids (NEFA) and lactate dehydrogenase (LDH) activity were measured according to standard protocols.

Total RNA was extracted from liver tissue and white muscle and isolated RNA quantity and quality were determined via spectrophotometry. For cDNA synthesis, 500 ng of RNA were reverse transcribed with PrimeScript RT Reagent Kit. The qPCR analysis was carried out with RT^2 SYBR Green qPCR Mastermix (Qiagen) in a Rotor-Gene Q 5plex. The qPCR assay was designed for the profiling of six glycolytic genes *(hk, gpi, eno1, g3pdh, alda, pk*), two genes related to fatty acid metabolism (*lpl* and *acc*) and two genes involved in cholesterol biosynthesis (*sqle, 7dhcr*). The geometric mean of β-actin (*actb*) and elongation factor 1 (*ef1*) expression was used as normalization factor.

Results

Within the FG and SG groups, the experimental feeding treatment did not significantly affect final body weight. Among slow growers (SG) the intestine somatic index (ISI) was smaller in fasted fish ($P < 0.05$). However, dietary treatments did not significantly affect condition factor (CF), hepatosomatic index (HIS), viscerosomatic index (VSI), spleen somatic index (SSI) and intraperitoneal fat ratio (IFR).

Glucose and NEFA levels were different between fed SG and FG ($P < 0.05$), and such difference was not observed for their fasted counterparts. Glucose of fed FG fish was significantly higher (27.6 ± 1.1 mg/dL) than in fed SG fish (16.9 ± 1.7 mg/dL) and NEFA of fed FG fish was significantly lower (5.6 ± 0.3 mg/dL), than in fed SG fish (10.7 ± 1.4 mg/dL).

(Continued on next page)

In the muscle tissue, all genes demonstrated significant differential expression in at least one -treatment-group, while in liver 5 genes (*g3pdh, alda, gpi, hk, 7dhcr*) out of 11 exhibited no significant difference ($P > 0.05$). Muscle transcription levels of *g3pdh, alda, gpi, ldha* exhibited upregulation in fed FG compared to fed SG, although such differences were not observed between fasted fish groups. Furthermore, mRNA levels of *g3pdh, hk, pk, lpl, acc, sqle, 7dhcr* were significantly different ($P < 0.05$) between fish in different dietary treatments (fed versus fasted), regardless of the growth group (SG or FG). In the liver tissue, only *pk* was significantly up-regulated ($P < 0.05$) in fed fish compared with the fasted ones, for both growth groups. *ldha, lpl* and *acc* mRNA levels were differentially expressed between fed and fasted fish, only for the SG group.

Discussion

In aquaculture, feeding strategies are critical because feeds typically represent more than 40-50% of the production cost and both underfeeding and overfeeding can have negative consequences for the production. As fish are relatively high-value products, conditions for successful aquaculture farming strongly relies on feed management (Chatzifotis *et al*., 2011). A key factor in view of obtaining the desired growth compensation after feed deprivation for a specific species, is to manage the appropriate duration and intensity of feed deprivation.

In the present study, the final weight between the fast growing (FG) and slow growing (SG) groups were not significantly affected by the short-term food deprivation periods. Any potential loss of weight during the 2-day (out of 10 days) fasting period was compensated during the refeeding to satiation periods, at least for a 40 days experimental period. The short-term intermittent fasting did not have substantial effect either on condition factor or other zootechnical parameters. No differences in blood biochemical parameters were observed between fed and fasted fish, supporting the hypothesis that short-term intermittent fasting (2 days out of 10) does not affect fish physiological status in the long term. On the contrary, expression of certain genes differentiated between groups. In conclusion, the study provides new insights on the impact of intermittent feeding of European seabass on gene expression levels.

PRELIMINARY COMPARISON OF THREE DIFFERENT INDUCTION METHODS FOR THE SPAWNING OF EUROPEAN ABALONE (*Haliotis tuberculata coccinea)*

B. Costa[ab], C. Nunes[a*], M. De Girolamo[a], E. Isidro[a]

[a]Okeanos – Institute of Marine Sciences, Rua Prof. Doutor Frederico Machado, 4 – 9901- 862 Horta, Faial, Açores, Portugal. [b]Aquaculture and Fisheries Group, Wageningen University Research, the Netherlands
Corresponding author: E-mail: mirko.d.girolamo@uac.pt

Introduction

Abalone spawning induction is considered to be well described, with three main reported methods: thermal shock, hydrogen peroxide and UV irradiation (Leighton, 1972; Moss et al., 1995; Leighton, 2008). Although all methods have been described to induce spawning in *H. tuberculata coccinea,* no comparative study has been conducted on the performance of each method. The aim of this study is to understand which method among thermal shock (Temp), hydrogen peroxide (H2O2), and UV irradiation (UV) is the most adequate for spawning induction of *H. tuberculata coccinea*, in order to optimize the reproductive performance of the species.

Materials and Methods

F2 broodstock of European abalone cultured at 20°C were selected according to weight (13.4 ± 4.5g) and gonad development (Stage 3). Animals were divided in groups consisting of 14 animals, 7 males and 7 females per treatment. Each specimen was kept in separate container, filled with 800ml of 1μm filtered sea water (FSW). Control (Ctrl) animals were placed in the spawning containers and only disturbed for spawning checks. Temp treatment was performed introducing specimens in preheated FSW at 23°C. The temperature was maintained for 1.5h. If no gametes were released, the temperature was increased to 25°C for 0.5h. H2O2 spawning induction method was carried out according to the description of Courtois de Viçose (2011). UV treatment was conducted using a flow through system with UV treated sea water with a calculated irradiation of 600m.W.h.l^{-1} applied for 2h. All treated animals were checked for spawning at every 30min for the 5h extent of the trail. When a spawning event occurred a 30min interval was given before sample collection. Eggs and sperm were counted for density (cell/ml). 50 eggs/ind were photographed and analyzed for diameter (mm) and area (mm^2).

Results and Discussion

H2O2 and Temp were the only treatments that induced spawning in the tested animals, in contrast with the initial expectation that all treatment, besides control, would be able to promote these events. According to Kikuchi and Uki (1974) time in between the initiation of the UV stimulation and spawning is inversely related to the amount of UV irradiation. According to Courtois de Viçose (2011) *H. tuberculata coccinea* starts spawning after 2 – 3 hours with a irradiance of 800m.W.h.L^{-1}. This way we might assume that our irradiance and stimulation time was not adequate for spawning. From the two treatments which induced spawning events, H2O2 had the highest percentage of spawning for both males and females. H2O2 induced spawning in 71% of the males and in 86% of the females compared to 29% and 43% for males and females respectively in the temperature treatment. No significant differences were observed for the frequency of spawning in males and females between the two treatments (χ^2 test, $p_{Treatment*female} = 0.094$; $p_{Treatment*male} = 0.109$). When looking at the number of gametes emitted by males, H2O2 presented a higher cell concentration (1.7E+07 ± 9.0E+06 cell/ml) compared to the Temp treatment (9.8E+06 ± 8.9E+06 cells /ml). The inverse was observed for the female gametes which revealed a higher concentration emitted in Temp (≈200 ± 96 cell/ml), compared with H2O2 (≈159 ± 52 cell/ml). Female gametes also showed significant differences in area (mm^2) and diameter (mm) between treatments, having higher values for Temp treatment (Fig. 1).

Conclusion

These results even though preliminary in variables and analysis, reveal that there might be differences in gamete quantity and quality when using different spawning induction protocols, suggesting further research into the influence of these protocols on the reproductive performance of *H. tuberculata coccinea*.

Introduction

P. candei has great economic value in the Macaronesia region. The interest on developing an aquaculture production of this resource has grown in recent years, due to high demand and sensitivity to exploitation (Hawkins *et al*., 2000). Therefore, this study is focused on the performance of two different methods of obtaining *P. candei* larvae: one by spawning induction, a non-invasive method, and another one using dissected gonads. Differences between methods were evaluated on the base of survival, settlement and growth of the larvae. As the suitability of a substrate with adequate biofilm coverage is a key factor for the induction of metamorphosis to the juvenile stage (Ferranti et al. 2018), the effect on the settlement and growth in two types of biofilms, *Ulvella lens* and *Ulvella leptochaete,* was also analysed. The results presented here represent the first steps on the definition of a reproduction protocol for *P. candei* and the optimization of larval and post-larval rearing.

Materials and methods

Wild *P. candei* specimens were collected from intertidal areas in Faial Island (Azores). Reproduction trials were performed in an acclimatized room, with filtered (1μm) and UV-sterilized seawater (FSW) at 17.3±0.4ºC (±SD).

Spawning induction (SI): The protocol, based upon the work of Ferranti *et al*. (2018), tested five treatments: intense bubbling, UV-light, hydrogen peroxide (H_2O_2) at 6%, thermal shock and a control group (FSW). All treatments had 8 independent replicates (1 *P. candei* per 500ml experimental container; sexes were not identified). Treatments lasted until the first individuals started to spawn (4h30min). Oocytes obtained were then fertilized with a mixed sperm sample obtained from the male spawners (table 1). Sperm acquired with the H_2O_2 (6%) treatment was not used.

Artificial reproduction (AR): At least 2 individuals from each of the treatments tested in the SI were sacrificed for the extraction of mature gonads. The protocol used for AR was based upon Peréz *et al*. (2016). Oocytes from 3 females (262.7oocyte.ml^{-1}) were matured in NH_4OH for 3 hours, resulting in 90.5±8.2% of active oocytes. A mixed sample of sperm obtained from 5 males was activated in FSW for 4h before fertilization (table 1).

Larval rearing and settlement: Swimming trocophora were reared at room temperature until they reached the competent pediveliger stage (table 1). They were then transferred to a 30l settlement tank, containing 6 corrugated fiberglass plates (172 800mm^2 total area per plate). Three plates had *U. leptochaete* as biofilm and three had *U. lens*. Progeny obtained from SI and AR were always kept separate.

Table 1 Fertilization conditions and the product of each type of reproduction at various stages of *P. candei* life cycle.

Stage	Age (days)	Spawning induction	Artificial reproduction
Fertilization		28.8±5.7oocyte.ml^{-1} 4.66x10^{5}sperm.ml^{-1}	53.3±0.6oocyte.ml^{-1} 4.66x10^{5}sperm.ml^{-1}
Gamete contact time		3h	3h
Fertilization rate		98.3 ± 3.0%	83.7 ± 4.0%
Density of trocophora	1	10.0 ± 2.8 ind.ml^{-1}	8.7 ± 3.9 ind.ml^{-1}
Density of pediveliger	3	10.0 ± 4.9 ind.ml^{-1}	4.8 ± 0.8 ind.ml^{-1}
Larval survival (72h)	3	100%	55.7%
Density settlement tanks	3	1.0 ind.ml^{-1}	0.5 ind.ml^{-1}
Settlement *U. lens*	30	0.48 ± 0.39%	0.07 ± 0.05%
Settlement *U. leptochaete*	30	0.04 ± 0.02%	0.02 ± 0.02%
Total survival	30	1.6%	0.3%

(Continued on next page)

Results and discussion

This study provides the first record of a successful spawning induction in *P. candei*. The most effective treatment was intense bubbling in which 37.5% of individuals spawned. Thermal shock induced 25% and exposure to H_2O_2 induced spawning in 12.5% of the individuals. There were no significant differences between treatments where gamete emission occurred (Fisher's exact test of independence, $p_{\text{Bubbling vs. H2O2}} = 0.2846$; $p_{\text{Bubbling vs. Thermal shock}} = 0.50$; $p_{\text{Thermal shock vs. H2O2}} = 0.50$).

Regarding fertilization, it was successful both with gametes obtained through SI and AR. The amount of pediveligers obtained (table 1) was significantly higher (repeated measures ANOVA, followed by a Tukey post hoc test, $p<0.05$) in the SI larvae. Overall survival was also higher in SI (table 1). Deformed larvae were only found in the AR larval culture. This could be consequence of over exposure of mature oocytes to NH_4OH, during the egg maturation process (Castejón *et al*., 2020). Post-larvae obtained from SI also performed better in terms of growth and overall survival after 30 days post-fertilization. Post-larvae from the SI had 0.456 ± 0.014mm (±SE) in length, which was significantly higher (Mann-Whitney U test, $p < 0.05$) than the ones originated by the AR (0.360 ± 0.033mm). They were also larger in width but not significantly different (Mann-Whitney U test, $p = 0.06$).

Overall, the settlement percentages on *U. lens* were higher than *U. leptochaete* both for SI and AR (table 1), although the differences between the biofilms were not statistically significant (Mann-Whitney U test, $p_{SI} = 0.100$; $p_{AR} = 0.400$). Additionally, post-larvae obtained by SI and grown on *U. lens* were significantly bigger (Mann-Whitney U test, $p<0.05$) in size (0.456±0.014mm in length and 0.380 ± 0.014mm in width) than larvae grown on *U. leptochaete* (0.309 ± 0.039mm in length and 0.225 ± 0.049mm). This trend was also verified in AR post-larvae (*U. lens*: 0.360 ± 0.033mm in length and 0.295 ± 0.039mm in width; *U. leptochaete*: 0.345 mm in length and 0.275mm in width). Although the highest settlement obtained was only 0.48 ± 0.39% in *U. lens*, these data represent a baseline for future settlement studies with *P. candei*.

OWNERSHIP PERCEPTION OF SUSTAINABLE DEVELOPMENT IN AQUACULTURE: AN EVENT STUDY OF SHAREHOLDER'S REACTION TO NEWS CONCERNING SUSTAINABILITY

R. Nygaard, *F. Asche, and B. Misund

University of South Eastern Norway
Raveien 215
3184 Borre, Norway
rune.nygard@usn.no

Producing food in a sustainable way to feed the world's growing population is a global challenge. Many claim aquaculture to be an important part of the solution. However, the industry has been criticized for not solving many sustainability challenges, such as emissions, escapees and disease. These issues are increasingly important for consumers of aquaculture products, and there is evidence that they are willing to pay a premium for sustainable products, potentially adding revenues to producers. Other stakeholders, like local societies, regulators and equity holders of aquaculture companies (green investors), have increasingly been working as pressure groups for the industry to move towards more sustainable production processes. However, this will not come without significant costs: New technology, equipment, on the job training and compliance routines require time and capital investments for successful implementation. New investments may come through either yearly profits, bank loans, issue of new shares, or a combination of these. All of these alternatives will affect return on equity (ROE). If the company is publically listed, the daily stock price is also affected by these decisions. In other words, moving towards more sustainable production processes is not only likely to affect the value of owners' equity, but its implementation may also need further investments from owners. We therefore believe that understanding ownership perception of issues concerning sustainability is critical for the industry going forward.

To address ownership perception of issues concerning sustainability we look at Norwegian salmon aquaculture using event study methodology. Salmon aquaculture production is the second largest aquaculture species in the world in terms of market value, and the major companies are listed on the Oslo Stock Exchange. They also follow IFRS accounting reporting standards. Event dates are determined through media databases and stock exchange announcements. These are categorized as either positive or negative sustainability news. We then combine these with financial data in an event study model and find whether there are abnormal share price movements at the event dates (news announcements). Our major findings is that owners perceive negative sustainability news as significantly negative. However, our findings on positive news are inconclusive. Our interpretation of this is that shareholders also have to take potential costs into consideration in deciding whether these news are positive for their investments.

A CLOUD PLATFORM FOR PRECISION AQUACULTURE

Introduction
Precision aquaculture is founded on a set of disparate, interconnected sensors deployed in aquatic environments to monitor, analyse, interpret, and provide decision support for farm operations. This trend parallels developments in agriculture where sensors and other observing technologies lead to enhanced insight into crop production as well as animal health and welfare (Precision Livestock Farming or PLF). The precision aquaculture fundamental approach has been summarised as a series of steps: observe, interpret, decide, and act (Føre et al., 2018).

One of the major challenges in Internet of Things (IoT) applications is the effective management of large amounts of time-series data and associated predictive models. Besides the sheer volume of data, substantial complexity arises from the heterogeneity of data sources. In aquaculture farms, these IoT data encompass multiple sensor and data types, with little or no uniformity in terms of communication protocols, or semantic descriptors explaining the data (O'Donncha & Grant, 2020). In this talk we present a service to integrate data from aquaculture sites (with data from pertinent external sources) and interrogate site conditions with a combination of machine learning and mechanistic models.

Materials and Methods
We demonstrate a cloud-based system for contextual IoT time-series data and model management at scale. The framework is designed to provide a bridge between the disparate data collected at aquaculture farms and the data scientists and subject-matter experts who analyse, model, and interpret the data. A contextual layer provides meta-descriptors to the data to aid the development of models which are then seamlessly stored and deployed in a cloud production environment. The tight coupling of time series data and associated models allows for efficient monitoring, visualisation, and retraining of the models at scale (i.e. hundreds-to-thousands of models). The main features of the system are: (1) an efficient pipeline for ingesting IoT time series data in real time; (2) a scalable, hybrid data management service for both time series and contextual data; (3) a versatile semantic model for contextual information which can be easily adapted to different application domains; (4) an abstract framework for interacting with the system in R or Python; (5) deployment services which automatically train and/or score predictive models upon user-defined conditions.

The architecture is composed of cloud-based microservices and provides an efficient pipeline for real-time data ingestion, time series, and model data management based on unified and intuitive application programming interfaces (APIs) to interact with the data and models.

Both the data scientist and the end user interact with the system using IBM Watson® Studio. This provides a unified user interface where the data scientist, the subject-matter expert, and the end user can collaborate and iterate to visualise and analyse (automated) time series forecasts, and augment with bespoke modelling systems that address specific farm requirements (as an example, in a related paper we describe how the system was used to interrogate the relationships between environmental data and hydroacoustic estimates of distribution of caged salmon (O'Donncha et al., 2021)). Figure 1 presents an overview of the different components of the service.

Results and Discussion
We present an overview of the system from the perspective of the data scientist, subject-matter expert, and farmer. Specifically, we describe the process of integrating data from disparate sources (including environmental sensors, hydroacoustic sensors, operational welfare indices, and open-ocean data from the E. U. Copernicus Marine Information Service) and contextualising with a semantic layer. We detail the development of time-series forecasting models of environmental variables in a scalable framework using serverless cloud, and an automated monitoring framework that tightly couples observation and forecast. Finally, we describe the interaction with the system using IBM Watson® Studio and how it enables a unified development (for both the data scientist and the subject matter expert) and dissemination platform to operationalise the heterogenous datasets collected on aquaculture farms. Results are presented for offshore, inshore, and land-based farms.

Introduction

Precision aquaculture (Føre et al., 2018) involves a variety of sensors used to gain insight into the farm environment, make decisions which optimize fish health, welfare, growth, and economic return, and reduce risk to the environment. Fundamental to those is monitoring of environmental and animal processes within a cage and processing those data towards farm insight using models and analytics. This paper presents an analysis of environmental and fish behaviour datasets collected at three salmon farms in Norway, Scotland, and Canada. Information on fish behaviour were collected using hydroacoustic sensors that sampled the vertical distribution of fish in a cage at high spatial and temporal resolution, while a network of environmental sensors characterised local site conditions. We present an analysis of the hydroacoustic datasets using AutoML (or automatic machine learning) tools that enables developers with limited machine learning expertise to train high-quality models specific to the data at hand. We demonstrate how AutoML pipelines can be readily applied to aquaculture datasets to interrogate the data and quantify the primary features that explains data variance.

Materials and Methods

Hydroacoustic methods provide a proxy measure for density and distribution of marine animals in form of acoustic backscattering (Foote, 2009). Advantages linked to hydroacoustic sampling techniques include, high spatial and temporal resolution, autonomous long-term sampling duration, range (especially during poor visibility when visual-based methods tend to fail), and a non-invasive surveying approach (Scherelis et al., 2020).

This study considers three salmon cage farms in Norway (NOR), Scotland (SCO), and Canada (CAN). For each site several environmental sensors were deployed monitoring a range of parameters, including temperature, dissolved oxygen (DO), and current speed. These were complemented with weather data from *in-situ* weather stations or model generated reanalysis, and open-ocean model from the E.U. Copernicus Marine Service Information model repository.

Data were processed using an automatic machine learning framework. AutoML systems uses a variety of techniques, such as, differentiable programming, tree search, evolutionary algorithms, and Bayesian optimization, to find the best machine learning pipelines for a given task and dataset (Drori et al., 2018)an automatic machine learning (AutoML.

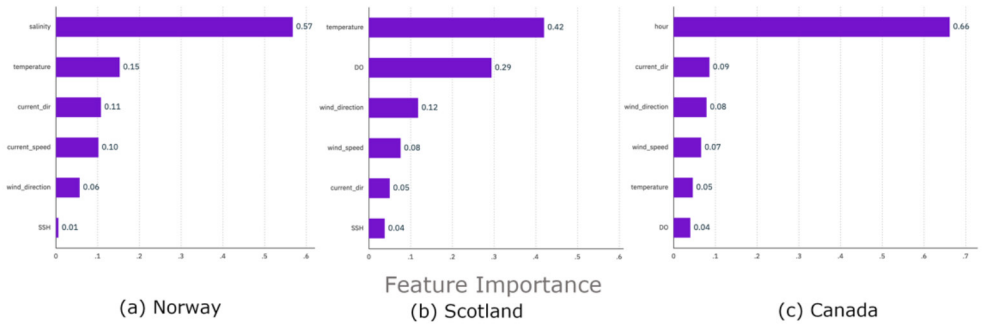

Figure 1: Plot of the relative amount of variance explained by environmental and external drivers of fish behaviour. The x-axis presents the proportion of variance explained for each variable described on the y-axis. Plots are presented for Norway, Scotland, and Canada sites in (a), (b), and (c) respectively.

(Continued on next page)

Results

We interrogated relationships between vertical distribution of fish in a cage and environmental variables at the three geographically disparate sites. Statistical analysis explored the diel patterns, and how data distributions varied over the duration of the study, while IBM AutoAI was used to quantify the effects of environmental variations on the vertical movement of the fish. For the machine learning interrogation, we provided input features that literature suggests influence salmon behaviour (and were available at the study sites). For our study, these were temperature, DO, current speed, wind speed, and salinity, together with hour-of-day (see Fig 1, Y-Axis). The resultant model explained 59%, 64% and 61% of variance for the NOR, SCO, and CAN sites, respectively. Figure 1 presents the variable importance computed for the three locations. While there were similarities in the drivers that influenced fish behaviour at the three sites, pronounced variations existed based on the different geography and characteristics of each site.

Results presented in this paper indicate pronounced differences between sites and the need to consider these variations for farm management. One could readily use this approach to quantify the difference between sites, and further to identify the fundamental drivers to these variations. This could be particularly valuable when comparing different farm systems such as inshore and offshore and the associated operational implications.

SIMULATING THE HYDRO-ENVIRONMENTAL EFFECTS OF SUSPENDED AQUACULTURE INSTALLATIONS IN A THREE-DIMENSIONAL NUMERICAL MODEL

Fearghal O'Donncha[1], Michael Hartnett[2]

[1]IBM Research – Ireland, Damastown Ind. Park, Mulhuddart, Dublin 15
Email: feardonn@ie.ibm.com
[2]Department of Engineering, National University of Ireland, Galway

Introduction

Aquaculture structures affect hydrodynamics of their environments by impeding and redirecting flow. Cages, rafts, and lines used in aquaculture systems often form porous suspended canopies extending from the free surface, see Figure 1. Field studies have shown that suspended canopies impact flow profiles in a number of ways, including reduced velocities within a canopy, accelerated flows beneath a canopy, and the development of shear layer processes at canopy interfaces (O'Donncha et al., 2015). Aquaculture canopies may alter vertical velocity profile as shown schematically in Figure 1.

Determining the hydrodynamic properties of these aquaculture systems is important in predicting the transport of nutrients and waste products to and from the system. Simulations can identify ways to improve productivity while minimizing environmental impacts. We applied an amended version of the hydrodynamic model Environmental Fluid Dynamics Code to explore hydro-environmental conditions within Killary Harbour, a fjord-like inlet on the West Coast of Ireland.

Materials and Methods

EFDC (Hamrick, 1996) is a public-domain, open-source, modelling package for simulating three-dimensional (3-D) flow, transport, and biogeochemical processes in surface-water systems. In the modified version of EFDC, we represent physical obstructions to flow by including an additional drag term in the momentum-conservation equation so that momentum was removed from model cells in which the canopy was specified (i.e., the region of the harbour containing aquaculture structures). In this formulation, the model incorporates a momentum sink due to the suspended canopy, as well as modification term terms representing the net changes to turbulent kinetic energy.

An EFDC model for Killary Harbour was developed at a horizontal resolution of 64m with 20 equidistant vertical layers. Open boundary water levels were prescribed on the Western boundary using data from a nearby tide gauge. Freshwater inflows from two rivers (Bundorragha and Erriff) were prescribed, while meteorological data was extracted from a local weather station. Location of aquaculture installations were prescribed from line surveys, and associated model cells were specified with appropriate canopy densities. Model coefficients were fine-tuned based on field data.

Results

We present results on the hydrodynamic calibration of the model against ADCP and water level data. The effects of the aquaculture installations on vertical flow profiles both within and around the canopy were investigated. Model simulations were conducted with three mussel dropper densities (high, medium, and low) and associated hydrodynamics characterised. A significant attenuation of flows through the canopy was observed with flow primarily being diverted under the farms rather than around (farms are land-bounded on one side). Flow dynamics were quantified in terms of velocity differentials of velocity and relative velocity. Figure 2 presents the relative velocity differential computed within the harbour. Differentials are presented relative to unimpeded flows. Hence, a positive value signifies a decrease in flows; while negative values indicate an increase in flows.

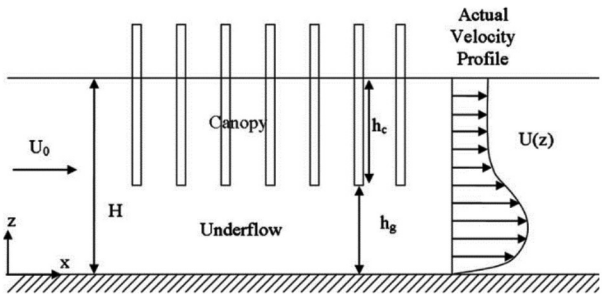

Figure 1: Schematic illustrating the configuration of suspended aquaculture installations representative flow profile that may develop

(Continued on next page)

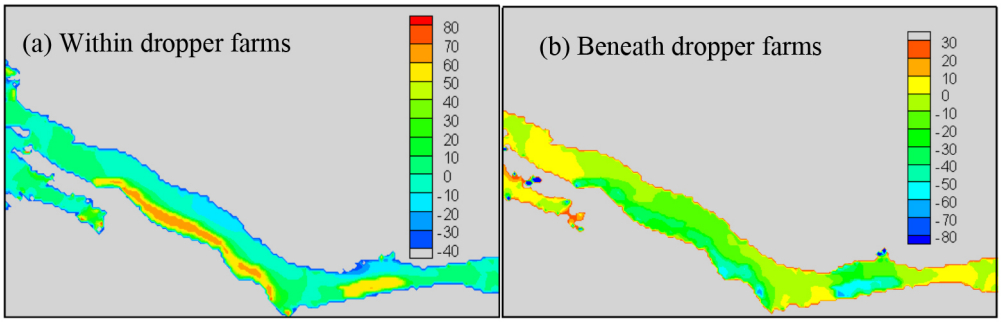

Figure 2: Relative percentage differentials of velocity (a) within mussel dropper farms and (b) beneath mussel dropper farms.

.

Effects of the aquaculture structures on material transport and residence times were also examined. The primary focus was on material transport time scales within the actual aquaculture farms. All cells containing aquaculture installations were coded as having uniform initial concentrations of trace, C_0 with subsequent spatial concentrations, $C_{n,}$ computed after n tidal cycles.

One of the significant conclusions from this research is that the impedance of flows due to the presence of aquaculture structures must be included in models when planning and developing environmental impacts assessments of certain types of aquaculture installations.

Introduction

Aquaculture is recognised as being the most promising source of animal proteins (FAO, 2018), however aquaculture faces a challenging future in the face of emerging threats. Increased risk of disease and harmful algae blooms connected with climate change along with production and infrastructure losses from extreme events, fluctuations in water temperature and oxygen levels, ocean acidification, changes in rainfall patterns, create many problems for sustainable aquaculture (Lafferty, 2015). Microplastics are also posing a threat to aquaculture and its products as they are widespread and can be found in aquatic fauna (GESAMP, 2016). ASTRAL will focus on the Integrated Multitrophic Aquaculture (IMTA) production to address these challenges. In IMTA systems, the waste of one crop (fed animals) are converted into fertilizer, food and energy for the other crops (extractive plants and animals). IMTA can reduce the environmental impact, diversify and increase production, lower investment risks, create jobs, increase consumers' trust, as well as supporting sustainable aquaculture and the circular bioeconomy (Chopin, 2015). The aim of ASTRAL is to boost IMTA with the implementation of innovative, and resilient production and the monitoring of environmental hazards with new technology to build long-lasting cooperation across the Atlantic.

Methodology

Five IMTA labs, four case studies and one prospective IMTA lab have been identified along the Atlantic coast. ASTRAL will assess the added value of the species combination throughout the production cycles, through developing health management systems, assessing biosecurity, food safety and profitability.

The IMTA lab in Brazil is an inshore recirculating system using intensive Biofloc technology. Shrimp hyper-intensive, zero water exchange, biofloc systems are a sustainable and biosecure alternative to intensive culture systems. During the shrimp production there is an accumulation of nutrients and organic matter (biofloc) that need to be removed mechanically or biologically. Therefore, the integration of species that consume organic matter (tilapia and oysters) and nutrients (seaweeds and halophytes) are being investigated as an alternative to maintain the water quality in the production system.

IMTA lab South Africa incorporates Buffeljags Abalone, a commercial farm growing abalone in land-based raceway tanks and Ulva in adjacent interconnected paddle raceways using abalone effluent. The Ulva serves as a biofilter allowing 50% of the water from the Ulva systems to be re-circulated back to the abalone tanks with the Ulva used as supplementary feed, contributing to sustainability and the circularity. Concerns regarding biosecurity and a paucity of information on production methods for emerging species, is limiting wider use of this technology. IMTA lab SA aims to develop and validate cost-effective IMTA in land-based pump ashore systems for new high value aquaculture species (sea urchins).

(Continued on next page)

IMTA lab Scotland, an open water system, will optimise cultivation techniques of macroalgal and shellfish to demonstrate an improved economic case for the co-cultivation of kelps spp. and the native oyster, and to achieve production scales necessary to produce widespread positive mitigation effects when collocated together with sources of anthropogenic nitrogen e.g. salmon farms. IMTA lab Scotland will undertake year-round environmental monitoring and sample collection to improve the cultivation system performance aimed at improving yield and composition, stocking density and biosecurity. The development of new cultivation systems will explore options to minimise cultivation waste through improved system design and reducing, reusing, and recycling polymer-based cultivation materials.

IMTA lab Ireland is developing and validating cost-effective IMTA processes in open water system. This IMTA system will explore the feasibility of the cultivation of Atlantic salmon, lumpfish, European lobster, native oyster, scallop spp., seaweed spp. and spiny sea urchins. Production technologies for these species will be assessed and optimised in the IMTA system. IMTA lab Ireland will operate in line with organic standards to enhance potential profitability and to mitigate environmental impact. IMTA lab Ireland will seek to establish best practice for the cultivation of these species by monitoring and assessing animal welfare, biosecurity and health management.

The prospective IMTA lab in Argentina will gain knowledge from the other IMTA labs. Feasibility studies will be carried out to assess local species and identify appropriate sites within the Beagle Channel to facilitate IMTA. Data will be acquired on water quality parameters as one of the primary inputs for choosing the species assemblages and to simulate a productive cycle. Due to the shortage of high-quality protein sources available locally in Tierra del Fuego for fish feed, it is proposed to assess the viability of earthworm as a dietary protein source for the potential fish species.

Results

ASTRAL will examine the potential of all the IMTA value chains throughout the growing seasons to establish optimal production conditions. Continual monitoring to help establish baseline data to achieve better yield and profitability, less environmental impacts and less waste is being undertaken.

MODELLING THE RENEWABLE POWER GENERATION OF A NOVEL OFFSHORE AQUACULTURE SYSTEM

M O'Shea[1],

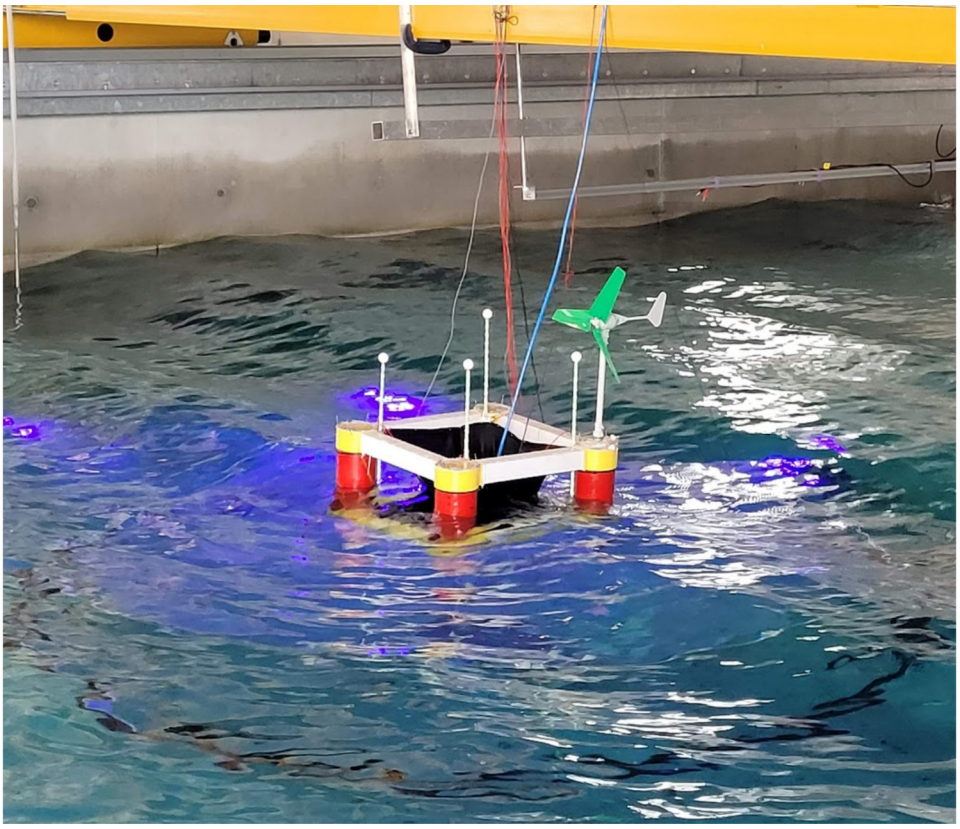
1 University College Cork, 2 Impact 9
Email: Michaeloshea@ucc.ie

Introduction

The potential for offshore renewable energy integration with floating aquaculture becomes operationally and economically very attractive as the industry moves further from the coast. The integration of the two technologies provides multiple benefits including reduced carbon footprint, reduced logistical challenges and crucially cost of production reduction. A renewable powered offshore aquaculture system in deep water however presents some integration challenges that have not yet been addressed.

Study Description

This study selects an Atlantic salmon farm off the west coast of Ireland as a case study for renewable energy technology integration. The power consumption of a novel offshore floating finfish system is simulated and calibrated with existing power consumption data from traditional finfish site. The renewable resources of wind, wave and solar from the site are collated and available renewable power form each is calculated. Renewable power technology solutions based on a range of renewable technologies are compared including the use of hybrid power solutions i.e. battery banks. Wave tank testing of the hybrid concepts is undertasken to assess the structural and hydrodynamic response of converting the floating offshore aquaculture system to renewable power, Figure 1.



TOWARDS AUTONOMOUS ROV OPERATIONS IN FISH FARMS – RECENT DEVELOPMENTS IN NAVIGATION AND CONTROL

Introduction

Operations with underwater robots such as remotely operated vehicles (ROVs) have become an important part of the aquaculture industry. Use cases includes net and mooring inspections, net cleaning, and biomass inspection during e.g., crowding operations. Though increasingly common in and around net pens, the potential of ROVs are not fully exploited today and several operations are still conducted using divers. The ROV is mainly used as a mobile camera and is controlled by an ROV pilot. The workload required by an ROV pilot can be demanding: The pilot must control the ROV in a dynamically changing environment and make sure the ROV does not damage the net pen while simultaneously inspecting the video images. These workload challenges, and challenges related to weather conditions and costs can be mitigated through increased use of autonomy. SINTEF Ocean has through research projects such as CageReporter (RCN 269087), Artifex (RCN 256241), Netclean 24/7 (RCN 296392) and SFI Exposed (RCN 237790) developed novel functions for autonomous navigation and robust control of underwater vehicles in net pens. This paper summarises some of the recent developments.

Materials and methods

Navigation under water is a challenging task as signals from global navigation satellite systems, e.g., GPS, does not penetrate the water column. Positioning systems based on acoustics, such as Ultra-short Baseline (USBL), and Doppler Velocity Logs (DVLs) are instead often used. The USBL consists of a transponder that is mounted on the ROV and a transceiver that is placed on the surface support vessel. The transceiver interrogates the transponder to pinpoint its location by determining the bearing and elevation angles as well as the time of flight of the acoustic signal. The DVL is mounted on the underwater vehicle and emits hydro acoustic beams. By calculating the Doppler shift in the returning beams, the speed relative to the seabed or any other fixed structure can be calculated.

One question was, however, how these systems would perform in a fish farm with hundreds of thousands of fish interfering with the signals. This was investigated in [1] and it was found that the performance of the USBL was acceptable, with small levels of noise from acoustic interaction with the biomass when the transponder and transceiver were on different sides of the net pen. Furthermore, it was found that a DVL could be used to calculate the ROVs speed and position relative to the net, instead of the seabed, by facing the DVL in the forward direction. Some interference was experienced if fish passed between the ROV and the net, but this was mostly an issue if the ROV was more than 3 meters from the net. As such, net-relative manoeuvring using a DVL would be possible. A recent study investigated whether a DVL, which is a quite expensive instrument, could be replaced by a combination of less expensive lasers, and cameras [2], see Figure 1. The results are very promising.

The measurements from the sensors are indispensable, but they are also prone to noise, drift, and lag which might render control systems unstable. Therefore, with the purpose of providing both the control systems and the operator with the best possible estimation of the ROV states, i.e., heading and position, model based sensor fusion techniques and filters such as the Kalman filter [3] are employed.

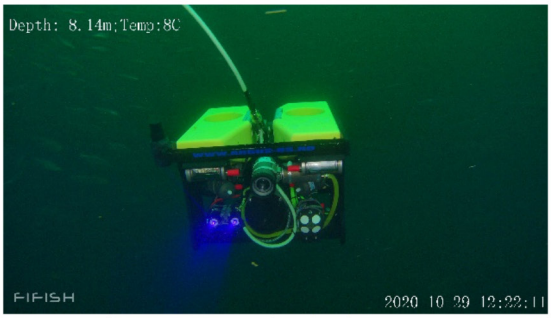

Figure 1: The ROV equipped with a laser.

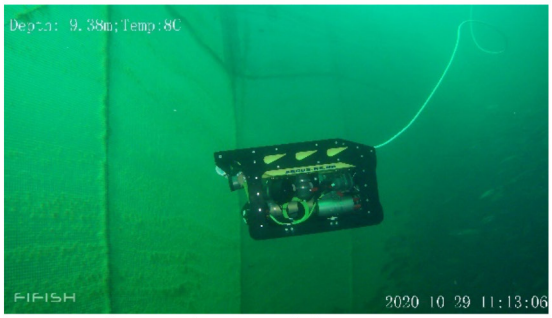

Figure 2: The ROV during net following.

(Continued on next page)

Most industrial ROVs are equipped auto-depth and auto-heading functions that make the ROV hold a given depth and yaw angle, respectively. Such features are very helpful, but more automatic functions are required if the ROV is to perform more advanced autonomous operations. One such example is dynamic positioning (DP) that makes the ROV hold the desired position, and automatically compensates for the disturbances arising from e.g., ocean currents, hence avoiding drift. Another example is path following. Here, the low-level control system in the ROV is provided a desired course angle, depth, and speed from a higher-level path planning algorithm. Combinations of DP and path following algorithms are very useful during operations in fish farms as it allows the ROV to stop and hold its position if it e.g., detects a hole in the net.

Results

SINTEF Ocean has achieved a high level of autonomy within net pen navigation (autonomy level 3, according to [4]). This has been achieved by: (1) estimating the vehicle state with sensor fusion techniques such as the Kalman filter that combines compass measurements, gyro data, DVL measurements and USBL positions; (2) developing a control system for automatic net pen traversing [5], see Figure 2; (3) developing a dynamic positioning control system for station keeping purposes. The systems have been successfully tested at the SINTEF ACE laboratory; a full-scale industrial fish farm laboratory owned by SINTEF Ocean.

Conclusion and future work

New autonomous functions are being implemented on ROVs operating in fish farms. These novel solutions can ensure better working conditions for ROV operators and can, if combined with e.g., machine vision algorithms, become a vital tool for fish farmers worldwide, aiding in the detection of holes and thus reducing risks of fish escaping. The ROVs can also be equipped with manipulator arms and thus aid in underwater maintenance and intervention operations. SINTEF Ocean is also conducting research into the interaction between fish and machines to develop control and navigation solutions that are preserving fish welfare. The overall goal is to achieve autonomy level 4 within the next 3 years [4].

Introduction

Fish farming at exposed locations is demanding with respect to personnel safety, structural integrity and fish welfare during operations. Operations in and around fish farms are often performed with a limited knowledge of how the environmental conditions at the specific site, e.g., waves and ocean currents, affects the structures at the fish farm. This reduced insight into the effect of the environmental conditions and the missing ability to properly assess the situation beforehand and while on site, narrows the operational window of potentially crucial tasks such as well-boat and de-lousing operations. Large volumes of data are gathered from fish farms, but the usage of this data is limited. This abstract presents recent developments in the use of sensor data from fish farms. Measurements from sensors located on a fish cage structure are integrated with a mathematical model of a fish cage, giving a holistic representation of structures and environments during operations. This **digital twin** of the fish cage can provide unique insight into the structural deformations happening below the surface, and as such function as a decision support tool for fish farmers and service providers.

Materials and methods

The digital twin model is developed in the software FhSim, a simulation environment featuring a large collection of mathematical models, including aquaculture net cages, closed containment systems, fish behaviour, underwater vehicles and more [1,2]. The main components of the model consist of a net structure model, a cable and mooring lines model, a floating collar model and a hydrodynamic environment model. The models need to be numerically efficient in order to run in real-time.

An integrated numerical model with adaptive flow field [3] is used to estimate net-cage deformations, where the magnitude and direction of the current flow can be adapted by continuously assessing deviations between the simulated and the measured positions of the net. The integrated modelling and estimation approach is well suited for real-time monitoring of cage deformations by using a significantly reduced number of sensors.

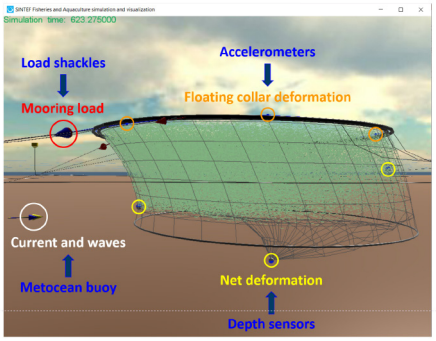
The mooring lines, bridles, chains, ropes and cables of the cage system are modelled as collections of six degree of freedom rigid-bar elements which are connected with axial and angular constraints to provide desired structural properties (i.e., bending, axial stiffness and torsional stiffness). An elastic version of the Baumgarte stabilization method [4,5] is used to avoid numerical instabilities in the cable endpoints when simulating at larger time-steps (which is necessary for real-time implementations).

Similar to the cables and mooring lines, the floating collar is modelled as a collection of rigid-bar elements connected with axial and angular constraints, regulated by the implemented Baumgarte stabilization method. The end points of each element are connected through constraints to create a ring. The vertical displacements of the floating collar, caused by wave excitation forces and the forces applied on the floating collar from attached objects such as the net and bridles, are derived from accelerometer data from the floating collar. This enables the floating collar to exhibit vertical displacements based on measurements while retaining horizontal behaviour based on input forces. To enable real-time implementations of the vertical displacements a cubic spline approximation of the collar's motion is implemented.

FhSim contains implementations of sea environments simulating ocean currents and wave fields, both regular and irregular. The sea environment supports realization of JONSWAP and ISSC wave spectra. An environmental model allowing updates of currents and wave parameters based on sensor inputs was specifically developed for the digital twin model.

(Continued on next page)

Figure 1: Overview of sensor placements and measurements incorporated in a digital model of a cage



Results

Data from load shackles, depth sensors, accelerometers, and a metocean buoy was gathered from a live fish farm in Norway during a 6-month period running from October 2019 to March 2020. This data was integrated in the digital twin model. Prior to integration the data was processed, and a time-period of two days was chosen to be used in the demo case. Data from 6 load shackles were used to estimate the mooring loads, only 3 depth sensor measurements were necessary to accurately estimate the net deformation, while the cubic spline approximation used for the floating collar estimation required measurements from 8 accelerometers to give an accurate result. The metocean buoy data were combined with depth sensor data to estimate the current speed. The variables of the simulated numerical models converged to the measured values, demonstrating the capabilities of the digital twin model.

Conclusion and future work

This work has demonstrated how numerical models can be used to accurately represent structures at fish farms using data collected by sensors. The numerical models are lean and efficient and thus suitable for real-time applications. The real-time capabilities of the floating collar model have been tested in a small-scale experiment using one accelerometer, but a remaining full-scale test is yet to be performed. Combining IMU data of ship motions with the developed models offers a possibility to monitor vessel operations near the cages. A fish behaviour model (as seen in Figure 1) and the corresponding sensor (e.g., echo-sounders) data will also be tested and included in the digital twin for monitoring fish distribution.

Introduction

One of the most important traits in aquaculture, following growth performance, is disease resistance. Diseases can be caused by parasites, viruses, bacteria etc. A common ectoparasite which significantly affects the European seabass aquaculture production is *Lernanthropus kroyeri* (Copepoda: Lernanthropidae) Van Beneden, 1851). Generally, *L. kroyeri* parasitizes the European seabass and affects both production and welfare by increased mortality after the infestation (Sobhana, 2009; Tokşen 2010; Chavanne *et al*., 2016).

Materials and Methods

In total, 2,425 European sea bass (*D. labrax*) juveniles originating from the Nireus breeding program were individually pit-tagged, fin-clipped and challenged to the copepod *L. kroyeri* through natural cohabitation in an environment heavily infested with the parasite (Sagiada site, GR 32 FISH 012). After 4 months in the sea cages, all fish were scarified. The parasite resistance trait was defined according to the counts of parasite found on each individual fish. Experienced personnel counted the number of parasites on each gill arch, on both sides of the fish, with the use of stereoscopes. The heritability of the parasite count was estimated using an animal model (BLUP) and selective genotyping was applied in order to genotype a sample of 1,078 fish with the 30K Affymetrix MedFISH SNP-array. Quality control was performed using plink software (SNP call rate 90%, MAF 0.05, HWE 10^{-6}) (Purcell *et al*., 2007). GWAS analysis was performed using GEMMA (Zhou and Stephens, 2012, 2014), a univariate animal model using as depended variable the parasite count, the genomic relationship matrix among candidates as a random effect while no fixed effect was fitted in the model. Bonferroni correction was also used in the analysis (Bonferroni, 1936). Finally, the linkage disequilibrium was estimated using the pairwise correlation between all pairs of SNPs using plink software.

Results and Discussion

Parasites were counted in all fish and their average number was 25 ±13.26 while the range was from 1 to 84 parasites. Heritability for parasite count (0.29, BLUP) revealed the existence of substantial additive genetic variation. Since both within and between family variation was evident, from the pedigree-based analysis (animal model), selective genotyping was applied based both on the within family variance of the parasite count and the discordant EBVs for parasite count from the animal model. This method of selective genotyping was utilized to capture both within and between family genetic variations in our genotyped sample (1,078 fish). The dataset which passed the quality control successfully was consisted of 1,076 offspring and 26,821 SNPs. SNP distribution is illustrated in Fig 1, while SNPs which were unstructured were collected in chromosome 25.

To our knowledge, this is one of the first applications of the newly designed 30K Medfish SNP-array in a genomic association analysis and our results indicate an average Linkage disequilibrium (LD = 0.07) in all chromosomes. The GWAS analysis performed revealed two SNPs (p-value: 0.0000023034, 0.0000060397, Fig 2) close to the Bonferroni correction limit in chr 8 (a=0.05, 0.0000018642). The phenotypic variation explained by the two SNPs was estimated to be 2% each. Nevertheless, a higher LD would improve the power of the GWAS analysis. Moreover, if a larger sample was available as well as a higher SNP density on chromosome 8 stronger associations could be revealed. Further analysis on genomic heritability and alternative modes of inheritance for the GWAS on parasite count is being conducted.

Introduction

The majority of the aquaculture breeding programs focus on growth performance traits (Chavanne et al., 2016)hindering an overall evaluation of their success. Here, we report on the results of an online survey of the major aquaculture breeding companies operating in Europe. Six main reared fish species were targeted. A total of 31 respondents contributed to the survey, representing 75 % of European breeding organizations. Family-based breeding schemes were predominant, but individual selection was more frequently applied in marine species. Artificial fertilization is the preferred means of reproduction; however, mass spawning is often used as a fallback method. The most frequently selected trait is growth performance, but the number of selected traits has been increasing over the years through the addition of traits such as disease resistance or product quality. The use of molecular tools is now common in all programs, mainly for pedigree traceability. An increasing number of programs use either genomic or marker-assisted selection. Results related to the seed production market confirmed that for Atlantic salmon there are a few dominant players at the European level, with 30–50 % market share. Only part of the European fish aquaculture industry today fully exploits selective breeding to the best advantage. A larger impact assessment still needs to be made by the remainder, particularly on the market share of fish seed (eggs, larvae or juveniles, which are quite inheritable traits. Apart from such traits, stress response could also be included in breeding programs. Literature suggests high stress response negatively affects the fish welfare (Pickering, 1993). Additionally, cortisol levels, which have been used as stress indicators, show negative genetic correlation with body weight. Moreover, a moderate heritability of cortisol levels has been identified (Chatziplis et al., 2020).The aim of this study is to estimate the heritability and genetic parameters in the European seabass for body weight and stress response using as indicators the hormonal (cortisol levels) and biochemical (glucose, lysozyme levels) factors and based on 57k SNP Dlab-chip array (Griot et al., 2021)"ISSN":"00448486","abstract":"Viral Nervous Necrosis (VNN.

Materials and Methods

European seabass offspring coming from two different years batches were used [533 offspring (Batch 10) and 332 offspring (Batch13)]. They were submitted into a stress challenge test as described by Chatziplis et al (2020). After the stress test, blood samples were collected and used to determine the plasma concentration of cortisol, glucose and lysozyme levels (318-334 Days Post Hatching). Offspring and broodstocks were genotyped with the ThermoFisher AxiomTM Sea Bass 57k SNP DlabChip (Griot et al., 2021)"ISSN":"00448486","abstract":"Viral Nervous Necrosis (VNN. Quality control was performed with plink software (Purcell et al., 2007), using the following criteria for exclusion: SNPs with call rate less than 90%, minor allele frequency lower than 0.05, deviation of Hardy –Weinberg equilibrium lower than 0.001. After quality control, 50,136 SNPs were used in the study. Heritability of the stress indicators and body weight as well as the genetic and phenotypic correlations between traits were estimated using Maximum Likelihood methods. The body weight and stress bio-indicators were utilized in a multitrait animal model to estimate heritability and genetic/phenotypic correlations among them. The batch was used as a fixed effect, while the polygenic effect which was fitted in the model, was estimated using a Genomic Relationship Matrix (GRM). All analyses were performed using AIREMLF90 (Aguilar et al., 2014).

$$Y = \mu + X + Zu + e$$

where y corresponds to the matrix of the body weight and stress response, μ is the mean of the body weight, X is the fixed effect, Z is the incidence matrix, is the additive genetic effect, which using GRM, is distributed as ~N (0, $G\sigma_a^2$) (G is the GRM and σ_a^2 is the additive variance). Finally, e is the random residual.

(Continued on next page)

Table 1 Descriptive statistics of the studied traits

Trait	Body weight (g)	Cortisol levels (ng ml^{-1})	Glucose levels (mmol l^{-1})	Lysozyme levels (kU l^{-1})
MEAN	65.26	339.43	6.78	568.2
SDV	20.85	79.77	2.25	287.45

Table 2 Heritability (bold), genetic correlation, and phenotypic correlation (above and below the diagonal, respectively) for body weight and stress response and standard errors are in parenthesis

Ratio	Body weight	Cortisol levels	Glucose levels	Lysozyme levels
Body weight	**0.60 (0.06)**	-0.46 (0.11)	-0.09 (0.12)	0.03 (0.09)
Cortisol levels	-0.11 (0.04)	**0.36 (0.06)**	-0.13 (0.14)	0.00 (0.02)
Glucose levels	-0.02 (0.04)	-0.03 (0.04)	**0.41 (0.06)**	0.06 (0.11)
Lysozyme levels	0.03 (0.05)	0.04 (0.06)	0.08 (0.04)	**0.79 (0.05)**

Results and Discussion

Descriptive statistics of the studied traits are illustrated in Table 1. The heritability of body weight in European seabass was 0.60 and for cortisol, glucose and lysozyme levels were 0.36, 0.41 and 0.79, respectively. Chatzplis et al (2020) estimated heritability of the cortisol, glucose and lysozyme levers to be 0.37, 0.33 and 0.56 using a subset of the present sample, combining three repeated measurements of all the stress indicators and pedigree relationship matrix. In our study, a negative genetic correlation between cortisol and body weight was detected using GRM and confirmed previous results (Vandeputte et al., 2016) and Chatziplis et al. 2020). No correlation between the rest stress indicators and body weight was detected, as well as no correlation between the stress indicators was identified.

Introduction

The gilthead seabream is one of the leading species in the Mediterranean aquaculture and many studies have been done to investigate the genetic architecture of growth and body weight. QTL affecting body weight and fat have been reported (Boulton et al. 2011; Loukovitis et al. 2011; Kyriakis et al. 2019)"ISSN":"00448486","abstract":"The gilthead seabream (Sparus aurata. The aim of the study is to identify QTL affecting growth performance and fat content using the newly constructed MedFish Array (Peñaloza et al. 2021).

Materials and Methods

1,428 gilthead seabream individuals, originating from 97 families, were randomly divided into two sea cages, which were fed on different diets; a high plant-protein containing 85% plant proteins and a high animal-protein containing 30% of marine animal protein. The body weight was measured at 11 months (465-481 DPH) and at 16 months (633-650 DPH) after tagging. Fat content was measured during the last body weight measurements. Fin clips were collected from the offspring and genotyped using the MedFish Array. Quality control was performed using Plink software (Purcell et al. 2007), with the following criteria for exclusion: SNPs with call rate less than 90%, minor allele frequency lower than 0.05, deviation of Hardy –Weinberg equilibrium lower than 0.001 were removed. Finally, after the quality control, 24,513 SNP were utilized in the study. A Genome Wide Association Study (GWAS) using growth as the depended variable and a GWAS using fat as the depended variable were performed using GEMMA (Zhou and Stephens 2012; 2014). The additive variance was estimated using a genomic relationship matrix among candidates as a random effect while the diet was used as a fixed effect (2 levels) and fitted in the model. Finally, Bonferroni correction was also used.

Results and Discussion

Table 1. Average and standard deviation of the traits

Population	BW4 (g)	BW6 (g)	GROWTH (g)	FAT (%)
Total	382.13±111.5	820.91±196.0	438.23±107.1	12.05±2.6
Plant-protein	355.73±107.7	754.27±176.1	397.45±90.1	11.56±2.5
Animal-protein	404.50±109.9	877.50±194.4	472.22±108.2	12.47±2.6

One putative QTL, affecting fat independent of the diet, was revealed in chr 13 explaining the 2% of the phenotypic variation. Moreover, SNPs in chr 5, 7 and 10 seem to show increased trailing (Figure 1). Kyriakis et al. (2019) identified SNPs associated with fat content at chr 4, 8, 7, 13 and 21 at 750DPH. Examining the growth in both diets, a QTL affecting growth at high temperatures (19ºC – 26ºC) was found in chr 16, explaining the 2.1% of the phenotypic variation. Kyriakis et al. (2019) identified SNPs associated with body weight in chr 1, 6, 8, 16 and 24 at 750 DPH. Interactions between selected SNPs are under investigation.

COULD KISSPEPTIN TREATMENT BE USED TO ADVANCE PUBERTY IN GREATER AMBERJACK (*Seriola dumerili*) FEMALES?

Introduction

The kisspeptin system is now accepted as a key regulator of vertebrate reproductive function, particularly the onset of puberty, acting upstream of the brain–pituitary–gonad (HPG) axis. Recently, this hormone has been used successfully as a hormonal treatment in teleost fish, with proved track records of eliciting gonadotropin release (Felip et al., 2009; Oliveira et al., 2020) and gonadal development (Beck et al., 2012) in different species.

The greater amberjack is a promising candidate for aquaculture diversification, presenting a good adaptability to the captive environment. However, reproductive maturation and spontaneous spawning has proven to be difficult in broodstocks formed of first generation (G1) fish (Mylonas et al., 2004). According to these authors, such reproductive dysfunctions in captivity could be counteract using GnRHa implants. However, for the establishment of greater amberjack as a commercial species, more alternative treatments are needed, namely for puberty development. Thus, the objective of this study was to test an innovative hormonal treatment with kisspeptin, to induce puberty in greater amberjack.

Methodology

To determine the effectiveness of an *in vivo* treatment with kisspeptin as a stimulator of puberty in greater amberjack (*Seriola dumerili*) juveniles, the present trial was performed in summer (July), coinciding with this species reproductive season, using an established stock of greater amberjack (2+ years old, 1171.79 ± 250.54 g, sex ratio 1:1) from IPMA - EPPO (Olhão, Portugal). According to the previously deduced amino acid sequence of the core kisspeptin-10 region in yellowtail kingfish, *Seriola lalandi*, KISS2-10 (NH2-FNFNPFGLRF-CONH2, GenBank Accession No. HQ449730) (Nocillado et al., 2013) amidated decapeptide was synthesized by CPC Scientific Inc. (San José, California, USA). Half of the females were treated with kisspeptin, while the other half were left untreated to serve as a control group. Fish were intramuscularly injected with KISS2 decapeptide at a dose of 250 μg/kg body weight, based on previous studies in fish (Beck et al., 2012; Felip et al., 2009; Oliveira et al., 2020). Both groups of females (Kiss Treated and Control) were sampled 2 days after. Blood samples were extracted, and separated plasma frozen at -80˚C until further analysis. After blood collection fish were sacrificed by anaesthetic overdose (1000 ppm) and immediately dissected. Gonads were extracted both for histological determination of maturation stage, and for gene expression determination through RNA-*seq* and *q*PCR. Gonad samples collected for RNA-*seq* were stored in Trizol (Merk, Lisbon, Portugal) at -80 ºC. Gonad samples collected for histology were fixed in 4 % PFA and later transferred to ethanol. Circulating levels of Testosterone (T) and Estradiol (E_2) were assessed by the respective ELISA kits from Cayman Chemicals (Ann Arbor, Michigan, United States), according to the manufacturer's protocol (Fernández et al., 2019; Oliveira et al., 2020).

Results and Discussion

The results obtained revealed an effect of the kisspeptin treatment on the puberty process of greater amberjack females. The histological analysis showed similar maturation stages in the ovaries of both groups, where oocytes were in previtellogenic stage. This result suggested that the juveniles were probably too immature for the treatment to produce an effect at level of ovary maturation. This information was confirmed in the quality check by nanochip performed in the RNA from ovary samples sent for RNA-*seq*, where an overexpressed peak of 5S rRNA was detected, while the 18S and 28S rRNAs showed low expression in both groups, revealing the ovary immaturity (Rojo-Bartolomé et al., 2016). On the other hand, both estradiol and testosterone levels showed a tendency to be increased in the group of fish treated with kisspeptin, although this difference was not significant. A multiple injection protocol or a slow-release implant would probably be needed to elicit a more pronounced effect. In Senegalese sole, a single injection was enough to activate the whole BPG axis (Oliveira et al., 2020), however the fish were in a more advanced state of maturation. Finally, the RNA-*seq* analysis revealed 99 transcripts differentially expressed in the kiss treated gonad samples (64 up- and 35 down-regulated), in relation to the gonads from the untreated females (FDR<0,05 and |log2FC| >1,5), exposing an effect of the kisspeptin treatment at transcriptional level.

(Continued on next page)

Conclusions

The obtained results reveal that the kisspeptin treatment is a promising therapeutic for advancing puberty in greater amberjack females, opening a window for future research in terms of protocol optimization, namely in terms of the adequate size of the fish and ways of administration.

A SLIPPERY SLOPE FOR AQUACULTURE REGULATION: DEVELOPMENT LICENCES AS A POLICY INSTRUMENT

M. S. Olsen*, T. C. Osmundsen, A. Gauteplass, F. Asche

NTNU Social Research, 7491 Trondheim, Norway
*E-mail: marit.olsen@samforsk.no

Introduction

The Norwegian aquaculture industry is a highly successful one seen in terms of production growth (Garlock et al., 2020), and this rapid production growth is seen as a result of a number of innovations that have improved productivity and competitiveness (Bergesen & Tveterås, 2019). However, the industry is also controversial as it constitutes a new way of utilizing aquatic ecosystems, and there are significant concerns with respect to its environmental sustainability (Belton et al., 2020). The regulation of salmon aquaculture in Norway, is strongly dependent on a licensing system where license gives the right to produce at a given location under a number of conditions that put limitations on how the production can occur (Hersoug et al., 2019). The past decade, increasing concerns with respect to the industry's environmental sustainability has prevented distribution of new commercial licenses for salmon production in Norway. A new regulatory system for growth has been implemented, and growth in terms of increased biomass is awarded through a traffic light evaluation, depending on the environmental performance of all actors within specific geographical areas. The political regulation of the successful, yet controversial, industry must take into account different concerns such as industry growth and development, but also environmental and societal sustainability.

This paper investigates the most recent addition to the licensing system, the development licenses, from the viewpoint of regulation, as a policy instrument and governing tool. The objective of the development licenses is to support the development of new technology that will improve environmental sustainability and benefit the entire industry. These licenses function as both a carrot and a stick, attempting to optimize both legitimacy and effectiveness. With these licenses the Norwegian government introduced a new path towards technology development, spurred by an implicit subsidy as the development license can be converted to standard commercial licenses once the project are completed at the low price of 10 million NOK per license independently of the project's outcome. Importantly, there are no requirements as to further use of the tested technology, after the initial project period is over. The scheme was designed as a competition at a "first-come, first-served" basis, where the degree of innovation in later applications would be compared to already awarded concepts. From the licenses were launched in 2015, 104 applications were filed before the deadline in 2017. Less than 20% of the applied concepts were accepted, however, these sum up to a total of 107 licenses, representing a substantial increase in the national capacity to produce salmon at a time where environmental concerns made it politically impossible to increase production by awarding new ordinary commercial licenses.

Materials and methods

The empirical data for this paper is publicly available material related to Norwegian aquaculture regulation in general, and documents concerning the development licenses in particular, e.g. white papers, green paper, responses to hearing round for the development license scheme, policy papers, regulations, and award and rejection letters from the Directorate of Fisheries and/or Ministry of Trade, Industry and Fisheries. In addition, the material is supplemented with interviews with public authorities.

Results and discussion

This paper draws on interactive governance theory, and our analytical starting point is the relationship between two systems that has earlier been termed the governing system and the system-to-be-governed (Jentoft, 2007). The governing system consists of institutions, and regulatory tools and mechanisms. It is a social system created by politicians and bureucrats, and influences by other stakeholder. The system-to-be-governed, on the other hand, is partly social and partly natural, and consists of the aquaculture industry, other users and stakeholders of the marine environment, as well as nature itself. The governing system aim to impact and steer the behavior of stakeholder in the system-to-be-governed, and though these actors aim to influence the natural system. Although it is too early to evaluate whether the development licenses ultimately will result in major technological advancement for the aquaculture sector, our findings show that the design and implementation of these licenses as a regulatory tool has implications for both the governing system; the overall system of aquaculture regulations, and for the impact that these tools have on the system-to-be-governed; aquaculture production and the aquaculture industry, and for the relationship between the two systems.

(Continued on next page)

We further discuss if this scheme with development licenses is fit for purpose. In a political atmosphere where growth of the Norwegian aquaculture industry has been a contested issue for many years, possible avenues towards growth needs to be coupled with ambitions to improve or solve negative environmental impacts to be politically acceptable. The competition arena, with the first-come, first-serve principle, may not be perceived as fair. The assessment took much time and resources at the Directorate, as the number of applications was much higher than expected and the assessment of the technological advancements was a laborious and difficult task. As the value of commercial licenses rapidly increased, the scheme ended up being much more favorable than planned, giving strong incentives for the industry to suggest more projects as the main motivation for applying may have been (cheap) access to new production capacity. The crucial role of the relationship between significant investments and the estimated value of the awarded licenses in the assessment of the applications, might have led some concepts with high costs to be awarded while others with lower costs to be rejected. The latter group may have had more efficient concepts.

The introduction of development licenses as a tool in 2015 gave environmental issues increased attention since these licenses were to be awarded to companies that would develop technological innovations that ultimately reduce the problem with salmon lice and escapees. However, the development license also provided a venue for obtaining new licenses in a period when no ordinary commercial licenses were awarded because of the environmental concerns.

SHOULD TRACEABILITY SYSTEMS IN THE AQUACULTURE INDUSTRY BE BASED ON BLOCKCHAIN TECHNOLOGY?

P. Olsen[1]*

[1] Nofima, PO Box 6122 Langnes, NO-9291 Tromsø, NORWAY
E-mail: petter.olsen@nofima.no

Introduction

Transparency and traceability is a key issue for food products in general, and for aquaculture products in particular. There are various reasons why the importance of traceability is increasing; partly it relates to the internal need for internal documentation and industrial statistics, and partly it is to meet customer and consumer requirements and preferences both in relation to product characteristics (species, ingredients, origin, processes undergone, etc.) and in relation to so-called secondary characteristics (sustainability, emissions, eco-label status, ethics, fair trade, etc.). Traditionally these characteristics are recorded, stored in relational databases, and transmitted in the chain using some form of Electronic Data Interchange (EDI). In recent years building a traceability system on blockchain technology has become a viable alternative, and this paper attempts to highlight the strengths and weaknesses associated with each option, and in particular to evaluate to what degree and under what circumstances a blockchain based traceability system is suitable for the aquaculture industry.

Blockchain-based traceability in the aquaculture industry

This presentation outlines applications, limitations, costs, and benefits related to the use of blockchain technology in the aquaculture industry, and in particular evaluates the pros and cons of having a blockchain-based traceability system compared to a traditional electronic traceability system. The core principles of blockchain technology are outlined, as well as the fundamental requirements and drivers relating to an electronic traceability system. The presentation compares traditional vs. blockchain-based food traceability systems in terms of database structure, data quality and veracity, immutability, integrity, transparency, confidentiality, trust, robustness, speed, efficiency, and interoperability.

Discussion and conclusion

The overall conclusion is that unless speed of operation or confidentiality are considered to be the most important characteristics of the traceability system, a blockchain-based implementation may be very suitable. The main benefit related to a blockchain-based traceability system is that, at least for now, the blockchain-based systems are more homogenous than traditional electronic traceability systems, so interoperability between different blockchain-based systems is likely to be easier to implement than interoperability between different traditional electronic traceability systems. Lack of interoperability is one of —, or probably the biggest current obstacle preventing system-wide, farm-to-fork aquaculture product traceability, so this advantage associated with blockchain-based implementations is significant.

SALMON PRODUCED FROM SMOLT TO HARVEST IN SUBMERGED CAGES WITH AIR DOMES REDUCES LICE INFESTATION, BUT CREATES PRODUCTION AND WELFARE CHALLENGES

F. Oppedal*, F. Warren-Myers, T. Vågseth, O. Folkedal, L.H. Stien, and T. Dempster

Institute of Marine Research, 5984 Matredal, Norway
Email: frodeo@hi.no

Introduction

Submerged production of salmon may alleviate surface challenges such as lice infestation (e.g. Sievers et al 2018), extreme environments and open new areas for farming. But to succeed, the physostomous fish must be able to maintain normal buoyancy and swimming behaviour during submergence. Unlike new technologies such as snorkel and skirt cages, use of submerge has halted as salmon require frequent access to the surface to gulp air and fill their swim bladders. Fitting submerged cages with underwater air domes provides an underwater air surface and appears to resolve buoyancy associated issues (Oppedal et al 2020), but they have not been long-term tested. Here, we tested the viability of using submerged cages fitted with air domes at an industry relevant scale over a full sea-cage production cycle.

Methods

Three cages were submerged to 15 m and fitted with air domes, while three standard surface cages acted as controls at Institute of Marine Research sea cage facilities in Smørdal, Masfjorden, Norway. All cages were filled with ~6000 salmon of Aquagen strain per cage at sea transfer (~ 0.2 kg) and grown until harvest size (~5 kg). Parameters compared between control and submerged cages included environmental conditions, growth rates, condition, swimming depth and speed, swim bladder fullness, key welfare parameters and lice infestation levels.

Results

Temperature followed a normal seasonal pattern with warmest waters at the surface in the summer and autumn and at depth in winter months. Oxygen conditions in the upper 5-12 metres were above 80% saturation for the entire trial and below 15 m deep until November, while lower values (70-80% saturation) occurred during winter, decreasing further (consistently < 75% saturation) in spring. The submerged airdomes enabled salmon to refill their swim bladders and maintain normal swimming behaviour for a period of 12 months. Submerged salmon displayed considerably less lice infestation away from the surface layers but slower growth, reduced conditions, higher mortalities and impaired welfare at the lower temperature and poorer oxygen conditions experienced deeper down compared to the surface produced fish.

Discussion

This is the first full-production cycle study to successfully grow Atlantic salmon in submerged cages from sea transfer to harvest with normal behaviours displayed. However, while long-term submergence reduced salmon lice infestation rates, production problems arose, as evidenced by the poorer growth, mortality and welfare experienced by submerged fish. These outcomes were tightly linked to the very different production environment that submerged fish experienced at this site compared to the surface cages, with sub-optimal temperatures and dissolved oxygen conditions for extended periods. Future studies are needed to explore the full potential of submerged salmon farming with airdomes at variable, site-dependent environments in possible combination with flexible, dynamic depth positioning.

A key conclusion of the study is that for submergence to be a successful strategy to alleviate problems such as sea lice infestations, submergence must be matched to farming sites and times when conditions at depth are optimal for production.

SOCIAL LICENSE FOR AQUACULTURE PRODUCTION – PUBLIC SKEPTICISM OR APPRAISAL?

Tonje C. Osmundsen*, Marit Schei Olsen, Vilde Steiro Amundsen, Karen Alexander, Maria Wilke and Ragnheidur Thorarinsdottir

NTNU Social Research, Dragvoll Alle 38b, 7491 Trondheim, Norway
tonjeo@samforsk.no

Sustainable growth in the aquaculture industry presupposes stronger social anchoring in aquaculture producing countries, both locally and nationally. Improving social approval for aquaculture is a two-way process where society's knowledge about and understanding of the aquaculture industry need to be strengthened, while the industry must acknowledge its social responsibility and respond to signals from society. In Norway as well as in other countries, we do know that the industry's social anchorage is surprisingly weak compared to other types of food production. However, we have less knowledge of how social approval and trust towards the industry is distributed in the public, how/whether this is linked to misconceptions, lack of knowledge, poor dialogue between the industry and the public, different values, and/or the influence of economic benefits on different societal levels. Other mechanisms expected to influence a social license include environmental impacts, the character of the relationship between a company and the community (e.g. business strategies for enticing support), and the role of media and public authorities in co-producing/dismantling a social license. Finally, research indicates that lack of a social license may result in public opposition with a high level of conflict. A social license may deteriorate if activities are deemed unacceptable or dubious, and stakeholder groups may protest or engage in other ways against the activities and actors involved (Kelly et al., 2017, 2018; Leith et al., 2014; Syn, 2014). How this plays out related to the aquaculture industry is uncertain, but conflict and opposition may affect perception of the industry and specific companies, their framework conditions, and can even affect stock prices and consumption.

Studies of social license in aquaculture have not been done in a Norwegian or an Icelandic context earlier, but has been more prevalent in other aquaculture regions, such in Tasmania (Alexander & Abernethy, 2019), Scotland (Whitmarsh & Palmieri, 2009; Whitmarsh & Wattage, 2006), Greece (Katranidis et al., 2003), Australia (Leith et al., 2014), Canada (Rayner & Howlett, 2007), and New Zealand (Quigley & Baines, 2014). In Norway, some studies relevant for a social license have been carried out, i.e. surveys from the Norwegian Seafood Council (kyst.no, 2016) portraying the vulnerable reputation of the industry, as opposed to salmon as a product. Other studies (Aanesen et al., 2018; Robertsen et al., 2012) show a greater resistance towards the aquaculture industry in urban vs. rural areas. Historically, the term social license, or social license to operate was used for industrial activities (often mining) in countries with relatively weak regulations, in an attempt to create legitimacy for industry in the absence of well-established formal institutions. In recent years, the concept of social license is increasingly applied to different types of industries. However, literature providing insight into the application of social license within the marine sector is limited. It is still considered an emergent concept and there are considerable research gaps (Kelly et al., 2017).

Data for this paper and presentation is based on a survey conducted in Norway (N=1183), Iceland (N=496) and Tasmania (N=406) comprising 2085 responses. The survey investigates the general perception towards aquaculture in these three countries/regions and compares these to background variables such as age, gender, income, and education level. A comparison to respondents' general trust in the national governance system, concern with environmental issues, knowledge/familiarity with aquaculture production, and with aquaculture companies (i.e. living in close proximity) is conducted.

Findings show in general a positive perception towards aquaculture. We also find that trust in public regulation of the industry corresponds with belief in the accountability of the industry. Our assumption that perception towards the industry is conditioned by how the public perceive that the industry is regulated and controlled is confirmed. In terms of negative perceptions, these are linked to environmental sustainability. Findings also point to comparative differences between Norway, Tasmania and Iceland, with regard to knowledge and familiarity of the industry, and acceptance.

Drawing on these findings, we discuss the determinants and mechanisms of a social license in aquaculture comparing data between Norway, Tasmania and Iceland. The influence of media and public authorities' role in co-producing/dismantling a social license is emphasized.

PROMOTING BLUE ECONOMY: TOWARDS A SUSTAINABLE AQUACULTURE PRODUCTION AND CONSUMPTION IN THE ATLANTIC

N. Ospina-Alvarez*, T. Li Chen and P. Silva

AIR Centre - Atlantic International Research Centre. 9700-702 Terceira Island, Azores (Portugal)

E-mail: nospina.alvarez@aircentre.org

The AIR Centre

The Atlantic International Research Centre (AIR Centre) is an international collaborative organisation that promotes an integrative approach to space, climate, ocean, and energy in the Atlantic, supported by emerging technological innovations and advances in data science, and through South-North and North-South cooperation.

The AIR Centre is based in Portugal, with headquarters in Terceira Island, Azores, and facilities in Lisbon, and is the outcome of a long process of scientific diplomacy called Atlantic Interactions, which is an ongoing intergovernmental initiative to unleash the full potential of the Atlantic Ocean for society. These diplomatic discussions resulted in an international collaborative scientific agenda for space, climate, energy, and ocean sciences in the Atlantic that started in 2012.

Promoting Blue Economy: The AIR Centre contribution to sustainable aquaculture for food security and ocean conservation

The AIR Centre thematic missions provide a clear orientation to foster knowledge-driven economic development in the Atlantic region and among them, the AIR Centre identifies, provides, and promotes activities, projects, and programs to look beyond their internal resources to develop new products, services, and financial frameworks in alignment with the Sustainable Development Goals (SDGs).

These thematic missions are:

- Clean and productive bays and estuaries.
- Resilience to coastal natural hazards.
- Sustainable food production.
- Improved management of marine and coastal resources.
- Improved environmental and maritime monitoring.

Within this framework, the AIR Centre, fosters through different projects the Blue Farming concept, as a low carbon source of food and feed and a sustainable food system.

Leading, co-leading and being part of those projects, the AIR Centre promotes the '*Strategic guidelines for a more sustainable and competitive EU aquaculture for the period 2021-2030'* of the European Commission and contributes specifically to the SDGs 1 (No poverty), 2 (Zero Hunger), 3 (Good health and wellbeing), 12 (Responsible consumption and production), 13 (Climate action) and 14 (Life below water).

ASTRAL Project
All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture

ASTRAL focuses on integrated multi-trophic aquaculture (IMTA) farming, aiming to define, support, and promote this type of sustainable aquaculture production across the Atlantic area. IMTA is the farming of species from different trophic levels in a way that allows one species' uneaten feed and wastes to be used as inputs (fertilisers and feed) for another species.

ASTRAL goals include the increase of circularity and the achievement of zero-waste aquaculture systems, as well as the creation of appropriate business models to increase profitability. Potential climate risks and emerging pollutant (microplastics, harmful algae blooms, pathogens) will be assessed, together with the development of innovative technology (specific sensors and biosensors, IoT and AI data analytics), with the final aim to provide monitoring recommendations to policy makers. Sharing knowledge and capacity development are among ASTRAL priorities, to build a collaborative ecosystem along the Atlantic Ocean with industrial partners, SMEs, scientists, policy makers, social representatives, and other relevant stakeholders.

ASTRAL is a HORIZON 2020 project (GA 863034) financed under the Blue Growth programme. Further information: www.astral-project.eu/

CE2COAST Project
Downscaling Climate and Ocean Change: Thresholds and Opportunities

CE2COAST aims to provide 'Climate Services Innovation' in the form of a new way of exploiting observations and modelling tools to deliver climate information (*e.g.* temporal changes, seasonal differences, time of emergence of the ocean change signals). One of the objectives of the project is to investigate the added value of improved downscaled projections for determining future pressure (stressor) changes relevant to key ocean services, such as aquaculture.

Aquaculture is vulnerable to climate change including warming, acidification, changes in rainfall patterns, sea level rise, and deoxygenation. Changes in these ocean pressures can result in serious reduction in productivity. The climatic information provided by CE2COAST will give maximal support to decision-making towards creating adaptation and mitigation plans to aid fish producers and aquaculture farmers to adapt and / or reduce the impact of climate change and extreme climatic events in their production.

CE2COAST is a JPI Climate and JPI Oceans project supported under the 2019 'Joint Transnational Call on Next Generation Climate Science in Europe for Oceans'. Further information: www.ce2coast.com/

Açores IntAIRsect Project
Internationalization of the AIR Centre within the scope of the Azores sectorial challenges
Açores IntAIRsect intends to promote all the scientific potential of the Azores within the international scientific community. The main goal is to strengthen relations between entities and countries and leverage scientific projects of international collaboration, with European, African and American partners.

Açores IntAIRsect will focus on 6 thematic areas, including Marine Resources and Biodiversity. The aim of this thematic area, is to promote the development of projects related to the sustainability of marine resources, including the development of sustainable fisheries and fishing communities, increase the value of fisheries products, and sustainable aquaculture. These projects will focus on addressing and finding solutions for challenges that affect the Azores and/or the Atlantic region.

Açores IntAIRsect is a Açores 2020 project (ACORES-01-0145-FEDER-000138) is co-financed by European Regional Development Fund (FEDER) under Operational Program Azores 2020. Further information: https://www.aircentre.org/projects/acores-intairsect/

(Continued on next page)

NEXTOCEAN
Next Generation of Fishing and Aquaculture Services

NextOcean aims to develop a set of operational Earth Observation based services in Sustainable Fishing and Aquaculture under a common service delivery platform, leveraging on Copernicus data and products and complemented by the assimilation of other sources of data including in-situ.

The project includes use cases that shall consider monitoring aquaculture sites and their impacts, allowing to understand their environmental impact and for risk assessments. Examples of this are detection of ocean color around productions sites, analyses currents before settling sites, and model disease risk. Support to decision making such as need to apply pharmaceutics, delay restocking, anticipate harvesting, or physically move cages are all dependent on the spatial dispersion patterns of pathogens that often follow currents.

NEXTOCEAN is an Innovation Action from H2020 under the frame of H2020-SPACE-2018-2020 topic DT-SPACE-01-EO-2018-2020 with the Grant Agreement nº 101004362.

Enteromyxum leei IN MEDITERRANEAN GILTHEAD SEA BREAM FARMS: HOW MUCH IS OUT THERE?

Introduction

Enteromyxum leei (Myxozoa) is an important pathogen of gilthead seabream (GSB), *Sparus aurata* and other Sparidae fish cultured in the Mediterranean. In GSB, *E. leei* induces chronic enteritis followed by anorexia, cachexia, and even death. It can cause significant growth delay and mortality in marine cage farms as well as land-based mariculture systems. Water temperature and water recirculation are critical risk factors in the contagion and onset of enteromyxosis (Palenzuela et al., 2006, Sitjà-Bobadilla and Palenzuela 2012). However, the relevance of other risks factors like farm management practices, and the epidemiological situation in gilthead sea bream farms, have not been thoroughly determined. In this study, a risk assessment questionnaire and cross-sectional epidemiological study was designed to get insights in the distribution and incidence of *E. leei* in more than 50 Mediterranean and Atlantic GSB farms throughout Western Europe.

Methods

A questionnaire for GSB cage farms was designed to ascertain information about farm background and self-awareness of risk relative to *E. leei* infection, as well as details on the facilities, production and farm management routines. In addition, the farms were invited to participate in a cross-sectional targeted epidemiological survey to test the presence of the parasite in their stock. The participant farms were recruited by local expert pathologists and consultants acting as nodes in each geographical region, and the samples and questionnaires were coded and studied blindly.

For those farms participating in the biological sampling, a protocol was submitted to sample one batch of fish at harvest time. The sampling was designed to detect prevalence higher than 9.5% with a 95% confidence. The intestinal rectal ampoules (portion with maximum predictive value for *E. leei* detection in GSB) were taken from at least 30 randomly selected fish during routine harvest from one or several cages. For the validation of the survey protocol, a land-based farm which is enzootic for the parasite was enrolled in the study and two different GSB lots were sampled as positive controls. The samples were fixed in 80-90 º Ethanol and paired into 15 tubes, which were shipped to the central diagnosis laboratory at IATS-CSIC.

The routine procedures for diagnosis of *E. leei* consist of a SYBR-green qPCR test with primers specific for the parasite against a standard curve containing known numbers of copies of the target gene. Upon reception at the laboratory the samples were individually processed and homogenised. DNA was extracted from an aliquot using a robotic system, its quantity and quality were evaluated, and samples were tested by qPCR at two different dilutions. They were considered positive when the cycle threshold (Ct) was <38.

Results and Discussion

A total of 45 cage farms from Croatia (12), Greece (12), Italy (13), Spain (7) and Malta (1) completed the questionnaires. Among them, 32% declared to have previous records of the parasite: 11 of them at some point in the last 5 years, 3 in the most recent production cycle, and 4 having infections recurrently. Among the farms with previous records, the disease was considered not relevant in 7, controllable in 7, and problematic in 4 sites.

(Continued on next page)

Country	# Farms	Infected (farmers opinion)	Infected (qPCR)
Croatia	9	0	7
Greece	9	8	9
Italy	12	5	11
Malta	1	1	1
Spain	5	2	5

Table 1: Comparison of infection rates estimated by farmers' self-awareness and by the cross-sectional study at harvest (for farms which supplied both questionnaires and samples).

Country	# Farms sampled	# Fish sampled	# Farms positive	# Farms negative	Minimum prevalence (range)
Croatia	9	270	7	2	0-33%
Greece	9	370	9	0	6-75%
Italy	12	390	11	1	0-47%
Malta	1	30	1	0	73%
Spain	7	210	7	0	3-93%
Control +	1	60 (2 lots)	1	0	20-100%
Total	**39**	**1330**	**36**	**3**	**0-100%**

Table 2: Results of qPCR analysis for *E. leei* in GSB farms.

A total of 40 cage farms sent a total of 1330 fish biological samples which were tested by qPCR. The results show that the infection persists unnoticed at many farms (Table 1), Famers were most aware of the presence of the infection in Greek waters. On the contrary, Croatian farmers were unanimously unaware of the presence of the parasite although it was detected at most of the tested sites. Prevalence of infection was generally lower in sites where the infection was not believed to be present, suggesting that low level infections, although widespread, do not cause any noticeable problems at many farms.

All countries sampled had the infection, and the only countries with farms in which the infection was not detected were Croatia and Italy. Prevalence was highest on average in Greece (Table 2).

The statistical analysis considered prevalence against farm level factors as well as batch level factors. For most variables no significant effect was observed. At a farm level, farms removing mortalities more frequently, and those with stronger water exchange have a lower prevalence of infection. The number of hatcheries supplying the farm and the size of fish at harvest showed the strongest positive association with prevalence. Larger farms with higher numbers of cages, cage sizes and annual production tended to have higher prevalence. At the batch level, fish which had experienced highest minimum temperatures and those introduced to the cages at larger sizes had higher prevalence, whereas shorter times on the farm and higher specific growth rates were associated with lower prevalence.

Introduction

Successful assisted propagation of the European eel will lead to a closed production cycle supplying the aquaculture industry with glass eels. The current protocol for the propagation of European eel requires a long period of weekly hormonal injections with pituitary extract (Palstra et al., 2005) which is stressful for the brood stock eels and has negative impact on gamete quality and reproductive success. This procedure can at least partly be replaced by a single injection of a steroid implant (Thomson-Laing et al., 2019). In this study, we have tested the effects of 17α-methyltestosterone (17MT), as potent androgen activating the androgen receptor (Todo et al., 1999), and 17β-estradiol (E2), as inducer of vitellogenesis.

Materials and methods

Four groups of feminized eels (Chai et al., 2010) were subjected to a simulated migration (Mes et al., 2016) and subsequently injected with implants containing 17MT (T-group) or E2 (E-group); 17MT plus E2 (TE-group) to test the synergistic effect, or without any steroids as controls (C-group). Effects of a 2-month treatment on sexual maturation were investigated by assessment of the eye index (EI), hepatosomatic and gonadosomatic index (HSI and GSI, respectively), plasma steroids as determined by liquid chromatography mass spectrometry (LC-MS; Blokland et al., 2017), gonadal histology and rtPCR of androgen receptors a and b (*ara*, *arb*); estrogen receptor 1 (*esr1*); FSH receptor (*fshr*); vitellogenin receptor (*vtgr*) and aromatase (*cyp19*)(Jéhannet et al., 2019).

Results and discussion

After simulated migration, experimental eels initiated early previtellogenesis as shown by an increase in eye size (Fig. 1), GSI and oocyte diameter and a lower HSI. Plasma steroid levels also showed marked changes, among others an increase in 11KT and a decrease in E2. For many parameters, both the T and E group showed an increase vs. controls, with the TE group showing an even further increase indicating a synergistic effect: EI, GSI (3.4 for T and for E, 6.6 for TE), oocyte diameter (Fig.1) and *ara*, *arb* and *esr1* expression. Some parameters reflected 17MT or E2 specific effects. Only eels of the T-group showed increased expression of *cyp19* and of *fshr*, while *fshr* expression increased 44 fold in the TE group showing that 17MT in combination with E2 is most effective in raising fshr mRNA levels. Specific for eels of the E groups were vitellogenic changes such as an increase of HSI, plasma dehydroepiandrosterone (DHEA) and E2, and the presence of yolk in the oocytes of E and TE (Fig. 1), not for eels of the T group. Of note are further the effects of time and/or starvation occurring in the controls so independently from 17MT and E2 steroid action after simulated migration. Thus, EI, GSI, oocyte diameter, but also *fshr* and *vtgr* expression, increased after simulated migration, and independent of exogenous steroid treatment.

In conclusion, E2 is necessary to start vitellogenesis but 17MT has specific effects on *cyp19* and *fshr* expression. The combination is necessary for the full array of synergistic effects although 17MT implant treatment, followed up in time by E treatment, may result in a more natural sequence of 17MT-induced previtellogenic and E2-induced vitellogenic effects. As such, steroid implants could be applied in assisted reproduction protocols for European eel as slow release systems to initiate the vitellogenesis and to reduce the number of weekly hormonal injections, potentially improving oocyte quality and leading to production of more viable and robust larvae.

Introduction

Common carp (*Cyprinus carpio* L.) is one of the most intensively farmed fish species globally (FAO, 2020). In Europe, traditional multi-pond production lasts depending on temperature of water approx. 33 months and include two wintering stages. In the autumn of the first and second year fish are harvested and transferred to deep (2 - 2.5 m) earthen ponds until all maintenance works are completed in the production ponds, the ponds are inundated and the appropriate level of water temperature is reached, usually in April or May. One of the GAIN project (https://www.gain2020.com/) objectives included ecological intensification of *C. carpio* farming by reducing the time needed to produce market size fish (1 – 1.5 kg) from 33 to 19 months. This has been possible by transferring common carp fingerlings to a RAS (Recirculating Aquaculture System) for overwintering (October – May) and afterwards moving the fish to on-growing ponds in the autumn of the second production year. However, wintering of common carp in RAS under an ambient temperature is a new concept and it is of paramount importance to assess health and welfare indicators in complement to zootechnical indices. Our studies revealed that molecular and histological characteristics of the intestine assured successful assessment of nutritional status in common carp and shed light on the importance of gut microbiota composition and intestine brain interplay as wellbeing and health parameters (Eljasik et al., 2021). Therefore, the aim of the multifaced study was to assess intestine morphology, gut-brain axis (GBA) gene activity and composition of gut microbiota in *C. carpio* overwintering in RAS compared to earthen ponds.

Material and methods

The study was conducted during 2019/2020 wintering period (October – May) in RAS system (6 tanks, 3 m^3 each, 100 fish per tank) under the tent and in earthen ponds (4.1 ha, density approx. 850 kg of carp per ha) of the Maliniec carp farm. Starting weight of fish in RAS and wintering ponds was approx. 45 ± 5 g. Fish in RAS were automatically fed two feed blends of different level of protein and fat, i.e., AL (42/12) and AG (30/9), while those in the ponds (ML) were not fed. Upon completion of the wintering AL, AG and ML fish (n = 5, each variant) were sacrificed, weighted and sampled, i.e. (i) proximate intestine to assess height of the mucosal folds (MS), width of lamina propria (LM), thickness of sub-epithelial mucosa (SM), number and area of goblet cells (GC), morphology of supranuclear vacuoles (SNV) and presence of eosinophilic vacuoles (EV); (ii) intestine and brain samples to assess health [*e.g. occludin*, *claudin-3c*, *interleukin 6* (*il6*), *mucin 5b* (muc5b), 70 kDa-heat shock protein (*hsp70*) in the intestine] and GBA-related welfare [*e.g. γ-glutamyl transpeptidase* (*ggt*), *cholecystokinin* (*cck*) in the intestine and *agouti-related protein* (*agrp*), *glucose transporter 2* (*glut2*), *orexin* in the brain] based on the expression of total 17 genes; and (iii) proximate intestine to characterise microbial communities by V3/V4 regions of the 16S rRNA gene sequencing with the Illumina MiSeq (300 PE), followed by raw data processing using DADA2 and analysis of composition of the gut microbiome using phyloseq in R package.

Results and Conclusions

Results from the histological evaluation showed that the AG fish had significantly (P = 0.01) longer MF (1108.9 ± 48,33 µm), bigger SNV sizes (23.2 ± 3.13 µm), lower LP sizes (19.3 ± 3.93 µm), lower GC numbers (28.0 ± 2.45) and lower SM thickness (45.1 ± 8.31 µm) comparing to AL (1012.8 ± 50.7; 18.8 ± 1.67; 24.5 ± 5.16; 57.6 ± 3.44; and 59.1 ± 7.07) and ML (898.3 ± 64.09; no SNV; 42.4 ± 11.69; 73.5 ± 7.77; 68.8 ± 13.23). The GC area was significantly (P = 0.01) larger among AG (50.7 ± 9.95 $µm^2$) and ML (50.7 ± 13.54 $µm^2$) fish comparing to AL (41.7 ± 10.63 $µm^2$) fish. All together histopathological indicators showed that AG fish overwintering in RAS were in better condition compared to AL common carp, and also unquestionably to ML fish from the typical wintering pond. The main reason for the poor health condition of the ML fish from the Maliniec farm was ceased feeding that eventually induced enteritis characterized, among other assessed parameters, by the absence of SNV and presence of eosinophilic vacuoles in the LP. Intestinal morphology in

(Continued on next page)

AL fish confirmed that common carp fed diet with higher fat content (12%) comparing to AG (9%) had lower condition presumably due to excessive amount of energy in the feed in relation to the needs during overwintering. Results of the gene expression analysis confirmed histological evaluation. Fish from the wintering ponds with clear symptoms of enteritis had the highest activity of *occludin* and *claudin-3c* both important in the assembly and maintenance of tight-junctions between enterocytes. Moreover, downregulated expression of *akp*, *ggt*, *muc5b* and *Na^+/K^+ ATPase* in ML fish showed low metabolic activity due to lack of feeding during the wintering period. Conversely, activity of those genes was significantly higher in AL common carp fed on a high-fat and -protein diet. However, the AL fish had also elevated expression values of *il-6*, *il1b, hsp70* and *claudin-3c* genes all together involved in inflammation process. In case of AG fish, results showed intermediate activity of genes involved in regulation of nutrients metabolism and functioning of the physical intestinal barrier, and low expression of pro-inflammatory genes. Our study, for the first time, characterised gut-brain axis in *C. carpio*. Activity of genes related to higher nutrient metabolism (*orexin*, *agrp*, *glut2*) had significantly higher expression in the brain of fishes from the AL group fed on a high-fat diet compared to fishes from the AG and ML groups. The analysis of microbiome based on V3/V4 regions revealed that composition of bacteria present in common carp gut was dominated by Proteobacteria and Firmicutes at the phylum level. Such microbial profile was previously described in literature for common carp (Liu et al., 2016), what may suggest no negative impact of wintering in RAS on common carp microbiota. Furthermore, on family level, microbiome was conquered by Enterobacteriaceae, particularly from genus *Escherichia-Shigella* and *Enterococcus*.

Concluding, wintering of common carp in RAS is a viable alternative to earthen ponds in which fish develop severe signs of enteritis, and thus lower condition before grow-out phase. The multifaceted study also provided first characteristics of the interplay within the gut-brain axis in common carp, crucial to assure optimal level of health and welfare.

Introduction

The increasing consumption of seafood products raised concerns over their sustainability and the conservation of marine resources. Seafood traceability, enabled by a regulated labelling system, is important to prevent overexploitation of these resources. Detailed seafood labels also help consumers to make informed choices about the products they purchase, enabling them to play a role in the conservation of marine resources. The regulations (EU) No.1169/2011 and (EU) No 1379/2013 are the European legislative tools that specify the mandatory information that must be present on seafood labels. The present study analysed the labels of seafood products found in fishmonger's shops and supermarkets of different European countries in order to verify the presence of mandatory information required by the EU regulations currently in place.

Material and Methods

The data were collected in 42 cities from 6 European countries: Portugal (PT), Spain (ES), France (FR), Germany (DE), United Kingdom (UK) and Ireland (IE). For each country, samples were collected in cities, in 3 supermarkets and 3 fishmongers' shops. Three groups of products were analysed (unprocessed non-prepacked, unprocessed prepacked and processed prepacked).

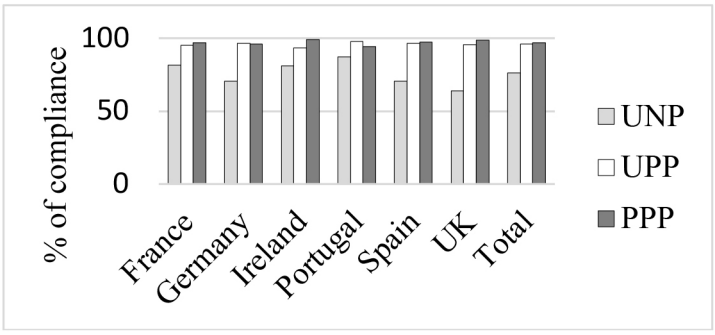

Figure 1. Compliance to labelling legislation for each country and for the three different groups of product assessed: Unprocessed Non-Prepacked (UNP), Unprocessed Prepacked (UPP) and Processed Prepacked (PPP).

(Continued on next page)

Results

The results show that there is a difference in compliance among groups of products and among countries. The country with the lowest level of compliance was United Kingdom (still part of EU in 2019, when the study was carried out), with an overall compliance of 63.7% (Fig. 1). The country with the highest level of compliance was Portugal (87.2 of compliance). Across all the countries analysed, supermarkets resulted more compliant than fishmonger's shops and processed prepacked products resulted more compliant, to the EU labelling legislation, than unprocessed non-prepacked products (Fig. 2).

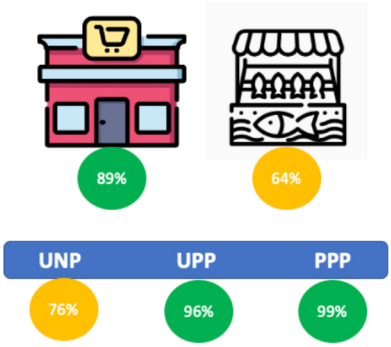

Figure 2. Compliance to the EU food labelling regulation in supermarkets and fishmonger's shops and in the three categories of product analysed.

DOES THE SCALE OF RAS MATTERS? COMPUTATIONAL FLUID DYNAMICS STUDY OF LARVAE PERFORMANCE IN RECIRCULATING AQUACULTURE SYSTEMS

Stepan Papacek[1], Karel Petera[2]

[1]University of South Bohemia in Ceske Budejovice, FFPW, CENAKVA, Institute of Complex Systems, 373 33 Nove Hrady, Czech Republic
Email: spapacek@frov.jcu.cz

The improved design of aquaculture systems is needed facing the demand for increased production as well as increased concern of fish wellbeing. Here, we make another step towards use of computational fluid dynamics (CFD) for design and operation of recirculating aquaculture systems (RAS), see e.g. [1]. The proposed CFD based methodology allows the modeler (the designer) to have an overall picture about hydrodynamic conditions within the fish tank and to manipulate (*in silico*) all key phenomena involved, both physical (i.e., the tank geometry and operating conditions) and biological (fish density). Further optimization of the tank hydrodynamics, mainly to ensure the optimal rearing conditions of fish larvae and fast biosolids removal, is being expected.

The scale effect on larvae performance, i.e., the effect of different tank volumes on European sea bass *Dicentrarchus labrax* growth, survival and stress variables, was investigated by Lika *et al*. [2]. The cornerstone in modeling this phenomenon is consisting in fact that certain level of turbulence can enhance the feeding rate of the larvae, see [3]. However, the relation between feeding rate and the turbulence intensity is dome-shaped, see [4] and references within there. Consequently, it exists an optimal setting of the operating conditions (water recirculation rate or the liquid velocity in the inlet and all details concerning the boundary conditions) for a pre-established tank geometry, providing the optimal biological performance of larvae.

The big challenge resides in the optimization of both the biological performance of fish larvae and the self-cleaning capacity of RAS. Therefore, some assumptions must be undertaken. First, we can limit ourselves to maintain a sufficient water quality index (i.e., by defining a limit superior of the hydraulic retention time) while looking for an optimal biological performance. Second, the influence of fish larvae on the flow field can be neglected, i.e., we deal with the one liquid phase in CFD simulations only. Obviously, this is not the first work where the CFD is used for RAS hydrodynamics simulation. Nevertheless, to the best of our knowledge, there are only few works dealing with the multicriterial optimization with the CFD model, based on ANSYS Fluent code [5], embedded. Let us remind that experiments at laboratory scale or at field are laborious and time consuming. In this context, it becomes of utmost importance to develop a reliable CFD based methodology being able to provide reliable description of the flow field within RAS tank and an ease of performing a large range of parametric studies for optimization of both RAS scale and operating conditions.

Introduction

Larvae of most teleost fish are mainly visual predators. The distance from which fish can identify an object is called visual ability and depends on the overall organization of the eye, the developmental stage of the fish, and the light conditions that prevail in the rearing tanks.

Rearing water temperature is considered as the main factor that affects all physiological processes in poikilothermic organisms. Especially during larval rearing, rearing temperature significantly affects the ontogeny rates of various organs and systems that are being developed during this period. The present study aimed to evaluate the development of the optical system, focusing on the eye of sea bass larvae during the early stages of development under the influence of different rearing temperatures. The study of visual aspects in the early developmental stages in aquaculture is fundamental since it is associated both with the type, size, and quantity of food and with the appropriate prevailing light conditions that larvae should be provided with in their rearing tanks (Papadakis et al., 2018).

Materials and methods

Rearing of sea bass larvae was performed in duplicate 500-l tanks connected in a closed recirculated system according to the methodology of pseudo green water. Three different water temperatures (15, 17.5, and 20°C) were used during the rearing procedure. For the histological analysis of the eye, larvae at five different developmental stages (mouth opening, first feeding, flexion, all fins, metamorphosis, and juvenile) were sampled (n=3) and preserved in a buffer solution containing 4% formaldehyde and 1% glutaraldehyde. The larvae were embedded in methacrylate resin. Sections of 4 μm in thickness were obtained from a microtome and were stained with Methylene Blue, Azure II, and Basic Fuchsin. The examination of the sections was performed in bright field microscopy and photographed with a digital camera in X40 magnification. Images were obtained from the areas toward the olfactory nostril (Nasal, n) and toward the larval body (Temporal, t,) (Fig. 1a). Following this process, the pictures obtained from the histological sections were examined through an image analysis software (image j). The cones and rods in the retina were counted (Fig. 1b), and the diameter (mm) of the lens was measured. Finally, larval visual ability was assessed, based on the above calculations, according to the methodology established by Neave (1984).

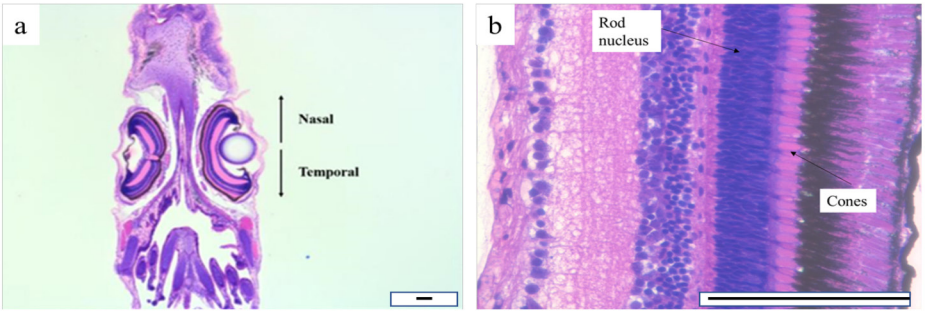

Figure 1. Histological sections of a sea bass larvae head, showing a) the Nasal and Temporal axes at the developmental stage of flexion and b) the cones and rods nucleus at the metamorphosis stage. Scale bar: 0.1 mm (black bar).

(Continued on next page)

Results and Discussion

The results of the study showed that temperature is a critical factor that causes significant differentiation in the number of cones and rods in the retina of the sea bass eye. The cones are the photoreceptors that are activated under high light intensities and are responsible for diurnal vision (Kusmic & Gualtieri, 2000). In sea bass, the diurnal vision abilities were differentiated according to the developmental stage and the rearing temperature. The number and the density of cones per unit of retina length were reduced at higher developmental stages. The lower number of cones after the flexion stage at 15ºC in comparison to 17.5ºC and 20ºC suggests that a lower visual acuity exists in larvae at lower temperatures, which means that at higher temperatures (17.5ºC and 20ºC) sea bass larvae can perceive a greater variety of different sized items. This offers new information related to the rearing protocol applied during larval rearing, concerning the size variation of preys - feeds that are included in the larval feeding protocol.

Differences also occurred in the number of rods in terms of the developmental stages and the rearing temperatures used. Rods are known to be structures that are responsible for nocturnal vision, activated under low light intensities. In most species the first appearance of rods occurs during the larval rearing period, and their number increases over time (Shand et al., 1999). In the present study, the rods appeared at the stage of flexion, and their number increased over time, which suggests that from this period onwards, the ability of objects perception under low light intensities was increased. The smaller number of rods at low temperature (15 ºC), indicates a lower ability to perceive objects under low light intensities. In contrast, at higher temperatures (17.5 ºC and 20 ºC), the ability of items perception under low light intensities was higher. Based on the above results, larvae reared in water temperatures close to 15ºC display reduced ability for small item visual perception.

The above data contribute to the knowledge for further optimization of feeding protocols (type - size of food) and the formation of visual conditions in the rearing tank (tank coloring). Additional studies on basic systems, such as the digestive and the visual system, focusing on the optimal relationship between the feeding protocols and the abiotic rearing conditions, such as lighting and temperature, will assist in the improvement of the larval rearing protocols, through the study of larval feeding behaviour.

EFFECT OF DIFFERENT DISSOLVED OXYGEN LEVELS ON GROWTH PERFORMANCE FOR EUROPEAN SEA BASS (*Dicentrarchus labrax*)

Ioannis Papadakis[1*], Lydia Katsika[1], Panagiota Tsoukali[1], Athanasios Samaras[1], Stavros Chatzifotis[1]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Center for Marine Research, P.O. Box 2214, Iraklion, Crete 71003, Greece
papad@hcmr.gr

Introduction

Among various physicochemical parameters, water temperature and dissolved oxygen (DO) play the most important role for optimum fish growth and maintenance of proper well-being and health status of fish. Low DO, (<40% saturation in the rearing water) combined with higher temperatures prevailing in summer months (>26 ^{o}C), reduces the fish's ability to feed (Mallekh and Lagardere, 2002). Therefore, fish farmers experience a significant economic loss. New systems are under development in the Mediterranean area, focusing on optimizing the DO levers during rearing in sea cage aquaculture. This study aims to gain knowledge on the management of dissolved oxygen in fish farms. An effort was made to estimate optimal DO levels under high rearing temperature (26.5 ^{o}C) for growth in European sea bass (*Dicentrarchus labrax*) culture.

Materials and methods

The study took place at the Institute of Marine Biology, Biotechnology and Aquaculture (IMBBC) of the Hellenic Centre for Marine Research (HCMR) Heraklion, Greece. At the beginning of the trial, 315 fish were lightly anesthetized and individually weighted (88.00 ± 0.12g), and they were randomly distributed in 9 tanks. Sea bass (35 fish/tank, 105 fish/group) were placed in three recirculating aquaculture systems (RAS) with fully controlled rearing conditions in tanks of 500 liters (500l) in each RAS. Three different oxygen saturation levels were applied to each RAS (80-100%, 60-80% and 40-60%) at 26.5 ^{o}C and 38 ‰ salinity. Each experimental condition was tested in three replicates. The targeted oxygen saturation levels were maintained through an automatic oxygen monitoring system. Fish were hand-fed to apparent satiation three times a day for 7 days a week during the trial period. Fish weights were recorded monthly and at the end of the experiment, 5 fish per tank were sacrificed and their livers, visceral fat and viscera were weighed, and growth and somatic indexes were determined. Additionally, image analyses were performed on pictures from histological sections taken from different parts of the digestive system, such as the midgut, foregut, and liver. Concerning the liver's histological examination, the parameter related to lipids deposition was estimated by measuring areas covered by lipids inclusions on liver histological sections according to the methodology of Papadakis *et. al.* (2013).

Results and Discussion

The present study reinforced earlier observations in sea bass, and other species, about the negative correlation of oxygen saturation level with growth rates in marine fish (Pichavant *et al.*, 2001). The results showed (Table 1) that at 26.5 ^{o}C the best growth performance for sea bass was achieved at 80-100% followed by 60-80% and 40-60% O_2 saturation levels. The final fish body weight, the percentage growth of average body weight of fish and the specific growth rate were significantly lower ($p<0.05$) at the lowest oxygen saturation of 40-60%. Specifically, there was a gradation between the three levels with a positive correlation of oxygen level and the parameters of the final weight of fish, daily growth rate, specific growth rate and hepatosomatic index ($p<0.05$). The above results also agree with the histological analysis performed concerning the lipids deposition in the liver. Low hepatosomatic index values in fish are related to nutrition issues. The mesenteric fat index was significantly lower ($p<0.05$) in the group with 60-80% O_2 saturation than the other two groups.

The visceral somatic index was higher in the 80-100% O_2 saturation group and did not differ from the 40-60% O_2 saturation group, while a significantly lower value ($p<0.05$) appeared in the intermediate group of 60-80% O_2 saturation. No significant difference was observed in the feed conversion ratio among the three oxygen groups. However, the feed conversion ratio was numerically lowest at 80-100% DO. Furthermore, there were no significant differences ($p> 0.05$) among the three oxygen groups regarding the fish weight dispersion coefficient and the condition factor. Thus, the growth reduction observed in the present study (40-60%, 60-80% DO) can be associated with reduced feed intake at lower oxygen levels. The maximum growth rate can be achieved at the highest oxygen saturation levels of 80-100%.

(Continued on next page)

Table 1. Growth performance and meristic parameters of seabass reared in three different oxygen saturation levels.

Duration (95 days)	Oxygen Saturation level O_2		
	80%-100%	60%-80%	40%-60%
Initial body weight (g)	88.02 ± 0.22	88.26 ± 0.65	88.15 ± 0.46
Final body weight(g)	252.40 ± 2.59^{a}	230.68 ± 4.24^{b}	197.18 ± 0.44^{c}
Specific growth rate	1.11 ± 0.01^{a}	1.01 ± 0.03^{b}	0.85 ± 0.02^{c}
Daily growth rate	1.96 ± 0.04^{a}	1.69 ± 0.07^{b}	1.30 ± 0.05^{c}
Feed conversion ratio	1.41 ± 0.02	1.40 ± 0.04	1.44 ± 0.02
Daily food consumption	1.41 ± 0.02^{a}	1.29 ± 0.02^{ab}	1.21 ± 0.07^{b}
Visceral somatic index	9.98 ± 0.40^{a}	8.61 ± 0.29^{b}	9.51 ± 0.30^{ab}
Hepatosomatic index	1.68 ± 0.02^{a}	1.41 ± 0.04^{b}	1.16 ± 0.02^{c}
Condition factor	2.03 ± 0.02	1.97 ± 0.04	1.95 ± 0.02

Introduction

Mediterranean trout (*Salmo cettii*) is an Italian sub-endemism, native to the Tyrrhenian peninsular regions, Corsica, Sardinia, Sicily and the western part of North Africa. In Italy the greatest number of populations is present in central-eastern Sardinia, south-eastern Sicily and a few in peninsular Italy. Over the last few decades, the Mediterranean trout has undergone a significant contraction, both numerical and areal, due to anthropogenic causes and hybridization with brown trout, leading to be included in the European Union Habitat Direct and considered a "vulnerable species" in Europe and "endangered" species in Italy. The guarantee of the survival of the species through planned and effective restocking plans is a relevant ecological objective, which can be also pursued by the application of aquaculture technologies, among which the production and storage of gametes, which could reduce the dependence on wild stocks, preserving at the same time the genetic resources of this species.

Sperm cryopreservation has been successfully performed in a number of important commercial aquatic species, particularly in some teleost fish and crustaceans (Diwan *et al*., 2020). The selection of pure breeders with high genetic variability and the storage of sperm obtained from these fish in a cryobank are important tools to make the management of the conservation of endangered species more efficient (Zuccon *et al*., 2017).

The purpose of this research was the development of a sperm cryopreservation protocol in order to create a cryobank for the conservation of milt obtained by pure breeders of Mediterranean trout (*Salmo cettii*) caught in west area of Sicily.

Materials and methods

During the the reproductivity season for Mediterranea trout (February – March 2021), 21 male breeders were caught in Cardinale torrent (located in the west of Sicily). The fish were previously anesthetized and then subjected to sampling of small fragment of adipose fin for genetic analysis and semen collection by squeezing for cryobank creation. The fish were also tested for the viral hemorrhagic septicemia (VHS) and infectious hematopoietic necrosis virus (IHNV) indemnity.

Semen samples were diluted in StoreFish solution (IMV) and transferred on refrigerate condition (4-6°C) in laboratory. Then, they were diluted in FreezeSol solution (IMV), containing the cryoprotectants to prepare the semen for the cryopreservation step and finally, the samples were packaged in French straws of 0,5 ml and frozen by the programmable freezer MiniDigit cooler (IMV), following a specific freezing curve (data not shown). The frozen straws were conserved in liquid nitrogen. To evaluate the effect of cryopreservation on the sperm quality, each semen was analyzed for the determination of motility, before and after thawing, using both microscope and image analysis CASA systems (IVOS II – Hamilton Thorne).

Results and discussion

The taxonomic analysis, based on phenotypic observations on the livery carried out *in situ,* revealed the presence of 9.5% of hybrids with brown trout on the total of males caught. Genetic tests are in progress to confirm this data. Only the 58% of fish, classified as "genetic pure individuals", provided enough sperm quantity to carried out all the quality tests and, the 73% of these, showed sperm quality parameters suitable for subsequent cryopreservation (fresh sperm motility > 50%). Motility average value of fresh semen, before cryopreservation was 58.1±9.2% while, after thawing it decreased to 26.2 ±3.5%, (representing a yield thawing of 46±11.2%), with an activation time post-tawing of 32.5±5.7 seconds.

(Continued on next page)

This preliminary study allowed to set up a cryopreservation protocol for the semen of autochthonous Sicilian trout (*S. cettii*). Further study will be focused on the application of cryopreserved sperm on eggs to perform fertilization trials, in order to confirm the sperm quality after thawing and the effectiveness freezing protocol for the sperm cryobank implementation. This vanguard technology, in synergy with an extensive genetic study, a migratory behavior survey and a recovery of the altered habitat, represent an important tool for the restoration of native population of the Mediterranean trout.

Funding

This work has received funding from PoFeamp 2014-2018, measure 2.47 "Innovation in Aquaculture", art. 47-regulation (UE) n.508/2014 May, 15 2014 (project MEDIT REPRODUCTION).

Introduction

Faced with the increase of harmful natural phenomena and infectious episodes, the shellfish and aquaculture industry in the world, has experienced major health crises since 2008 (Garcia et al. 2011). Several phenomena have disastrous consequences on the herds, such as microbial infections or anoxic crises (called "malaïgue") (Hamon et al. 2003) resulting in a rapid depletion of oxygen in the environment, vital for organisms. Beyond shellfish farming, lagoon environments such as Thau Lagoon (France) are real reservoirs of biodiversity, directly impacted by these phenomena. The SENSITHAU[1] project aims to integrate into the Lagoon Observation Network (ROL), an ecosystem database, for integrated management of the lagoon, combining ecology, health risks and shellfish production. Bringing together several key players in the Thau lagoon, the SENSITHAU project seeks the deployment of several *in situ* sensors measuring a wide range of physicochemical parameters in real time and at high frequency. Using data generated from *in situ* monitoring, sampling, and satellite, the project will be articulated around 2 axes:

- Deployment of an *in situ* telemetry network on various parameters of the lagoon water
- Development of predictive algorithms to anticipate risks associated with episodes of (i) malaïgue, (ii) microbial contamination and (iii) algal blooms.

Material and methods

The project takes place in the Thau Lagoon (Hérault, France), a semi-open environment.
Three datasets will be constructed to gather as many information as possible.

The 1st dataset is the physico-chemical data (temperature, dissolved oxygen, turbidity, salinity, and chlorophyll) monitored continuously (Aqurareal, Bioceanor) at 2 depth (surface and bottom).

The 2nd database is the water analysis from sampling at different strategic areas in the lagoon (where event occurs) of biotic (*Escherichia. coli* and enterococcus, phytoplankton) and abiotic (NO3, NH4, SO4, PO4, chlorophyll and phytoplankton diversity).

The 3rd database is the satellite images, exploring the analysis of 3 parameters (chlorophyll, backscattering coefficient of suspended inorganic matter and suspended particulate matter) using the Sentinel 2 and 3 satellite.

The 4th database includes other data such as wind, air temperature, rainfall level, flow rates of rivers and releases from wastewater treatment plants around the area.

The data is collected, harmonized, and stored for analysis. We will run preprocessing to identify the global behavior of different parameters (i.e., seasonality, extreme values). We will also analyze correlation between parameters to have a complete data exploration. At the end, we will build and compare various models: from statistical models to machine and deep learning methods to find the most performant one.

Results

The deployment of sensors and data collection in April 2021 constituted the first step for a global monitoring of the lagoon, including sensitives areas, susceptible for anoxic event, bacterial contamination, and blooms. All the sensors deployed in the lagoon represent a sentinel network for risk visualisation in real-time thanks to the continuous and connected devices. Different parameters monitored are redundant and measured at different scales (continuously with the autonomous devices, locally by sampling and by satellite). The data will be intercompared and will serve for statistical analysis. Those analysis will allow to identify key parameters and their variation overtime before, during and after an event of interest. Machine learning analyses will subsequently allow to anticipate events before they occur (Lafont et al. 2019). By the end of the project, correlation between *in situ* data and satellite images will give a role of sentinel for the satellite in the lagoon (Fig. 2). It will allow to alert the final user before an event occur.

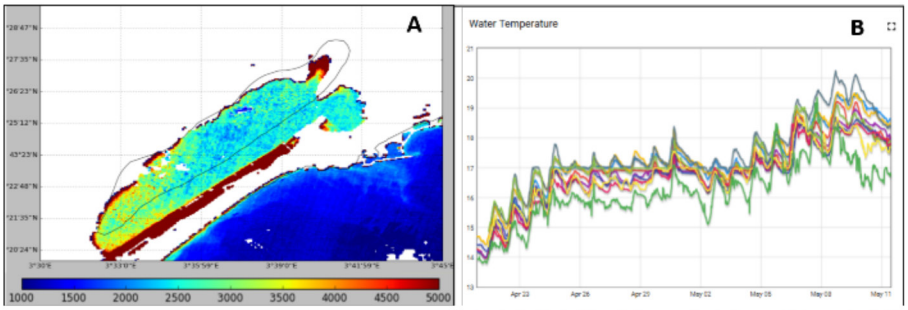

Figure 1: Example of data collected in the SENSITHAU project. A: Satellite data analysis for a-Chlorophyll (10^3 mg/m3) ; B: Water temperature monitoring thanks to autonomous devices (°C; 10 sites across Thau lagoon)

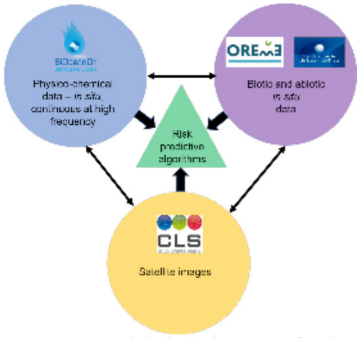

Figure 1: Global scheme of the construction of a large environmental data set

Discussion and conclusion

The development of IoT (internet of things) simplifies the collection of large amounts of data, in real time and at high frequency. Correlated to water sampling and data collections that remains impossible autonomously, it will allow to build large and more robust data sets. Using these data with machine learning opens the world of anticipation (Lafont et al. 2019). Different risks exist for the industries dependent of the water quality (i.e. oyster farming). Being able to anticipate those risks can give advantage to protect the farm and the business against phenomenon that can be disastrous (HAB, oxygen drop, bacterial contamination…). The SENSITHAU project propose to develop tools to anticipate those risks. In long term, satellite data and continuous monitoring will allow to have a survey of the lagoon 24/7 and automatically alert end-user to a potential risk. The development of this technology will be applicable all around the world and will benefit to many sensitive areas, where anticipation of exceptional events is essential.

Introduction

Anthropogenic litter on the sea surface, beaches and seafloor has been significantly increasing over recent decades (Galgani et al. 2015). In present days, marine litter is worldwide distributed, and the Atlantic Island of Madeira is no exception (Álvarez et al. 2020). This accumulation of litter in the ocean is severely affecting ocean and coastal ecosystems in numerous ways, with impacts ranging from debris ingestion and entanglement that directly endangers marine life (i.e., seabirds, fishes, mussels, turtles and marine mammals) to smothering benthic communities (Kühn S et al. 2015) or spreading pest species and diseases (De la Torre et al. 2021; Lamb et al. 2018). In addition, there are also known economic impacts that may increase the cost associated with marine and coastal activities (Mouat et al. 2010). The aquaculture sector, widely recognised as an ocean-based source of marine litter (Bringer et al. 2021) but is also likely to be affected by marine litter. However, the impact of marine litter on open-ocean marine aquaculture facilities has received little attention. In this context, the present study combines information from video inspections of the cages, macro plastic in stomach contents and interview-based perception surveys to evaluate interactions between marine litter and open-ocean aquaculture of *Sparus aurata* in the south coast of Madeira Island.

Material and Methods

To assess the presence of marine litter in the proximity of offshore seabream aquaculture cages, video recording techniques were employed. The recorded videos were visually inspected and manually annotated to record presence of marine litter items and classify them following OSPAR hierarchical classification (OSPAR commission 2010). In addition, to assess correlation between macro plastic ingestion and the survivorship of aquaculture' fishes, gastrointestinal contents were inspected on specimens collected alive (n=164) and dead (n=233). Morphometric data from specimen was collected and plastic fragments were classified according to the Fulmar EcoCO methodology (MSFD 2013). Finally, a survey questionnaire was designed for aquaculture facilities' personnel to assess the perception of interference between marine litter and aquaculture activities. Data were gathered both through in-person and online interviews. Descriptive statistics were used to summarise results from the surveys, and statistical analyses were conducted using IBM SPSS statistic version 27.

Results

From 103 video surveys conducted, only 10.68% showed plastic debris around the offshore cages. A total of 12 plastic items was identified, being the category OSPAR2 (i.e. bags) the most frequent one (66.7%). While none of the specimens collected alive (n=164) contained macroplastic in their gastrointestinal tracts, a small percentage of individuals collected dead (5.15%, n= 12) contained plastics in their gastrointestinal content. All plastic debris found corresponds to the category "plastic sheet" of Fulmar EcoCO classification (e.g. remains from bag, agricultural sheets or rubbish bags). A maximum of 1 piece of debris was found in each individual of 0.96 ±0.59g (mean ±ST) and 9.19±3.81cm (mean ±ST). No particular relationship was found between fish and debris sizes (g nor cm). Overall, data gathered from the survey questionnaire showed low marine litter interference with daily aquaculture activities (7.2%). Respondents believed that presently, marine debris does not particularly affect the aquaculture sector in Madeira. However, it was the general opinion that marine litter can become a real threat to this activity in the future (96.3%). Respondents believe that marine litter represents a significant risk for the native fauna and flora in general and that local fisheries are the most affected economic activity. Respondents

(Continued on next page)

also identify fishing activities as the major source of marine litter and consider that aquaculture is currently an irrelevant source of marine litter production. Overall, respondents showed a weak willingness to pay for a tax on marine litter (55.6%), but they revealed a stronger willingness to participate in voluntary initiatives to reduce and collect marine debris (88.9%). Moreover, the majority of respondent (68%) believed that action to reduce marine litter should be done globally and further suggested that the aquaculture sector should reduce plastic use.

Discussion

The present case-study provides baseline information on the interactions and impacts of marine litter and offshore aquaculture facilities and activities. The results of this study are limited to the specificities of Madeira Island and existing facilities, warranting particular care in drawing general conclusions. The perception that marine litter currently has low interference with open-ocean aquaculture facilities is compatible and in line with the findings from video inspection of cages and gastrointestinal content examination. However, it is important to underline that the video inspection and ingestion assessments included in the present study were focused on macro-plastics and did not take into consideration the presence, abundance and effects of microplastic (<0.5 cm) contamination and their accumulation in the trophic chain. Finally, results of survey questionnaire highlight the need to develop a dedicated monitoring program to assess the management of waste generated from aquaculture activities.

Introduction

Gilthead seabream (*Sparus aurata*) is an important commercial species, greatly appreciated for consumption and one of the most used fishes in aquaculture (Jouvenel and Pollard 2001). Offshore aquaculture is a growing industry trying to face the increasing demand for seafood, however, fish escapes are cause for concern as they can represent a threat to the marine environment, especially in locations where the farmed species were not previously present (Ramirez et al. 2015). Although this seabream is native in the North-eastern Atlantic it is considered a non-indigenous species (NIS) in Madeira archipelago (Alves and Alves 2002). In Madeira Island, this species was introduced in 1997 for aquaculture purposes (Alves and Alves 2002) which currently hosts three open-ocean aquaculture farms breeding and producing *S. aurata*. Three years after introducing the species in the archipelago, a first sighting of 5 individuals in the wild was reported in the south coast of Madeira (Alves and Alves, 2002). Generally, unwanted escaping of fish from offshore cages often results from equipment malfunction, accidents and storms. As such, depending on the frequency and severity of such accidental incidents, the number of fishes escaping to the wild could result in the establishment of a local population. Recent studies highlight the presence of wild *S. aurata* along the coast of Madeira, being caught by recreational spearfishers from 2004 (Martinez-Escauriaza et al. 2020a) and representing the sixteenth most caught fish species by recreational shore anglers in 2017 (Martinez-Escauriaza et al. 2020b). In this context, this study aims to better understand the distribution and occurrence of *S. aurata* in Madeira coastal habitats and assess their invasiveness in the archipelago.

Material and Methods

Information on captures (i.e., species, date, location and size) during sport fishing contests held in Madeira between 2010 and 2019 (n=443) were compiled and analysed to assess *S. aurata* occurrences, distribution and trends. In addition, a custom designed online survey questionnaire targeting stakeholders from three maritime activities (1- SCUBA diving; 2-spearfishing; and, 3-fishing) was developed to assess the presence of *Sparus aurata* in the coastal waters of the Madeira archipelago. The survey was designed using the application 'Maptionnaire' (www.maptionnaire.com), that allows users to interact and report georeferenced data through a web-based interface. Data were later analysed and plotted with ArcGIS and IBS SPSS version 27. Finally, a risk analysis was conducted to assess invasiveness and evaluate possible impacts of *S. aurata* in Madeira habitats, under current and future climate change scenarios, using the Aquatic Species Invasiveness Screening Kit (AS-ISK, Coop et al 2016). Concerted scores for Basic Risk Assessment (BRA), Climate Change Assessment (CCA) and BRA+CCA were estimated from multiple screenings by users with different expertise. Concerted BRA and BRA+CCA scores were compared with thresholds for marine fishes in both temperate and tropical regions to assess invasiveness risk.

Results

Sport fishing contest data from 2010 confirmed the presence of *S. aurata* in the wild with capture in both south and north coasts of the island; whereas data from 2018 showcase that *S. aurata* specimens were captured almost every month. Similarly, the 73 validated respondents of the online survey reported sightings and captures in 120 sites around the island, most of which reporting small groups of 5 individuals (57%) but with larger groups of more than 20 individuals also being reported (14%). Moreover, respondents' perception is that seabream sightings in Madeira have been increasing since 2015. Concerted BRA and BRA+CCA scores rank high despite ranging confidence intervals, with average scores above thresholds for marine fishes in both tropical and temperate regions.

(Continued on next page)

Discussion

Considering the spatial distribution of *S. aurata* sightings and captures around Madeira Island, with reports from sites distant from aquaculture farms, and increasing trends in captures and sightings, it is reasonable that it has successfully established a local population. This is not surprising considering that Madeira island environmental conditions are within the range of conditions suitable for *S. aurata*. In addition, *S. aurata* averaged BRA and BRA+CCA scores are above the threshold for marine fishes, suggesting it may be a high or medium risk species. Such scores are not surprising as well, due to the high adaptability in food and habitat (Balart et al., 2009), *S. aurata* can potentially become a fierce competitor of local native species (e.g., *Pagrus* spp., *Diplodus* spp.). Overall, findings of this study warrant further investigations into local *S. aurata,* specifically to confirm its reproduction in the wild and assess impacts from its behaviour and feeding habits.

Introduction

Lagoons and deltas, are highly heterogenous transitional systems, subject to multiple pressures. Species inhabiting these areas have adapted to cope with the natural heterogeneity (Bertolini et al. 2021) but local and global anthropogenic pressures, including climate change, may increase stress and in some cases lead to mortality. Studying behavioural responses can be the key to identify sub-lethal stress, as behaviour can have physiological links. Mussel gaping, for example, is a highly dynamic process, linked to key functions of metabolism, such as feeding and respiring: changes in its temporal pattern can affect energy intake and allocation, ultimately influencing growth and reproduction. This can be important in the context of sustainable cultivation of these species, where resource utilisation should be optimised by maximising the return from the input of seed, thus avoiding periods of metabolic suppression or energetically costly processes. The aim of this study was therefore to (1) test the use of a machine learning algorithm to identify key behaviours and (2) understand whether consistent patterns of behaviour could be linked to specific environmental conditions.

Methods

Biophys sensors (Bertolini et al. 2021) were deployed at multiple aquaculture sites of *Mytilus galloprovicnialis* within the Venice Lagoon (VL: 6 sensors, 3 sites, 1 year) and *M. edulis* in the Wadden Sea (WS: 30 sensors, 2 sites, 1 month). With the use of these electro-magnetic sensors the valve gaping amplitude (between 0: close and 1:open) can be obtained every minute, coupled with the temperature of the surrounding water.

Other environmental parameters likely to influence behaviour were measured in continuum (VL, 1 station: Dissolved Oxygen, Chlorophyll, Turbidity, sampling frequency 12 minutes ; WS, 2 stations: Chlorophyll, Turbidity, sampling frequency 5 minutes). A clustering algorithm (fuzzy k-means) was applied to daily patterns of gaping and to the environmental parameters measured. Within the days corresponding to a specified "environmental cluster", the occurrences of the different "gaping clusters" were counted in order to understand the prevalence of certain behaviours under specific combinations of environmental conditions.

Results

The algorithm led to identify the three distinct gaping clusters shown in Fig. 1, named "narrow", "mid", "wide" at all sites, except one, where the "mid" cluster was not found. Environmental variables also resulted in distinctive environmental clusters (VL: temperature and dissolved oxygen: 5, chlorophyll: 4 and turbidity: 3 ; WS: temperature: 3, chlorophyll and turbidity:2). At all sites in the VL mussels were more frequently widely opened (20 vs 10 days) at the highest temperature (cluster means 25-27°C) and when dissolved oxygen exhibited a more evident fluctuation. On the other hand, they were more frequently narrow (15 vs 5 days) when temperatures were in the mid-low (cluster means 10-12°C) and oxygen saturation mid-high. No relation could be found in VL with chlorophyll and the number of observations for medium and high turbidity were too low. In the WS there was a separation between the two sites, which exhibited distinct patterns of chlorophyll and turbidity. One site had low levels of chlorophyll and turbidity and mussels were more frequently narrow gaping (narrow: 35, mid:50, wide:18) while in the other site, where both chlorophyll and turbidity were higher they predominantly had medium and wider gaping (narrow: 30, mid: 80, wide: 50).

(Continued on next page)

Discussion

This study found that, an unsupervised consolidated clustering algorithm, allowed to identify patterns of behaviour and characterise some of its potential drivers. For example, at higher temperatures, mussels were consistently displaying a wider opening angle. This is consistent with shellfish physiology and formulations used in bioenergetic models, which predict an increase in oxygen demand with temperature. However, this behaviour could also increase the energy intake, which, on the other hand, is assumed to be maximum at the organism optimal temperature. Therefore, a more detailed analysis of these data could lead to improve shellfish bioenergetic models, which are being increasingly used in shellfish farming. Furthermore, mussels maintained a wide gape even in high turbidity conditions. At this site mussels have wider palps and grow less, suggesting adaptation to the conditions coming at a cost.

Introduction
Conservation of aquatic genetic resources is crucial for both the preservation of biodiversity and for aquaculture. However there is not much information regarding the effects of the cryopreservation itself. Babiak et al. (2002) found that in the rainbow trout sperm of fish originating from eggs fertilized with cryopreserved sperm shows a higher cryoresistance in terms of fertilizing capacity. The present study evaluated the same method in common carp *(Cyprinus carpio)*.

Materials and methods
Six F1 full-sib families were created using the eggs of a single female which was fertilized with either 50 µL fresh or with 50 µL cryopreserved sperm from the same males (N=6). After sexual maturation spermiation of each F1 male was induced with Ovopel mammalian GnRH analogue. After 24 hours the males were spawned and the sperm was collected into 5-mL Eppendorf tubes. The fresh sperm parameters were measured with CASA (Computer Assisted Sperm Analysis) system. 100 µL of the samples were cryopreserved, 50 µL into each staws. Before cryopreservation the samples were diluted in grayling extender (200 mM glucose, 40 mM KCl, 30 mM Tris, pH: 8.0±0.2, Horváth et al. 2012) and methanol (10%) to the concentration of 10^9 spermatozoa per mL. The diluted samples were loaded into 0.5-mL plastic straws (Minitube GmbH, Tiefenbach, Germany). The samples were cryopreserved in the vapour of liquid nitrogen 3 cm above its surface for 3 minutes. After cryopreservation the samples were plunged into liquid nitrogen. The samples were thawed for 13 sec at 40 °C and post-thaw motility parameters (total motility, progressive motility, VCL, VAP, VSL, STR, LIN) were measured by CASA. A two-way ANOVA was conducted to investigate the main effects of sampling date and origin of the fish (fresh or cryopreserved sperm) on the motility parameters using the JASP software.

Results
It was found early on during the study that the family had no effect on the motility parameters of common carp sperm. Thus, our studies concentrated on the main effects of the origin of fish (fresh or cryopreserved sperm) and the sampling dates.

We found that the origin of fish ($p = 0.024$) as well as the sampling date ($p < 0.001$) had a singnificant main effect on the progressive motility of cryopreserved common carp sperm. The progressive motility of cryopreserved sperm from fish originating from eggs fertilized with cryopreserved sperm was 65 ± 15% while that of cryopreserved sperm from fish originating from eggs fertilized with fresh sperm was 59 ± 20%.

In case of all other parameters, no significant main effect of the origin of fish was detected. The sampling date had a significant main effect of motility parameters in all cases except for STR ($p = 0.206$) and LIN ($p = 0.051$).

Discussion
We have found that common carp originating from fertilization with cryopreserved sperm had a significantly higher post-thaw progressive motility measured by CASA than those originated from fertilization with fresh sperm. This is indirect proof that cryopreservation has a lasting effect on the reproductive characteristics of fish.

(Continued on next page)

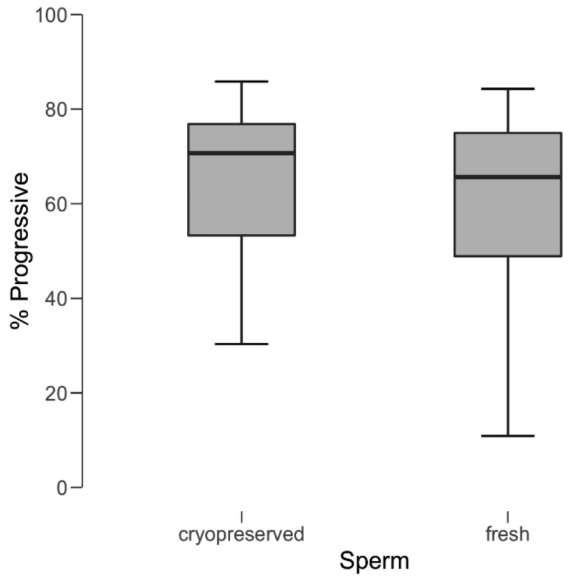

Fig.1. Progressive motility after cryopreservation of the sperm of males originated from fresh ($N = 63$) and cryopreserved sperm ($N = 46$). Significant differences can be found between the group originated from fresh and the group originated from cryopreserved sperm.

Introduction

In a recent study, [1] showed that the INRA rainbow trout synthetic line, developed in the early 1980s by intercrossing several domesticated lines to create an experimental line with a large genetic variability, has a lower effective size than expected on the basis of its census size, while the population size has been kept constant over time by annually mating balanced numbers (60 to 80) of females and males. We hypothezise that it may be due to the well-known Sweepstakes Reproductive Success (SRS) phenomenon in fish [2], which results in very unbalanced parental contributions to the next generation. SRS may induce a large variance in reproductive success among individuals not only breeding in the wild, but also in multigenerational trout hatchery programs [3]. To validate this hypothesis, we carried out an experiment at the INRAE facilities (PEIMA, Sizun) to investigate the parental contributions and the offspring survival for a set of genotyped parents from the INRA synthetic line.

Materials and Methods

To assess the parental contributions to egg fertilization and offspring survival until first feeding, a full factorial mating plan was designed with 15 dams and 9 sires of the INRA rainbow trout synthetic line. All parents were genotyped for 57,501 SNP with the AxiomTM Trout Genotyping array. From the total spawn of each female, we retain 3 duplicate packages of 21 eggs each for parental contributions' study and 2 packages of 50 eggs for egg quality measurements. From the milt of 9 sires randomly divided into 3 groups of 3 males and the eggs of 15 dams also divided into 3 groups of 5 females, we fertilized ova according to a full factorial mating design made of 9 small factorial plans (each group of 5 females mated to each group of 3 males) generating 9 batches of 105 ova (duplicate batches). The eggs fertilization of each batch of 5 females was carried out male-by-male on a mixed set of 35 ova (7 ova from each of the dams). After fertilization, all eggs from a small factorial plan were grouped together in the same incubator until the eyed stage. In total for each duplicate batch, each sire could fertilized 105 eggs and each couple may have up to 7 offsprings. At eyed egg stage (20 dpf at 12°C), all embryos from the first duplicate batches were genotyped on a 96 SNP-array used for parental assignment. From the eyed egg stage until the end of the experiment (3 weeks after first feeding), all dead offsprings were collected each day and all dead and alive offsprings were genotyped with the AxiomTM Trout Genotyping array to perform both parental assignment and GWAS on offspring survival. Starting from the day of fertilization, offspring survival was evaluated at 3 stages: eyed egg stage (Se), hatching (Sh) and 3 weeks after first feeding (Sf). Parental contributions were assess at these 3 stages by counting the number of alive progeny for each parent and couple. Fisher exact tests were performed to assess imbalances in parental contributions to offspring survivals Se, Sh and Sf. In addition, time to death (TD in days) from eyed egg stage to hatching was analyzed under a GBLUP model including the fixed effect of the incubator, the random animal additive genetic effect and 3 covariates accounting for the offspring inbreeding coefficient (F) and its dam and sire inbreeding coefficients (F_{dam} and F_{sire}).

Results

Offspring survival rates were in average 91.0% for Se, 87.2% for Sh and 84.4% for Sf (Table 1). While no unbalanced sire contributions to the progeny cohort was detected, significant unbalanced dam contributions to offspring survival was observed at eyed egg stage and at hatching with values ranging from 71.4% to 100% for Se and from to 65.1% to 98.4% for Sh, depending of the dam (Table 1). After hatching, mortality was low and no strong variability was observed among the dams for their offspring survival beween hatching and the end of experiment. Therefore, we only investigate the genetic variability of offspring survival at hatching stage (TD). Heritability of offspring survival until hatching was low under a linear model (h^2=0.11±0.04). No significant QTL was detected. While dam and sire inbreeding levels did not significantly impact their offspring survival, offspring survival increased with its own inbreeding level (regression coefficient b = 11.2 ±3.4 d).

(Continued on next page)

Table 1. Dam size and reproduction mean performance and phenotypic correlations of dam characteristics with offspring survival rates.
FL: female fork length (mm); PW: female post-spawning body weight (g); SW: spawn weight (g); EW: average egg weight (mg); ED: average egg diameter (mm); CF: weight of coelomic fluid (g); F_{dam} : dam inbreeding coefficient. Se: Offspring survival from fertilization to eyed egg stage (22 days after fertilization); Sh: Offspring survival from fertilization to hatching (35 days after fertilization); Sf: Offspring survival from fertilization to 3 weeks after first feeding (64 days after fertilization).

Trait	Mean	Min	Max	Correlation with Se	Correlation with Sh	Correlation with Sf
FL	487,8	437	522	- 0.07	- 0.12	- 0.03
PW	2053,4	1382	2753	- 0.45 *	- 0.54 **	- 0.46 *
SW	267,1	177,8	406,5	0.50 *	0.54 **	0.58 **
EW	71,3	63,3	80,4	-0.09	- 0.31	- 0.38
ED	5,3	5,1	5,52	-0.17	- 0.24	- 0.29
CF	27,8	19,2	35,2	0.21	0.20	0.11
F_{dam}	0,18	0,11	0,42	0.22	0.19	0.18
F_{sire}	0.17	0.10	0.28	- 0.39	- 0.30	- 0.27
Se	91.0%	71.4%	100%	1	0.89	0.84
Sh	87.2%	65.1%	98.4%	-	1	0.97
Sf	84.4%	63.5%	95.2%	-	-	1

** p_value < 0.05 * p_value < 0.1

Investigating how dam characters correlate with offspring survival (Table 1), we only observed significant correlations with the dam post-spawning weight and her spawn weight, but in opposite trends. While high spawn weight was favourable to offspring survival, post-spawning weight of the dam was negatively correlated with offspring survival. Negative but not significant trends were also observed between egg quality traits (egg weight and diameter) and survival rates. Surprinsingly, it seems that the higher the number of eggs in the spawn is, the better the survival of each of them is.

Discussion and conclusion

Unbalanced dam contributions to the offspring cohort were identified and may explain the reduction in effective size of the INRA rainbow trout synthetic line over generations. Explanations for these unbalanced contributions remain unclear, but seem to relate to the dam fecundity and some intreseque egg quality traits that do not refer to egg size.

POLLUTION EFFECTS OF AQUACULTURE ACTIVITIES IN THE COASTAL MARINE ENVIRONMENT, Eastern mediterranean

A.Pavlidou*, Th. Zoulias, P. Zachioti, E. Rouselaki and I. Hatzianestis

Hellenic Centre for Marine Research, Institute of Oceanography, 46.7 Km Athens-Sounio Av., Anavyssos, 19013, Greece

Introduction
Marine finfish aquaculture industry is expanding, as the demand for seafood rises and cannot be met by wild catch fisheries. Greece dominates the Mediterranean aquaculture industry, largely based on the production of the Mediterranean sea bass and gilthead sea bream. However, aquaculture is associated with a wide range of environmental concern which need to be addressed for its sustainable development. Pollution problems caused by the application of antibiotics, chemicals and medicines, overstocking and overfeeding fishponds, fish waste etc, may affect the water quality, contribute to eutrophication problems and reduce dissolved oxygen concentration (Ahmed and Thompson, 2019). Eastern Mediterranean Sea (EMED) presents an oligotrophic character, thus, the rich protein food for feeding fish species such as the sea bream and sea bass, is an important source of nutrient inputs to coastal areas. The aim of this work is to investigate the effects of fish farms on the water column and the sediments, and assess the trophic status of the coastal marine environments affected by the fish cultures in relation to the undisturbed coastal waters.

Methodology
Water and sediment samples from eight coastal stations located very close to the floating finfish cages were taken monthly during two sampling periods: 2012-2013 and 2015-2016. Chemical parameters (e.g. dissolved oxygen, nutrients, total nitrogen, total phosphorus) were measured in the water column together with organic contaminants in sediments (aliphatic and polycyclic aromatic hydrocarbons), according to standard methods. The total amount of nitrogen and phosphorous released through the added food from the cages was evaluated, based on feed data from the aquacultures. Moreover, the trophic indexes developed for the oligotrophic waters of the Eastern Mediterranean were estimated (Pavlidou et al., 2015).

Results
Increased concentrations of inorganic and organic nitrogen have been recorded in the water column beneath the cages. It seems that the fish farms enrich the Greek coastal waters in inorganic nitrogen, mainly ammonium, but not in phosphorus, keeping the phosphorus limiting character of the EMED. Organic nitrogen and organic phosphorus predominated, whereas, ammonium was the predominant inorganic nutrient in the study areas. The organic nitrogen and phosphorus were higher during summer, leading to the relative downgrade of the trophic status of the water environment very close to the cages. The majority of stations has been classified into Good and Moderate trophic classes. Strong positive correlation between ammonium concentrations measured in the water column below the cages with the nitrogen and phosphorus released via feed, and negative correlation between dissolved oxygen and the released nitrogen and phosphorus was observed indicating probable effect of aquaculture activities in the marine environment.

Pollution from aliphatic and polycyclic aromatic hydrocarbons (PAH) was found in some of the aquaculture sediments. The predominant PAHs at the contaminated sites were of petrogenic origin, which is a quite unusual distribution for marine sediments, but it is similar to aquaculture sediments in other places of the world and is probably related to the fish feed (Wang et al., 2010; Tsapakis et al., 2010). Enrichment of some aquaculture sediments in organic carbon and phosphorus was also observed.

Conclusions
During summer the aquaculture activities seem to consist an important anthropogenic pressure for the surrounding marine environment, since the metabolic rate of the fish and the feed are increased. Ammonium and total nitrogen values were higher below and very close to the cages, compared to unaffected coastal waters, indicating the impact from the aquaculture to the marine environment, which however, is restricted close to the cages. Organic pollution from hydrocarbons was detected, which, even though lower than in other polluted areas (e.g. ports) should be considered as a pressure in the marine environment, thus PAHs should be included in any monitoring scheme regarding aquacultures. In order to meet the demand for food from a growing global population, aquaculture production should increase sustainably while at the same time its environmental impacts should be reduced considerably. Producing fish in an environmentally sustainable way is essential.

Introduction

Marine macroalgae are valuable sources of bioactive compounds which are used in nutritional and/or pharmaceutical products. Marine algae can be classified based on pigment contents which have various biological activities such as antioxidant and anti-inflammatory activities (Catarino et al., 2018). Widely distributed Fucus genus of brown macroalgae is an excellent source of fucoxanthin carotenoid which contributing around 10% estimated total production of carotenoids in nature (Kim and Pangestuti, 2011). Chlorophyll a, is the most important chlorophyll for photosynthesis since allow the conversion of light into biological energy (Osorio et al., 2020). The inherent characteristics of each species and different environmental factors induced by seasonal variations in their normal ecosystem (temperature, light, salinity) controls the macroalgal growth rate in nature and may also affect their pigment contents (Marinho-Soriano 2012). However, the potential impact of seasonal variations in their bioactivity profile is often neglected in analytical studies. The brown alga *Fucus virsoides* is an endemic species in the Adriatic Sea and its typical habitat is in the intertidal zone, an extremely variable environment (Najdek et al., 2014).

Therefore, the aim of this study was to evaluate the effect of seasonal environmental variations on pigment content of *Fucus virsoides* from the Adriatic Sea.

Materials and method

Environmental parameters water and air temperature (°C) and salinity were measured with Hydrolab (DS5X).

Sampling of the brown alga *Fucus virsoides* was performed seasonally (Viz. January, May to October 2019) in coastal area of the Adriatic Sea (44°12 02´N to 15°28´51E, Croatia) at 0.5 m depth or along the surface of the sea. Samples were washed in seawater and then rinsed with distilled water, frozen at -60 °C, freeze dried (CoolSafe lyophilizer, Model: 55-9 PRO, Labogene, Denmark) and milled. Ultrasound-assisted extraction (Elmasonic 40H, Elma, Germany) was performed 20 minutes at 30 °C with acetone. Extracts were filtered and stored at 4 °C until analysis. Determination of pigments was performed using HPLC system (Agilent Infinity 1260 system) with UV/VIS PDA detection according to method described by Castro–Puyana et al. (2017). The identification of individual carotenoid and chlorophyll compounds was performed on the basis of their retention times and UV-VIS spectra and quantification was performed by the external standard method using calibration curves of the authentic standards (β-carotene, fucoxanthin, zeaxanthin, chlorophyll a and b). Data analyses were performed with the Excel and all values are expressed as mean±SD of three parallel measurements.

Results

Measured environmental parameters such as water and air temperature and salinity considerably differed in the winter period (13 °C, 8 °C and 33) compared to spring (17 °C, 19 °C and 38) and autumn (20 °C, 22 °C and 38) period. The highest pigment content was determined in acetone extract of brown alga *Fucus virsoides* sampled in January (35.6 mg/100 g) and lower in algae extracts sampled in October (27.14 mg/100 g) and May (26.79 mg/100 g) of 2019. Pigment content in all obtained extracts was mainly composed of carotenoids. Fucoxanthin was the predominant carotenoid (16.04–23.21 mg/100 g) followed by derivative of fucoxanthin (4.18-5.64 mg/100 g) and violaxanthin (2.80-4.09 mg/100 g). The β-carotene was determined in the lowest content in all samples (0.68-0.80 mg/100 g). Chlorophylls were determined in significantly lower contents and chlorophyll a was the most abundant (0.029-0.044 mg/100 g).

(Continued on next page)

Discussion and conclusion

In our study pigment composition and content was determined in the seasonally sampled brown alga *Fucus virsoides* located in Adriatic Sea. Carotenoids are the major pigments in *Fucus virsoides* and approximately 60-65% of the total carotenoid content corresponds to xanthophyll fucoxanthin what is in accordance with literature data (Catarino et al., 2018). Chlorophyll a is major chlorophyll in all samples. Results showed that pigment content was significantly higher in algae extracts sampled in winter (January of 2019) than in spring (May 2019) and autumn (October 2019) period. Pigment content decreased in the spring and then slightly increased again in autumn. Loss of pigment content during spring and autumn compared to winter period is probably related to environmental conditions such as light, temperature and salinity (Osório et al., 2020). Measured environmental parameters such as water temperature, air temperature and salinity were considerably lower in the winter period while in spring and autumn period slight differences were observed. According to literature data, pigment content especially of xanthophylls decreased in algae if the light intensity was increased due to increase in temperature (Ismail & Osman, 2016). Salinity and temperature have significant effects on photosynthetic pigments also (Ding et al., 2013).

In conclusion, the present study showed that the most suitable period for collection of *Fucus virsoides* from the Adriatic Sea with high pigment content is winter.

Introduction
Macroalgae are natural products rich in bioactive compounds with antioxidant and anti-inflammatory activities supplying bioactive substances with a wide range of applications, including human and animal nutrition. However, from the edible seaweed of European Atlantic shores, there are still many species that call for further investigation. Bearing this in mind, the three macroalgae *Bifurcaria bifurcata*, *Carpodesmia tamariscifolia* and *Codium sp*. were selected and harvested in two different seasons. The main goals of this work were to assess the *in vitro* bioactivities variation with the season of these understudied seaweed species from the Portuguese coast and consequently disclosure their potential interest in animal feed and human diets.

Material and Methods
The brown macroalgae *Bifurcaria bifurcata* and *Carpodesmia tamariscifolia*, previously classified as *Cystoseira tamariscifolia*, and the green macroalgae *Codium sp.* were harvested in the proximities of Farol do Cabo Raso, Portugal (38°42'38.7"N 9°29'09.7"W), in August and November of 2020. After immediate transport, the fronds of the three seaweeds were rinsed with potable water, freeze-dried, ground and stored at -80ºC until further analysis. Free fucose was determined by the cysteine-sulphuric acid method for methyl pentoses (Xing et al., 2013) and total polyphenol content of ethanol extracts was determined by the Singleton and Rossi (1965) method, using the Folin-Ciocalteu reagent. As for the antioxidant activity, the DPPH radical (Miliauskas et al., 2004), Ferric Ion Reducing Antioxidant Power (FRAP) (Benzie and Strain, 1996) and ABTS radical cation (Re et al., 1999) assays were applied. Anti-inflammatory activity was quantified, by testing ethanol extracts at 1 mg/ml, using a commercial cyclooxygenase (COX) inhibitory screening assay kit (Cayman Chemical Company, USA).

Results
Results showed that the highest total polyphenol level was found in *B. bifurcata* regardless of the season, varying between 10.13-11.01 mg GAE/g dw seaweed. On this species, seasonality showed no effect, however on *C. tamariscifolia* and *Codium sp.* there was an increase of phenolic content from Winter to Summer. Fucose was not detected in *B. bifurcata* and the overall results were low except for the *Codium sp.* Summer extracts which reached 4.68± 10.42 mg/g dw seaweed.

As for the antioxidant activities, by the DPPH method, the ethanol extracts of *B. bifurcata* were more antioxidant than the extracts from *C. tamariscifolia* and season affected both species. However, values were higher in the Summer extracts of *B. bifurcata* and Winter extracts of *C. tamariscifolia*. Moreover, the antioxidant levels assessed by the method FRAP showed high levels for the *Codium sp.* extracts, these being 20% more antioxidant in the Summer than in the Winter. On the other hand, *Codium sp.*, when compared to the other species, showed the lowest antioxidant levels according to the ABTS method, including in the Summer.

In addition, the extracts from all the species showed inhibition of the COX-2, the most anti-inflammatory extract being from the *C. tamariscifolia* harvested in Summer (94.2 ± 4.0 %). Season affected both *B. bifurcata* and *C. tamariscifolia*, where Summer extracts were more anti-inflammatory than Winter extracts, and there was no difference in the extracts from *Codium sp.*, that showed the lowest anti-inflammatory activity (13.6-15.5 %).

Overall, the results attained from the three species harvested in Summer and Winter showed a significant biotechnological potential, especially the studied brown macroalgae.

Introduction

Amino acids (AA), such as tryptophan, play several regulatory functions on key metabolic pathways that may be important, among other functions, to immune and neuro-endocrine responses. The inflammatory process is responsible for an increase of the metabolic needs which results in the depletion of essential nutrient provisions. For this reason, a higher nutrient demand has to be supplied in order to avoid the risk of an inefficient response and damage by self-mechanisms. Therefore, dietary supply of specific nutrients such as AA could be a strategy to be applied in specific situations when requirements are higher, such as stressful conditions and inflammation. This study aimed to contribute to this endeavour by assessing the immunological profile and inflammatory response of European seabass (*Dicentrarchus labrax*) fed dietary tryptophan supplementation undergoing a chronic inflammatory condition.

Materials and methods

European seabass juveniles (33.0 ± 3.78 g) were randomly distributed in 12 tanks and maintained in two recirculated seawater systems (temperature 20 ± 0.5°C; salinity 32; photoperiod 10h:14h D:L). At the beginning of the trial, a group of fish was sampled (undisturbed group). Afterwards, half of the fish were intraperitoneally injected with 100 µL of either Freund's Incomplete Adjuvant solution (FIA) to induce a peritoneal inflammation, while the other half was injected with Hanks' Balanced Salt solution (HBSS) and served as a sham group. In a complete randomized design, two dietary treatments were evaluated in triplicate groups: a control diet (CTRL), meeting the indispensable amino acids profile established for seabass, and a CTRL-based diet supplemented with tryptophan (0.3 % DM basis; TRP). Fish were fed these diets for 4 weeks, twice a day with a daily average ration of 2 % body weight. Sampling at 0 (undisturbed), 1, 2, 3 and 4 weeks (n=9) allowed the collection of data regarding haematological profile, plasma immune parameters (i.e. peroxidase, lysozyme and bactericidal activities) and gut immune and oxidative stress parameters (i.e. lipid peroxidation, reduced glutathione: oxidized glutathione ratio, peroxidase, bactericidal, superoxide dismutase and catalase activities). For all five sampling times fish were euthanized by anaesthetic overdose with 2-phenoxyethanol.

Results

Total peritoneal leucocyte counts increased in fish injected with FIA compared to HBSS group regardless diet and sampling point. Compared to the undisturbed group, FIA-injected fish augmented total white blood cells and this parameter increased in this group from 1 to 2 weeks. Red blood cells increased at 3 weeks post-injection and remained high until the end of the experiment, irrespective of dietary treatment or stimulation. FIA-injected fish decreased gut peroxidase and bactericidal activities compared to those injected with HBSS. However, gut bactericidal activity increased from 2 to 3 weeks, remaining high at 4 weeks regardless stimuli and diet. Regarding oxidative stress, superoxide dismutase activity, total glutathione and oxidized glutathione contents peaked at 2 weeks in FIA-injected fish gut, regardless diet, but decreased to basal levels at 4 weeks. Finally, regarding humoral immune parameters, bactericidal activity decreased after 1 week post-injection irrespective of dietary treatment or stimulation, while no significant differences were detected in either lysozyme and peroxidase activities.

(Continued on next page)

Discussion and conclusion

Preliminary data from the present study illustrate the effect of FIA-induced chronic inflammation, with both cellular response and the oxidative stress being enhanced in the presence of the phlogistic agent. Moreover, a clear time-dependent response was observed in most of the analysed parameters, evidencing their regulation over a prolonged timeframe, as expected in a chronic inflammatory setting. Tryptophan immune modulation has been shown to be closely associated to its role in the neuroendocrine response (Azeredo et al., 2017; Machado et al., 2019). The absence of tryptophan-mediated effects might be related to the neuroendocrine status of the fish throughout the experiment, where besides the intra-peritoneal injection and the development of an inflammatory response, there was no particular stressful condition. Nevertheless, future plasma cortisol measurements as well as brain and head-kidney neuroendocrine- and immune-related molecular analyses will assist in better understanding the interactive effects of tryptophan nutrition and chronic inflammation.

Introduction

Senegalese sole (*Solea senegalensis*) is a highly valuable flatfish species targeted for aquaculture in Southern-European countries. This species, as most farmed fish, is potentially subjected to stress and pathogens due to environmental factors. Functional feeds are fortified with selected ingredients/additives, rich in natural molecules and/or vital nutrients that improve fish health status, reducing infection and severity during an outbreak of infectious diseases. Also, can improve immunocompetence prior to or during vaccination counteracting immunosuppression caused by stress and contaminants. Microalgae have been included in diets for farmed aquatic animals due to their antioxidant capacity and bioactive compounds, promoting optimal growth and health. For these reasons, this study intended to evaluate the effects of dietary microalgae inclusion in both health status and growth performance of Senegalese sole post-larvae.

Materials and methods

Senegalese sole post-larvae with 34 days after hatching (DAH) were randomly distributed by 15 tanks with an initial density of 2650 post-larvae/m^2 and three isonitrogenous (60% crude protein) and isolipidic (17% crude lipids) diets were randomly distributed by triplicate groups of tanks. The experimental diets comprised a control (CTRL) diet based on marine protein sources (i.e. fish meal, squid meal and krill meal) and 3 % of cellulose filler, whereas four other diets were based on the control diet but replaced cellulose by 3 % *Isochrysis galbana* (ISO), *Nannochloropsis sp*. (NANO), *Skeletonema* sp. (SKELO) and *Tetraselmis striata* (TETRA). The experimental diets were supplied through automatic feeders set up to supply 8 meals in a 24 h period. At 65 DAH, 30 post-larvae/tank were sampled for analyses of parameters related to health status. The total length, dry weight, feed conversion ratio, relative growth rate, and survival were also assessed.

Homogenates of 10 individuals were performed for the analyses of immune (i.e. lysozyme and bactericidal activities) and oxidative stress (i.e. reduced glutathione: oxidized glutathione ratio, catalase, lipid peroxidation, glutathione S-transferase and superoxide dismutase activities) related parameters. Visceral cavity plus head of 12 individuals from each treatment were used for gene expression analysis (i.e. hepcidin, complement component 3, interleukin-1β, interlukin-10, g-type lysozyme, toll-like receptor 1 and toll-like receptor 5).

Results

Survival, relative growth rate and feed conversion ratio were not altered by the dietary treatments. However, post-larvae fed ISO presented lower dry weight compared to the other dietary treatments whereas the total length of post-larvae fed NANO dietary treatment increased compared to those fed the ISO diet.

Regarding immune status, an increase in lysozyme levels and bactericidal activity against *T. maritimum* of the whole post-larvae in fish fed TETRA and SKELO, respectively, it was observed. Catalase and superoxide dismutase activities presented lower values in fish fed NANO, TETRA and SKELO when compared to CTRL and ISO dietary treatments. Reduced glutathione: oxidized glutathione ratio was shown to be lower in post-larvae fed ISO and NANO dietary treatment, but contrary to NANO, post-larvae fed ISO increased their levels of glutathione S-transferase. The mRNA expression levels of hepcidin, interlukin-10, toll-like receptor 1 and toll-like receptor 5 were up-regulated in fish fed NANO dietary treatment compared to the other dietary treatments.

(Continued on next page)

Discussion and conclusion

Results from the present study seem to be in line with the widely known recognition of microalgae in terms of antioxidant capacity and growth promotion, which usually translates into good welfare of farmed fish. Senegalese sole post-larvae fed dietary treatments presented normal ranges for growth performance and survival. Fish homogenates reveal that in general NANO improves the antioxidant system, whereas SKELO and TETRA showed improvements in fish immune status. Nonetheless, molecular biomarkers in fish fed NANO suggested that this microalga seems to also improve the Senegalese sole immune status by the up-regulation of immune related genes, such as toll-like receptor 1, toll-like receptor 5, hepcidin and interleukin-10. This up-regulation can be related to the described immunostimulatory characteristics of *Nannochloropsis* sp., improving the innate defense mechanisms in the fish and thereby providing enhanced resistance to pathogens. According to results from the present study, *Nannochloropsis sp*., *Skeletonema* sp. and *Tetraselmis striata* seem to be promising candidates for inclusion in microdiets for Senegalese sole post-larvae.

Introduction
Nowadays Mediterranean farmed gilthead sea bream (*Sparus aurata*) production and health is threatened by the hematophagous gill parasite *Sparicotyle chrysophrii* (Sitjà-Bobadilla et al., 2010). To counteract this problem, natural functional feeds could be a sustainable solution to promote fish health, to help the animal ward off pathogens, and to reduce the use of chemical treatments thus minimizing environmental impact (Rigos et al., 2016; Firmino et al., 2020). To this aim, the present study explored the effect of two different natural functional feeds at two different dosages on gilthead sea bream growth and welfare conditions.

Materials and methods
Five iso-energetic and iso-proteic diets (42% crude protein, 18% crude fat, digestible energy 17.3 MJ/kg) were tested in triplicated fish groups: one as control, and other four containing natural additives - caprylic acid (CA), and a blend of organic compounds (MIX) - at two different dosages (5 and 10 g/kg MIX as MIX5 and MIX10, 15 g/kg and 30 g/kg as CA15 and CA30, respectively). Fish (initial body weight: 71.7 g) were fed to visual satiation twice a day over 79 days. To evaluate both additive and dosage effects, samplings occurred at the beginning (T0) and at the end of the trial (T1). Growth performances, feed utilization and carcass composition were estimated. To access fish welfare response, gill arches were sampled from 3 fish per tank for histomorphology evaluation and plasma biochemistry and haematocrit were performed from 5 fish per tank.

Growth and proximate composition data were analysed by one-way ANOVA, while plasma biochemistry and haematocrit were analysed by two-way ANOVA followed by a Tukey's multiple comparison test. Differences among treatments were considered significant when P value was lower than 0.05.

Results
Significant diet effect on growth (final body weight FBW, weight gain WG, specific growth rate SGR) was detected, with highest values for animals fed MIX10 and the lowest for ones fed CA30. Significant differences were found on feed intake (FI) and feed conversion rate (FCR) with lowest values in specimens fed CA30 and highest in ones treated with MIX10. Concerning nutritional indices, significant diet effect was found on protein and lipid efficiency ratios (PER and LER, respectively), with most elevated values in animals fed CA15 and CA30. On proximate body composition, no significant diet effect occurred. Among most relevant plasma analytes, iron content and haematocrit displayed significant diet effect, with an overall increase for all treatments at T1. On gill arch histomorphology, no significant differences were found among treatments.

Discussion and conclusion
Preliminary growth results suggested that MIX10 additive exerted a major growth in sea bream rather than CA dosages. On the other hand, protein and lipid utilization were slightly improved by CA added diets. Furthermore, the comparable iron level in plasma and haematocrit increased in all diets at T1 with no morphological alteration of gill arches. In particular, MIX5 and MIX10 seemed to display a stronger increment in plasma Fe compared to the other diets results that may suggest the potential of the tested additives to alleviate anaemic conditions caused by *Sparicotyle* infections (Sitjà-Bobadilla and Alvarez-Pellitero, 2009). In conclusion, this study provided a preliminary investigation concerning the growth and pro-health effect of natural functional additives necessary for a further in-field investigation in order to alleviate *Sparicotyle chrysophrii* outbreaks in gilthead seabream.

The work presented here is one of 11 so-called “application experiments” (AE) embedded in a consortium of more than 30 partners in the EU-project DIH4CPS (digitial innovation hubs for cyber-physical systems). Our AE titled “Smart Aquaculture” is about digital innovations in an Indoor Shrimp Farm in Germany (www.die- landgarnele.de). Indoor aquaculture is a growing sector of food production but still in a young stage of development, to be enhanced by using the opportunities of digital technologies.

One central issue is the determination of the optimum daily feed dose, which is related tothe live biomass in a tank. So far the biomass largely is an estimate based on assumptions on growth and survival rate of the cultured organism. This can easily lead tounderfeeding or overfeeding, both may have negative effects: either reduced growth or reduced water quality, in turn creating reduced growth. Accordingly, a sustainable production requires the knowledge of how much live organisms are present in a tank at any time, giving reliable values for their feed demand.

Still, the operation of an indoor aquaculture plant largely is based on manual data assessment and data evaluation. Thus, important information is not readily available in situations when rapid decision-making on adequate measures to positively influence theproduction process is required. This leads to significant inefficiencies and overall to a poor performance of the plant.

As a first step to support the operator in decision-finding all data must be brought together, which is achieved by an IoT platform. The PLC data of the plant are transferreddirectly to the platform. Some parameters cannot be measured online and are acquired, e.g. by manual sampling or laboratory tests. These values have so far been stored in separate protocol files, but not returned to the system. In this regard, an app was developed to speed up manual data collection. These data are now stored directly in theIoT platform.

Data visualization is another step to support the operator by providing an overview aboutwhat is going on in the plant at any time. For a comprehensive understanding of all collected data these are processed to give a clearly arranged visualization. A pending task is the interpretation of this data collection by applying AI.

In future steps, the collected data will be analysed by AI and trends as well as correlations will be searched for. Through the further analyses, detrimental developments and errors can be detected and prevented at an early stage. This way the operation of an aquaculture plant can be simplified, and the yield can be increased as astep towards a more sustainable way of producing animal proteins for human consumption.

DOES INDUSTRIAL PROCESSING AFFECT HEALTH AND NUTRITIONAL PROPERTIES OF AQUACULTURE SEAFOOD PRODUCTS?

Irene Peral*[1], Raquel Llorente[1]

[1]AZTI, Food Research, Basque Research and Technology Alliance (BRTA), Parque Tecnológico de Bizkaia, Astondo Bidea, Edificio 609, 48160 Derio, Bizkaia, Spain

Introduction

Aquaculture is one of sectors for seafood production with higher potential of growth which allows the suitable maintenance of fish consumption in the world, which make up 60% of total fish consumption, but is expected to continue rising (FAO, 2018). Thus, new food products based on aquaculture products are required on the market to fill the consumers´ needs. For this reason, AZTI (Spain) has successfully developed four new food products based on aquaculture species (seabass, gilthead seabream and meagre) in the frame of H2020 MedAID project.

Global health authorities recommend consuming fish on a regular basis as part of a healthy diet due to their rich source of nutrients including protein, minerals and micronutrients. Particularly, dietary recommendation for fatty fish indicates a consumption of one to two portions per week (ISSFAL, 2004). Farmed gilthead seabream, seabass and meagre supply a high level of omega-3 long-chain polyunsaturated fatty acids, particularly eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids (Llorente, 2020).

However, when these raw materials are employed by food industry to develop other final products, their nutritional composition might change due the fish flesh content and the ingredients employed in the product formulation and depending on the industrial technology applied. So, the aim of this study was (i) to analyse how the nutritional composition varies in the new aquaculture seafood product elaborated in H2020 MedAID project from seabass, gilthead seabream and meagre raw materials and (ii) to determine the potential nutritional and health claims might be made on these aquaculture products.

Materials and methods

Fillet samples from fresh aquaculture seabass, gilthead seabream and meagre and the final products derived from them were analysed in quadruplicate for moisture, ash, crude protein, fibre and fat content employing AOAC methods. Salt content was calculated theoretically using USDA Nutrient database. The sugar profile was analysed by gas chromatography mass spectrometry GC/MS and fatty acid profile by gas chromatography and flame ionisation detector (GC–FID) extracting and converting fatty acids to methyl esters. Total Energy (kcal/kJ) was calculated theoretically using conversion rates of Food Regulation (EU) 1169/2011.

Taking into account the nutritional composition obtained previously, nutritional and health claims related to protein and fat content in final products developed were evaluated according to Food Regulations (EU) 1924/2006 and (EU) 432/2012.

Results

The nutritional composition obtained in fresh fish and processed products is described in Table 1. Differences among raw material and final products can be explained by the fish flesh percentage in the final product and other ingredients employed in food formulation, but not by the industrial processes applied. Such processes as cutting, chopping, mixing, stuffing, pasteurization and freezing did not affected nutritional composition due to an optimization of processing parameters and food ingredients selection.

Nutritional claims linked to the high protein content and fatty acid profile are presented in Table 2. Due to their high composition of unsaturated fatty acids, health claims could be included in the marketing of this product. Specially, in the case of unsaturated fatty acids, EPA and DHA, those related to the heart and brain function, normal vision and maintenance of normal blood cholesterol levels.

Conclusions

Aquaculture seafood products with high quality nutritional profile can be developed by food industry as a healthy option for consumer due to their high protein content and fatty acid profile, specially DHA and EPA. Good formulation and technological practices assure the nutritional value of them.

Introduction

Nutrition can have significant health implications for animals. Grape seed are reportedly rich in polyphenols [1], whereas some micro and macroalgae genus are rich in carotenoids and vitamins [2]. Some of these bioactive compounds have the ability to modulate the oxidative status and immunity of several fish species and it is reasonably studied [3]. Tenacibaculosis is an ulcerative disease caused by *Tenacibaculum maritimum* that affects diverse fish species, including *Solea senegalensis* [1]. This work aimed to study the effects of dietary supplementation with micro- and macro-algae, and a grape seed extract on immune and oxidative stress responses of Senegalese sole (*Solea senegalensis*) post-larvae subjected to a bacterial challenge assay against *Tenacibaculum maritimum*.

Materials & Methods

Post-larvae of Senegalese sole were reared at SPAROS facilities (Olhão, Portugal) from 30 to 63 days after hatching (DAH) to assess the effects of two experimental diets (Blend and GS). A commercial diet (COMM) served as control, Blend was supplemented with a micro- and micro-algae mixture at 3% of inclusion, while GS was supplemented with a grape seed extract (GSE). All diets were formulated and manufactured by SPAROS with premium marine and plant-based ingredients. Each diet was administered to 3 random replicates (n= 425 /tank), divided in 8 meals in a 24-hour period. Larvae with 63 DAH were transferred from SPAROS to CIIMAR facilities and were immediately subjected to a bath challenge assay with *Tenacibaculum maritimum*. Bath infection was performed for 12 hours in 20 L with 5 x 10^2 cfu/mL of bacteria. Larvae from 9 tanks were separated in unchallenged (n= 50) and challenged treatments (n= 100), where both treatments had equal handling conditions, except for unchallenged groups where marine broth was used instead of bacteria. Feeding was not provided during infection but continued with the same scheme after that period. After 1 and 3 days post-infection (DPI), pools of larvae (n= 15 per tank) were sampled to assess immune parameters and oxidative stress biomarkers.

Results & Discussion

Regarding immune parameters, peroxidase activity increased in unchallenged larvae fed GS compared to COMM after 3 DPI, also shown in [4] with different doses of GSE. Considering oxidative stress responses, superoxide dismutase (SOD) activity decreased in unchallenged larvae fed GS compared to COMM after 1 DPI, this trend also found in other fish species supplemented with various doses of *Vitis vinifera* oil [5]. However, in our study SOD activity increased in challenged larvae fed GS. Total glutathione (GSH) levels increased in challenged larvae fed Blend compared to COMM diet after 1 DPI. Those levels were also higher than unchallenged larvae fed Blend. These results could suggest boosting of GSH synthesis influenced by alga extracts supplementation, unlike what described by [2], that showed its decrease. Moreover, catalase (CAT) activity increased in challenged larvae fed GS compared to unchallenged ones fed with the same diet after 1 DPI, hinting that possibly the bioactive compounds of grape seed extract elicited a boost in the production of CAT. After 3 DPI, alterations were only found in GSH:GSSG ratio, where challenged larvae had significant lower ratios in Blend and GS diets than the unchallenged ones. These results might indicate higher amounts of oxidized GSH (GSSG) in larvae.

Conclusions

In conclusion, diets supplemented with grape seed extract and a blend of micro- and macro-algae seem to benefit oxidative stress responses in sole. Still, gene expression analyses are in progress to allow a better understanding of the health-related effects of these diets in post-larvae of Senegalese sole.

Aquaculture development in the Mediterranean is limited by several constraints relying on zootechnical, ecological, economic and social issues. Social acceptability (SA) is one of the main bottlenecks to aquaculture development. This concept is complex to apprehend since it includes considerations which are vague and intangible. SA is the result of social interactions that lead to the acceptance or opposition to private or public decision-making processes from one or several social groups. The increasing complexity of interactions between ecosystems and social systems in coastal and marine areas exacerbates this problem mainly in the case of new activities development. Aquaculture is a recent activity that is trying to find a place in the blue economy but often must to face social opposition from other existing users or by citizens in general.

Many recent works addresses this issue through different perspectives. A large majority of them focuses on the analysis of public opinion to identify the key drivers of SA. In this work, the authors focuses on SA from the institutional and governance perspective with an emphasis on the impacts from social interaction processes.

To investigate this issue, this work analyse the social acceptability of aquaculture development in Andalusia (Spain) in the framework of the H2020- MedAID project. A joint collaboration with the regional agency of Andalusia in charge of aquaculture planning was built to explore the local conditions on coastal areas for the social support of aquaculture development. This concern was considered a key issue to address in the regional plan of aquaculture development that each European Region must to build in the framework of the Common Fisheries policy.

The work conducted emphasises the existence of institutional gaps between the high institutional levels, which build political strategies that are not always suitable to be implemented by local institutions, given the social complexity of the territories. It is also highlighted the lack of frameworks, protocols and means to effectively conduct participatory processes in the context of coastal planning, especially in the case of aquaculture development plans. These shortcomings result in social conflicts, particularly due to the lack of transparency and trust with the Administration as a result of the poor inclusion of stakeholders in decision-making processes. The fieldwork carried out showed that the conditions are not yet in place to conduct participatory processes, even in the framework of an experimental exercise.

HISTOLOGY REVEALS THE TISSUE FACTORS COMPROMISING THE DIFFERENTIAL GROWTH RATE AND PHYSIOLOGICAL PERFORMANCES OF THE MUSSEL *Mytilus galloprovincialis*

Introduction

One of the traits of bivalves that affects aquaculture, and specially mytiliculture, consists in the existence of large differences in growth performances between individuals. A great proportion of such differences appear to be genetically determined and hence to be heritable, and they are turned into measurable differences in the energy balance of individuals. However, genetic clues are not clearly identified and more studies are needed at different biological organization levels to better manage the mussel production. Under high organic content rations, the differences between fast and slow growing individuals are determined by distinct inter-individual capacities to acquire and process food particles, with a higher metabolic efficiency[5]. The size of the digestive gland has also been reported to constitute a gross measurement of the digestive[6] and growth[7] performances, and different gill-surface areas seem to point out a different food acquisition capacity[5]. Yet the underlying structures are still unknown. The aim of these study was to stablish the histological bases of the differential physiological performance between differentially growing individuals of *Mytilus galloprovincialis*.

Methods

Juvenile mussels (shell length of 10.98 ± 0.52 mm) sampled from an intertidal rocky shore were maintained in the laboratory under conditions of continuous feeding with *I. galbana*. After three months, mussels were subdued to a two-week acclimation under two different food-rations: high (H: 50 000 part · mL^{-1}) and low (L: 10 000 part · mL^{-1}). To analyse the differential growth of mussels, the largest 40 (fast-growers – F), the 40 medium-sized mussels (intermediate growers – I) and the smallest 40 (slow-growers – S) were selected and characterized in terms of energetic physiology and histology. The main components of the energy balance (clearance rate -CR- ($L \cdot h^{-1}$) and routine metabolic rate -RMR- (mL $O_2 \cdot h^{-1}$)) were measured following standard procedures[6]. Once the physiological measurements were completed, dissections were performed for histological examination. To determine the status of the digestive gland, the mean epithelial thickness (MET), mean luminal radius (MLR), mean digestive diverticula radius (MDR), and the connective to diverticula ratio (CTD) were quantified. In addition, the adipogranular cell density and the gill integrity were calculated.

Results

Fast mussels were 3.5 times heavier than S ones (1.35 ± 0.21 g *vs*. 0.37 ± 0.08 g), and had almost 70 % larger shell lengths (24.73 ± 1.11 mm *vs*. 14.57 ± 1.11 mm).

Physiological measurements. Both growth condition (F, I or S) and food ration (H or L) exerted a significant effect on the CR of mussels: CR was two times higher at low food ration (0.411 ± 0.16 $L \cdot h^{-1}$) as compared with high food ration (0.233 ± 0.15 $L \cdot h^{-1}$); and fast growers attained two times higher values than slow growers (0.429 ± 0.19 *vs*. 0.216 ± 0.12, respectively). Medium growers (I) had intermediate CR values that were not significantly different to those in F and S mussels. In good correspondence with CR values, the gill surface-area of F mussels was significantly higher than that of S ones, irrespective of the ration. However, no significant effects on RMR were recorded.

(Continued on next page)

Histological assessment. Significant differences in the gills were associated with the growth condition factor. F and I mussels had a higher organization level of the epithelium with an evident higher frontal and latero-frontal cilia density than S mussels. In addition, irrespective of the ration, S mussels had lower MDR and MET values than F and I ones (MDR: 23.53 ± 0.89 *vs*. 26.27 ± 1.23 and 25.72 ± 1.91; MET: 7.50 ± 2.45 *vs*. 13.44 ± 1.98 and 12.29 ± 2.09). Mussels fed high food ration achieved significantly higher MDR and MLR of the digestive diverticula than those fed with low ration. The adipogranular cell index was two times higher in F and I mussels than in S individuals, and no significant effect of food ration was recorded.

Discussion

Both fast and slow growing individuals showed a similar regulatory response to the particle concentration increase through CR reduction, a phenomenon that has been comprehensively addressed and interpreted in bivalves as a mechanism allowing the regulation of ingestion rate and gut passage time[1,2]. In this context, the food acquisition and processing capacities of fast and slow growers differ considerably. This has to do, to a great extent, with the different capacity of their gills, digestive gland and energy-storage capacity, as observed herein. Previous studies[3,4,5] have shown that both inter-specific and size-related intra-specific differences in CRs may be explained by corresponding differences in gill surface areas. The data from the present study not only agrees with that, but also has revealed that gills of slow growers possess a lower cilia density and a disorganised structure overall. Histological analysis showed that F individuals have a greater digestive capacity, thanks to a higher digestive diverticula to connective tissue proportion, and larger and thicker digestive diverticula, which could lay bare higher intracellular digestive and absorption capacities. In addition, fast growers showed a higher level of investment in storage in the form of adipogranular tissue, which is expected to reflect an increase in gamete production. These evidences could be of a mayor importance since the selection of animals with enhanced digestive capacity and growth conditions could be an improvement in aquaculture management.

PHYSIOLOGICAL BASIS FOR INTER-FAMILY AND INTER-INDIVIDUAL GROWTH VARIABILITY IN THE SPAT OF CLAM *Ruditapes decussatus:* LONG-TERM AND ACUTE GROWTH

Maitane Pérez-Cebrecos[*1,2], Daniel Prieto[1], Irrintzi Ibarrola[1], Kristina Arranz[1], Iñaki Urrutxurtu[1], Miren Bego Urrutia[1] and Enrique Navarro[1]

E-mail: maitane.perez@ehu.eus

Introduction

In bivalve populations reared either under controlled laboratory conditions or under environmental conditions, inter-individual growth rates attain an outstandingly high variability[1,2,3,4]. This variation indicates the existence of endogenously determined differences in the physiological capacity of individuals to acquire and metabolize food energy, which happens to be of great interest in aquaculture, setting a potential for the selective breeding of commercial species of bivalves. Hence, sibling specimens (families) constitute an excellent biological material to test such dissimilarities. The carpet shell clam *Ruditapes decussatus* is one of the most gainful molluscs in European aquaculture. Indeed, the FAO pointed out a global production of 5389 tonnes for this species in the year 2018. In this context, the present study was designed to identify the physiological parameters responsible for the differences between four families (inter-family differences) and between sibling individuals (inter-individual differences) in the growth potential of the clam *Ruditapes decussatus*.

Methods

Four different families (Fam 1, Fam 2, Fam 3 and Fam 4) of the clam *Ruditapes decussatus* were produced simultaneously at the Institut de Recerca i Tecnologia Agroalimentàries (IRTA) (Montbui, Catalunya) and maintained under constant immersion and food supply for 12 months. When arrived at our laboratory, clam spat was classified into two different size-groups based on shell-length (long-term growth): fast growers (F) (> 11 mm) and slow growers (S) (5-7 mm). After three months under identical feeding conditions, again large inter-individual differences were found within those two groups (acute growth), which enabled a new selection by growth condition of fast (F) and slow (S) growing individuals, resulting in four experimental groups within each family: F_F, F_S, S_F and S_S. Six individuals from each experimental group within all the families were employed to measure the complete set of parameters taking part in the energy balance: clearance rate (CR: $L \cdot h^{-1}$), routine oxygen consumption (RMR: mL $O_2 \cdot h^{-1}$), absorption efficiency (AE: decimal units), absorption rate (AR: $mg \cdot h^{-1}$), ammonia excretion rate (U: µg $NH_4 \cdot h^{-1}$), and scope for growth (SFG: $J \cdot h^{-1}$).

Results

After the acute growth, the live-weight of fast growers was around six-fold higher than that from slow growers (Fam 1: 425.2 ± 155.0 *vs*. 61.8 ± 10.9; Fam 2: 402.2 ± 170.8 *vs*. 73.9 ± 22.4; Fam 3: 421.9 ± 146.8 *vs*. 67.2 ± 16.5; Fam 4: 464.9 ± 229.4 *vs*. 72.7 ± 21.3), and the shell-length two-fold larger (Fam 1: 13.6 ± 1.9 *vs*. 6.9 ± 0.5; Fam 2: 13.2 ± 1.7 *vs*. 7.4 ± 0.9; Fam 3: 13.5 ± 1.6 *vs*. 7.0 ± 0.6; Fam 4: 13.8 ± 2.1 *vs*. 7.3 ± 0.9).

Inter-family differences. Both for CR and AR, family 2 attained virtually two-times higher values than family 4 (3.40 ± 1 $mg \cdot h^{-1}$ *vs*. 1.99 ± 0.86 $mg \cdot h^{-1}$). The same pattern was true for U. Such higher clearance capacity was not translated though into higher RMR for family 2; indeed, family differences in the metabolic cost fall to the lower values of family 1, which showed a 63.5 % lower rate. Yet it was family 1 the one with the lowest absorption efficiency. Consistently with CR, AR and U, the SFG of family 2 is roughly 60 % higher than in family 4 (2.37 ± 0.95 *vs*. 0.95 ± 0.56).

Intra-family differences. Irrespective of the growing period (long-term or acute), CR values were persistently higher in the fast-growing groups, without affecting the AE. AR and U followed the same trend recorded for CR. Besides, oxygen consumption rates were not different between sizes or growth conditions, indicating a higher metabolic efficiency for those growing faster. However, the SFG was only affected by the size factor; in other words, the acute growth of clams did not have an effect on their growth potential.

(Continued on next page)

Discussion

The physiological differences underpinning inter-family differences between the faster and slower growing families (2 and 4, respectively), turn out to be similar to those causing intra-familiar differences between fast and slow-growing siblings: higher clearance rates are linked to higher metabolic expenditures and ammonia excretions that, as a balance, give place to an enhanced energy budget. A conceptual framework where the results obtained herein fit together, and that utterly explains the fast-growing behaviour reported at long-term growth, acute growth and family-level (Fam 2 *vs*. Fam 4), is the acquisition model proposed by Bayne[5,6]. This model is supported by a good number of studies[7,8,9], which show that individuals with a high growth-rate, or fast-feeders in this model, hold up their advantage in the capacity to develop higher filtration rates without causing an evident lessening in the absorption efficiency. Nevertheless, the non-significant differences at acute growth or family level in the SFG, evince that the inter-individual growth differences at long-term are such that almost overshadow the effects that the other factors presumably exert upon the growth of individuals. The results obtained imply that not only selective breeding of fast-growing individuals should be encouraged in clam production, but also that the choosing of families that behave as fast growers should be weighed up.

Introduction

The exponential growth of the aquaculture sector requires the development of sustainable aquafeeds with less dependence on marine products. Tolerance to fish meal (FM) and fish oil replacement in the economically important gilthead sea bream (*Sparus aurata*) is being extensively studied with many products emerging as alternative feed ingredients. It has been demonstrated that alternative diets influence the composition of intestinal adherent microbial populations, which have a key role on host metabolism, health and disease resistance. In addition, low fish meal diets showed an increased susceptibility to enteric parasites (Piazzon et al., 2017). Clearly, differences in diet have an impact on the overall health and metabolism of the fish and many parameters have to be taken into account when studying alternative diets for their use in aquaculture. In this study we evaluated the effect of a novel feed formulation (NoPAP SANA) with total replacement of FM by insect meal and bacterial fermentation biomass, and supplemented with the health-promoter additive SANACORE®GM (Palenzuela et al., 2020), on growth performance, gene expression, intestinal microbiota and disease resistance in gilthead sea bream.

Methods

Tagged gilthead sea bream of mean weight 21.3 g were distributed in two open-flow tanks (160 fish/tank) and fed *ad libitum* during 34 days with control or NoPAP SANA diets. Twelve fish/diet were sacrificed and head kidney (HK), liver (L) and posterior intestine (PI) were taken for RNA extraction. From the same fish, the adherent bacteria of PI were collected and immediately used for DNA extraction. RNA from HK, L and PI was used to run three customized PCR-arrays including genes of interest for each tissue, with markers of performance and metabolism (L), immune system (HK and PI), epithelial integrity, nutrient transport and mucins (PI). Using the bacterial DNA, the V3-V4 region of the 16S rRNA of each individual sample was amplified and sequenced by Illumina MiSeq. After quality filtering, taxonomic assignment was performed with a custom-made pipeline using the RDP database. Alpha diversity was calculated using Phyloseq and beta diversity using PERMANOVA and PLS-DA models. Metagenome prediction and pathway analysis were performed using Piphillin. Differential gene expression and OTU presence and abundance correlations were studied using the corrplot R package. From the remaining fish, 70 fish/group were challenged with the intestinal parasite *Enteromyxum leei* by effluent exposure and the remaining fish were used as controls. The challenge lasted 78 days, including a non-lethal diagnosis sampling at day 40. At the end of the challenge all fish were sampled for histological and molecular diagnosis. Biometric values from all fish were taken in all sampling points.

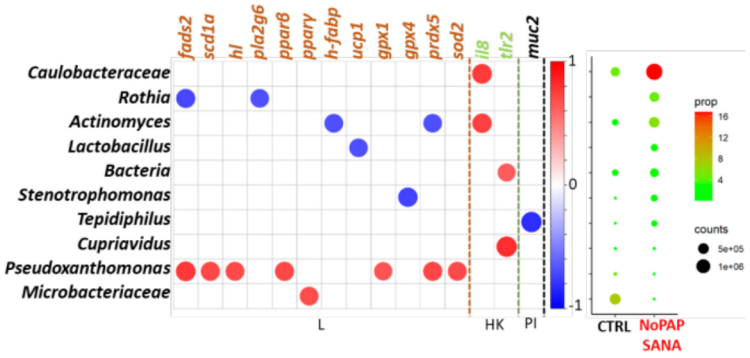

Figure 1: Correlation plot showing significant correlations between OTUs and liver (L), head kidney (HK) and posterior intestine (PI) differentially expressed genes. Positive and negative correlations are represented in red and blue, respectively. On the right, dotplot depicting the relative abundance of the respective OTUs in proportion (colour scale) and normalized counts (dot size).

(Continued on next page)

Results

A slight decrease in condition factor and specific growth rate was detected in the NoPAP SANA group. However, all fish grew efficiently considering gilthead sea bream standards. NoPAP SANA group showed differential expression of 17 out of 44 genes in L, two out of 29 in HK, and 4 out of 44 in PI. The bacterial composition at the PI showed no major differences in diversity or at the phylum level. However, 29 abundant (>1%) OTUs significantly changed with the diet. From these, 10 OTUs were significantly correlated with differential expression of genes in the different tissues, highlighting *Pseudoxanthomonas* which was positively correlated with the expression of seven L genes, or *Actinomyces*, significantly correlated with the expression of L and HK genes (Fig. 1). Inferred metagenome analyses revealed that the altered microbiota with NoPAP SANA diet could account for changes in 15 metabolic pathways. The intensity and prevalence of infection after the parasite challenge was not significantly different between diets. In fact, infected fish from both groups showed similar recovery rates.

Conclusions

NoPAP SANA promoted good growth parameters and efficient conversions arising as a good alternative for a FM-based diet in gilthead sea bream diets. This diet modulated the expression of several genes in L showing the capacity to reduce lipogenesis, mitochondrial activity and the risk of oxidative stress and, at the same time, promoting an anti-inflammatory gene expression profile in HK and PI. Changes were also detected in the adherent bacterial populations of PI, with significant changes of OTUs that could potentially account for significant metabolic alterations. The correlations between presence and abundance of intestinal bacteria with changes in gene expression of different tissues, together with the pathway analysis results, show that microbiota changes can have an impact on host metabolism at a systemic level, and *vice versa*. Clearly, the changes induced by this novel FM-free diet supported an accelerated growth with an overall feed conversion ratio close to 1 and no increased susceptibility against this intestinal parasite, as often observed in studies when replacing a FM-based diet.

ONTOGENETIC SHIFT AND LATERALIZED SWIMMING BEHAVIOR IN ATLANTIC HALIBUT (*Hippoglossus hippoglossus)*

P. Perrichon[1*], Ø. Sæle[2], T. Furmanek[2], T. Harboe[1], B. Norberg[1]

[1] Institute of Marine Research, Austevoll Research Station, NO-5392 Storebø, Norway
[2] Institute of Marine Research, NO-5817 Bergen, Norway
* E-mail: prescilla.perrichon@gmail.com

Introduction

Atlantic halibut (*Hippoglossus hippoglossus*) is a large, long-lived flatfish inhabiting boreal and subarctic waters and is an attractive demersal species of high commercial value (Haug, 1990). Despite a slow success in farming halibut in 1980's, juvenile production has increased by 5.4-fold from <300 000 in 2015 to ca 1 500 000 in 2019 and continues to grow. A key component in aquaculture is the production of good quality larvae, which is inherently tied up with the metamorphosis phases in flatfish species (Harboe et al., 2009). Flatfish metamorphoses from bilaterally symmetrical larvae to asymmetric juveniles (body pigmentation and eye migration), with a change in swim posture angle to transit from pelagic to a benthic lifestyle (Figure 1; Sæle et al., 2004).

Processes driving metamorphosis and settlement are important for understanding connectivity between life history stages and to solve major problem related to larval fish health. Variation in life traits is often related to environmental variables (i.e. temperature, turbidity, light intensity, photoperiod, or life feed organisms). Illumination has been shown to be an important factor in control of metamorphosis asymmetry through the endocrine regulation and activation of phototransduction pathway in flatfish skin (Alves et al., 2016; Power et al., 2001; Shao et al., 2017). The body tilting and related lateralized behavior initiated before metamorphosis raise questions about when tissue programming and preparation of the larvae for tilted swimming and metamorphosis are initiated and how these both processes are linked (Schreiber, 2006). This work explored the ontogenetic dynamic of lateralized swimming and the key developmental trigger driving settling side behavior (dependent or independent of light) in Atlantic halibut larvae.

Materials and Methods

Halibut larvae were reared in a 1100 L first-feeding tank on enriched brine shrimp (*artemias*) during 53 day under natural photoperiod. Light were used as a factor influencing the metamorphosis process. Therefore, two rearing light conditions were tested: i) a standard condition with regular top light ("control") and ii) an extra underwater illumination with regular top light. The underwater illumination started after 5 days post-first-feeding. Lighting conditions were tested in triplicates.

A morphological screening was performed at the end of metamorphosis, by manually scoring eyes migration and pigmentation phenotypes, as well as general biometric analyses. Lateralized swimming behavior of larvae was monitored every day during first-feeding in a production tank, using a video system comprised of 4 underwater cameras. Videos were then digitalized using Tracker, a video analysis and modeling tool, and the body tilting angle of larvae were extracted. Comparative RNA sequencing was also conducted in the head regions of larvae to examine the potential mechanisms triggering this lateralized swimming.

Results and Discussion

The developmental window of tilting swimming was identified and preceded the morphological remodeling in Atlantic halibut. The genetic basis for this settling side behavior is ongoing and might contribute to understanding of factors necessary for metamorphosis success in flatfish. Understand biological processes in fish species should be further investigated to better estimate larval welfare and health in aquaculture.

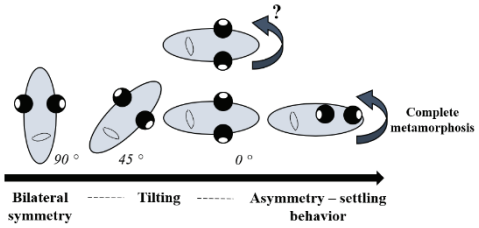

Figure 1. Schematic of the lateralized behavior during metamorphosis in flatfish

EVALUATION OF ENVIRONMENTAL AND ECONOMICAL IMPACTS OF NOVEL FEED INGREDIENTS FROM AQUACULTURE SIDESTREAMS

M. Perucca*, S. Anegalla, S.Truffa

Project Hub 360, Corso laghi, 13, 10090, Buttigliera Alta (TO), Italy.
E-mail: massimo.perucca@project-sas.com

Introduction

The innovative approach of Sidestream project in secondary bio-production of high value compounds by utilization of low trophic marine invertebrates (polychaete worms and gammarid shrimps) and bacteria, which are reared on aquaculture side streams, allows to assess the environmental and economic consequences. In attempts to achieve zero waste following sustainability and circular principles, life cycle assessment (LCA) and life cycle costing (LCC) methods play a major role. Due to the lack of Aquaculture datasets for LCA, these analysis in project gives an opportunity to build database for aquaculture systems. The assessment takes into account the entire life cycle: starting from pre-production stages to the final disposal. The outcomes of the analysis are intended to clarify the methodological choices made, identify possible data gaps, hotspots and provide recommendations in the direction of environmental and economical sustainability.

Methods

The LCA analysis corresponds to the ISO 14040/14044:2006 standards[1] with 11 global, local and toxicological impacts. From a full analysis of methodology in LCA, a modular approach has been accounted for the whole sidestream exploitation routes with specifications in system boundaries, functional units, assumptions and allocations. The analysis also accounts for performing comparisons of project products with the benchmark. The LCA inventory results are evaluated under design for costing through the LCC in order to keep the same or possibly lower the costs for the processing and exploitation of side streams. The analyzed modules are integrated through a synthesis, renormalization and weighting process with reference to the identified functional units allocations (output products) in order to obtain assessment of the whole functional system.

Results

The LCA results are the evaluations of the potential impacts associated with inputs and outputs of a product/process. The inputs section often requires more attention when dealing with material input coming from a sidestream as allocation factors and data sourcing are critical. The following fig.1 shows the preliminary assessment of processing aquaculture sludge which then fed as primary feed to Polychaetes (at lab scale).

Conclusion

The amount of input energy utilized for modular (lab scale) processes should be noted as they determine a relevant contribution to impacts. For the upscaling of the aquaculture sludge processing specific attention has to be paid to the energy efficiency and direct energy sources to comply with the sustainability requirements. Apart from this, developments in the fields of aquaculture databases and data quality for LCA are foreseen to enhance the assessments involved and also allows to perform comparisons with benchmark.

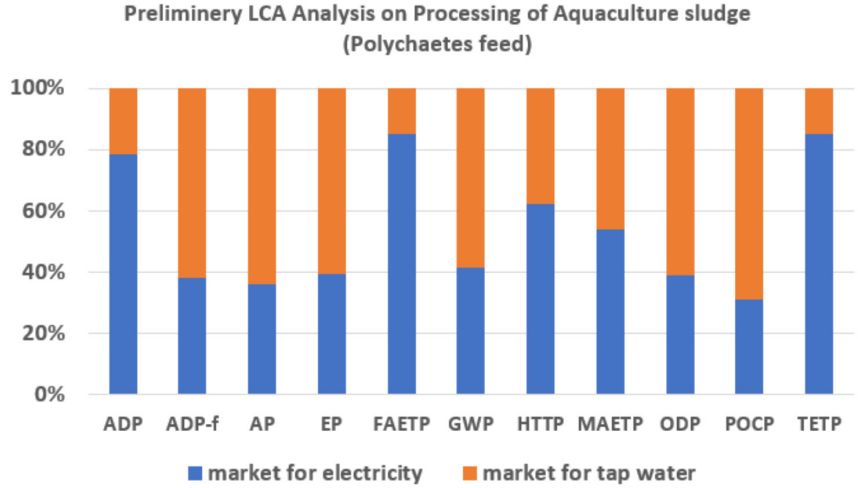

Fig 1: Preliminary LCA analysis on processing aquaculture sludge (model has been developed for 5kg sludge as reference technical Unit).

MARINE HEATWAVES SIGNIFICANTLY IMPAIR THE PERFORMANCES OF MANILA CLAM *Ruditapes philippinarum* AT MULTIPLE PHYSIOLOGICAL LEVELS

Peruzza L.[1*], Bonsembiante F.[1], Panin M.[2], Poli F.[2], Smits M.[1], Manuzzi A.[1], Dalla Rovere G.[1], Babbucci M.[1], Milan M.[1], Gelain M. E.[1], Bargelloni L.[1]

Email: luca.peruzza@unipd.it

Introduction:

Climate extreme events such as Heat Waves (HWs) are a serious threat for marine ecosystems since they can lead to massive mortality of benthic organisms, to biodiversity loss, ecosystem changes and extensive damage for human activities, e.g. aquaculture. One of the most threatened activities from HWs is bivalve aquaculture, since bivalves are particularly susceptible to HWs and are mostly farmed in coastal ecosystems where the effects of HWs will be more intense. However our knowledge regarding the effects of HWs on bivalves at physiological, immune and molecular level is still limited. In order to fill this gap, we used the Manila clam *Ruditapes philippinarum* (the most farmed clam species worldwide and an important ecosystem engineer) as a model species to characterise in detail the responses of clams when challenged by an HW.

Materials and Methods:

A population of 240 Manila clams (shell length 23 – 31 mm) was purchased from SATMAR, one of the biggest hatcheries in Europe and acclimated to lab conditions for 15 days (20 ˚C and 32 psu). After acclimation half population was exposed to HW conditions (30 ˚C for one month) and the remaining half was kept at 20 ˚C as control. After the exposure a series of physiological performances (growth, condition index, hepato-somatic index, clearance rate, burying speed, total haemocyte count) were evaluated in order to reveal the effects of HWs on the physiology of this species.

Results:

No increased mortality in HW-exposed clams was observed during the experiment. Our results indicated a significant decrease in growth, condition index and hepato-somatic index of HW-exposed animals, suggesting that energy reserves were diverted to counteract stressful conditions. Further, the burying speed was significantly increased in animals after the exposure to HW. Interestingly, clearance rate was higher in HW-exposed animals, while no change has been found in total haemocyte count or in the composition of the haemocyte subpopulations (e.g. granulocytes, hyalinocytes).

Conclusions:

Overall, the exposure to HW is able to induce a series of important changes to the physiology of clams, by impairing fundamental processes such as the burying velocity or the energy reserves in the hepatopancreas, thus posing a great concern for the aquaculture sector. Further in depth characterisation of the molecular responses triggered during HW-exposure are currently in place in order to reveal the transcriptomic and metabolomic responses of HW-exposed animals and provide a comprehensive picture of the impact of HWs on the physiology and ecology of the species and on its aquaculture.

COMPARATIVE TRANSCRIPTOMICS OF SUSCEPTIBLE AND RESISTANT NNV-INFECTED GILTHEAD SEA BREAM LARVAL STAGES REVEALS THE PUTATIVE MOLECULAR MECHANISMS OF TOLERANCE TO NNV INFECTION

Peruzza L.[1*], Pascoli F.[2], Dalla Rovere G.[1], Franch R.[1], Ferraresso S.[1], Babbucci M.[1], Biasini L.[2], Abbadi M.[2], Panzarin V.[2], Toffan A.[2], Bargelloni L.[1]

Introduction:

The gilthead sea bream is an important marine fish for Mediterranean aquaculture. This species has historically been considered resistant to viral nervous necrosis (VNN), a devastating fish disease affecting several major aquaculture species. However, with the emergence of RGNNV/SJNNV reassortant strains, also sea bream hatcheries are now seriously threatened, as these viral strains severely affect larvae and juveniles. While host response to betanodavirus in adult fish has widely been investigated, little is known regarding the most sensitive early life stages and currently the transcriptomic response of gilthead sea bream to RGNNV/SJNNV reassortant is still limited. Interestingly, early life stages (i.e. larvae younger than 35 days) are susceptible to VNN, while later stages (i.e. larvae older than 35 days) are resistant. This offers a unique opportunity for a comparative approach in order to understand the transcriptomic mechanisms that are triggered in susceptible vs resistant larvae, understand the genes and pathways that are activated in resistant larvae and pinpoint the molecular bases of resistance to RGNNV/SJNNV.

Materials and Methods:

This study reports the first time-course RNA-seq analysis on 21-day old (susceptible) and 35-day old (resistant) sea bream larvae experimentally infected with a RGNNV/SJNNV strain. Infected and mock samples from each developmental stage (i.e. 21 and 35 days) were collected at 6h, 12h, 24h, and 48h post infection (hpi). Four biological replicates, of five pooled larvae each, were analysed at all the time points.

Results:

Results highlighted a large set of significantly regulated genes, especially at 6hpi and 12hpi in 21-day old larvae. Particularly, several heat shock protein encoding transcripts were up-regulated (e.g. *hspa5*, *dnaj4*, *hspa9*, *hsc70*), while many immune genes were down-regulated (e.g. *myd88* and *irf5* at 6hpi, *pik3r1*, *stat3*, *jak1*, *il12b* and *il6st* at 12hpi). A gene set enrichment analysis (GSEA) was implemented to identify altered pathways/processes. Interestingly, many immune processes were found down-regulated in susceptible larvae and up-regulated in resistant larvae. In particular, the neutrophil degranulation process was down-regulated at 6hpi, 12hpi and 24hpi in susceptible larvae, while it was up-regulated at 6hpi, 12hpi and 24hpi in resistant larvae; the autophagy pathway was down-regulated at 6hpi in susceptible and resistant larvae, while it was up-regulated at 12hpi and 24hpi in resistant larvae only; the peroxisome, an important component of the antiviral immunity, was down-regulated at 6hpi in susceptible larvae, while there was no impairment of this process in resistant larvae; the immune system process was up-regulated at 12hpi and 24hpi in resistant larvae while it was not differentially regulated in susceptible larvae.

Conclusions:

Differently from previous studies in which it was proven that the RGNNV strain is able to induce mortality only in sea bream larvae infected by intramuscular route (while no mortality nor severe NNV signs are observed in older fish), our data confirms the hypothesis that the reassortant RGNNV/SJNNV induces transcriptional changes in the early larval stages of this species putatively by interfering with important immune processes and ultimately leading to the death of infected larvae.

DIETARY ROTIFERS REQUIREMENT FOR ZEBRAFISH OPTIMAL LARVAL GROWTH AND SKELETAL DEVELOPMENT

Introduction

Currently, saltwater rotifers (e.g., *Brachionus plicatilis*) represent an excellent live food to be used for zebrafish (*Danio rerio*) larval feeding. They are considered better than *Artemia salina* nauplii for several reasons: smaller size, higher reproductive rate, adaptability to salinity and temperature changes, and slower swimming behaviour (Lawrence et al., 2015). Even though their nutritional profile is suboptimal for fish larvae, they are filter feeders and can be enriched through bioencapsulation, generally with microalgae containing a balanced nutritional value (such as *Nannochloropsis* sp.). This method allows the improvement of rotifers nutritional profile according to the predator's requirements (Rodríguez et al., 1996). Since the 1970's, rotifers have been intensively used in zebrafish facilities, yet a standardized feeding protocol (i.e., rotifers concentration, bioencapsulation, etc) to optimize zebrafish growth and larval quality has not been established. Several authors and studies used different concentrations of rotifers, thereby making it impossible to cross-check and make comparative assessments (Allen et al., 2016; Aoyama et al., 2015; Hernandez et al., 2018; Martins et al., 2016; Monteiro et al., 2018).

The aim of this study was to estimate the optimum concentration of rotifers that meets the zebrafish nutritional requirements during larval development, and the optimization of resources in zebrafish production.

Materials and Methods

Wildtype zebrafish embryos (AB) were obtained from an in-house breeding program. At 5 days post fertilization (dpf), larvae were selected and divided in 15 tanks in a static condition, in 1L of water with a density of 98.3±7.3 larvae L^{-1}. At 15 dpf, water level was increased to 2 L and larval density adjusted at 38.4±5.47 larve·L^{-1} in order to maintain biomass density and promote growth. Salinity was adjusted daily to 4 ppt, with the scope of maintaining salinity within the tolerance range of both zebrafish larvae and rotifers, without impacting the swimming behaviour of live preys. Photoperiod was set as 14h light :10h dark. Five different rotifer concentrations were added daily to each tank for 25 days (25, 50, 100, 150 and 200 rotifers·mL^{-1}). Rotifer concentrations and health of the culture was evaluated on a daily basis. Prior to feeding, rotifers were enriched with 2mL·mL^{-1} of *Nannochloropsis* sp. liquid concentrate (19% microalgae dry weight, Green Formula, Necton SA, Olhão, Portugal) for 2h. A 100% water renewal was performed daily in fish tanks. Zebrafish growth parameters (i.e., total length, body depth, wet and dry weight) were assessed at 15 and 30 dpf. In particular, in order to assess zebrafish total length and body depth, whole larvae were imaged using a Leica MZ10F stereoscope and analysed using ImageJ 1.53v software. To assess dry weight, zebrafish were dried for 24h at 60°C in VWR VENTI-line® drying oven and weighted with a Sartorius (MSA36S-000-DH) microbalance. Finally, to evaluate the impact of the different treatments on zebrafish skeletal development, fish from the second sampling were fixed in PFA 4% and stained with alizarin red S (0.05%). The mineralization of bone structures and incidence of skeletal deformities was determined through stereo microscopical observation.

Results and Discussion

Our results showed a significant difference in growth among the groups, with a statistically significant higher growth in terms of total length, body depth and weight in fish fed with 100, 150 and 200 rotifers mL^{-1} at 15 dpf (Figure 1 A), while only fish fed with 150 and 200 rotifers mL^{-1} had a significantly higher growth at 30 dpf (Figure 1 B). Analysis of the skeletal anomalies revealed that lower rotifer concentrations did not induce a higher incidence of skeletal anomalies or affected skeletal development and larval quality, although it showed a reduction of growth and mineralization status of the larvae. These results indicate that it is possible to feed zebrafish larvae using a lower number of rotifers than previously reported (Aoyama et al., 2015; Hernandez et al., 2018; Lawrence et al., 2015).

Introduction

Aquaculture feeds are urgently needing alternative sources of protein for the declining fish meal supplies as well as their mostly unsustainable origin (Ceccotti et al., 2019). Most of these current alternatives consist of plant-based ingredients, whereby these alternative protein sources often lead to a decreased digestion rate, health as well as welfare of the fish across species (Booman et al., 2018; Pelletier et al., 2018).

In our study, we investigated the effect of alternative feed formulation on growth characteristics, feed utilization and stress response of European seabass (*Dicentrarchus labrax*).

Material and Methods

From June to September 2020 experiments were conducted with European seabass in a recirculating aquaculture system (RAS) at the Alfred Wegener Institute (Bremerhaven, Germany). Fish were kept at standardized conditions (20 ± 0.9 °C, 95.21 ± 6.71% oxygen saturation, salinity 49.95 ± 0.87 mS cm^{-1}, pH 7.7 ± 0.04) in 700 L tanks (1 m^2 bottom area) throughout the entire trial.

A total of 375 fish were individually pit-tagged and randomly distributed to 15 tanks (25 fish/tank). The mean fish weight was about 320 g ± 72.4 g as well as the mean fish length about 30.5 ± 2.1 cm. Fish were fed twice a day (at 9:00 a.m. and 2:00 p.m.). Feeding at 9:00 a.m. was based on approximately 50 g pellets/tank and the feeding at 2:00 p.m. was *ad libitum*.

Five experimental diets (Sparos Ltd, Olhão, Portugal) were tested in four replicate tanks: (i) control (CTRL) consisting of 18 % fish meal and 10 % poultry meal; (ii) no processed animal protein (NOPAP) consisting of approx. 3 % fish meal from hydrolysates and 35 % insect meal, fermented biomass and algae; (iii) processed animal protein (PAP) consisting of 3 % fish meal from Hydrolysates and 31 % animal and insect meal; (iv) PLUS consisting of 23 % fish meal and was used as a positive control for the best growth performance; and (v) MINUS consisting of 3 % fishmeal and 34 % animal protein and was used as a negative control for growth performance (see Table 1).

Every four weeks all fish were weighted and measured in length to identify the growth performance. Additionally, blood and organs were sampled of five fish per tank at the end of the trial to identify the health and welfare parameters. Further, another five fish per tank were sampled at the end of the trial to identify the sensory quality of the fish filet.

Table 1 Diet formulation for 4 alternative diets in European seabass and the commercial CNTRL feed.

Ingredients (%)	CTRL	NOPAP	PAP	PLUS	MINUS
Fish meal	18.0	3.0	3.0	23.0	3.0
PLANTs					
PAPs	10.0		21.0		34.0
Insect meal		15.0	10.0	13.5	
Fermentation biomass		20.0	15.0	16.0	
Macroalgae & Microalgae		2.8	2.8	2.8	2.8

(Continued on next page)

Results and Discussion

The parameters for the growth performance showed no difference between the alternatively fed diets, neither for final weight (lowest MINUS group 459 ± 104 g; highest NOPAP group 475 ± 102 g), nor for voluntary feed intake or condition factor (lowest MINUS group 1.18 ± 0.006; highest PLUS group 1.21 ± 0.02). Significant differences were found in the relative growth rate between the control group and the fish fed NOPAP, MINUS and PLUS diets. This indicates that the fish fed the control group still had the best growth performance. However, this trend was not observed for the FCR, as the control group was not significantly different from the fish fed the alternative diets.The results showed slightly decreased health parameters for the PAP and MINUS groups with a significant increase in the viscerosomatic index between the fish fed the control/PLUS diet and the fish from the MINUS group.

The biochemical analyses of the fish plasma was conducted for a better interpretation of the growth parameter results as well as the fish stress response (Papaharisis et al., 2019). Lactate dehydrogenase showed no significant differences, ruling out diet-dependent effects on the inflammatory response of the fish. Blood parameters glucose and lysozymes did not show significant differences between fish fed the alternative diets, but interestingly, total protein content showed significant differences. Further analysis of the data is needed to better interpret the alternative diets in regard to welfare parameters.
Sensory analysis of the fillet showed no significant differences in taste, odor, juice deposition, protein deposition, and fat deposition. Post-cooking consistency was affected by the alternative diets, with fish fed the control being significantly firmer to the bite than fish fed the MINUS and PLUS diets.

Overall, these preliminary results seem to support the hypothesis that the NOPAP and PLUS diets are viable options for feeding European seabass compared to the commercial diet (CNTRL). However, results showed slightly decreased health parameters for the PAP and MINUS groups, while sensory function was not significantly affected by any of the diets tested (except for consistency after cooking). Interestingly, fish fed the PLUS diet had significantly lower total plasma proteins and significantly firmer-to-bite filets after cooking.

Introduction

To conserve and sustainably use aquatic resources, the reduction of the environmental footprint of aquaculture feeds has become a high priority (Hardy and Barrows 2003; Olsen and Hasan 2012). The challenge is to feed farmed fish with diets that are nutritious but at the same time economically and environmentally sustainable (Glencross et al. 2020). In Europe, turbot (*Scophthalmus maximus*) aquaculture has a high potential for sustainable production but the low tolerance to fishmeal replacement in the diet represents a big issue (von Danwitz et al. 2016). Therefore, this study investigated the effects of more sustainable feed formulations on growth and feed performance of market sized turbot in recirculating aquaculture systems.

Material and Methods

In a 16-week feeding trial (trial registration number 500-427-103-1/2019-1-19) with 301 ± 10 g turbot, one control diet (CTRL) and four experimental diets were tested. The CTRL was based on a commercial formulation and in the experimental diets, 30% and 60 % of fishmeal was substituted with insect meal and fermentation biomass. Furthermore, the plant protein content in the control was replaced by sustainable terrestrial plant proteins (PLANT) or processed animal proteins (PAP) (see Table 1). 400 fish were individually marked with pit tags and distributed randomly into 20 tanks with 4 tanks per diet. During the trial period the turbot were fed twice a day and measured and weighed every four weeks.

Results and Discussion

Turbot from the CTRL group had on an individual basis (n=65) a significantly higher weight gain (210 ± 87 g) and growth rate (0.46 ± 0.17 % d^{-1}) than the PAP30, PAP60 and the PLANT60 group (158 ± 63 g, 0.37 ± 0.13 % d^{-1}; 149 ± 72 g, 0.35 ± 0.13 % d^{-1} and 159 ± 75 g, 0.37 ± 0.14 % d^{-1} respectively). The FCR was significantly lower in the CTRL (1.3) compared to the PAP30, PAP60 and the PLANT60 group (1.7; 1.9 and 1.7 respectively); with no significant differences to the NOPAP30 group (1.5). The weight gain (184 ± 66 g), growth rate (0.42 ± 0.11 % d^{-1}) and FCR (1.5) in the NOPAP30 group did not differ significantly from the CTRL.

In general, the PLANT diets with insect meal and fermentation biomass performed significantly better than PAP in market sized turbot. Furthermore, the performance of the diets significantly decreased with the substitution level, with no interaction between the protein source and substitution level. In conclusion, the PLANT diets are more suitable, but the lower costs for diets with PAPs might be an economic benefit for turbot farmers outbalancing the slightly poorer growth and feed performance of turbot.

Table 1 Formulation of the five experimental diets for marked sized turbot

Ingredients (%)	CTRL	PLANT 30	PAP 30	PLANT 60	PAP 60
Fishmeal	40.0				
Fishmeal from by-product		28.0	28.0	16.0	16.0
Fish protein hydrolysate	4,0	4,0	4,0	4,0	4,0
PLANTs	42.0	30.0	12.0	30.0	12.5
PAPs			21.0		21.0
Insect meal		9.0	9.0	14.0	14.0
Fermentation biomass		9.0	9.0	14.0	14.0
Krill meal		3.5	3.5	3.5	3.5
Macroalgae & Microalgae		2.5	2.5	2.5	2.5
Lipids	11.5	11.0	10.0	11.5	10.0
Vitamins, Minerals, AAs etc.	2.5	3.0	2.0	4.5	2.5

Introduction

Animal welfare represents a key issue in global and European strategies for sustainable food production, including aquaculture (Keeling et al., 2019; Green Deal, F2F). The strategic guidelines for EU aquaculture highlight the need to improve the welfare of farmed fish, focusing on good farming practices and the use of common, validated, species-specific and auditable welfare indicators (COM(2021) 236 final). Sea bass and sea bream are major marine species farmed in Mediterranean with over a billion of specimens harvested every year (www.fishcount.org.uk). Operational welfare indicators (OWIs) and benchmarking systems are thus necessary to measure the welfare of these species during farming cycles. This work describes the *Bass&Bream Welfare Scoring Tool (BBW-Tool)*, a methodology developed in PerformFISH project (http://performfish.eu/) with the aim to assist the Mediterranean Marine Fish Farming sector in evaluating fish welfare and improving welfare standards.

Materials and Methods

The BBW-Tool has been developed following the composite indicators approach which consists in a wise aggregation of a certain number of elementary indicators representing different issues of the same multi-dimensional phenomenon (Alaimo & Maggino, 2020). The tool measures the welfare of sea bass and sea bream in different sea cage systems across the Mediterranean Sea during the grow out phase.

i) *Selection and validation of OWIs* – a set of 9 OWIs was derived by the 9 Welfare-KPIs validated by the MMFF industry for the PerformFISH KPI-benchmarking system (ISPRA, 2018). Additional 15 OWIs were identified through a PerformFISH online welfare survey and the expert judgment (Petochi et al., 2019). A total of 24 animal-based and environmental/management based OWIs make up the BBW-Tool.

ii) *Development of W-Index*: the fish W-Index applies the Adjusted Mazziotta–Pareto Index (AMPI). It requires data normalization and equal weighting of the indicators and is based on a min–max transformation, consisting in re-scaling individual indicators to two 'goalposts', i.e. a min and a max value of each variable across time periods and units (e.g. batches, farms, companies, geographical areas). The normalized values and the aggregated composite indicator fall in the range 70-130 (Mazziotta and Pareto, 2018), allowing the evaluator to identify batches and farms with higher or lower level of fish welfare than the average.

iii) *Testing the BBW-Tool*: the tool has been tested in 12 farms for sea bass and in 10 farms for sea bream. The analysis was performed by individual batch (a group of homogenous rearing units) analysed within the period 2016-2020, for a total of 61 and 54 batches of sea bass and sea bream respectively accounting for about 49 million of stocked fish. Production data have been provided anonymously by companies through the KPI-VRE hosted in PerformFISH Gateway D4 Science (ISPRA, 2018). A subset of 11 OWIs (fish mortalities total, by diseases, at 3 and 10 days after transport-stocking; vaccinated fish; antiparasitic and antibiotic treatments; feed intake; stocking density at harvest; discharged fish at slaughter; oxygen depletion days) was measured at two stages of production cycle: from stocking up to 50g and on whole cycle up to harvest-800g.

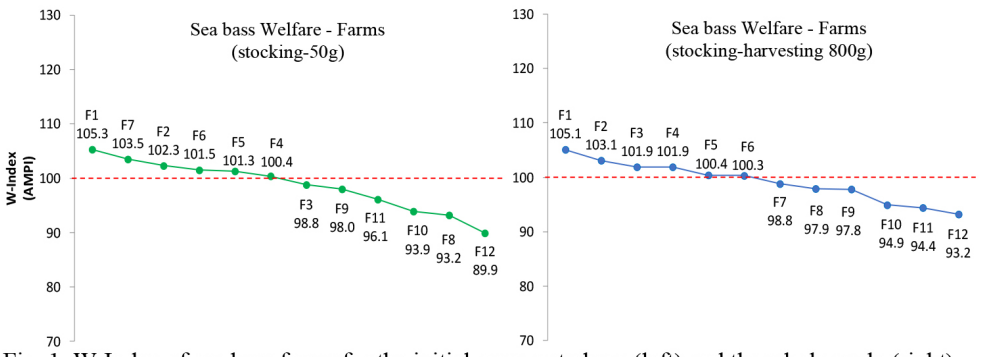

Fig. 1. W-Index of sea bass farms for the initial grow out phase (left) and the whole cycle (right)

(Continued on next page)

Results

Consistently with the assumption of the model, W-Index values for all batches and farms fall in the range 70–130. For sea bass, the W-Index at farm level for the whole production cycle ranges from 93.2 to 105.1. The best performing farm F1 keeps its advantage from stocking and confirms the top of the ranking at harvest. Similarly, the farm F12 shows the worst W-Index, being at the bottom in both ranks. Most of the other farms show improvement or worsening of W-Index between the two phases (Fig.1). Similar patterns result for sea bream data. Additionally, a multivariate linear regression model with W-Index as depend variable and the OWIs as explanatory variables reveals that the most relevant OWIs which negatively affect the W-Index in both species are mortality (total, by diseases, first 3 days) and number of treatments. The "percentage of discarded fish at slaughter" is a key OWI in W-Index, mainly reducing the welfare score in sea bream while "feed intake" increases the W-Index in sea bass. The "percentage of vaccinated fish" positively affects the W-Index in both species.

Discussion and conclusion

Two main challenges in assessing the welfare of farmed fish are: i) construction of a set of reliable welfare indicators and ii) their synthesis in a holistic welfare index. The Adjusted Mazziotta–Pareto Index (AMPI), already applied to measure complex multidimensional phenomena in the field of quality of life and well-being of citizens, has been successfully developed in PerformFISH to provide robust and repeatable assessments of the level of welfare of sea bass and sea bream from stocking to harvest. The BBW-Tool has been tested on 115 batches of sea bass and sea bream in different culture systems across the Mediterranean, and represents a promising non-invasive methodology to assess the overall well-being of sea bass and sea bream for:

- Company self-evaluation and benchmarking; audits, official controls
- Code of Conduct and certification standards
- Improving social acceptability of Mediterranean aquaculture products

Introduction

Disease outbreaks caused by different nontuberculous mycobacteria (NTM) in Mediterranean farmed fish show an increasing trend in recent years (Mataragka et al., 2021; Mugetti et al., 2020, 2021) affecting productions and posing risks for potential zoonosis. This work reports on the first record of systemic mycobacteriosis characterized by cutaneous granulomas occurred in gilthead sea bream (*Sparus aurata*) farmed in land-based systems in Italy.

Materials and Methods

Farming systems: sea bream farmed in land-based recirculating (RAS) and flow-through (FT) tanks were examined for the occurrence of cutaneous granulomatosis episodes on July 2020 and February 2021. Both culture systems are served by wells with water temperature in the range 22-23°C and pH 6.9-7.2. Water salinity was 9.5‰ in RAS and 38‰ in FT. Dissolved oxygen was kept around saturation levels. Fish were analyzed for: i) *Anatomo-histopatology*: a total of 150 fish (200 g) from RAS and 100 fish (400g) from FT farms were examined for the presence/absence of external and visceral nodules. *S*amples of skin, muscle, spleen, liver, kidney, stomach, intestine and brain from symptomatic fish were fixed in 10% buffered formalin and processed through routine histological techniques. Sections were stained with Hematoxylin & Eosin and Ziehl-Neelsen; ii) *Bacterial isolation and identification*: samples from cutaneous lesions, spleen of fish from RAS were inoculated on Löwenstein-Jensen medium and bacterial isolates identified by molecular analysis. Additionally, samples from skin lesions, spleen, kidney and intestine were cultured at 25°C for 24h on TSB and TSA media and bacteria characterized by vitek iii) *Blood chemistry*: after fasting, 30 fish were sampled from RAS and anaesthetized (150mg/l MS 222 Pharmaq) for blood withdrawal. Serum samples were stored at -80°C for analysis of cortisol, osmolality, minerals and metabolic, liver and kidney profiles according to Di Marco et al. (2017).

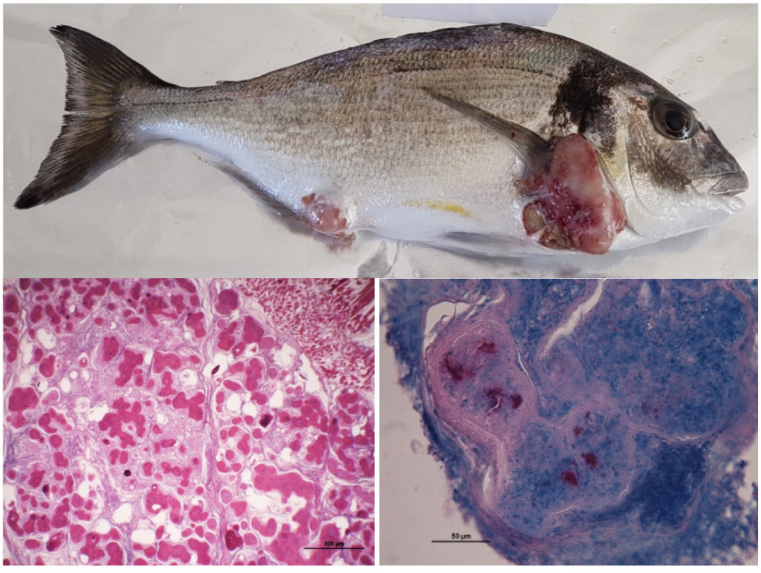

Fig. 1. Skin lesions caused by NTM in sea bream (top). Multiple granulomas in dermal tissue (H&E, bottom left); acid-fast bacilli stained in red inside granulomas (ZN, bottom right).

(Continued on next page)

Results

Prevalence of fish with cutaneous granuloma differed between farming systems, being 69% in RAS and 3% in FT. Clinical signs of disease were characterized by reddish-pinkish colored hyperplastic nodules with different degree of severity, ranging from pinhead-sized lesion (79%) to larger granuloma (21%), with necrotic foci. Lesions were observed on the lateral side, at the base of fins and tail, head, eyes and operculum (Fig. 1). No multifocal nodules were observed in the visceral organs and only two fish from RAS displayed a small single subcapsular nodule on spleen.

Histological analysis showed severe chronic inflammation with multinodular granuloma with a necrotic centre and epithelioid organisation in dermal, hypodermal and muscle tissues and other visceral organs, with the exception of brain. All lesions revealed acid-fast bacilli by ZN staining (Fig. 1). *Mycobacterium marinum* was isolated and identified from skin and spleen. Morover opportunistic pathogenic Gram-negative bacteria (*Sphingomonas paucimobilis*; *Aeromonas hydrophila/caviae)* were isolated from the skin lesions.

Serum cortisol, glucose and triglycerides were significantly lower and albumin significantly higher in symptomatic fish. No significant differences were found for other parameters.

Discussion and conclusion

The cutaneous granulomatosis described in the present study is comparable to that one reported in sea bream cultured in RAS in Israel and caused by *Mycobacterium marinum* (Davidovich et al., 2020). Movement of live fish could have been the main source of the infection, especially in the RAS farm where different fish species are farmed (sea bream, sea bass, red drum). Compared to FT, environmental condition in RAS could have further favoured the permanence of pathogens, enhancing fish exposure to mycobacteria and thus resulting in a more severe infection. Blood chemistry analysis revealed a lowering of energy status in symptomatic fish and a worsening of their physiological status probably due to the persistence of chronic stress conditions and systemic inflammation. Since there are still no commercial vaccines and effective treatments against fish mycobacteriosis, epidemiological surveillance, application of strict quarantine, biosecurity protocols and best management practices shall be implemented, also to minimize the risk of zoonosis.

Introduction
Fish meal has been progressively replaced by plant ingredients in salmonid feeds to good effect with respect to macro-nutrients. However, metabolic consequences of altered micro-nutrient supply is less studied. It is known that Zn and Cu are important essential trace elements and involved in several metabolic reactions. Although the role of dietary Zn and/or Cu in influencing lipid metabolism is beginning to be understood in teleost (Zheng et al., 2015; Meng et al., 2016), their practical implications for aquaculture are less clear. It was shown that LC-PUFA bioconversion in fish is improved by a multi-micronutrient supplement including Zn (Lewis et al., 2013; Giri et al., 2016). The requirement for Zn and Cu to rainbow trout is 37 mg Zn/kg feed and 5 mg Cu/kg feed, respectively. Plant based salmonid feeds are limited in Zn supply, while provide excess Cu. These dietary changes warrant investigations on the functional importance of Zn and Cu nutrition at critical windows of early life stages on their impact during later stages. In this context, we hypothesized that the metabolic capacity of fish towards utilization of dietary lipids might be altered by early nutritional history of dietary Zn or Cu.

Material and methods
The feeding trial lasted 24 weeks and had three phases. Growth was recorded every 3 weeks, mortality and feed intake were monitored daily. In Phase I, 200 first feeding rainbow trout fry (52 ± 3 mg) were fed for 6 weeks with one of the four experimental feeds with two levels of Zn (Zn-, 70 or Zn+, 130 mg/kg) or Cu (Cu-, 10 or Cu+, 20 mg/kg) in a 2 x 2 factorial design, in triplicate. At the end of phase I, ninety fish per tank were sampled for growth and body composition analysis. In Phase II, all the groups were fed with a commercial feed for the next 12 weeks. In Phase III, all the groups were challenged with the Zn-Cu- diet for another 6 weeks. At the end of Phase II and III, eight fish per tank were sampled for plasma metabolite, liver fatty acid profile and gene expression, and whole-body proximate composition analysis.

Results
Growth: Dietary Zn supplementation significantly increased mean body weight and whole-body Zn levels, while body lipid and gross energy level was reduced by Cu supplementation at the end of Phase I. In Phase II, when all groups were fed the commercial feed, no differential effect was observed on growth or body composition. In phase III, when the fish were re-introduced to the Zn-Cu- diet, growth differences became significant. Rainbow trout fed Zn supplemented diet during first feeding (Zn+ and Zn+Cu+) showed significantly higher weight gain and final weight at the end of phase III. On the contrary, they also had significantly low whole-body Zn levels.

Body trace element status: Fish fed Zn+ diets had significantly increased body Zn status at the end of phase I, which was no more apparent at the end of phase II and the contrary was significant at the end of phase III. Dietary Cu did not affect body Cu status at any stage of the experiment. Dietary Mn concentrations were reduced in fish fed Zn+ and Cu+ until end of phase II, but the effect disappeared in phase III when all the groups were fed Zn-Cu- diet.

Plasma lipid metabolites: Circulating levels of total cholesterol and phospholipids in the plasma at the end of phase III were significantly lower in fish with Zn+ early history. No effect was seen on plasma glucose, triglycerides or non-essential fatty acid concentrations.

Hepatic lipid metabolism: Although total lipid content was the same, the fatty acid profile in the polar lipids was affected by early stage Zn or Cu nutrition. Notably, 18:3n-6, 18:4n-3 and 22:5n-3 were lower in fish with Zn+ history. Whereas, 20:2n-6 and 20:3n-3 were lower with Cu+ history. Expression of genes involved in LC-PUFA biosynthesis especially those involved in the fatty acid chain elongation (*elovl2 and elovl5)* and desaturation *(d6d and d9d*) were downregulated by Zn+ early history.

Discussion
In plant-based feeds, increased dietary Zn at first feeding not only improved the growth of rainbow trout fry, but also enhanced growth when sub-optimal Zn supply was encountered later in the juvenile stage. Growth dilution due to enhanced growth in Zn+ fed fish reduced whole body Zn levels at the end of phase III. Impact of Zn or Cu restriction at first feeding on hepatic fatty acid profile and expression of genes in intermediary metabolism at juvenile stage indicate of a possible programming effect, warranting further investigation.

DIET AND HOST GENETIC BACKGROUND DRIVE DIFFERENCES IN THE TRANSCRIPTOMIC PROFILE OF INTESTINAL MICROBIOTA IN GILTHEAD SEA BREAM

M.C. Piazzon*[1], F. Naya-Català[2], A. Sitjà-Bobadilla[1], J. Pérez-Sánchez[2]

[1]Fish Pathology Group and [2]Nutrigenomics and Fish Growth Endocrinology Group, Institute of Aquaculture Torre de la Sal, CSIC, Spain
E-mail: carla.piazzon@csic.es.

Introduction

In the animal production sector, there is an increasing interest in manipulating intestinal microbiota due to their undeniable key effects on host health and welfare. To that aim, numerous studies have been conducted in order to define microbial populations and changes in fish intestine under different conditions. However, most of the studies conducted so far are focused on describing the presence and abundance of bacterial populations based on DNA sequencing technologies. In the current study, we aimed to define the actual metabolic potential of fish intestinal resident microbiota, by studying the gene expression of all gut microbes instead of just defining presence/absence of bacteria. To that aim, we used two families of gilthead sea bream (*Sparus aurata*) selected for heritable growth (fast- and slow-growth families) and fed control or plant-based diets. In previous studies, the fast-growth family showed a more continuous growth across seasons, genetically regulated intestinal plasticity to maximize nutrient absorption when fed plant-based diets, improved resilience to intestinal parasites, and a plastic microbiota that efficiently adapted to the metabolic challenges induced by diet changes (Perera *et al*., 2019; Piazzon *et al*., 2020). Upon diet changes, only a small percentage of the adherent bacterial populations changed in the fast-growth family, but these small changes seemed to account for higher metabolic changes (inferred metagenome and pathway analysis) when compared to the slow-growth family. Here, we compare the transcriptional profile of the total microbial populations in fast- and slow-growth families in order to validate and have further details on the previous observations.

Methods

Two gilthead sea bream families, selected for fast- (e6e2) and slow-growth (c4c3) were kept together in the same open-flow tanks and fed a control or a well-balanced plant-based diet during nine months. Eight animals per group were sacrificed and the adherent microbiota from the anterior intestinal portion was collected and used for RNA extraction. RNA samples were pooled in groups of two to yield a total of four samples per group. After rRNA removal, RNA was sequenced (Illumina, 150PE). Reads were quality filtered and the transcriptome was reconstructed using Trinity. For annotation, the obtained unigenes were aligned with Bacteria, Fungi, Archaea and Viruses sequences from the NCBI's NR database using Diamond. Partial least squares discriminant analyses (PLS-DA) and DESeq2 were used to determine group differences and differentially expressed genes among groups. Gene ontology analysis was performed using GOSeq.

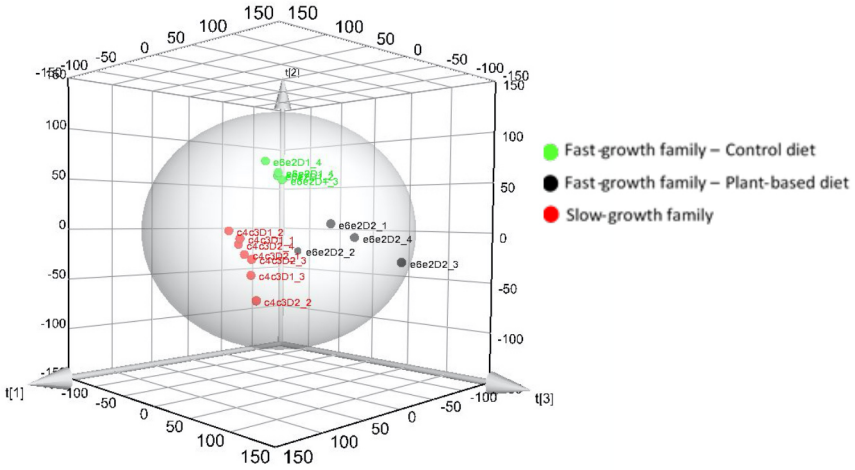

Figure 1: Three-dimensional PLS-DA score plot of the model constructed using all transcripts expressed by the microbiota of the four groups. Note that the model significantly separated fast-growth individuals fed the control (green) and plant-based (black) diets, but failed to separate the slow-growth group (red) by diet.

(Continued on next page)

Results

The total number of annotated transcripts found in this study was 35,144, from which 232 (0.7%) were Archaea, 17,516 (49.8%) Bacteria, 15,703 (44.7%) Fungi, and 1,693 (4.8%) Virus. Regarding the level of expression of the transcripts per group and organism, no differences were detected between families, but differences were found between dietary groups. Plant-based diets increased the number of Fungi transcripts and decreased bacteria transcripts. Diet and genetic background were responsible for changing the expression of 425 and 329 transcripts, respectively. PLS-DA analysis showed a significant separation between fast- and slow-growth families, and within the fast-growth family the different diets showed a significantly different profile. However, diet driven differences were not detected in the slow growth family (Fig. 1). This was supported by the DESeq2 analysis which showed a change in 271 transcripts in the fast-growth family when fed different diets, whereas only 40 differentially expressed transcripts were found in the slow-growth group. GOSeq analyses revealed that plant-based diets were upregulating genes involved in anatomic structure morphogenesis and development, and downregulating genes involved in several metabolic pathways, lipid localization, cytolysis and killing of cells of other organisms, and response to stress in the fast-growth group. Downregulation of vitamin metabolism and upregulation of carbohydrate metabolism, cytokine production, movement and entry into host, and cell proliferation was found in the slow growth group.

Conclusions

Fungi and Bacteria transcripts constitute almost 95% of the transcriptome of gilthead sea bream intestinal microbiota and Fungi transcripts are found roughly in the same abundance as bacterial, highlighting the importance of these two groups of microorganisms in the metabolism of intestinal microbiota. Microbial expression of genes related to tissue remodelling in fast-growth families when fed plant-based diets indicate a possible role of the microbiota in intestinal reshaping (Perera *et al*., 2019). Gene expression patterns found in the slow-growth family indicate a shift towards inflammation and bacterial invasion when these animals are fed plant-based diets. The current results support the previous findings describing fast-growth families' microbiota as plastic communities able to achieve large metabolic changes with fewer changes in the bacterial composition (Piazzon *et al*., 2020) allowing the animals to efficiently adapt to diet changes. These results highlight the relationship between selection for heritable growth and metagenome and the impact on animal health and ability to adapt to changes without detrimental effects.

CAN COMMON CARP (*Cyprinus carpio*) BE ACUTELY STRESSED ?

Constanze Pietsch*

School of Agricultural, Forest and Food Sciences, Bern University of Applied Sciences, 3052 Zollikofen, Switzerland
constanze.pietsch@bfh.ch

The rearing of fish in aquaculture often includes exposure of the fish to acute stress as well as chronic stress. Distress interferes with appetite and well-being of an animal, but also eustress leads to increased activity and therefore is classified as a stressor. Although carp are often assumed to be robust fish showing a high stress tolerance, the question was if there are markers that indicate that carp have previously been exposed to acute stressors. In addition, fish obviously are thought of being capable of distinguishing different stressors in order to react appropriately to environmental changes. For persons working with fish, it is essential to identify the stress levels of the reared fish and especially negative effects of stress effects should be avoided. Consequently, it is a pre-requisite to better understand the stress responses of fish. The presentation will therefore summarize the factors influencing carp welfare and will reveal effects of different acute stressors on the subsequent stress responses that can be observed within the fish body.

IMPROVING MICRODIET FORMULATIONS FOR LARVAE OF TWO FLATFISH SPECIES: SENEGALESE SOLE AND TURBOT

Introduction

Flatfish species, such as Senegalese sole (*Solea senegalensis*) and turbot (*Scophthalmus maximus*) are successful niche species in European aquaculture, due to their high quality white flesh and high market value. However, these species face different scenarios in husbandry during the early developmental stages: while in Senegalese sole a significant R&D effort performed in weaning procedures during the last two decades has translated into an evolution in feeding regimes, microdiet quality and optimization of larval zootechnical procedures (Pinto et al., 2018), published effort on turbot early life-stages feeding and nutrition is very limited. Currently, under normal rearing conditions, Senegalese sole larval survival at the end of two months of development may reach 60-70 %, whereas in turbot lower values are commonly reached (20–30%). One of the hypotheses for this limitation in turbot survival during the early development stages is the lack of microdiets tailored to its nutritional requirements and feeding behaviour. To this end, this study aims at demonstrating the impact of microdiet formulation evolution in Senegalese sole larval husbandry, as well as demonstrating the first steps in the creation of tailored diets for turbot larvae.

Materials and methods

In Senegalese sole, a trial for specific microdiet development aimed at establishing its dietary preference for a main protein source. To this end, four microdiets were formulated and produced by cold-extrusion, comprising of the following main protein sources: fishmeal (Fish), squidmeal (Squid), mixture of plant-proteins (Veg) and mixture of marine and plant-based ingredients (Mix). Sole were reared under standard procedures in triplicate tanks and fed on these experimental diets from 28 to 53 DAH. Diets were supplied to the tanks using automatic feeders, set to supply 8 meals in a 24 hour period (two hour feeding and one hour of stoppage time). In turbot, a trial aiming at determining its dietary preference for a main protein source was also conducted. In this case, four microdiets were also produced by cold-extrusion and the following dietary treatments were considered: Fish, Squid, krillmeal (Krill) and Mix. Turbot post-larvae were reared under similar zootechnical procedures described for Senegalese sole from 23 to 49 DAH. At the end of both trials fish were analysed for dry weight, survival, relative growth rate (RGR) and feed conversion ratio (turbot only).

Results

At the end of the sole experiment, no significant differences were observed in larval dry weight, RGR (varying from 6.3 to 8.6 % per day) and survival (Figure 1) when post-larvae were fed diets Fish, Squid, Veg and Mix. Conversely, diet Squid negatively affected turbot dry weight, survival (Figure 1) and feed conversion ratio (0.7-1.1), with post-larvae dealing positively with diets Fish, Krill and Mix. No significant differences were found between treatments for larval relative growth rate during the course of the experiment (varying between treatments between 14.5 and 15.1 % day^{-1}).

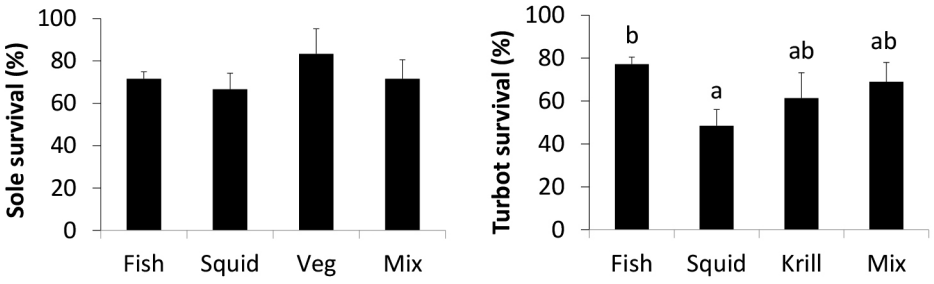

Figure 1. Survival of Senegalese sole (left) and turbot (right) fed microdiets containing different main protein sources. Fish: fishmeal; Squid: squidmeal; Veg: Mixture of plant protein sources; Mix: mixture of marine and plant-based proteins; Krill: krill meal.

(Continued on next page)

Discussion

In general terms, Senegalese sole and turbot post-larvae displayed different responses to microdiets containing different protein sources. Senegalese sole post-larvae were more eclectic, not showing a clear preference between diets containing marine or plant-based proteins. The relative growth rate (RGR; up to 8.6 % day^{-1}) reached for the different treatments was satisfactory, but continuous research focusing on the impact of different nutritional compositions, including protein complexity (Canada et al., 2017), indispensable amino acid profile (Canada et al., 2016), dietary lipid levels and essential fatty acid composition (Pinto et al., 2016), have boosted Senegalese sole growth performance, nowadays reaching RGR values of 12-13 % day^{-1} during weaning. On the other hand, turbot larvae performed best on diets containing fishmeal, krill and a mixture of marine and plant-based proteins, with a clear detrimental effect on larval performance being observed in fish fed a high quality squid-meal based diet.

Interestingly, both flatfish species also present opposite feeding behaviours: while Senegalese sole is more passive and feeds in the bottom of the tanks, turbot is more active and feeding occurs at water surface (Bruno et al., 2018). Such comparison of feeding behaviour, together with diet preference results herein obtained, suggest that microdiets suitable for Senegalese sole may not be optimised for turbot, both in terms of nutrition and, particularly, in terms of microdiet physical properties in water (dispersion at surface and sinking behaviour). Overall, results support that diets should be optimised in terms of nutritional composition and physical behaviour in water to boost turbot growth and survival at early developmental stages. Moreover, this work supports the concept that dietary customisation for marine fish larvae of different species will contribute to the production of high quality juveniles in aquaculture.

FEEDING FISH THROUGH CIRCULAR BIOECONOMY: MICROALGAE AS AQUAFEED INGREDIENT CULTURED IN HYDROPONIC EFFLUENTS

Microalgae present a high potential for application as an ingredient for aquafeeds, due to their high-quality biomass, rich in proteins and long chain fatty acids. In addition, microalgae are also a more sustainable source than other traditional feed ingredients obtained by unsustainable sources, such as fisheries. However, improvement of industrial microalgae production is crucial in the upcoming years towards to increase sustainability and reduce production costs. This is essential for the application of microalgae as a whole aquafeed ingredient[1]. An interesting approach to reduce microalgae production costs is the use of effluents instead of fresh or seawater, which complements wastewater treatment procedures. Hydroponic cultures have nitrate contents that are generally above the legislation permits and are difficult to dispose of safely in the environment, resulting in a public health issue. The ALGACYCLE project aims to re-apply the nutrients from greenhouse hydroponic effluents, improving water quality, and to develop two microalgal products, thus promoting circular bioeconomy. The resulting microalgal biomass will be tested for application in the aquaculture and agriculture sector, in the form of biostimulants and aquafeeds, the latter to be used in the feeding of salmon *(Salmo salar*). In 15 European countries, the percentage of the population exposed to nitrate levels in drinking-water above 50 mg/L that promote nitrate toxicity problems, is estimated to be consumed by 10 million people, being a public health issue. Hydroponic cultures effluents have nitrate contents that are generally above the legislation permits and are difficult to dispose safely in the environment. These nutrients are being wasted and can be re-used to produce high quality biomass and facilitating the agricultural waste disposal. The vectorization of the nitrates for microalgae production would support the sequestration of a health and environmental harmful component (nitrates) in a valuable biomass, to be further applied in the production of aquaculture fish. Two species with tolerance to high nutrient concentrations and a high potential for aquaculture nutrition are being tested, namely *Scenedesmus* sp. and *Koliella antarctica*. Altogether, this strategy will contribute to the sustainability of microalgae industrial production while reducing production costs and contributing to the Blue Growth sector.

Introduction

Total suspended solids (TSS) increase during the shrimp production in BFT system, which can affect water quality and animal performance. To control the excess of TSS during the shrimp production in the BFT system can be used mechanical filters (settling tanks) or the alternative integration with species that act in different trophic levels – Integrated Multitrophic Aquaculture (IMTA). The present study aimed to evaluate two stocking densities of tilapia in integrated culture with the shrimp *Litopenaeus vannamei* in biofloc system on a pilot scale.

Material and Methods

Two stocking densities of tilapia were tested, 35 and 65 fish m^{-3} in a recirculating system with 18 m^3 tanks for shrimp culture and 4 m^3 for tilapia culture with recirculation of 965.66 ± 92.83 L h^{-1} during 78 days. The initial weight of the shrimp was 0.9±0.1 g and of the tilapia was 7.1±3.2 g. The shrimp received the amount of feed according to the feeding table and the fish were underfed to stimulate them to consume the bioflocs.

Results

Tilapia densities did not affect shrimp growth (11.5±1.9 g for treatment with 35 fish m^{-3} and 10.1±0.7 g for treatment with 65 fish m^{-3}). The tilapia presented a FCR less than 1, proving the consumption of the bioflocs by the fish. The clarification time was shorter when compared to other studies with shrimp monoculture and among the treatments, where there was lower fish stocking density, there was a reduction of 10 hours in the system clarification when compared to the treatment with higher fish stocking density. The results demonstrate the feasibility of integrated shrimp and tilapia culture on a pilot scale, without compromising shrimp productivity.

RECENT CARP EDEMA VIRUS ISOLATES FROM CZECHIA ARE HIGHLY SIMILAR TO ISOLATES FROM CONTINENTAL EUROPE

Introduction

With a stable annual production of around 20 000 tonnes, common carp *(Cyprinus carpio)* is the most valuable aquaculture species in the Czech Republic. Emerging diseases, such as the carp edema virus disease (CEVD) detected in the country since 2013 (Matejickova et al. 2020) pose a threat to the industry. Molecular epidemiology, in the form of sequencing of isolates, can help understand the distribution of the virus in the country.

Material and Methods

In total, 637 samples representing 124 locations (individual farms or ponds) were examined in the year 2020 for the presence of the virus using conventional and real-time PCR (Way et al, 2017). Partial P4a gene sequences (357 bp) of detected CEV isolates were obtained via Sanger sequencing and compared to isolated uploaded to the GenBank database.

Results

CEV was diagnosed in six locations, namely four common carp farms and two koi carp ponds. Clinical signs in farmed common carp varied from asymptomatic to a 100% mortality rate in one of the facilities, meanwhile both positive koi in ponds showed sleepy-disease-like symptoms. Phylogenetically, two of the established CEV genogroups were detected: Genogroup I in common carp and genogroup IIa in koi. The isolates from common carp showed up to 100% identity with previously published sequences from Czechia (Matejickova et al. 2020), Germany (Adamek et al. 2017), Hungary (Adamek et al. 2018) and Great Britain (Way et al. 2017).

Conclusions

High levels of similarity in the routinely sequenced partial P4a gene of carp edema virus suggest wide dissemination of the pathogen and possible transmission of specific isolates, most probably via the transport of live fish, ornamental or farmed.

Funding

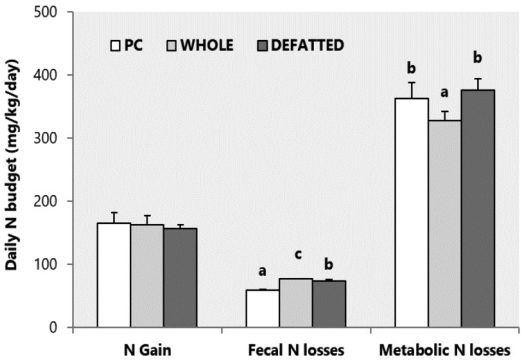
Introduction

Being an emergent industry, microalgae biomasses cannot yet be used as commodity ingredients in current aquafeeds. However, the future presents new consumer-driven challenges that are shifting the focus away from cost minimization production strategies, towards enhanced consumer confidence and product value. Microalgae, being a rich source of protein, n-3 LC-PUFAs, such as EPA and DHA, vitamins, trace minerals, carotenoids and antioxidants, may contribute towards a more sustainable and nature-like image of aquafeeds. Major criteria driving the industrial use of such novel and alternative ingredients are their nutritional profile, cost-effectiveness and market availability. In a foreseeable microalgae biorefinery scenario, the downstream processing entailing the extraction of specialty high value products, such as LC-PUFA rich oils and other liposoluble compounds, will generate large quantities of defatted biomasses, which need to be assessed as raw materials in aquafeeds. A study was undertaken to assess the potential of whole and defatted *Nannochloropsis oceanica* biomass in alternative feeds for gilthead seabream.

Methods

The trial comprised 3 dietary treatments: a control diet (CTRL), mimicking a commercial formulation containing 17.5% fishmeal, 2.5% fish protein hydrolysate, 10% poultry meal and several vegetable ingredients (wheat gluten, corn gluten, soybean meal) as major protein sources; and two alternative diets with lower levels of fishmeal (10%), higher levels of PAPs (poultry meal, feather meal hydrolysate, blood meal), soy-free and EU-derived rapeseed and sunflower meals, as major protein sources. These two diets comprised also the incorporation of microalgae (*Nannochloropsis oceanica*) at either 2% for the whole biomass (WHOLE) or 4% for the defatted biomass (DEFATTED). The defatting process of the algae biomass comprised cell disruption by bead milling followed by a supercritical fluid extraction (SFE). A blend of fish and rapeseed oils was used as main lipid source. In the algae-containing diets, due to the reduction of fishmeal, a minor addition of algae oil (derived from *Schizochytrium spp*.) was done to guarantee an identical dietary level of EPA+DHA among the feeds. Diets were isonitrogenous (CP: 49% DM), isolipidic (CF: 19% lipid) and isoenergetic (GE: 19.4 MJ/kg DM).

Homogenous groups of 26 seabream (IBW: 194 g) were stocked in 1000 L tanks. Each experimental treatment was tested in quadruplicate tanks over 89 days. Rearing tanks were supplied with flow-through gravel-filtered, aerated seawater (salinity: 36 ppt; temperature: 22.7 ± 2.5°C; dissolved oxygen > 5.8 mg·L^{-1}) and subjected to natural photoperiod during summer conditions. Additionally, at the end of the trial the apparent digestibility of protein and energy of the various diets was measured by the indirect method in tanks equipped with a fecal decantation column.



(Continued on next page)

Results and discussion

After 89 days of experimental feeding, no significant differences in survival, weight gain (FBW, SGR) or feed utilization (FCR, PER) were observed among treatments ($P>0.05$). No differences were found on the whole-body composition of fish in terms of moisture, ash, protein and energy ($P>0.05$), whereas fish fed the DEFATTED diet showed a significantly lower fat content than those fed the CTRL diet ($P<0.05$). In line, fish fed the DEFATTED diet showed a significantly lower whole-body lipid retention than those fed the CTRL diet ($P<0.05$). In comparison to the CTRL diet, both WHOLE and DEFFATED diets resulted in a significantly lower digestibility of protein and energy ($P<0.05$).

Dietary treatments had no impact on the daily N gain ($P>0.05$). However, in association to a lower protein digestibility, fish fed diets WHOLE and DEFATTED showed significantly higher daily fecal N losses than those fed the CTRL diet ($P<0.05$). Although associated to the highest fecal N losses, the WHOLE diet showed also a significant reduction of daily metabolic N losses ($P<0.05$)

Fish derived from the various treatments were assessed by a consumer panel (n=100). This consumer acceptance test, performed by SenseTest Lda (Portugal), evaluated not only the external appearance of fish, but also sensory properties (odour, flavour, texture) in cooked fillets. In a scale of 1 to 9, with 9 representing a highly liked attribute, average scores for the various criteria ranged between 7.7 and 7.8, without a statistical differentiation among treatments ($P>0.05$).

Conclusions

Data from this study indicates that microalgae (*Nannochloropsis oceanica*) presented as a whole or defatted biomass can be useful ingredients in alternative feeds for gilthead seabream. However, further attention should be paid to aspects related to the digestibility of the whole algae biomass to avoid a potential increase of fecal nutrient losses. Additionally, the evaluation of microalgae in aquafeeds should also assess its potential benefits on the immune status of fish and comprise an estimation of environmental impact using Life Cycle Assessment (LCA) criteria.

EFFECT OF A DIETARY BACTERIA AND YEAST BASED PARAPROBIOTICS AND THEIR COMBINATION UPON THE MUCOSAL BARRIER DEFENCES AND IMMUNITY OF JUVENILE RAINBOW TROUT (*Oncorhynchus mykiss*)

Pontefract, N.[a]*, Rawling, M.[a], Leclercq, E.[b], Castex M.[b], Merrifield, D.[a]

Introduction
The importance of the mucosal-associated lymphoid tissues (MALTs) present in the gut, gills and skin (GALT, GIALT and SALT respectively) of fish is well established. Due to their direct contact with the external environment, MALTs are one of the primary barriers to pathogens. Recently, the potential interconnectivity of the MALTs is receiving increased attention, particularly with regard to how feed additives may exert a beneficial influence upon the skin and gill mucosa. This study assessed the effect of two Paraprobiotics on rainbow trout mucosal responses: a multi-strain yeast fraction product (MsYF; Rawling et al., 2021) and a bacteria paraprobiotic compound (Para; heat-killed bacteria), tested alone or in combination.

Materials and methods
An 8-week feeding trial was conducted on rainbow trout (BW_i= 36.7 ± 0.5g) at the Aquaculture and Fish Nutrition Research Facilities of the University of Plymouth (UK). Four iso-nitrogenous and iso-lipidic diets were manufactured and randomly assigned to tanks in triplicate: 1] Control, 2] MsYF (1.5 kg/t), 3] Para (0.3 kg/t), 4] Combination (Comb: MsYF: 1.5kg/t + Para: 0.3kg/t). The functional ingredients were provided by Lallemand SAS (France). Skin, gill and distal intestine were sampled for histological analysis and qPCR gene expression at two successive time-points (5 and 8 weeks).

Results
Compared to the control group, fish fed the supplemented diets exhibited significantly increased goblet cell area fractions (GCAF) in the skin epidermis at both 5 and 8 weeks (Fig 1). No diet effect on the goblet cell population was observed in the gill (not shown).

Upregulation of a number of genes associated with mucin production and tight junction permeability were observed in the GIALT (*Mucin-17-like, Claudin 10d, 10e* and *12*; Fig 1A) and the SALT (*Calreticulin, claudin 30* and *Mucin-17-like;* Fig 1B). Further, several genes associated with Th2-type cytokines (*IL4/13a, TGFβ*) were affected in the GIALT (Fig 1A) and GALT (Fig 1C) at week 5 and 8, suggesting that the presentation of different microbial associated molecular patterns within the MsYF and bacterial parabiotic show the potential to initiate specific cell-mediated immunity in these tissues.

Discussion
This study indicates the potential of the dietary additives to distinctly influence the mucosal barrier defences of the gill, skin and gut at the inclusion levels tested. Significant increases in the expression of several immune-related genes were observed in the GIALT and GALT, along-with significantly elevated expression of tight junction (TJ)- and mucin-related genes within the GIALT, SALT and GALT. These were associated with increased goblet cell area fraction in the skin epidermis.

Conclusion
These results support the proposed interconnectivity of the MALT and suggest distinct transcriptomic responses associated to the dietary application of different Paraprobiotics and their combination. Further research is required to investigate implications in terms of fish phenotypic responses under different situations.

EXTREME EVENTS AND LAGOON FARMS: THE INFLUENCE OF DRASTIC CHANGES IN SALINITY ON OYSTER GROWTH

Introduction

Coastal ponds and lagoons are among the most productive ecosystems in the world and play a fundamental role in providing different ecosystem services, including food provision. In Italy most of the oyster farms are located in Sardinia, where *Crassostrea gigas* is mainly farmed in lagoons and coastal ponds (Graham et al., 2019). These areas are subjected to extreme and rapid perturbations, such as freshwater intrusion, leading to marked seasonal salinity fluctuations.

The present study was carried out in S'Ena Arrubia, a small and shallow lagoon located in the centre-western coast of Sardinia, which borders the Arborea plain, a natural depression which is part of the coastal flood plain, reclaimed at the beginning of the 1900s. In this area, freshwater input is supplied from two affluent rivers, "Rio Sant'Anna" and "Canale delle acque basse", the latter is a channel below the sea level, where a dewatering pump is located. From September to December 2018 an experimental oyster farm was positioned in the sea-mouth of S'Ena Arrubia lagoon to evaluate the effects of two different gears (*i.e.*: Ortac and floating bag) on the oyster's quality aspect (see Brundu et al., 2020). In November 2018, during this experimental rearing farm an exceptional rainy event took place causing a marked drop in salinity in the lagoon.

In this preliminary study we evaluated the potential oyster growth in S'Ena Arrubia lagoon applying a Dynamic Energy Budget (DEB) model, secondly we implemented the model including salinity as a forcing variable. The aim of this study is to: (i) evaluate the potential oyster growth in a Sardinian lagoon through a DEB model application; (ii) include salinity in the DEB model; (iii) compare the model outputs considering and not considering the salinity.

Methods

We collected data on *C. gigas* growth through an experimental field study, in order to parameterise, and subsequently, validate the DEB model. Contextually, temperature, salinity, and chlorophyll-a data were collected in the experimental area and used as environmental forcing variables for the model. The individual DEB model implemented in this study was originally developed by Pouvreau et al. (2006) and further improved by Lavaud et al. (2017) to account for the salinity effects. The parameters used in the model are based on previously published papers (Pouvreau et al., 2006; Bertolini et al., 2021).

Based on the results obtained for *C. virginica* (Lavaud et al., 2017), we considered the main impact of salinity modification on the filtration rate, due to a reduced or stopped oyster feeding at low salinity. In order to simulate this effect, a linear correction factor on filtration rate was applied (Lavaud et al., 2017):

$$C_S = \begin{cases} 1, at\ S \geq S_H \\ \dfrac{S - S_L}{S_H - S_L}, at\ S_L < S < S_H \\ 0, \quad at\ S \leq S_L \end{cases}$$

where, based on literature values, SL and SH (low and high salinity threshold) are fixed at 13 and 25 respectively (Graham et al. 2020), and S is the registered salinity value. We ran two DEB models, considering and not considering the salinity correction on filtration rate. Finally, we evaluated the model outputs comparing the predicted and observed values.

(Continued on next page)

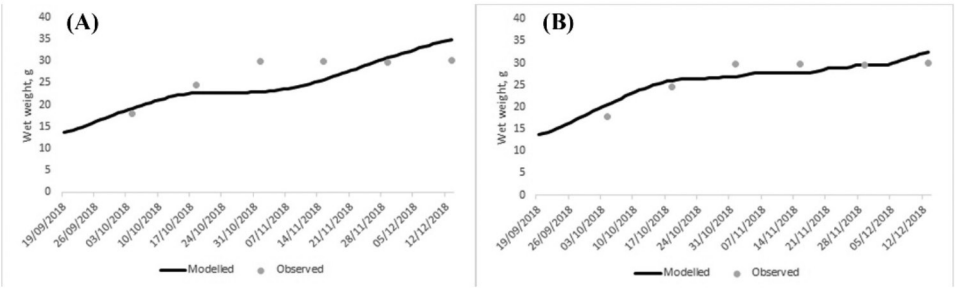

Figure 1. Model validation: predicted and observed values for the total mean wet weight of oysters without (A) and with (B) salinity correction.

Results and discussion

The two DEB model outputs, without and with the salinity correction, are represented in Figure 1 (A and B respectively). In general, the prediction for oyster growth in terms of wet weight provided a good agreement for both models, with a more accurate prediction for the model considering the salinity correction. The visual impression provided is confirmed by the results obtained from the comparison of predicted and observed values. Indeed, the linear regression of predicted versus observed values of oyster mean wet weights gave a determination coefficient $R^2 = 0.83$ considering the salinity correction, and $R^2 = 0.49$ without considering the salinity effect.

This preliminary application highlights how the implementation of salinity within a DEB model can improve the growth prediction. In recent years intense rain events have become more frequent, and are expected to increase due to climate change, inducing consequent pressures on lagoons and coastal ponds. In this context, being able to predict oyster growth applying well established models including the salinity as an environmental forcing could drive to more reliable results, which can contribute to assess the suitability of the different lagoons for aquaculture use. Hence, these results could also be meaningful for the site selection process within the Allocated Zone for Aquaculture identification process, currently ongoing in the Sardinia region.

Introduction

The advances of functional feeds for farmed fish are now regarded as a key factor in improving fish health and performance. Although there has been significant research on the impact of functional feeds on the immune system, the mechanisms by which these occur is still poorly understood, as such there is a need for further research into the nutrition health interface for aquaculture species. As part of our research to examine direct immune responses to functional feed ingredients, cell lines and primary cell cultures are being used as an alternative method which also addresses 3Rs in reducing whole animal experiments. Cell cultures offer a quick and non-invasive method of identifying immune responses, however, the number of cell lines available is limited and the phenotype of these cells is likely to have changed from their original *in-vivo* state, especially in the intestine with the complex nature and multiple cell types present. Gut associated lymphoid tissues (GALT) leucocytes have been extracted and have shown to be a good screen to PAMPs in previous studies by Attaya et al, (2018) but their role as a viable alternative to traditional feeding trial methods is yet to be seen.

The present study was undertaken to identify the suitability of both cell culture and primary GALT leucocyte models as potential alternative methods to test functional feed ingredients on. In addition to the primary culture cells, a rainbow trout macrophage cell line (RTS11) and a rainbow trout gut epithelial cell line (RTgutGC), were used as the cell line models (Ganassin and Bols, 1998) (Kawano et al., 2011). The cells were challenged with a variety of PAMPs and multiple types of the prebiotic β glucan to test their suitability as a health screen for functional feeds.

Materials and Methods

RTgutGC cells were cultured in flasks at 20oC in growth media (Leibovitz L-15 media + 10% FBS + 1% Penicillin/Streptomycin). RTS11 were cultured in flasks at 20oC in growth media (Leibovitz L-15 media + 30% FBS + 1% Penicillin/Streptomycin). Fish for GALT leucocytes extraction were maintained in 1 m-diameter fiberglass tanks with recirculating freshwater at 14 °C and fed twice a day with a commercial diet at 1.5% bodyweight. Fish were sampled at the same time of day on each occasion used. GALT leucocytes were extracted from the distal intestine using the method previously described by Attaya et al, 2018 with some alterations: cells were washed in PBS containing 1% Penicillin/Streptomycin, cells were digested for a singular two-hour digestion. GALT leucocytes, RTgutGC and RTS11 cells were added to a 24 well plate at a concentration of 2.5x105 cells/well and resuspended in 1ml total of stimulation media (Leibovitz L-15 media + 1% FBS + 1% Penicilin/Streptomycin). Cells were stimulated with 100μg/ml Poly IC, 10μg/ml PHA, 20μg/ml rIL-1β (Provided by Dr. Tiehui Wang (Scottish Fish Immunology Research Centre)), and β-glucans 1 and 3 100μg/ml (provided by Skretting Ltd) for 4 hours before RNA extraction. Following cell stimulation cells were lysed directly in TRIzol and stored at 80oC. RNA was then extracted following the manufacturer's instructions Reverse Transcription was completed using the Quantitect® Reverse Transcription Kit (Qiagen) following the manufacturer's instructions. Primers for each gene were designed using NCBI primer blast or were identified in published papers and then checked using Primer-Blast. Primers were designed with at least one primer across an exon-exon junction to ensure only the cDNA was being amplified. qPCR on the cDNA was carried out using the Lightcycler 480 machine (Roche). Relative gene expression was calculated using GenEx which included the use of three housekeeping genes for normalization.

Results

Stimulations with Poly IC (Figure 1) show a significant upregulation in both MX and IFN1α for RTS11 at all time points, RTgut and GALT leucocytes. The results also show that RTgut are more sensitive to Poly IC stimulation at the 4hr time point compared to the GALT leucocytes and RTS11 cell lines. The RTS11 and GALT Leucocytes show similar responses to Poly IC.

(Continued on next page)

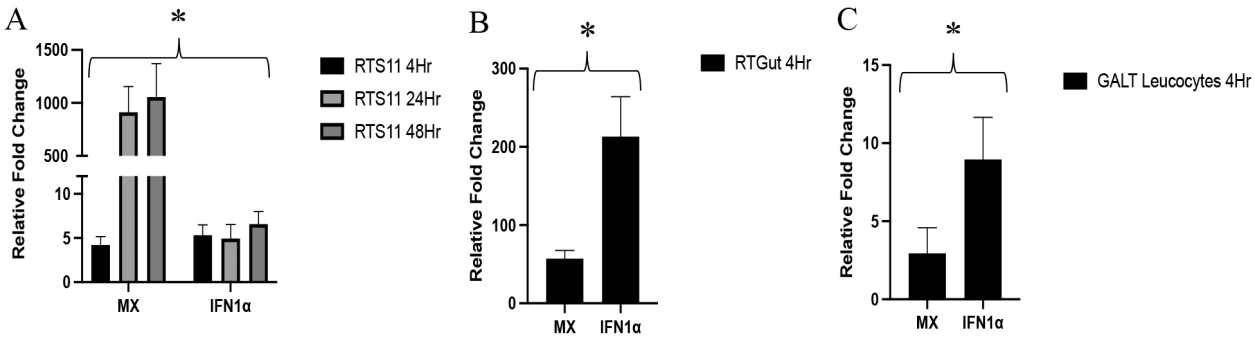

*Figure 1 - RTS11, RTguGCt and GALT leucocyte response to Poly IC. A – RTS11 response to Poly IC at 4hr, 24hr and 48hr time points. B – RTgutGC Immune response to Poly IC at 4hrs. C – GALT leucocyte Immune Response to Poly IC at 4hrs. * = P<0.05*

Discussion

The results of this study suggest that both cell lines and GALT leucocytes provide a novel insight into the immune response to functional feeds. The results show that whilst both the RTS11 and RTgutGC cell lines do respond to both PAMPs and β-glucans their immune responses are similar but not the same as primary cell cultures, primarily since there is only one cell type rather than multiple cell types that would be seen in-vivo. This suggests that the cell lines are a beneficial precursor to feeding trials if they are used to screen novel feed additives prior to the feeding trial. The GALT leucocytes are a good alternative to identify the immune response of the gut directly rather than looking at the systemic effects. The results from the GALT leucocyte stimulations show that stimulation with the PAMPs; Poly IC, PHA, rIL-1β show expected responses to target genes. Poly IC showed significant upregulation in MX and IFN1α compared to the control in RTS11, RTgut and GALT leucocytes. MX encodes for a guanosine triphosphate (GTP)-metabolizing protein that participates in the cellular antiviral response which is induced by Type I and II interferons such as IFN1α; an antiviral cytokine that is released as a key part of the innate immune response to viral infections. Other stimulants including the T cell mitogen PHA and proinflammatory cytokine Il-1β were also examined in the model systems which also showed expected immune modulation to PAMPs. B-glucan stimulated results show similar responses to published data (Douxfils et al, 2017, Ji et al, 2019) with β-glucans causing an upregulation in il-1β, il-8, il-4 and tnfα. These results suggest further research into the direct mechanisms of actions of both β-glucans will help define the direct immunological effects of these functional feed components, enabling focussed future designs of diets.

OSTREID HERPES VIRUS INFECTION IN PACIFIC OYSTER TISSUE EXPLANTS

Robert Potts*, Tim Bean, Ross Houston

The Roslin Institute, University of Edinburgh, Midlothian, EH25 9RG
Email: r.potts-1@sms.ed.ac.uk

Introduction

Pacific oysters (*Crassostrea gigas*) are one of the most important aquaculture species globally. Sustainable production of oysters is hampered by outbreaks of mass mortality caused by Oyster Herpes Virus (OsHV). Better understanding of the genetics underlying resistance to OsHV is essential to preventing future outbreaks, as vaccination or treatments are not feasible in the field, leaving biosecurity as the main defence. Furthermore, it is important to consider the full range of life stages of the oyster as they are exposed to OsHV throughout their life.

The aim of this study was to use whole-tissue explants challenged with OsHV to determine gene expression changes in different tissues and at different life stages. This data can then be used to inform selective breeding or gene editing approaches to enhancing OsHV resistance.

Materials and methods

Live pacific oysters from three key life stages (spat <2cm, juvenile 5-6cm, and adult >15cm) are obtained from a UK oyster farm. Heart, mantle, muscle and gill tissues are dissected and sterilized using antibiotic and antifungal treatments under sterile conditions. Tissues were cultured in custom media. OsHV was added to challenge groups. RNA and DNA were extracted from samples across 96 hours. RNAseq and qPCR were used to quantify gene expression.

Discussion and future work

The development of a system for maintaining whole tissues from pacific oysters is an exciting development that has been investigated for the first time (Potts et al. 2020). This system facilitates investigation into the host genetic response to infection at different life stages and backgrounds of disease resistance (Degremont et al 2021). Elucidation via qPCR and RNAseq will reveal genes of interest as potential targets for genome editing. Furthermore, tissue specific responses will be valuable for better understanding OsHV virology. Key questions to address are the main site of OsHV replication within the oyster and potential sites for virus latency or senescence. Additionally, this approach may enable the complete OsHV lifecycle in the laboratory, which has not been achieved to date.

Introduction

Oxidative stress has been related to various skeletal pathologies altering the activity of osteoclasts and osteoblasts, affecting bone remodelling. Reactive oxygen species are key components to increase oxidative stress, increase bone resorption and inhibit bone formation. A large number of studies suggests the importance of the antioxidant system to reduce the effect of bone pathologies.

Materials and Methods

Microdiets were prepared manually mixing squid powder first with water-soluble components, then with fat and lipid-soluble vitamins, and finally with gelation dissolved warm water. Resveratrol (34mg/kg) and Doxorubicin (30mg/kg) were dissolved on polar molecule were as MitoTempo was dissolved in water. *S. aurata* of 30 days were randomly stocked into 18 experimental tanks at a density of 2100 larvae/tank. The larvae were fed with experimental microdiets with antioxidant and pro-oxidants alone or in combination. The antioxidants microdiets were fed every hour from 8:00 to 20:00 whereas, prooxidant was fed only once a week and was continued with a respective combination of control or antioxidant diets. The microdiets combinations were Control, antioxidants (Resveratrol and MitoTempo) prooxidant (Doxorubicin), and in combination (Doxorubicin with Resveratrol and MitoTempo). The effect of antioxidant and pro-oxidant supplemented diet on skeletal formation, the incidence of skeletal deformities and the stages of bone mineralization, mineral content were examined.

Results

At 45 dah, pro-oxidant supplementation increased the incidence of bone deformities and affected areas and decreased bone mineralization, effects that were significantly reversed with combination with antioxidants. Doxorubicin significantly reduced the total length of larvae which was significantly reversed with the co-treatment with Resveratrol. Deformities charge were significantly high on Doxorubicin supplemented group and were significantly reduced on combining with antioxidants. Cluster analysis shows a distinct difference between the groups on the distribution of skeleton anomalies. The mineralization of the skeleton elements were significantly affected by Doxorubicin. However, while combining with Resveratrol the effect was rescued. The differences were also observed on Meristic count between the groups supplemented with antioxidants and pro-oxidants supplemented microdiets. Calcium and Phosphorus content were also decreased on Doxorubicin supplemented groups.

Conclusion

In conclusion, our results showed that antioxidant supplements effectively prevent incidence of bone anomalies and mineralization defects. Resveratrol and MitoTempo supplementation can reverse pro-oxidant induced effects on bone anomalies, mineralization and oxidative stress.

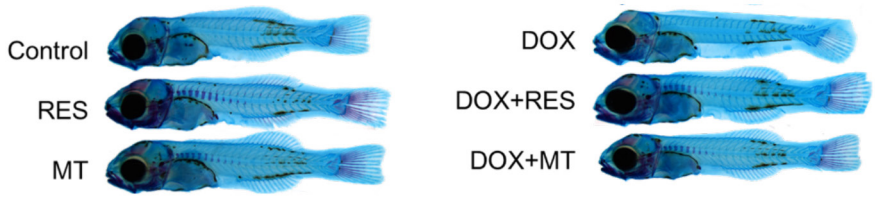

Figure: *S. aurata* larvae at 45 dah fed with microdiets supplemented with antioxidants and pro-oxidants stained with an Acid-free double staining protocol for bone and cartilage.

Introduction

Various skeletal disorders have been linked to oxidative stress, which affects bone remodelling by modifying the activity of osteoclasts and osteoblasts. Increased oxidative stress, increased bone resorption, and inhibited bone formation are all caused by reactive oxygen species. Antioxidants that can counteract the toxic effect of pro-oxidants on bone would be helpful for the prevention of secondary osteoporosis in humans and for promoting a better skeletal health in fish produced in aquaculture.

Materials and Methods

We used two antioxidants, Resveratrol, a natural antioxidant, and MitoTempo, a mitochondria-targeted antioxidant, to counteract the negative effects of doxorubicin on bone using zebrafish. Microdiets were supplemented with Resveratrol (34mg/kg), MitoTempo (5mg/kg), and Doxorubicin (30mg/kg). Zebrafish (5 dpf) were randomly stocked into 24 experimental tanks at a density of 100 larvae/tank for 30 days. The larvae were fed with experimental microdiets with antioxidant and pro-oxidants alone or in combination. The antioxidant supplemented microdiets were fed by standardized spatula 15mg/day and increased by 5mg/day every week. Antioxidant supplemented microdiets were fed 4 times a day, whereas pro-oxidant diet was fed only once a week. The microdiet combinations were Control, Resveratrol, MitoTempo, Doxorubicin, Doxorubicin + Resveratrol and Doxorubicin + MitoTempo. The effect of antioxidant and pro-oxidant supplemented diet on skeletal formation, the incidence and distribution of skeletal deformities and the stages of bone mineralization and mineral content were determined.

Results

At 30 days, survival of zebrafish larvae was significantly decreased under doxorubicin treatment but significantly reversed upon co-treatment with antioxidants. Doxorubicin supplementation also delayed larvae development and significantly decreased total length, however this effect was significantly reversed by co-treatment with antioxidants. The effect of microdiets on standard length was compared with the standard Zebrafeed diet (Sparos Lda, Olhão, Portugal). Resveratrol supplementation significantly increased the length as compared to Zebrafeed and control microdiet. Doxorubicin also induced an increase on the incidence of skeletal deformities and affected areas, and decreased bone mineralization. These effects were significantly reversed with an antioxidant co-treatment. Calcium, Phosphorus, Sodium, Potassium and Magnesium contents were also decreased on Doxorubicin supplemented groups whereas, while in co-feeding with antioxidants the loss of mineral content were significantly rescued.

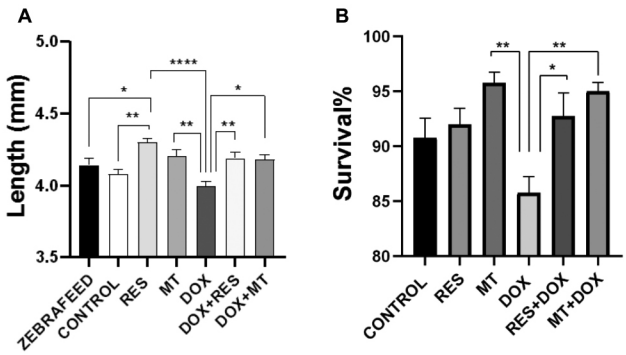

Figure: *Zebrafish* larvae fed with microdiets supplemented with antioxidants and pro-oxidants. Total length at 15 days (A), Final Survival (B).

(Continued on next page)

Conclusion

Our results showed that microdiets supplemented with antioxidant effectively prevent the incidence of bone anomalies and mineralization defects in Zebrafish. The antioxidants supplementation also protects against pro-oxidants induced bone anomalies, delay in development, defective mineralization, and oxidative stress. The use of antioxidants in fish diets can be beneficial for improving the health and quality of aquaculture produced fish.

E-mail: ana.matias@ipma.pt

Introduction

Atlantic sardine (*Sardina pilchardus*) is one of the most important, social and economic, species found throughout the eastern Atlantic Ocean and its associated seas, mainly due to their precious nutritional characteristics such as richness in omega-3 fatty acids (Bandarra et al., 2018). However, in the beginning of 2015 the sardine biomass reached worrying lowest historical levels being the stock considered at risk of reduced reproductive capacity (Silva et al., 2015). For this reason, Atlantic sardine production in aquaculture is an opportunity to circumvent this stock risk situation with concomitant contribution to the species diversification in this sector. One main target of aquaculture sardines could be the canning industry, a Portuguese tradition with more than one century of existence. The Aquaculture research station in Olhão from the Portuguese Institute for the Ocean and Atmosphere (EPPO-IPMA) invested on sardine production and has now second-generation sardines. Animal production implies the fulfillment of a bunch of conditions such as their nutritional needs to insure an optimal growth and health status. In fish diets, protein usually represents the most expensive dietary component, therefore it is important to understand and determine fish protein requirements not only from an economical perspective but also from zootechnical and environmental ones. With this study, we intend to investigate the protein requirements of *S. pilchardus* juveniles based on protein degradation analysis and growth performance.

Materials and methods

Second generation sardine juveniles (19.9 ± 2.8 g) produced at EPPO-IPMA were fed with five diets containing different crude protein concentrations (CP 15%, 25%, 35%, 45% and 55%) for 97 days at 16.2 ± 0.5 ºC. The resulting growth parameters, protein expression and proteolytic activity enzymes in hepatic and muscle tissues were analyzed to evaluate the effect of dietary protein concentration in protein turnover and growth. Techniques like protein extraction, enzymatic activity and semi-quantitative protein expression were employed.

Results

Fish growth increased proportionally to the crude protein content in the diets, being 15% protein concentration responsible for growth arrest (Figure 1). At the cellular level, this growth impairment was reflected in significant high levels of protein degradation in the muscle of sardine juveniles but not in the liver. Also, this study allowed us to identify a novel tool to analyze protein degradation in *S. pilchardus*.

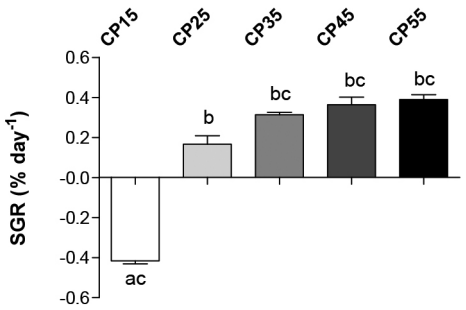

Figure 1 - Specific growth rate (SGR) of juvenile sardine (*Sardina pilchardus*) fed diets containing different protein concentrations (CP 15%, 25%, 35%, 45% and 55%). Values presented as mean ± SD. Significant groups are indicated by different letters for $p \leq 0.05$.

(Continued on next page)

Discussion and conclusion

The balance between protein synthesis and breakdown (protein turnover) regulates whole-body protein mass. A slightly increase in protein synthesis over protein degradation results in somatic growth. Low levels of crude protein in fish diets implies less amount of available amino acids for metabolism. Since the deficiency of amino acids may change protein turnover (Higuera et al., 1998), we hypothesized that the amount of these molecules could affect protein degradation and consequently juvenile sardine growth. In our study, fish growth seems to be related to the increasing crude protein concentration, which can be explained by a decrease of protein degradation in muscle. Our results based on protein turnover analysis, suggested that sardine juveniles can be fed with a diet containing 35% CP without compromising growth performance.

Introduction

Seaweeds show potential for climate change mitigation, biodiversity increase, and waste nutrients removal[1,2]. Therefore, their cultivation is attractive as it shows ecosystem services potential, while the biomass can be used in a wide range of industries. The red seaweed species *Plocamium cartilagineum* and *Sphaerococcus coronopifolius* are present in Portugal and thrive on our coasts, namely in Algarve. These two species have been considered for many industries, like pharmaceutical, medical, and cosmetics, due to their properties and the fact that they can produce compounds that are not usually found in terrestrial plants, like unique bioactive, complex, exotic acyl lipids and fatty acids[3], but despite these properties, there is still little knowledge on their cultivation potential. The objectives of this work were the cultivation of *P. cartilagineum* and *S. coronopifolius* in inland IMTA system, assessment of their bioremediation potential, and produced biomass' characterization.

Materials and methods

Seaweed cultivation: Trial 1- *Plocamium cartilagineum (6 weeks: June* 9th - July 21st); Trial 2- *Sphaerococcus coronopifolius* (6 weeks: July 27th - September 7th). Different densities (2, 4, 6, and 8 g DW L^{-1}) were tested in duplicated, the water flow was 68 L h^{-1} and there was a nutrient supply of nitrogen (NH_4CL, $NaNO_3$) and phosphorus (NaH_2PO_4). The productivity of the tanks was calculated by the equation: (g DW m^{-2}) = (DW / FW) x [($F_{FW} - I_{IW}$) / A]. The produced biomass was analysed in terms of carbon and nitrogen tissue content (% DW) carried out in an Elementar Analyzer coupled to an Isotopic Ratio Mass Spectrometer, protein content (% DW) by the Dumas method, total lipids content (% DW) by the Bligh and Dyer method, ash content (%DW) by the AOAC method (AOAC 920.153), total polyphenolic content (mg GAE/100 g DW) using a spectrophotometric method, antioxidant activity using the ABTS method (µmol Trolox/100 g), FRAP and DPPH methods, and fatty acid profile (mg/g) by acid catalysis and GC.

Results and discussion

On the two trials, there were no significant differences on the productivity between the different densities tested ($p < 0.05$). The productivity of the two species was low when compared to other species[4,5], and the productivity of *P. cartilagineum* was higher than the productivity of *S. coronopifolius*. The nutrient removal capacity of the two species was analysed in terms of the N removed in the seaweed biomass produced and calculated from N content and seaweed yield. Because of the lower productivity, these results were also low, but when comparing only the N content, *P. cartilagineum* and *S. coronopifolius* showed to have bioremediation potential if the ideal conditions for their growth are found[4,5].

Table 1: Total polyphenolic content of the analysed seaweed, initial and final of the different densities tested. Values are expressed as the mean ± SD (n = 4). Values in a column without a common lowercase letter and values in a row without a common uppercase letter are significantly different ($p < 0.05$).

	Total polyphenols (mg GAE/100 g)

Density 4 g L^{-1}	207.9 ± 10.30^{b}	100.4 ± 7.22^{b}	154.7 ± 5.52^{b}	109.1 ± 13.72^{b}
Density 8 g L^{-1}	189.7 ± 5.02^{c}	63.0 ± 6.98^{c}	158.6 ± 27.01^{b}	79.4 ± 6.38^{a}

Table 2: Results of the evaluation of the antioxidant activity of the analysed seaweed, initial and final of the different densities tested. Values are expressed as mean ± SD (n = 4). Values in a column without a common lowercase letter and values in a row without a common uppercase letter are significantly different ($p < 0.05$).

	Antioxidant activity ABTS method (µmol Trolox/100 g)			
	P. cartilagineum		*S. coronopifolius*	
	Water	Ethanol 96%	Water	Ethanol 96%
Initial biomass	$1617.0 \pm 177.76^{a\,A}$	$1687.7 \pm 561.11^{a\,A}$	$2829.8 \pm 128.09^{a\,B}$	$1738.1 \pm 539.44^{a\,B}$
Density 4 g L^{-1}	4434.8 ± 262.04^{b}	3336.2 ± 169.89^{b}	4488.8 ± 243.57^{b}	3778.1 ± 579.95^{b}
Density 8 g L^{-1}	4296.3 ± 531.97^{b}	2310.5 ± 305.50^{a}	4137.0 ± 250.60^{b}	3274.2 ± 493.96^{b}

(Continued on next page)

In phenol content and antioxidant activity there was an increase at the end of the trials and *S. coronopifolius* had higher values than *P. cartilagineum*. The results obtained were in the range previously obtained in different studies for other species, being variability dependent on species, environmental conditions, and time of harvesting[6,7].

At the end of the two trials, there was an increase in the levels of polyunsaturated fatty acids, as seen before, there was also an increase in antioxidant activity that will serve to reduce fatty acid oxidation, since polyunsaturated fatty acids have a greater tendency to oxidize. On the two tested species the main saturated and unsaturated fatty acids were C16:0 and C20:5 (n-3), respectively. These results are in accordance with others obtained for other red seaweed, and had lower values than brown species[3].

Conclusion

Although *P. cartilagineum* and *S. coronopifolius* did not have high productivity values, they showed a high content of nitrogen in their tissues, which can show that both species have a bioremediation potential, dependent on an improvement of the biomass production. The results also show that EPA concentrations are in the range of values reported for red species, and these two species are a rich source of n-3 PUFA (18 – 29 %). At the end of the trials, the composition of the two species changed, total polyphenolic compounds, antioxidant activity and fatty acids composition increased, which indicate that the cultivation conditions had an impact on their composition, and can bring benefits to industrial applications, so further experimental work is required.

IPMA - Portuguese Institute for the Ocean and Atmosphere/EPPO - Aquaculture Research Station, Avenida do Parque Natural da Ria Formosa s/n, 8700-194 Olhão, Portugal

*pedro.pousao@ipma.pt

The Portuguese Institute for the Ocean and Atmosphere (IPMA, I.P.) is a public research institute and act as a counselor to the national authorities on the sea and atmosphere. IPMA, I.P., possesses a strong cluster of competences for the ocean and marine resources related to research, carried out by different groups, particularly dedicated to aquaculture and fisheries.

The Aquaculture Research Station of Olhão (EPPO, figure 1) stands out for the unique experimental conditions on aquaculture at the national and international levels. This marine core facility is equipped to carry out production studies at every scale from bench-top laboratory work to a much larger semi-industrial level. EPPO has an area of about 7ha with more than 200 tanks, including an hatchery fully equipped for research and experimental production with different rearing circuits (for broodstock, larvae, juvenile production and research with live animals), a support building (with rooms for trophic chain production, daily routines and biological sampling), several analytical laboratories (biochemical, histological, molecular, microbiological and fish pathology), an unit for seafood packing, an area for pre-fattening (for earthen ponds and sea cages production) and 17 earthen ponds. It holds breeders of several marine fish species (e.g. meagre, gilthead seabream, seabass, Senegalese sole and sardine among others), microalgae and invertebrates as well as the know-how on the production of these species.

Production of new species, nutrition, welfare, environmentally friendly production systems and assessment of onshore and offshore and production systems for fish grow-out are some of research lines developed at EPPO (figure 2).

Acknowledgments: The research was funded by DIVERSIAQUA II (Mar2020-P02M01-0656P) project.

NUTRITIONAL VALUE OF *Holothuria poli:i* A NEW RESOURCE FOR AQUACULTURE EUROPEAN

Ermelinda Prato*, Isabella Parlapiano, Giovanni Fanelli, Francesca Biandolino

CNR-IRSA, Water Research Institute, Via Roma 3, Taranto, Italy
*E-mail: linda.prato@iamc.cnr.it

Sea cucumber (Echinodermata: Holothuroidea) represents an important seafood whose consumption is becoming popular around the world because of their bioactive compounds which have many human health benefits.

The increasing market demand and retail prices of up to USD 300–500 kg-1 (dried), has led to an exploitation often indiscriminant and excessive with a reduction of sea cucumber stocks. Although information on food composition is essential for market exchange and for consumer protection, only a few studies refer to the nutritional profile of sea cucumbers. In this study, the nutritional properties of body wall and gonad of *Holothuria polii* male and female collected from central Mediterranean Sea, were analysed. Specimens of *H. polii* were collected from an area of Mar Grande in Taranto (Ionian Sea, southern Italy) by scuba diving, during October-November 2019.

Table 1. Proximate composition of *Holothuria polii*

	Body wall		Gonad	
	Female	Male	Female	Male
Moisture (%)	82.20 ± 0.4	81.85 ± 0.6	80.51 ± 0.5	83.32 ± 1.0
Ash (%)	4.32 ± 0.3	4.27 ± 0.4	5.17 ± 0.3	4.15 ± 0.5

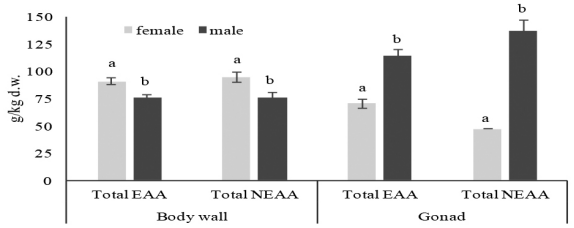

Fig. 2. Sum of Essential and Non essential AAs of *H. polii*

(Continued on next page)

In general, *Holothuria polii* was found to have low fat and high protein contents so, can be considered as a dietetic food. The *H. polii* species was rich in terms of PUFA, especially the gonad of female. Arachidonic acid (20:4 n6) and eicosapentaenoic acid (20:5 n3), which are significant for nutrition are present in highest concentration. This sea cucumber species was a good source of Essential Aminoacids (EAA) and an ideal nutritional seafood for human consumption. The EAA/Total AA ratio of *H. polii* was in the range 45.4-59.8%, with the highest value in the gonad of female.

Therefore, *H. polii* could be take into account for its potential culture. Our results indicate that *H. polii* has a balanced nutritional quality and contains compounds that can contribute for a healthy and well-balanced diet.

GENOME-WIDE ASSOCIATION STUDY OF HYPOXIA STRESS TOLERANCE IN RAINBOW TROUT

Introduction

Hypoxia is one of the most critical threats for future aquaculture sector due to the global climate changes. Global warming decreases dissolved oxygen leading to decline of health and welfare of cultured aquatic organisms and has also deleterious impacts on growth, reproduction, immunity and other energy demanding activities (Farrel and Richards, 2009; Gallage et al., 2016). Although many studies have revealed that there is an adaption strategy in low oxygen tolerance for fish species (Zhu et al., 2013), Genome-Wide Association Studies (GWAS) of hypoxia stress tolerance in aquaculture species are rare (Li et al., 2017; Wang et al., 2017).

Rainbow trout (*Oncorhynchus mykiss*) is one of the most commonly farmed salmonid species that requires high level of dissolved oxygen in comparison to other fish species. However, GWAS of hypoxia stress tolerance in rainbow trout is still missing. Therefore, objectives of this study were to estimate heritability and to detect quantitative trait loci (QTL) associated with hypoxia tolerance.

Materials and methods

The experimental stock was established from 190 dams and 98 sires of a commercial selected diploid population of Milin Nevez breeding company (Bretagne Truite Group, France). The stock was reared under commercial conditions until the experiment. Fish were then transported to the ANSES-SYSAAF Fortior Genetics platform and acclimatized before acute hypoxia challenge test. 1,320 individuals were P.I.T. tagged and fin-clipped for later DNA extraction and genotyping. The challenge to hypoxia was sub-divided into seven batches (one per day) and in each batch a random sample of fish (app 188 fish per batch) was challenged. At the beginning of each batch the initial oxygen level was recorded. Gradual decline of oxygen was conducted by bubbling nitrogen. When fish lost their equilibrium, they were removed from the tank, identified (PIT-tag reading), weighed (mean weight 50.8 g) and euthanized in Eugenol. The corresponding time and oxygenation level were recorded. The challenge ended when the last fish lost its equilibrium and was removed of the tank.

All individuals were genotyped for 57,501 SNPs with the Axiom™ Trout Genotyping array at the INRAE genotyping Platform Gentyane. After quality controls and imputation of missing genotypes approximately 28,875 SNPs and 1,297 individuals were used in the statistical analysis. Tolerance to hypoxia was analysed as time to loss equilibrium (TLE) with the day of trial as a fixed effect in the final model. Using BLUPF90 package (Misztal et al., 2014) GBLUP analysis was performed to estimate heritability of the trait with AIREMLF90 program and to detect QTL with POSTGSF90 program (Aguilar et al., 2014).

Results

Genomic heritability of hypoxia tolerance was moderate (0.37 ± **0.04). We also identified** a few QTLs with the most significant one on chromosome 31 with possible candidate genes in the region spanning approximatively from 20 Mb to 23 Mb on the Arlee genome reference assembly (USDA_OmykA_1.1.).

Discussion and conclusion

Preliminary results revealed that the tolerance to hypoxia is a heritable trait. In addition, a significant QTL was identified on chromosome 31 with several putative QTLs detected on other chromosomes. However, further statistical analyses including more dense genotypes and Bayesian approach need to be conducted to precise our preliminary results.

Introduction

Innovation has played a major role in shaping European aquaculture, and it remains essential for the sector's continued survival. Advances in digital technology offer new opportunities for innovation that might contribute to the industry's continued success, stimulating initiatives for the development of artificial intelligence, automation, and Internet of Things based solutions. The iFishIENCi project aims to optimise feeding in fish production systems through combined application of machine learning algorithms, video observation of fish behaviour, and water quality digital sensors and software. The approach uses FishMET, a model simulation of fish feeding behaviour and related physiological and metabolic processes. The ability of FishMET to accurately simulate these processes is limited by a lack of data describing their functional relationships for different species within varying conditions. Obtaining the required data is challenging as these relationships have a dynamic and apparently complex nature. To address these issues, an ongoing series of experiments are being performed to a) validate a combination of methods for obtaining data that describe rainbow trout (*Oncorhynchus mykiss*) feeding behaviour, feed intake, and stomach fullness, to b) identify and describe relationships between these processes and c) generate data that is useful for the development and training of machine learning algorithms. If distinct levels of stomach fullness and hunger are associated with different behaviours, it may be possible to use a combination of machine learning and real-time video monitoring of fish behaviour to assist with the optimisation of feeding regimes beyond what is currently possible.

Materials and methods

A recirculation aquaculture system facility was stocked with rainbow trout of varying size and held at densities of approximately 35kg/m^3. The fish were subject to varied meal regimes delivered by automated feeders, and feed consumption, stomach fullness, behaviour and water quality data were assessed. Behaviour was recorded by video camera, and feed consumption was quantified using a labelled diet and X-ray imaging, as described by McCarthy et al. (1992). Digital sensors and cloud integrated monitoring were used to record temperature and dissolved oxygen. Machine learning algorithms based on the Sciit-learn python library were trained and used for target acquisition and fish tracking, and *k*-means clustering techniques were used to evaluate inter-fish distances and grouping.

Results

Fish in video images were successfully targeted and tracked using algorithms. Aggregations of fish below feeders were observed before feeding events and were effectively characterised by *k*-means clustering algorithms. Strong schooling is observed post feeding but increased clustering pre-feeding was not consistently observed. In feed markers are visible in X-ray images and calculated feed consumption quantities compare well to known quantities of feed consumption.

(Continued on next page)

Discussion

The ability of algorithms to identify, track, and characterise clustering is promising, although more exploration is required. *k*-means clustering scores were not consistently higher before mealtimes despite the absence of aggregations post-feeding. The incidence of aggressive behaviours, which may disrupt clustering, appear to increase before meals, and singles behaviour types may not be reliable as standalone cues. Aggregation may be an anticipatory response in fish conditioned to receiving feed at set times and from the same location, and so its usefulness as an indicator of hunger is yet to be determined. Behaviour such as aggression or higher swimming velocity may be more appropriate indicators of hunger state, although behavioural expression may differ across cultivation conditions and size classes. The McCarthy et al. (1992) method was successfully used to quantity feed consumption. Its suitability for quantifying relative fullness across separate regions of the gastrointestinal track is now being investigated. This information can be useful for understanding hunger, satiety, anticipation, and associated behaviours. Ongoing experimentation continues to assist the development of machine learning algorithms that may reveal relationships between stomach fullness, hunger state and behaviour.

Introduction

As part of the European Horizon 2020 project UNITED (UNITED, 2021), an offshore longline system (Morse and Rice, 2010) will be installed to assess the feasibility of cultivating European flat oysters (*Ostrea edulis*) in the Belgian part of the North Sea 25 nautical miles off shore. Five different culture systems are studied: SEAPA baskets stacked on a ladder frame; oysters glued on dropper lines; frames consisting of horizontal and vertical grow-out sticks; frames as spat collectors; trays on dropper lines. To accommodate these culture systems, a mooring configuration suitable for the harsh offshore environment is designed. The main cultivation line is 57 m long, making up the total length of 263 m of mooring and backbone ropes from South-West screw anchor to the North-East screw anchor. The distance between both anchors is 250 m. The water depth at the test location is at -30.1 m Mean Lower Low Water Spring.

Materials and methods

A set of boundary conditions are defined based on the operational limitations, space available and guidelines' recommendations. Fig.1 shows the flowchart of the mooring design iterative process. The longline system will be installed with anchors within a zone of four wind turbines. Taking this into account, during the operational conditions, the area taken by the mooring system has to be less than 0.12 km^2. This governs the longline design characteristics as initial input. Then, a hydrostatic calculation is performed to ensure that the cultivation line can be lifted 5 m above still water level and the lifting capacity of the vessel is adequate to perform maintenance/installation operations. Lastly, dynamic simulations incorporating waves and current induced load are performed for various scenarios to determine the material properties of the mooring components. Numerical simulations are performed utilising an in-house mooring dynamic solver based on the lumped-mass approach to discretize the lines (Hall and Goupee, 2015; Pribadi et.al, 2019) and the Morison Equation (Morison, 1950) to model the hydrodynamic forces. The Morison coefficients are taken from the guidelines set in the DNVGL OS301 (DNVGL, 2018). The sea states used for the Ultimate Limit States (ULS) calculation and safety factors for the line elements are taken from the recommendations provided in the NS9415 document (Norwegian Standard, 2010).

Results

The ULS simulation that is taking the 50-year return period of waves () and current (parallel to the longline, is giving the maximum predicted tension of 125 kN on the mooring lines. The state of the mooring system during the ULS simulation at = 63.8 s is shown in Fig. 2. A maximum load of 71 kN is calculated for the 1-year return period of waves () and current parallel (to the system. The load time-series of the two sea states are shown in Fig. 3.

Discussion and conclusion

An iterative design process has been performed to define the technical requirements needed to install a mooring system for the cultivation of flat oyster in an offshore wind farm. The mooring system is designed with a "set and forget" principle, meaning that the system will start with an excess buoyancy on day-1 of installation. By the winter season when the worst storm occurs, the backbone would be fully submerged up to 10 m of depth, due to the increase of biomass (oysters and biofouling), making it less exposed to the wave actions. Then, after one year of installation, a maintenance operation will be needed to adjust the buoyancy.

Introduction

Skeletal responses of vertebrates to increased mechanical stimuli overrule genetic determination, ranging among shifts on bone volume, size, shape, composition and mineralization (Suniaga *et al*. 2018). Through exercise, an effective means of imposing increased mechanical loads to the fish skeleton, a V-shaped curvature in the haemal part of the vertebral column can be induced (Printzi *et al*. 2021). Haemal lordosis, a common skeletal abnormality reported in several aquaculture species, has been recently observed to be reversible in Gilthead seabream and European sea bass during on-growing period (Fragkoulis *et al*. 2019, 2021). Given the fact that the most important bone cell remodeling procedures (Witten and Hall 2015) and underlying signaling molecules have been identified, the aim of the present study is to examine the recovery potential of haemal lordosis and the underlying mechanisms in zebrafish, a model vertebrate species.

Materials and methods

Early juveniles of 12 mm TL (total length) and normal skeletal phenotype were subjected to continuous exercise against water velocity of 8.0 TL·s^{-1} (Printzi *et al*. 2021) for a four-day period. Lordotic juveniles after the swimming challenge test (SCT) were monitored individually for a week under common husbandry conditions (0.0 TL·s^{-1}). Feeding regime and abiotic conditions remained constant throughout the experiment. During the trial, lordosis development was followed by means of in vivo examination, whole mount staining for bone and cartilage, histology and gene expression analysis. Two control groups consisting of normal fish after SCT, as well as non-exercised juveniles of the same size were acquired. Three replicates out of a single spawning event were performed.

Results and Discussion

Macroscopic examination of the fish revealed that haemal lordosis has a great recovery potential in zebrafish juveniles. Recovery of the lordotic phenotype was first detected at 4 days post-SCT, with the 72.5% of the originally abnormal fish (Fig. 1b) presenting a completely normal phenotype (Fig. 1c). Likewise, the progress of the recovery process reached 89.5% at the end of the recovery week (Fig. 1a).

The present study demonstrates that complete recovery of haemal lordosis in zebrafish is achieved within one week of fish swimming in "static" water. Our results obtained from histological and transcriptomics analyses (data will be presented on the poster) present evidence for the involvement of extensive bone formation through remodeling in the recovery process. These results agree with the observation that bone remodeling is involved in the partial recovery of vertebrae centra fusion in Atlantic salmon (Witten *et al*. 2006). Obtaining control of skeletal abnormalities that effect the external phenotype, either through prevention or recovery, can enhance the quality of final aquaculture products.

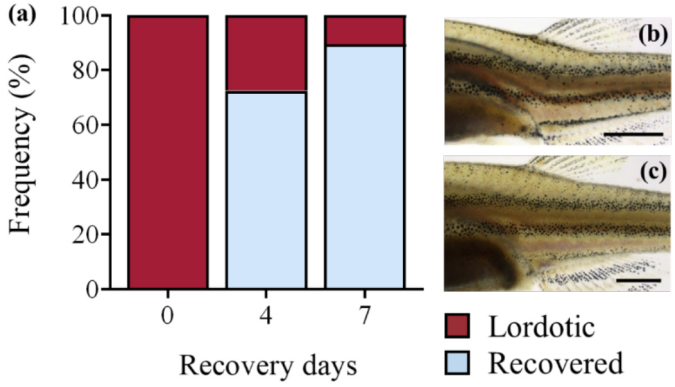

Figure 1. Development of the lordotic phenotype after swimming challenge test (recovery period, 0.0 TL s^{-1}). Fish categorization into lordotic (b) or recovered (c) is based on external morphology. Scale bars equal 1mm.

EMBRYONIC TEMPERATURE AFFECTS SKELETAL DEVELOPMENT IN ZEBRAFISH

A. Printzi[1,2*], A. Kekelou[1*], G. Koumoundouros[1]

[1] Biology Department, University of Crete, Heraklion, Crete, Greece
[2] IFREMER, University of Brest, CNRS, IRD, LEMAR, F-29280, Plouzané, France
Email: alikipr95@gmail.com, grad1002@edu.biology.uoc.gr

Introduction
Teleost skeleton is subjected to continuous changes as a response to internal (e.g. allometric growth) or external stimuli (Witten & Hall 2015, Balbuena-Pecino *et al*. 2019). Water temperature during the early life stages is an important driving factor of fish phenotypic plasticity, with significant effects on the ontogenetic pattern and the meristic counts of skeleton (e.g. Sfakianakis *et al*. 2004, Christou *et al*. 2018). In the present study zebrafish was used as a model to examine whether a short temperature exposure during the embryonic stage affects a) skeletal development (ossification rate, vertebrae counts) during the following larval period, and b) the response of vertebral column against intense swimming activity.

Materials and methods
Experimental temperatures (24, 28, 32 °C) were applied in duplicate, during the embryonic period, whereas after hatching all groups were reared under the same conditions (Fig. 1). The ossification rate of different skeletal elements was studied on random samples of larvae, taken from each experimental population every 2-3 days. Larvae were subjected to a calcein staining protocol following Du *et al*. (2001), anesthetized, photographed under a fluorescence stereoscope (Olympus SZX16) and measured for total length (TL). In total, ca 180-220 larvae per developmental temperature (TD) were examined.

Swimming challenge test (SCT) followed the protocol of Printzi *et al*. (2021) and was applied for four days (at 8 TL s^{-1}), on 20 fish per thermal group and replicate. SCTs were performed at the end of metamorphosis (ca 13 mm TL). After the test all fish were stained for bone and cartilage (Walker & Kimmel 2007) and examined for the presence of haemal lordosis.

Results and discussion
During the early larval stage (<6.5 mm TL), fish having experienced a higher embryonic temperature (32°C) presented a delayed ossification rate against those of 24 and 28 °C (Fig. 2A). In the following developmental period (>6.5 mm TL), no significant effects of temperature on ossification rate were observed. Furthermore, embryonic temperature significantly affected the number of haemal vertebrae and the response vertebral column to SCT. As embryonic temperature increased the number of haemal vertebrae decreased ($p<0.05$, Kruskal-Wallis test) and the incidence of lordosis increased ($p<0.05$, G-test).

Our results demonstrate that a short temperature raise (withing the species tolerance zone) during the critical embryonic period may have significant, long lasting effects on zebrafish skeleton. In addition to their relevance to global climate change, our findings have relevance to the mitigation of lordosis development in reared fish.

Histone post-translational modifications act as dynamic regulators of the genome. Despite their crucial role in genome regulation, the impact of dietary nutrients upon histone modification landscapes remain poorly understood, particularly in fish models. In this project, by supplying Atlantic salmon (*Salmo salar*) with a surplus nutrient package, we measure the impact of altered one-carbon (1C) metabolism on the enrichment of two histone modifications associated with activation: H3K27ac and H3K4me3.

Crucial to cell function, one-carbon (1C) metabolism provisions methyl groups for a range of biological processes. These particularly include the regulation of gene expression via DNA methylation and histone post-translational modifications. The activity of 1C metabolism is dependent upon the availability of select nutrients, particularly folic acid, pyridoxine (B6), cobalamin (B12), and methionine.

To measure the impact of an increased intake of 1C nutrients upon growth, epigenetic state, and gene expression, we raised groups of Atlantic salmon (*Salmo salar*) on two plant-based diets with varying levels of 1C nutrients: one control (Low1C) using nutrients at recommended levels, and one moderate+ diet (Med1C) with increased levels of 1C nutrients (NRC 2011). Respectively, the Low1C and Med1C diets contained 2.6 mg/kg and 4.8 mg/kg folate, 6.75 mg/kg and 9.31 mg/kg B6, 0.15 mg/kg and 0.18 mg/kg B12, and 6.7 g/kg and 9.5 g/kg methionine (Espe *et al*. 2020; Adam *et al*. 2021). Muscle tissues from the Low1C and Med1C treatment groups were collected for various sequencing applications during both freshwater and saltwater life stages.

To characterize the changes in chromatin landscape resulting from limitation of 1C nutrients, we mapped the enrichment of two histone post-translational marks associated with activation: H3K4me3 (a marker of active promoters) and H3K27ac (marking active enhancers and promoters). We performed Cut&Run of both marks in single muscle samples from the Low1C and Med1C treatment groups (n=2 per tank, 3 tanks/treatment). Sequencing was performed for both freshwater and saltwater life stages. Levels of gene expression (RNA-seq) and DNA methylation (RRBS) were measured in these same muscle samples, allowing for multi-omic comparisons across data types (Saito *et al*. 2020; Adam *et al*. 2021).

Comparative enrichment analysis between the diet treatments identified differentially bound regions for both marks (p-value<0.05). Annotation and functional enrichment analysis of these regions implicated multiple pathways involved in cell signaling and amino acid metabolism. These results reflect those obtained from DNA methylation and transcriptome sequencing of the same samples, suggesting that regulatory changes in response to altered 1C metabolism are coordinated across epigenetic mechanisms and transcription. In this poster, we characterize the impact of altered 1C metabolism on two major histone modifications in a teleost model, contributing to the growing area of investigation concerning the impact of nutrition on chromatin architecture.

lribeiro@ipma.pt

Introduction

The natural richness of Ria Formosa coastal wetlands (South Portugal) provides significant economic resources to the local community, with its impact visible since the late 19th century [1]. Several human activities exist along these areas (aquaculture, salt farming, fishing, etc.) and balancing the interests of the different economical activities and other from environmental protection and recreational use is challenging.

With the aim to better understand these spatial relations, project AQUA&AMBI (phase 1 and phase 2) aimed to identify and rank present-day economic activities in Ria Formosa, in terms of compatibility with aquaculture, by analysing existing legal framework, spatial constrains, and infrastructure development. The resulting ranking system reflects areas where many activities may be developed simultaneously with aquaculture and without major constraints (High convergence), and areas where compatibility is reduced but also no major constraints are identified (Medium convergence). Low convergence areas have significant constraints for economic activities development, with a corresponding low compatibility. The identification of these areas greatly contributes to the creation of sustainable management models for Ria Formosa that can be expanded with further data sources harnessing the flexibility Geographical Information Systems (GIS).

The characterization of the water physical-chemical properties in the proximity of high convergence areas can verify the real potential of these areas for aquaculture development. The present work outlines a short campaign focused on collecting observations during representative seasonal periods (Summer, Autumn, Winter, Spring), providing an indicative description of existing conditions.

Material and methods

Two sampling areas (Fig. 1) were selected based on proximity to high convergence areas related to salt farming ("Bela Mandil" section, 9 points), and earthen ponds aquaculture ("EPPO" section, 8 points). Points distribution was defined to cover the tidal channels in each section, with a maximum distance of 500 m between each point. Sample collection was performed at the peak of high tides (max. 3.6 m in august and min. 3.24 m in January). Physical, chemical, and biological parameters were acquired at different sampling points for the two areas. Samples and data were collected from August 2020 until May 2021 during five campaigns. The water quality parameters and indicators analysed were dissolved oxygen (DO), temperature (T), pH, turbidity, chlorophyll, nutrients (ammonia, nitrites, and nitrates), and suspended particulate matter (SPM). The first five parameters were measured *in situ* with oxygen meter (model HI9829, Hanna Instruments) and a multiparametric probe (model EXO2, YSI). For the remaining parameters, water samples were collected at each sampling station, for nutrients water was filtered on site with Whatman membrane filters (pore size 0.45 μm and 47 mm diameter) using a swing-lock support, and kept refrigerated for further laboratory analysis.

(Continued on next page)

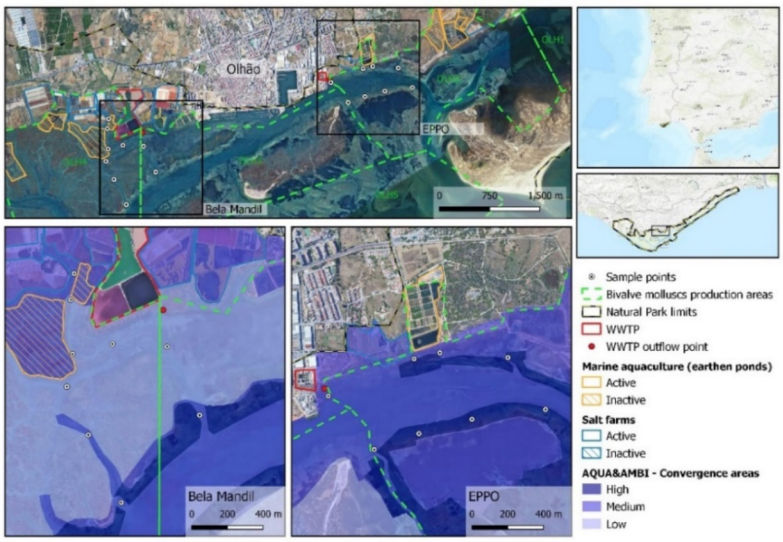

Figure 1 – Convergence areas in Ria Formosa, identified during phase 1 of AQUA&AMBI project, with potential for aquaculture development and other activities without major constraints within legal framework.

Results and Discussion

The studied parameters varied within similar range of values for the different sampling points at both convergence areas, suggesting a quite stable environment. Autumn affected the magnitude and variability between these areas, specially of chlorophyll, with values ranging between 1.60 ± 0.53 μg/L in EPPO area and 0.60 ± 0.30 μg/L at BELA-MANDIL area. Regardless of the convergence area, the lowest and the highest temperature measured were 12.3 in Winter and 22.9 ºC in Summer. Dissolved Oxygen values ranged between 5.28 and 11.4 mg/L, and pH from 7.90 and 9.38. The highest variations observed across both areas and seasons were, in decreasing order, for chlorophyll (from 0.00 to 2.44 μg/L), ammonia (from 0.11 to 1.84 μg/L), and nitrites values (from 0.62 to 49.35 μg/L). No major differences were evident between sampling points regarding the main channel proximity, except for dissolved oxygen in Summer, with lower values (≅ 6.0 mg/L) farthest and higher values (≅ 8.0 mg/L) in the proximity of the channel. The homogeneous water quality at both convergence areas seems to be related with the high hydrodynamic conditions of Ria Formosa Lagoon [2]. The preliminary results evidence the good water quality of the studied areas along the year, which varied within values adequate to rear marine fish and shellfish species common in this region [3]. Understanding either natural or anthropogenic processes around each convergence area will increase the capacity to predict how internal processes in Ria Formosa affect the water quality coming from the sea [2].

CLINICAL CASES OF FISH PATIENTS IN PRIVATE PRACTICE

Presented by Jena Questen DVM CertAqV

World Aquatic Veterinary Medical Association and Aspen Park Veterinary Hospital

fish@drquesten.com

Introduction

Private clinical aquatic animal practice provides the opportunity for the veterinary practitioner familiar with aquatic species to treat a variety of species and diseases. This talk is a selection of interesting cases seen by this aquatic practitioner over the past few years. We will discuss species as varied as Koi, Goldfish varieties, Oscars, and Axolotls. Diseases diagnosed in this practice include husbandry concerns, parasites, and sand impactions. Most cases have radiographs which are useful for learning. This presentation is good for anyone interested in the common diseases and presentations of a variety of fish species.

Materials and Methods

This is a case review of the medical records of multiple fish patients.

Conclusion

There is ample opportunity for learning in the private practice area of aquatic animal medicine. A variety of species and diseases can be encountered at any time which will be of interest to anyone involved in the health and care of aquatic animal species.

FIRST ATTEMPTS OF ONTOGENY DEVELOPMENT IN THE GOLDEN MULLET (*Liza aurata*)

Raquel Quirós-Pozo[1*], Javier Roo-Filgueira[1], Juan Antonio Calderón[2], Sara Ramírez-Bolaños[1], Anais Ventura-Castellano[1], Lidia Robaina[1]

Introduction

The Mugilidae family presents a great potential for the sustainable diversification of aquaculture, due to their eurythermal, euryhaline, and low trophic nature (Crosetti & Blaber, 2015). Among them, the golden mullet (*Liza aurata*), is an interesting species due to its fast growth in the early stages (Hotos et al., 2020) and good filet quality (Quirós-Pozo et al., 2021). However, the culture of these species continues depending on fry collection from the wild, which produces high mortalities and potential impact in wild populations, so as international interest in mullet's rises, the control of broodstock management and larval rearing increase in importance. In this respect, the knowledge of the sequential timing of appearance and functionality of the different organs and tissues is crucial to develop adequate rearing protocols and feed formulas. In this regard, histological studies are among the major tools to identify the larval critical periods and growth patterns (Sarasquete et al., 2014).

Material and Methods

Broodstock management

125 golden mullets (*Liza aurata*) were captured from a semi-natural estuary in San Fernando (Cádiz, Spain) and stocked in 10 m3 tanks in an open-water system in the facilities of the CIFP Zaporito (San Fernando, Cádiz). Fish were initially sampled to determine the medium size and weight, sex ratio, and the rate of sexual maturation in mature animals. Fish had been fed just from natural feed present in the estuary, being the natural conditions determined at the moment of sampling between 20.9ºC and 23.4Cº (sunrise and sunset respectively) for the temperature, and 7.99 mg/l and 30 ppm for the oxygen level and salinity respectively; photoperiod was approximately 12 hours light and 12 hours darkness.

Larval rearing and samplings

After being acclimated indoor in an open-water system with similar conditions to that of the estuary, natural spawnings were obtained from September to late November. The broodstock was fed for all the period with a commercial extruded feed (R5 Europe, Skretting). Eggs were daily collected and incubated in a 350l tank with soft aeration from the bottom, and seed in the final tanks (1 m3) at 3 dph (days post-hatching). Green water culture was carried out with a 1:1 mix of *Nannochloropsis gaditana* and *Isochrysis galbana*. Rotifers (*Brachionus plicatilis*) were added every day to achieve a total amount of 6-10 rotifers/ml in the tank. Microdiet (Gemma wean, Skretting) was offered from 20 dph, and Artemia sp. nauplii (1-0.5 nauplii/ml) was used when rotifers were retired from 24 to 28 dph. From 28 dph the larvae were fed just with the microdiet. Photoperiod was natural, the temperature ranged from 15.1 to 18.5ºC, and medium values for salinity and oxygen were 30.9±1.9 ppm and 7.3±0.5 mg/l, respectively. Two different spawnings were used to carry out all the samples, the first one (S1), from 0 dph to 9 dph, and the second one (S2) from 5 dph to 16 dph. Samples of larvae were taken every day at the first hour in the morning (before larval feeding) and preserved in 4% formalin for histological analyses (n=10 for S1 and n=20-30 for S2).

Results

Total weight and length of mature fish ranged from 398-150g, 38-26cm, and 564-274g, 43-35cm, for males and females, respectively, being fish able to spawn naturally after one year of stocking at cultured conditions. At hatching, the larvae presented unpigmented eye spots, and the digestive system consisted in a closed tube of cubical simple epithelium. Melanofores covered the different layers along the body. At 1 dph, olfactory vesicles were visible. At 2 dph, retinal cells and eye pigments started to differentiate. Also, the primordial liver and exocrine pancreas could be identified caudoventral to the yolk sac. At 3 dph, the mouth was opened while the yolk sac was mostly reabsorbed, being present the oil globule. Pseudo-stratified epithelium started to differentiate in the primordial stomach and gut. From 6 dph, the digestive system increased in complexity, with intestinal villi well developed and the ileocecal valve well differentiated. The spleen was visible from 7 dph onwards. Liver increased cell organization and lipid deposition, and progressively reabsorbed oil globule until days 11-16. Present results may help to better understand *Liza aurata* physiology and development, and thus to obtain a higher insight to adjust this species culture conditions and feeding pattern.

Introduction

In the global context of climate change, the reduction and reuse of waste are necessary to reduce the carbon footprint of human industrial processes (FAO, 2018). Aquaculture, and its expected growth in the next decades, should play a fundamental role beyond circular economy by highly promoting the use of more sustainable ingredients and additives from the recirculation of matter. In the Macaronesian region, islands context, several projects are being developed to point out the value of different scalable agricultural by-products for their possible introduction in the aquaculture industry, like Islandap Advance (MAC2/1.1a/299) and Aquacircular (Bioasis/1.1b/086), where this study has been developed. To better understand novel by-products benefits before running large in vivo assays, a in vivo test of the bioactivity present in residues have been developed, to complement their previous characteristics. From the preliminary results obtained with different materials, establishing 3 steps for the bio-prospection & characterization of agricultural by-products result more useful to pre-determine their potential in feeds for aquaculture.

Material and Methods

The characterization of the aloe vera (*Aloe barbadiensis)* by-product (ABP), carob pod (*Ceratonia siliqua*) (CBP) and acacia pod (*Prosopis julifera*) (JBP) were performed following the next steps:

1. Proximate composition was determined following the protocols of AOAC (1995) for moisture, ash and crude protein, and lipids were determined by Folch *et al*. (1957). The fatty acids composition was obtained by transmethylation of total lipids (Christie, 1982) and separated and quantified by liquid chromatography following the protocol of Izquierdo *et al*. (1989).
2. The polyphenol content was obtained following three different protocols (Arranz *et al*., 2009; Hartzfeld *et al*., 2002; Pérez-Jiménez *et al*., 2008; Pérez-Jiménez *et al*., 2009).
3. The in vivo bioactivity was determined in zebrafish larvae (5 dpf). The extractable and hydrolysable fractions were freeze-3.dried and resuspended in DMSO to a final concentration of 50ug/mL. Lipids reducing activity were quantified by Nile Red Assay (Noinart *et al*., 2017), and lipase 6 and protease activity were measured using PED6 kits (Thermo Fisher, USA).

Results and Discussion

All the by-products under these assays had been tested in previous nutrition trials, ABP and PBP were tested in feeds for rohu fingerlings and golden mullets, as an alternative source of carbohydrates (Chovatiya *et al*., 2018; Quirós-Pozo *et al*., 2021); furthermore, CBP use is widely extended in human nutrition (Arribas *et al*., 2019). The results of this experiment are in agreement with previously reported ones; thus, the three by-products showed a high amount of carbohydrates (from 78 to 88%) and a low quantity of lipids (0.98 to 2.93%); ABP has the highest amount of ashes and, PBP and CBP display 8.9% and 6.5% of proteins. Also, they all 3 are rich in palmitic acid, oleic acid and linoleic acid, and ABP moreover presents 14% of DHA. All by-products were demonstrated to be rich in Non-Extractable Polyphenols (NEPP); CBP presented the highest amount of NEPP and, also total polyphenols. These compounds can be responsible for the antioxidant capacity described in CBP (Ibrahim *et al*., 2020), and they also can explain the activity of lipid reduction that was observed in zebrafish in the present trial exposed to the extractable polyphenol fraction of ABP; CBP and JPB presented antagonist effects on protease activity in zebrafish treated with the extractable fractions. In the light of the results obtained, the three by-products are promising for aquafeeds and further and comprehensive in vivo research studies should be performed. On the other hand, the in vivo bioactivity test developed was a useful extra test to better support biochemical analysis and is being better implemented in our labs.

Introduction

Aquaculture is playing, and will continue to play, a significant role in boosting global fish production and in meeting rising demand for fishery products. A recent session of the FAO Committee on Fisheries stressed the increasingly key role of aquaculture in fish production for human nutrition and poverty alleviation in many rural areas. The huge growth expected for aquaculture products makes necessary a more sustainable aquaculture development to mitigate the environmental impacts linked to this growth. Aquaculture can contribute to the objective of filling the gap between EU consumption and production of seafood in a way that is environmentally, socially and economically sustainable (COM (2013)229). Indeed, when practicing responsibly, fish farming can help provide livelihoods and feed a global population that will reach nine billion by 2050.

In 2013 European Commission proposes the Product Environmental Footprint (PEF) and Organization Environmental Footprint (OEF) methods as a common way of measuring environmental performance (COM2013/179/EU). To validate the methodology, a series of pilots for different products are developing, and Marine Fish was selected as one of the 11 food products. The package establishes the Life Cycle Assessment (LCA) methodology to measure environmental performance of European products and organizations.

Within this framework the LIFE+ AQUAPEF project was launched in 2018. The aim of the project is to provide the first software tool specifically designed for Mediterranean aquaculture sector that enables the calculation in an easy way of a harmonized environmental impact, complying PEF methodology.

Methodology

Based on the method described in Marine Fish PEF category rules, where main steps for a common use of LCA in marine fish are established, a webtool to facilitate the calculation of environmental footprint of Mediterranean aquaculture products has been developed.

The webtool gather the information of the main steps of the Mediterranean offshore aquaculture sector: feed production, hatchery, growing, preparation and distribution. Moreover, it also considers consumption and end-of-life based on average data.

AQUAPEF tool provides a common framework in which users from different stages of the supply chain introduce a series of production data. To facilitate the data gathering, the tool offers the possibility to send the questionnaires to the main suppliers of the chain. This data is confidential, and it will be visible to the user just if the suppliers give the authorization for that.

The collected inventory data is then transformed into the 16 environmental impact categories recommended by the International reference Life Cycle Data system (Fazio et al., 2018) based on the PEF-compliant public datasets. As far as the aim of the tool is to provide a system for the SME's, it has been designed as user friendly and very intuitive. The effectiveness and usefulness of the tool has been validated with the companies of the AQUAPEF project.

(Continued on next page)

Results and discussion

The webtool has been developed during 2020. Three main section has been distinguished:

- User profile: The first section of the tool comprises the creation of company-profile where the company interested in the assessment of the environmental footprint should include the information required for the evaluation of the environmental footprint, such as location of facilities or product/species produced.

- Questionnaire: Afterwards a second section is enabled, where an easy-to-understand questionnaire is presented for each type of stakeholder. As such, feed producers should include data regarding plant and animal-based ingredients (quantities and origin), energy and water consumption and packaging requirements. Hatcheries should include inventory data regarding feed, energy and water consumption, while Growing Farms should introduce data related to feed, energy, packaging and net maintenance material consumption, together with waste and biowaste management data. Finally processing facilities should include data regarding the energy, water and packaging requirements, together with the waste and wastewater quantities.

  A model based on Bringolin et al., 2014 has been implemented in the tool in order to account for the N, P and C emissions of the fish metabolism and faeces.

- Results: In the result section, users could obtain the full Environmental Footprint of their products. A specific table with hot-spot assessment is also including.

Finally, they will be able to compare their results with average values for their sector.

The tool has been validated in 3 case studies by comparing the outcome of the AQUAPEF tool with the calculations performed with SimaPro 9.1 commercial software. Results confirms that the tool calculates the EF correctly. Additionally, based on a qualitative questionnaire, potential improvements to increase the user-friendliness of the tool have been identified. For instance, automatic data gathering from ERP and benchmark possibilities will be added to ensure the usability.

Conclusion

The AQUAPEF webtool is currently in beta-testing stage and is expected to be commercialized by 2023. We have validated that this tool could promote the calculation of the environmental footprint linked to the aquaculture products. Moreover, the obtained results could be also used to improve the environmental performance of the aquaculture products. Main barriers for a large-scale implementation are, on the one hand, the amount and the quality of data required to feed the tool and, on the other hand, the lack of certification schemes which guaranteed that obtained results reflects the real consumption and waste ratios.

Acknowledge

This project is co-funded by LIFE European Environment Programme (LIFE17 ENV/ES/000193), which is the EU's financial instrument supporting environmental, nature conservation and climate action projects throughout the EU.

Introduction

In recent decades, research on species-specific and tailormade feeds that potentiate not only fish growth but also their welfare condition and immune status, has been recognized by the aquaculture industry. Reduced reliance on fish meal and oil in the formulations of diets for farmed fish is a priority to sustain aquaculture growth, which led the feed industry to explore alternative sources. In this regard, owing to their chemical composition, microalgae appear as a promising alternative aimed at enhancing the nutritive value of new feed formulations. Microalgae have gained considerable importance in recent decades due to potential exploitation in several markets (Odjadjare et al, 2017). Hence, some waste can be used for feed production following the idea of circular bio-economy. Microalgae have antioxidant properties, high-quality dietary protein and are a source of bioactive compounds (Shields and Lupatsch, 2012). Nonetheless, information about their use in diets for salmonids species, particularly in rainbow trout (*Oncorhynchus mykiss*) is still scarce. Hence, this work aimed to evaluate whether *Acutodesmus obliquus* and *Chlorella vulgaris* inclusion in aquafeeds could lead to optimal growth and healthy fish.

Materials and methods

Rainbow trout (32.6 ± 0.11 g) juveniles were obtained from a commercial hatchery (Trutalcôa Viveiros Lda) and maintained under a quarantine period of 2 weeks at the experimental research station of the University of Trás-os-Montes e Alto Douro (UTAD, Portugal). Triplicate groups of 30 fish were fed one of the four experimental diets for 60 days, three times a day. Four diets were tested in triplicates: a good quality commercial formula, positive control (PC), a circular economy driven formula without microalgae (NC) and a similar NC formula with 5% inclusion of *Acutodesmus obliquus* (ACUT5) or *Chlorella vulgaris* (NCHLO5). All these diets (2.5mm) were produced at SPAROS facilities and are isoenergetic, isonitrogenous and isolipidic. At 15 days (early) and 60 days (final sampling) of feeding the experimental diets, 18 fish from each experimental group, 6 per replicate tank were euthanized by an overdose of anaesthetic and weighed. Thereafter, liver was collected to assess hepatic oxidative stress status, whereas head-kidney (HK) was suited for gene expression analysis (both at 15 days and 60 days feeding period). Plasma samples were only collected after 60 days of feeding to evaluate humoral immune parameters.

Results

No mortalities were observed throught the feeding trial. Regarding plasma humoral parameters at the final sampling point (60 days), no differences were observed in plasma bactericidal activity and anti-proteases activity. However, IgM values increased in fish fed ACUT5 compared to those fed the PC diet. Regarding hepatic oxidative stress responses, rainbow trout fed ACUT5 for 15 days had higher catalase (CAT) activity than those fed other dietary treatments. While also during this short feeding period, fish fed ACUT5 presented lower total glutathione (tGSH) content compared to those fed PC and NC. After 60 days of feeding, no differences were observed on CAT activity and tGSH content. Though, glutathione S-transferase (GST) and lipid peroxidation (LPO) increased in fish fed NCHLO5 and PC diets, respectively, compared to those fed all other dietary treatments. LPO also increased in fish fed ACUT5 compared to those fed PC and NC. Regarding HK gene expression data, most differences were observed after 60 days of feeding. Fish fed NCHLO5 presented an upregulation of *il-8, pcb* and *cath* compared to NC diet. Also, fish fed NCHLO5 increased *il1b* expression compared to PC diet. Trout fed the ACUT5 diet increased *cd3* and *cath* transcripts compared to those fed NC diet.

(Continued on next page)

Discussion and conclusion

Several studies have already reported data regarding the effects of microalgae inclusion in diets of farmed fish species. However, few studies investigated their effects on health status and oxidative stress of rainbow trout. The results obtained in this trial suggest that the inclusion of both *A. obliquus* and *C. vulgaris* at 5% of feed does not negatively affect the rainbow trout survival and modulates immune status. In the present study, tGSH decreased in fish fed ACUT5 compared to PC and NC dietary treatments after 15 days. Peixoto et al., 2021 suggested that natural compounds present in microalgae can have advantages, decreasing the dependency on glutathione metabolism. Additionally, the antioxidant enzyme catalase, involved in key oxidative defence mechanisms, increased in trout fed ACUT5 after 15 days. Plasma IgM increased in fish fed diets with 5% inclusion of *A. obliquus* for 60 days, suggesting that this dietary treatment could boost the acquired arm of the immune system. Likewise, fish fed ACUT5 and NCHLO5 for 60 days displayed an immunostimulant state observed by the upregulation of the pro-inflammatory cytokines *il1b* and *il-8*. Also, the T cell marker, *cd3* was upregulated in fish fed ACUT5 compared to those fed control diets. This study suggests that inclusions of 5% of *A. obliquus* or *C. vulgaris* in diets for rainbow trout can represent a viable alternative to substitute other more recurring protein sources, ultimately leading to satisfactory performance and health status.

Introduction

The Pacific white shrimp (*Penaeus vannamei*) is one of the principal crustacean species cultured worldwide, particularly in coastal areas of Pacific Ocean (Huang et al., 2016). This species has been affected by disease outbreaks worldwide, mostly caused by virus and bacteria, due to poor water quality and stressful rearing conditions, with important economic losses and serious mortality outbreaks (Kalaimani et al., 2013). Halophyte plants such as *Salicornia ramosissima* have the ability to grow in saline soils (marginal land) and/or be irrigated with seawater. The green tips of Salicornia are sold as food, while the woody part is considered a residue. However, this residue biomass is rich in valuable bio-active molecules that can be extracted using simple and affordable processing. These compounds include hydroxycinnamic acids (strong anti-inflammatory, and antioxidant), high quality protein, omega 3 and 6 fatty acids, carotenoids, and chlorophyll (Buhmann and Papenrock, 2013). The present study aimed to valorise the utilization of this residue in a circular economy concept by the inclusion of *S. ramosissima* biomass in diets for shrimp. For this purpose, the immunological profile, inflammatory response and disease resistance of shrimp fed diets rich in Salicornia were assessed.

Materials and methods

Pacific white shrimp (6.07 ± 0.05 g) were randomly distributed in 25 tanks (200L) and maintained in a RAS system (temperature was maintained at 28.1 ± 0.5 ºC, dissolved oxygen at 5.9 ± 0.3 mg L^{-1}, salinity at 19.4 ± 0.1 g L^{-1} and pH at 7.6 ± 0.1). Water parameters were measured daily. Five diets were tested in quintuplicates: a commercial like diet (CTRL) and 4 experimental diets including *S. ramosissima* stems (SS5 and SS10) or *S. ramosissima* leaves and seeds (SL5 and SL10) both in two different concentrations (5 and 10%, respectively). Shrimp were given 4 meals per day. In order to evaluate shrimp immune condition, haemolymph and hepatopancreas were collected from 3 shrimp per tank on days 31 (middle) and 55 (end of the experiment) to assess immune condition. After the 55 days feeding period, shrimps were bath challenged with *Vibrio parahaemolyticus*. 25 shrimp were immersed in tanks (20 L) in triplicates per diet with the inoculum adjusted to a final concentration of 2 x 10^8 cfu ml^{-1}, with strong aeration for 1 hour. Afterwards, shrimp were moved to new tanks with clean water and the recirculation system was re-established. After that, shrimp were fed according to the previous regime and 5 individuals from each tank (15 per group) were sampled for haemolymph collection at 4, 24 and 48 hours after the challenge period in order to assess cell proliferation and plasma immune parameters.

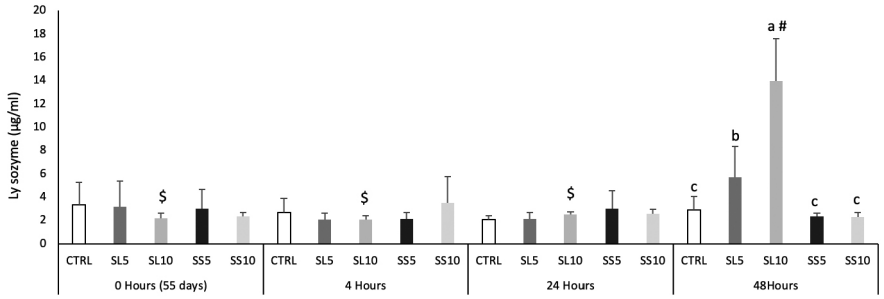

Figure 1. Lysozyme activity measured in plasma of Pacific white shrimp fed the dietary treatments at 55 days (0 hours) and at 4, 24 and 48 hours post-challenged with *Vibrio parahaemolyticus*. Values are expressed as means ± SD (n=15). Lower case letters indicate differences between diet within the same time. Symbols indicate differences between time within the same dietary treatment.

(Continued on next page)

Results

In terms of immune condition, no changes in haemocyte number among dietary treatments were observed after both 31 and 55 days of feeding. However, some modulation of the humoral parameters from haemolymph and gene expression of hepatopancreas were observed. A decrease of lysozyme and nitric oxide production was observed in diets containing an incorporation of *S. ramosissima* biomass while an increase of the antioxidant enzyme glutathione peroxidase expression in hepatopancreas was found up-regulated in shrimp fed SS10 after 31 days of feeding. Nonetheless at 55 days no clear changes were observed on the parameters analysed among dietary treatments. In response to the bath bacterial challenge with *V. parahaemolyticus*, haemocytes in circulation decreased following exposure to the pathogen regardless dietary treatment. Also, shrimp fed SL5 showed a higher production of nitric oxide than those fed SS10 at 24h. Lysozyme activity at 48h post infection increased in shrimp fed SL5 and SL10 when compared to those fed CTRL, SS5 and SL10 diets (Fig. 1). Moreover, shrimp fed SS5 dietary treatment displayed a significant higher cumulative mortality than the individuals fed the SL5 and CTRL diets after 5 days.

Discussion and conclusion

The present study suggests that the inclusion of *S. ramosissima* biomass in diets for juvenile shrimp does not clearly affect immune condition. Nonetheless, once immune mechanisms were activated by the presence of bacteria, the inclusion of 5% *S. ramosissima* seeds and leaves (SL5) seemed to modulate the inflammatory response resulting in a lower disease resistance to *V. parahaemolyticus* compared to the commercial like diet. Moreover, during the inflammatory response, an inclusion of 10% of leaves and seeds (SL10) was able to modulate shrimp humoral immune response by increasing lysozyme activity. Preliminary data from the present study point to health-promoting effects through the inclusion of *S. ramosissima* biomass in shrimp feeds, contributing to the principles of circular economy and avoiding waste of resources. Hepatopancreas gene expression is also being performed in fish sampled after the inflammatory stimulus.

Introduction

The flathead grey mullet represents a potential candidate in the diversification of European aquaculture products mainly in the Mediterranean area. However, flathead grey mullet broodstock held in intensive conditions show reproductive dysfunctions; females remain arrested at previtellogenesis (Ramos-Júdez et al., 2021) or early stages of vitellogenesis (Aizen et al., 2005) and males with fluent milt are not usually observed (Aizen et al., 2005; De Monbrison et al., 1997; Ramos-Júdez et al., 2021). In a previous study, the application of a long-term treatment with species-specific single-chain recombinant gonadotropins (rGths), recombinant follicle-stimulating (rFsh) and luteinizing (rLh) hormones, produced in CHO cells, and the use of rLh and Progesterone (P_4) at the later maturation stage was successful for obtaining eggs from females arrested at early stages of gametogenesis and sperm in males with no running milt that were used for *in vitro* fertilization. Nevertheless, low fertilization percentages (< 1%) were obtained (Ramos-Júdez et al., 2021). The present study aimed to demonstrate that long-term treatment with rFsh and rLh can result in eggs with higher fertilisation rates than the previously described.

Materials and Methods

The flathead grey mullet broodstock (mixed wild and from semi-extensive culture held for 1.5 to 3.5 years in intensive conditions) remained under natural light with 36 ‰ salinity water at 24ºC in one 10m^3 tank in recirculation (IRTAMar®) during the experiment, timed to be in the natural spawning season in summer. Maturity was determined from ovarian biopsies and ease to obtain sperm. A total 21 of females and 9 males received weekly treatment with species-specific single-chain recombinant gonadotropins (rGths) while 9 control females and 6 control males received weekly saline injections. The pattern of application of rFsh and rLh aimed to mimic the physiological fluctuations of Fsh and Lh; rFsh during first stages of gametogenesis followed by a subsequent decrease with an increase of rLh to regulate late gametogenesis (Lubzens et al., 2010; Schulz et al., 2010). Doses ranged from 6 to 12 μg kg^{-1} for rFsh and from 2.5 to 12 μg kg^{-1} for rLh. Females with completed vitellogenic growth (oocytes near to 600 μm in diameter) and males with running milt were selected for spawning induction. The individuals were stocked in a separate 10m^3 tank per treatment with the same conditions than the holding tank. To induce maturation, ovulation and spawning, females were treated with either (i) a priming dose of 30 μg kg^{-1} of rLh and a resolving dose of 40 mg kg^{-1} of P_4 as in Ramos-Júdez et al. 2021, (ii) priming and resolving doses of 30 μg kg^{-1} of rLh, or (iii) priming and resolving doses of 40 mg kg^{-1} of P_4 given 24:05 ± 0:40 h apart. One male from each spawning tank received a dose of 24 μg kg^{-1} of rLh while the others followed the weekly treatment. Spawning events had a sex ratio of 1:2 or 1:3 (female:male). Eggs were collected by surface out-flow egg collectors. Fertilization and hatching were examined and larvae survival was monitored in 96-well plates at 21 ºC until all hatched larvae had died.

Results

At the beginning of the experiment, 12 of the females (57%) belonging to the treated group were in previtellogenesis and 9 (43 %) in early vitellogenesis. All these females (100% of n = 21) completed vitellogenic growth with 603 ± 8 μm diameter of the most developed oocytes after 6 to 13 weeks of rGths treatment. Fertilized spawns were obtained after inducing with rLh + P_4 or rLh + rLh (priming and resolving injections) with a spawning success of the 85% (8 of 9 attempted) and 100% (n = 6), respectively. All treated males were spermiating. The eggs obtained after both treatments presented 64 ± 22 % embryo survival and 58 ± 25 % hatching percentages. The mean fecundity of the females with fertilized spawns was 1,245,600 ± 552,117 eggs kg^{-1} bw (~ 1,700,000 eggs female^{-1}). The percentage survival of larvae in 96-well plates was 67 ± 18 % at 9 days post hatching. The treatment P_4 + P_4 for maturation induction had a lower ovulation success (50%) and spawning success (17%) with no fertilized eggs. Success was independent of the initial gonadal stage of females (previtellogenesis or early vitellogenesis). In comparison, control females did not show any advance in gonadal development from initial stages (remained at previtellogenesis or developed atresia in some of the early vitellogenic oocytes) and control males did not produce fluent sperm.

(Continued on next page)

Discussion and Conclusion

The present study indicates that oogenesis from previtellogenesis until spawning can be driven by the application of exogenous species-specific rFsh and rLh in a teleost species, as 100% of flathead grey mullet females completed vitellogenic growth, and maturation, ovulation and spawning were successfully achieved with the application of rLh as priming and resolving injections. The use of single-chain recombinant gonadotropins produced in CHO cells as a treatment to induce oogenesis from previtellogenesis or stimulate vitellogenesis to the completion of oocyte growth with high spawning success and egg quality as described in the present study offers reliability and replicability to control reproduction of the flathead grey mullet. The obtention of tank spawning contrasts with the study by Ramos-Júdez et al. (2021) in which eggs were hand stripped as no spawning was observed. The presence of good quality males with very fluent sperm in the tank in the present study may have played an important role in the stimulation of spawning and the spawning success. The fecundities and larval survivals obtained in the present study from flathead grey mullet females, indicate that the induction of 6 - 7 females (~1 kg) per season could enable a hatchery production of ~ 1 million fry. In addition, it would be possible to apply the present protocol to develop out-of-season breeding programs in this species.

Introduction

The flathead grey mullet (*Mugil cephalus*) exhibits a severe reproductive dysfunction in intensive captive conditions that arrests gametogenesis in the early stages. Homologous single-chain recombinant gonadotropins (rGths) produced in Chinese Hamster Ovary (CHO) cells provided a solution to the dysfunction. Treatment with recombinant follicle stimulating hormone (rFsh) followed by recombinant luteinizing hormone (rLh) has been used to induce the entire process of vitellogenesis in order to produce viable eggs and larvae (Ramos-Júdez *et al*., 2021), with up to 80 % egg fertilization and a mean of 96 % hatching from fertilized eggs (unpublished data). Considering these promising results by the application of rGths to induce complete oogenesis in the flathead grey mullet, the present study aims to characterize the molecular pathways and temporal gene expression patterns throughout the rGths-induced vitellogenesis.

Materials and Methods

Oogenesis was induced from previtellogenic stages through to oocyte maturation and ovulation as described by Ramos-Júdez *et al*., (2021). Repeated ovarian samples were collected by cannulation from the same five females at four sampling points in this induced ovarian development; (i) from initial arrested gonad before rGths application (previtellogenesis at primary growth and cortical alveoli stage), (ii) from early-mid vitellogenic follicles after rFsh administration, (iii) from late secondary-growth follicles after combined treatment with rFsh and rLh, and (iv) from full-grown follicles after rLh administration that completed the vitellogenic growth. The RNASeq libraries were constructed for all the aforementioned stages, sequenced on an Illumina HiSeq4000 and a *de novo* transcriptome assembly was constructed. Quality check of raw reads was performed using FastQC v0.11.8, and reads were pre-processed through a pipeline using Trimmomatic v0.39. Trimmed reads from all gonadal stages were assembled together to obtain a single transcriptome. Trinity software v2.8.5 was used to construct the *de novo* assembly and BUSCO v3.1.0 was utilized to assess the transcriptome completeness (the vertebrate orthologs database was used as reference). Trimmed reads were back-mapped to the assembly with Bowtie2, and the relative abundances of transcripts were calculated by means of RSEM. Transcripts with less than 1 FPKM were excluded. The assembled transcripts were functionally annotated using Trinotate pipeline v3.2.1 with e-value cut-off of 10^{-5}. The SwissProt, GO and KEGG databases were employed to annotate the sequences that formed the final assembly. Count data matrix from the filtered transcriptome was constructed and imported in R v3.6.1. Genes with < 30 reads in all samples were excluded from the differential expression gene analysis which was performed by DESeq2 v1.26.0 under the Bioconductor package. Pairwise differential expression analyses were performed with special attention to comparisons of gonadal stages in time lap sequence. Genes with an adjusted P-value < 0.05 were considered as statistically significant differentially expressed genes.

Results and Discussion

Illumina HiSeq4000 paired-end sequencing generated a total of 614,942,156 raw paired reads of which 506,875,944 paired reads were maintained after trimming. The assembled transcriptome produced by Trinity consisted of 513,643 transcripts with an average contig length of 919.18 nucleotides (nt) and N50 value of 1,561 nt. BUSCO revealed an 86.4% of transcriptome completeness. Moreover, an average of 89.68 % of the reads were back-mapped on the transcriptome. The final assembly was constituted of 287,089 transcripts with an expression value of FPKM≥1. The BLASTx against the Swiss-Prot databases resulted in 58,306 (20.3 %) transcript gene assignments. A total of 57,021 (19.9 %) sequences had a match against the GO database, of which 50,268 (88.2 %) represented biological processes, 53,992 (94.7 %) were associated with cellular components, and 48,190 (84.5 %) matched molecular function (MF). A total of 51,237 (17.8 %) sequences were associated to a KEGG pathway. The analysis of differentially expressed genes (DEGs) throughout oogenesis showed that 6147 genes were significantly up-regulated in the stage from previtellogenic follicles to vitellogenic

(Continued on next page)

follicles obtained after rFsh treatment. From vitellogenic follicles to late-vitellogenic follicles, obtained after rFsh and rLh combined treatment, 814 genes were up-regulated, while 994 genes were up-regulated in the transition from late-vitellogenic to full-grown follicles after rLh application. The corresponding numbers for downregulated genes were 2807, 299, and 593, respectively. Throughout oogenesis more genes were up-regulated than down-regulated. To gain insight into the biological roles of the most significantly up- or down-regulated genes, DEGs will be linked with GO terms and classified into categories. In addition, DEGs will be mapped to the reference pathways of KEGG.

The analysis will examine a wide range of genes focusing on those related to the Fsh/Fshr and Lh/Lhcgr pathways that may reflect temporally distinct functions during vitellogenesis, such as genes associated with electron transport chain, estrogen receptors, mitochondrial function, lipid uptake and oocyte maturation. This study will enable a better understanding of rGths-targeted genes to improve induction protocols and facilitate the control of flathead grey mullet reproduction as well as of other species with similar reproductive dysfunctions.

CAN *ARTEMIA* PRODUCE ESSENTIAL FATTY ACIDS? ROLES OF ELONGASES IN THE BIOSYNTHESIS OF LONG-CHAIN POLYUNSATURATED FATTY ACIDS

Introduction

Artemia nauplii are one of the most commonly used live preys in marine larviculture. However, a major drawback associated to using *Artemia* nauplii is their deficient nutritional value for marine fish larvae that is primarily linked to suboptimal levels of long-chain (C_{20-24}) polyunsaturated fatty acids (LC-PUFA) (Sorgeloos et al., 2001). LC-PUFA including eicosapentaenoic acid (EPA, 20:5n-3), arachidonic acid (ARA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3) are essential compounds for normal development of vertebrates including fish (Monroig and Kabeya, 2018). Since *Artemia* contains low LC-PUFA, with only trace levels of DHA, nauplii must be enriched with LC-PUFA-rich products prior use as live prey for marine larvae. However, it remains unknown whether *Artemia* has some capacity for LC-PUFA biosynthesis itself (Ito and Simpson, 1996; Reis et al., 2013). Elongases (Elo) are key enzymes in the LC-PUFA biosynthetic pathway that catalyse the limiting step reaction in the fatty acid (FA) elongation pathway resulting in a 2-carbon extension of the FA substrate (Monroig and Kabeya, 2018). In the present study, we aimed to clarify the repertoire and function of Elo with putative roles in the LC-PUFA biosynthesis of *Artemia franciscana*, arguably the most commonly used *Artemia* species in aquaculture.

Materials and methods

To collect the full-length sequences of candidate elongases from *A. franciscana*, putative transcripts were retrieved through *tblastn* searches against Sequence Read Archive (SRA) database in the *A. franciscana* BioProject (PRJNA524488). Putative sequences of the encoded enzymes were analysed to identify specific domains and conserved motives (Hashimoto et al., 2008). Six Elo gene candidates were identified and selected for further functional characterisation in yeast. Briefly, the open reading frames (ORF) of each Elo were amplified by PCR using *A. franciscana* complementary DNA (cDNA) as template and with primers containing specific restriction sites designed for further cloning into pYES2 expression vector. Purified pYES2-ORF constructs were transformed in yeast that were subsequently supplemented with potential PUFA substrates. After two days at 30ºC, transgenic yeast was harvested and washed. Total lipids were extracted and processed to prepare fatty acid methyl esters for analysis by gas chromatography. Conversions of PUFA substrates to the corresponding products were calculated by the proportion of substrate FA converted to elongated FA product(s) as [areas of all products with longer chain than substrate/(areas of all products with longer chain than substrate + substrate area)] × 100.

Results

Six elongases, termed Elo1 to Elo6, were identified, cloned and characterised. Identified enzymes contained the motif [(Q/H)(V/I/L)(S/T)(F/L/V)LH(V/I/L)(Y/V/I)HH] and six transmembrane spanning regions. The ability of the *A. franciscana* Elo enzymes to elongate PUFA substrates was assayed in yeast. The capacity of the *A. franciscana* Elo to elongate the exogenously supplemented PUFA varied among enzymes (Table 1). Both Elo2 and Elo5 were able to convert all PUFA assayed (18:3n-3, 18:2n-6, 18:4n-3, 18:3n-6, 20:5n-3, 20:4n-6, 22:5n3 and 22:4n-6) to the corresponding 2-carbon elongated products (Table 1). Moreover, both Elo1 and Elo6 had the ability to elongate all C_{18} PUFA substrates, as well as 20:5n-3, although Elo1 but not Elo6 elongated 22:5n-3 to 24:5n-3 (Table 1). Finally, the *A. franciscana* Elo3 and Elo4 recognised only two out of four C_{18} PUFA as substrates, namely 18:4n-3 and 18:3n-6 for Elo3, and 18:2n-6 and 18:3n-6 for Elo4, with no activity detected towards any C_{20} and C_{22} PUFA (Table 1).

(Continued on next page)

Table. Functional characterisation of the six *A. franciscana* elongases (% conversion).

FA substrate	Product	Elo1	Elo2	Elo3	Elo4	Elo5	Elo6	Activity

Discussion and conclusions

PUFA elongases have been found and characterised in several invertebrates including crustaceans (Monroig and Kabeya, 2018). The *A. franciscana* Elo genes share the motif [(Q/H)(V/I/L)(S/T)(F/L/V)LH(V/I/L)(Y/V/I)HH], which is characteristic from PUFA elongases (Hashimoto et al., 2008). The *A. franciscana* Elo1 can be classified in the group of Elovl4, an Elo type that is widespread in animals including the branchiopod crustacean *Daphnia magna* (Monroig and Kabeya, 2018). Interestingly, the *A. franciscana* Elo2-6 belong to a group of unclassified elongases arbitrarily named "novel" elonganses, which have been found extensively in crustaceans such as the marine gammarid *Echinogammarus marinus* (Ribes-Navarro et al., 2021). Our functional data clearly show that the *A. franciscana* Elo1-6 can catalyse all the elongation reactions involved in the LC-PUFA biosynthetic pathways and, while further studies are required to clarify the presence of fatty acyl desaturases, we can conclude that *Artemia* has some capacity for biosynthesis of essential FA.

Instroduction

During growth, microalgae are able to synthetize high value compounds, such as pigments and polyunsaturated fatty acids (PUFA) giving them significant potential for nutritional purposes, e.g. in aquaculture. For aquafeed preparation the most important fatty acids are linoleic acid (LA; C18:2, n6), α-linoleic acid (ALA; C18:3, n3), arachidonic acid (AA; C20:4, n6), eicosapentaenoic acid (EPA; C20:5, n3) or docosahexaenoic acid (DHA; C22:6, n3) which are essential for fish larvae development (Nogueira et al. 2020). Pikeperch (*Sander lucioperca*) is highly demanded fresh and brackish water fish. Most of pikeperch production currently comes from wild fisheries, but the production in recirculating aquaculture systems (RAS) has been increasing, due to its high market value and fast growth rate in RAS. The survival rate of pikeperch larvae is usually low, below 20%, due to unsuitable nutrition. The introduction of some rotifers (e.g. *Brachionus plicatilis*) as suitable microalgae feed has been successfully performed, increasing the survival rate of pikeperch and overall physiological conditions (Yanes-Roca et al. 2020). In general, rotifers retain the nutritional composition of their diets. They are, hence, regarded as live-feed capsules for the transfer of crucial nutrients, mainly polyunsaturated fatty acids (20:5, n-3 and 22:6, n3), to fish larvae. Thus, microalgae with substantial fatty acid profile might be used as a feed for rotifers enhancing the rearing successfulness of pikeperch in RAS.

Material and methods

Five different microalgae strains, either Chlorophyceae or Eustigmatophyceae *(Chlorella vulgaris, Monoraphidium* sp., *Trachydiscus minutus, Vischeria helvetica and Monodopsis* sp.) were cultivated in a novel, short light path, annular column photobioreactior (AC-PBR) with internal LED illumination and full control of cultivation variables. The annular interspace (photostage) for microalgae culturing was only 4.6 cm thick and the highest PAR light intensity that could be achieved was 1600 μmol photons m^{-2} s^{-1}. During the cultivation of microalgae diets, the physiological status was monitored by several Chl fluorescence techniques. The effect of cultivation conditions on the fatty acid profile was investigated. The microalgae cultures produced in AC-PBR were used for rotifer (*Brachionus plicantilis*) feeding. These were introduced to pikeperch larviculture in RAS as live feed and the effect on overall fitness of larvae was studied.

Results

All microalgae cultures revealed high photosynthetic activity during the trial due to precious adjustment of required cultivation conditions and reached biomass density up to about 5 g DW L^{-1}. Under continuous illumination the volumetric productivity was found to be about 0.3 g DW L^{1} d^{1} during trials, corresponding to the areal productivity of about 15 g DW m^{-2} d^{-1}. Based on effective cooling, the temperature of cultures could be kept at the optimum value, potentially down to 10 °C within the trial. The proposed model of AC-PBR could even be placed outdoors to further increase cell irradiance for even higher biomass productivity in dense cultures.

IN SEARCH OF STRESS BIOMARKERS: LABEL-FREE SHOTGUN PROTEOMICS ANALYSIS OF GILTHEAD SEABREAM HEPATIC AND SKIN MUCUS PROTEOME

Cláudia Raposo de Magalhães*, Ana Paula Farinha, Raquel Carrilho, Denise Schrama, Marco Cerqueira, Pedro M. Rodrigues

Centre of Marine Sciences (CCMAR), Universidade do Algarve, Faro, Portugal
csraposo@ualg.pt

Introduction

Managing fish stress is crucial to ensure a sustainable aquaculture production. In a research context, high plasma levels of cortisol, glucose and/or lactate are universally used to assess fish welfare. However, the heterogeneity of responses demonstrate that these should be interpreted with caution in cases of long-term stressors. The standardization of stress biomarkers would be an important contribute to the existing species-specific stress management protocols. Proteomics was employed in this study as a tool to discover more robust fish stress biomarkers, since proteins are ubiquitously affected by abiotic and biotic stimuli in a slower timescale when compared with endocrine responses. The analysis of proteome changes in different tissues, e.g. liver and mucus may offer not only tissue-specific protein fingerprints, but can be also highly advantageous in the context of fish welfare, as skin mucus allows for sampling in a non-invasive way. Moreover, this combined proteomic analysis provides a more detailed insight into the molecular mechanisms, as a complementary picture of the animal´s physiological state under stress.

Methods

Sparus aurata was exposed to different suboptimal rearing conditions in three separated trials: overcrowding (OC30 and OC45), repetitive net handling (NET2 and NET4), and hypoxia (HYP30 and HYP15), using fish reared under optimal conditions for the species, as control. By the end of the trials, fish were sampled and protein extracts from liver and mucus samples were prepared for further analysis by reverse phase nano liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS). Proteins identified with high confidence (protein FDR <0.5%; peptide FDR <0.1%) within each trial were analyzed by One-way ANOVA followed by Tukey's HSD test ($p < 0.05$). Proteins were screened for enriched KEGG and Reactome pathways. Pairwise comparisons between control and stressed fish samples were also established within each trial (T-test, $q < 0.05$) and up- and down-regulated proteins were further classified according to Gene Ontology Enrichment (Fisher's Exact test, FDR <0.05). Cortisol, glucose and lactate were measured from blood samples, and glycogen stores were assessed in the liver.

Results and conclusions

Label-free shotgun proteomics reproducibly identified a mean of 1300 proteins in at least 4 out of 6 fish per treatment, either in the liver or in the skin mucus of gilthead seabream. A total of 297 (liver) and 250 (skin mucus) differentially regulated proteins were identified between stressed and control fish across the three trials. A tissue-specific stress regulation was observed, although 40 common proteins, mostly implicated in translation and protein folding processes, were found to be differentially regulated in both tissues. Liver-specific proteins were involved in metabolism regulation, while mucus-unique proteins were implicated in signal transduction and immune response. Plasma cortisol levels and liver glycogen storages were significantly altered exclusively in net-handled fish. The overall results suggest that the net-handling was the most impactful stressor, and the fish physiological stress response was tuned according to the challenge's severity. This integrated approach provides a starting point for the development of more reliable fish welfare assessment measures in comparison to cortisol levels solely, to further improve aquaculture sustainability.

CONTRIBUTIONS TO THE INTENSIVE CULTIVATION OF *Hediste diversicolor*

I. Rasines-Pérez*[1], I. Martín-Montero[1] and F. Aguado-Jiménez[1*],

E-mail: inma.rasines@ieo.es

Introduction

The "ragworm" *Hediste diversicolor* is a suitable species for industrial aquaculture because of its adaptability to wide environmental conditions, feeding flexibility and high growth rates. Its use can be the traditional one, as fishing bait or the more recently as feed supplements for farmed fish and crustaceans (Batista *et al*. 2003).

The relationship between growth rate and density is well known and no more than 1000 individuals/m^2 is recommended for the cultivation of this species (Nesto *et al*. 2012). Nevertheless, production with this low density is scarce an intensification of the cultivation is needed to achieve industrial profitability. Depending on the final commercial use, production objectives can be larger individuals or higher biomass/m^2.

This species lives buried in the substrate and burrow depth increases with size (Esselink and Zwarts, 1989), so an increase in depth culture bed could result in increased space for growing worm. The relationship between density and substrate height has not been studied in this species and we hypothesise that there will be an interactions between these two factors.

Material and methods

Two substrate heights (60 and 120 mm) and two densities (1000 and 4000 ind. m^{-2}) were evaluated in a factorial design in the culture of *H. diversicolor*. Independent replicates (three for high density and six for low density) were considered for each of the substrate height x density combinations. Juveniles of wet body weight (BW) 48 ± 3 mg, (mean ± SEM), obtained from a captive population stock, were used in the experiment. Each replicate consisted of 10 or 40 worms stocked in cylindrical containers (0.01 m^2 and 0.2 m high) made with PVC frame closed at the base and sides by 335 μm mesh. Substrate was quarry sand (0.25 - 1.0 mm grain size). These cylindrical containers were immersed in 3 polycarbonate trays (width: 0.35 m; height: 0.30 m; length: 0.54 m) provided with aeration, top water inlet (2.5 renewals/hour) and bottom drainage connected to a Recirculating Aquaculture System (RAS).The RAS had biological and mechanical filtration, UV sterilization, and temperature control.

Temperature, salinity and photoperiod were fixed at 20 °C, 36 and 16/8 h light/dark, respectively. Dissolved oxygen (DO), pH, temperature and salinity were monitored daily and ammonia and phosphates once a week.

Polychaetes were fed with sole (*Solea senegalensis*) feed (0.35-0.50 mm in size) in a total amount equivalent to 4% of the daily wet biomass, distributed three times a week. Fortnightly, wet BW and survival was estimated and the diet adjusted to account for increases in mean polychaete weight throughout time.

Table I. Physico-chemical parameters during experimental period (57 days).

Temperature	DO	Salinity	pH	Ammonia	Phosphate
18.7±1.0 ºC	94±3 %	36.1±0.9 ppm	8.06±0.18	<0.025 mg/l	<0.25mg/l

Table II. Growth performance and productions parameters calculated in *H. diversicolor* reared at different densities. Data are expressed as mean ± SEM. Mean values with different superscript letters in the same column were significantly different ($p < 0.050$).

Density (ind/m^2)	Mean wet weight (mg)	Survival (%)	SGR (%/day)
1000	459±20[a]	92±2	4.01±0.07[a]
4000	384±11[b]	90±2	3.71±0.05[b]

(Continued on next page)

Mean wet BW, survival and specific growth rate (SGR= (ln BW_f- ln BW_i)*100/ T_f-T_i) at day 57 were calculated as growth performance, and number of individuals greater than 0.6 g and total biomass production (g/m^2) as a proxy of productivity. The factors height and density were analysed by two-factorial ANOVA. The Mann-Whitney test was used for non-parametric data. Values with $p < 0.050$ were considered statistically significant.

Results and Discussion

The physico-chemical parameters were in the correct range for the culture of this species (table I).

At day 57, the two-factor ANOVA showed no significant interactions between density and substrate height (p=0.392), nor significant substrate height effects (p=0.207) but a significant effect of density on BW (p=0.021). Similar results were obtained for SGR: interaction p=0.435, height p=0.179 and density p=0.010. No significant differences were found in survival (Mann-Whitney test, density p=0.615, height p=0.920) (Table II).

Nevertheless, the total final biomass was 415±16 and 1378±46 g/m^2 for low and high densities respectively, i.e. about 3 times higher when an initial stocking density 4 times higher was used. Nesto *et al*. 2012 found a higher SGR and similar final biomass when the stocking density was 1000 or 3000 ind /m^2. In our case, the similar survival rate between the two densities tested could have counterbalanced the lower growth. Additionally, in 8 weeks, the number of individuals that can be sold as bait (greater than 0.6 g) is 2.75 times higher with the high density (550±43 ind>0.6g)/m^2) than whit the low (200±30 ind>0.6g)/m^2).

The high survival rates obtained in this work could be due to the culture system used that allows a very good water quality.

We conclude that *Hediste diversicolor* can be reared at a high stocking density in order to obtain a major profitability, especially if low-cost feed, e.g. waste of fish aquaculture, will be used.

Introduction
The microbial communities that inhabit the vertebrate gastrointestinal tract are tightly connected to many traits displayed by its host[1,2]. Applying a multi omic framework to investigate host-microbe interactions could be used in aquaculture related to improve growth, health, and sustainable production[3]. Here, we investigate the functional effects of pro- and synbiotic feed additives on microbiome associated functions in the commercially important rainbow trout (*Oncorhynchus mykiss*). We combine complementary insights from multiple omics datasets from gut content samples, including 16S bacterial profiling, genome resolving metagenomes, and untargeted metabolomics, to investigate bacterial metagenomic assembled genomes (MAGs) and their molecular interactions with host metabolism.

Methods
An experimental feeding trial was carried out over an eight-week period. Three experimental, proprietary feed formulations were selected: I) a control feed without any pre- or probiotic additives (CTRL), II) control feed plus the commercial probiotic with commercially available *Pediococcus acidilactici* MA18/5M (PRO), and III) control feed with a synbiotic additive, consisting of same probiotic and galactooligosaccharides (SYN). Bacterial profiling using the V3-V4 region of the bacterial 16S rRNA gene, were applied to investigate microbial profiles related to usage of supplemented feed in two gut sections of 120 individuals (40 individuals per feed group) of rainbow trout. A subset of these samples was whole-genome sequenced to investigate bacterial functionality of MAGs. Furthermore, A combination of two untargeted metabolomics approaches, including UHPLC-MS/MS and IC HR-MS/MS, were applied to 30 individuals (10 individuals per feed group) in order to decipher the metabolic landscape in the intestinal environment.

Results
Our findings reveal, that **(I)** feed additives changed the microbiome and that rainbow trout reared with feed additives had a significantly reduced relative abundance of the salmonid related species *Candidatus* Mycoplasma salmoninae in both the mid and distal gut content (Figure 1a), **(II)** genome resolved metagenomics revealed that alterations of microbial arginine biosynthesis and terpenoid backbone synthesis pathways were directly associated with presence of the native gut bacteria *Candidatus* Mycoplasma salmoninae (Figure 1a), **(III)** differences in the composition of intestinal microbiota among feed types were directly associated with significant changes of the metabolomic landscape, including lipids and lipid-like metabolites, amino acids, bile acids, and steroid-related metabolites (Figure 1b-d).

Conclusions
Our results demonstrate how use of multi-omics to investigate complex host-microbiome interactions enable us to better evaluate the functional potential of probiotics compared to studies that only measure overall growth performance or that only characterise the microbial composition in intestinal environments.

(Continued on next page)

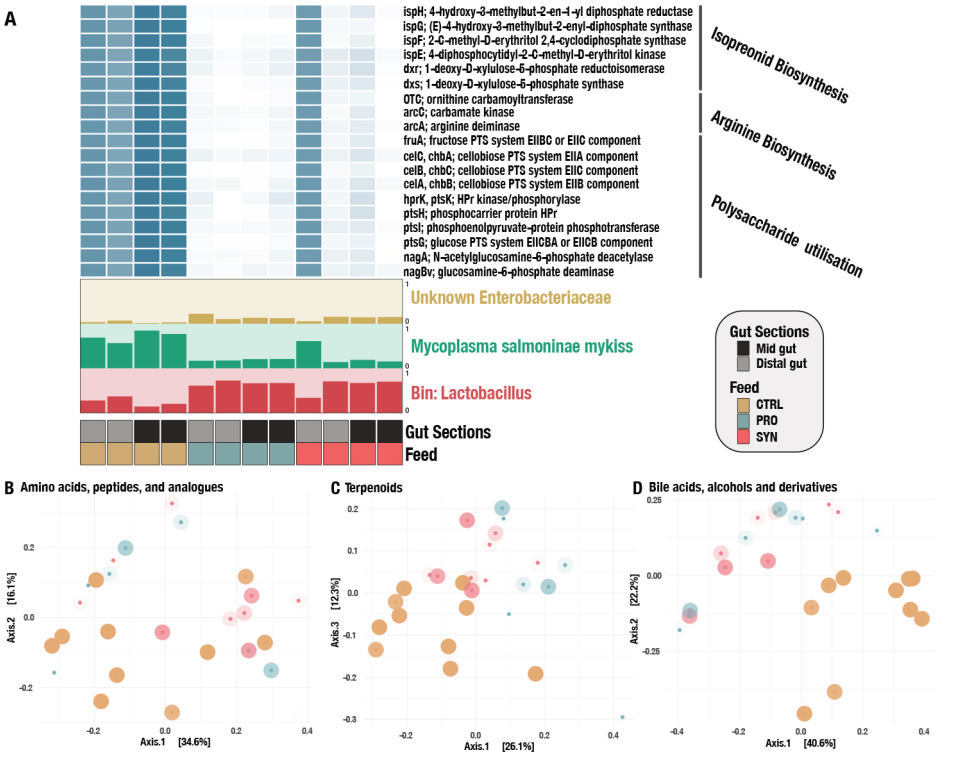

Figure 1 Feed related metagenomic and metabolomic variation in the intestine of rainbow trout. A) Heatmap visualises a series of genes of interest, which are related to isoprenoid biosynthesis, arginine biosynthesis, and polymer utilisation. Intensity of blue colour indicates log10 of coverage of genes across samples. Bar plots indicate relative abundance of the two MAGs and the bin within each sample. Intestinal sections (gut sections) were coloured as black for mid gut and grey for distal gut. B-D) Principal Coordinate Analysis (PCoA) of *in silico* classified metabolites across all three feeding types based on B) Amino acids and analogues, C) Terpenoids, and D) Bile acids, alcohols, and derivatives. Opacity of nodes is related to relative abundance of Mycoplasma. Grouping of rainbow trout reared on different feeding types were visualised as orange for CTRL, blue for PRO, and red for SYN.

Introduction

In the sea, sometimes devoid of light and with high turbidity, organisms depend heavily on chemosensory systems to detect food, avoid predators and for reproduction (Hara, 1994). In vertebrates, the olfactory system is essential to sense the chemical environment, whereas in molluscs chemoreception is thought to be mediated by the osphradium. Although several studies have investigated chemical communication and the role of the osphradium in gastropods and cephalopods, there is little knowledge of chemical communication or chemosensory systems in bivalves. The detection of chemical cues is essential in several aspects of bivalve biology, such as food selection and detection of pheromones. To address this lack, we have adapted an electrophysiological technique used extensively in vertebrates - the electro-olfactogram - to record from the osphradium in the oyster (*Crassostrea gigas*). This was validated using amino acids as stimulants. The 'electro-osphradiogram' (EOG) may prove to be a powerful tool in the isolation and characterization of pheromones and other important chemical cues for bivalves.

Material and methods

Adult oysters were anaesthetized with magnesium chloride (50g L^{-1}) as suggested by Suquet et al. (2009). The right valve was then carefully removed by cutting the adductor muscle. The oysters were then replaced in normal seawater overnight. Amino acid solutions were prepared by dissolving directly in charcoal-filtered (natural) seawater (10^{-3} M to 10^{-7} M) to use as chemosensory stimulus. L-cysteine (10^{-3} M) was used as a positive control (or standard) whereas the blank or negative control was prepared in the same way, but without addition of any amino acid. The chemosensitivity of the osphradium was assessed through the EOG, a D.C. field potential. The electrodes were borosilicate glass micropipettes filled with 3 M NaCl bridged to solid-state electronics via an Ag/AgCl pellet (Hubbard et al., 2011). The recording electrode was placed close to (but not touching) the osphradium, near the ventral area of the adductor muscle and the reference electrode was placed close by on the mantle (not the osphradium) (Haszprunar, 1987). The optimal positions for electrodes and stimulus-delivery tube were determined using 10^{-3} M L-cysteine as stimulus. The voltage signal was amplified (x2000 - x20 000) with the low-pass filter set at 30 Hz. The signal was then digitised and recorded on a PC running Axoscope TM software. All stimuli were administered randomly, but each amino acid was given in order of increasing concentration (10^{-7} M – 10^{-3} M). The EOG peak amplitude was measured in millivolts. All recorded responses were blank-subtracted and normalized to the standard (10^{-3} M L-cysteine). Concentration-response curves and thresholds of detection were calculated for each odorant.

Results

The osphradium proved to be highly sensitive to some amino acids (L-cysteine, L-leucine, L-proline, L-methionine, L-serine and L-tryptophan), evoking EOGs with a slow negative deflection at stimulus exposure onset, followed by a tonic response during which the EOG showed little or no sign of accommodation (in stark contrast to vertebrates). When stimulus delivery ended, the potential returned to baseline levels within seconds. However, other amino acids (L-glutamate, L-arginine and L-aspartic acid), and the neurotransmitter serotonin, did not evoke any response. Conspecific sperm evoked a strong EOG response similar in form and magnitude to those evoked by amino acids. The amplitude of EOG responses was strongly concentration-dependent. Thresholds of detection varied between $10^{-6.36}$ M and $10^{-5.30}$ M for L-methionine and L-cysteine, respectively. Different isomers of alanine (L, D and β) and leucine (L-; D-) evoked different EOG responses. β-Alanine evoked significantly lower response than L- and D-isomers, whereas L-leucine evoked significantly larger responses than its D-isomer.

(Continued on next page)

Discussion

To our knowledge, this was the first time an EOG recording was successfully carried out in any bivalve, and strongly supports the hypothesis that the osphradium is a chemosensory organ (Haszprunar, 1987) in this taxon, as it is in other molluscs. Subsequently, a whole series of questions about chemoreception in bivalves may finally be answered. As in the olfactory system of fishes (Caprio, 1978; Hubbard et al., 2011), the chemosensory organ of oysters proved to be sensitive to amino acids; however, the EOG in oysters is much slower, of somewhat lower amplitude and is more tonic. Apparently, oysters are more selective in which amino acids they detect than fishes; the responses varied substantially between amino acids, with some of them not eliciting any response. Furthermore, the rank order of potency is different from that of fishes; for example, L-proline was highly potent in the oyster, but is of minor potency in fishes (e.g., Hubbard et al., 2011). Like fishes, oysters seem to be more responsive to L-amino acids, probably due to its involvement in food identification and location (Hara, 1994).

IS BLUE GROWTH A DRIVER OR A CONSTRAINT TO THE SUSTAINABILITY OF MARINE AQUACULTURE DEVELOPMENTS? REVIEWS OF BOTTLENECKS AND LESSONS FROM PAST DEVELOPMENTS

Pascal Raux*, José Antonio Pérez Agúndez•

After an initial rapid and strong growth, the development of marine aquaculture in Europe (EU) has shown signs of stagnation, even regression in some Member States. The explanatory factors of this stagnation have often taken the form of technical constraints, disease control and environmental management, constraints on production factors (access to capital, access to space, access to knowledge…). In addition to these constraints, there are significant conflicts of use with other activities, both for access to resources and for environmental impacts suffered or emitted. However, the explanatory factors have paid little attention to socio-economic forcing, whether it be the adequacy between production systems and markets, or even the consumption modes, or the adequacy of aquaculture developments with the territories where they take place. In addition, the growth of production has often been accompanied by increasing difficulties in terms of farms' profitability.

Notwithstanding these issues and following the financial crisis of 2008, Blue Growth has been perceived as a development opportunity through a series of key sectors that are expected to boost the economy and provide jobs and welfare (EC, 2017). Among these sectors, marine aquaculture raises high expectations through Blue Growth and its declination into the European Union's integrated maritime policy and its marine spatial planning tool (MSP). Seen as a tool for integration, and even integrated management, the MSP is also put forward as a factor for improving the social acceptability of aquaculture developments, especially through the approach of Allocated Zones to Aquaculture (AZAs), reinforced by communication actions aimed at mitigating the misperceptions that consumers and citizens might express about aquaculture and its products. The stagnation of catches from fisheries, the increasing demand per capita in seafood products supported by an ever increasing world demography and confirmed by the various models reinforce the role henceforth devolved to aquaculture to provide for this growth.

A review of issues and bottlenecks to the development of marine aquaculture in Europe and in the world nevertheless makes it possible to underline an important number of constraints which can break and question the desired or planned development, but also a certain number of contradictions between the stated objectives and the reality of developments. This long-standing dynamic linked to the first developments related to the Blue Revolution still seems to be at work. The same causes leading to the same effects, the adequacy of the objectives assigned to aquaculture developments with a sustainability approach is questionable. A review of development experiences within the H2020 MedAID project reinforces an initial statement related to the lack of attention paid to the adequacy of aquaculture objectives with the territories that support them, with markets and their evolution and with consumer expectations. If technological solutions and innovations remain at the heart of aquaculture developments, these constraints underline their necessary but not sufficient property and the needs for more holistic approach centred on governance.

EC (2017). Report on the Blue Growth Strategy, Towards more sustainable growth and jobs in the blue economy. Commission Staff working document on Blue Growth 2013-2016, SWD(2017) 128 final, 61p.

DIFFERENCES IN THE CIRCULAR RNA TRANSCRIPTOME BETWEEN WILD AND CAPTIVE-BRED NILE TILAPIA

Introduction

Domestication of organisms started as early as in the Neolithic period (c.14 000 years ago). Historically, fish domestication began almost 1000 years later than many other species, such as cattle, dogs, pigs, and horses. Domestication is a complex and long process in which organisms are subject to human control in many aspects, including feeding and breeding, thus changing their phenotype compare to their wild ancestors. Accumulating shreds of evidence suggest that domestication plays crucial roles in modulating behaviour, size, colouration, morphology, and physiology in teleosts (Balon et al. 2004). These modifications are often linked to changes in genetic structure through mutations and allele fixation. Investigations into more recently domesticated species reveal that phenotypic change is relatively fast, and expression of hundreds of gene can be altered in a single generation. Epigenetic modifications, potentially heritable modifications of the chemical structure of the genome without affecting the nucleotide sequence, are important in the shaping phenotypic differences during the domestication process. The role of methylation, hydroxymethylation in domestication of fish has been described in artificial selection, environmental adaptation, and genome evolution (Podgorniak et al. 2019; Konstantinidis et al. 2020). In addition, non-coding RNAs can also influence phenotypic diversity and fitness by regulating transcription mechanisms and give rise to the emergence of domestication traits. Circular RNAs (circRNAs) are a class of endogenous non-coding RNAs that have attracted interest in transcriptional regulation. They act as miRNA sponges and play a regulatory role in normal physiology as well as in pathological conditions. Despite the importance of circRNAs in several biological processes, their role in fish domestication remains largely unknown. In the present study, we compared wild and first-generation Nile tilapia (*Oreochromis niloticus*) reared in captivity to determine the potential role of circRNAs in domestication.

Materials and methods

The RNA-seq dataset for the wild and domesticated group (twelve samples) were obtained from ribosomal RNA depleted RNA-seq libraries published by Konstantinidis et al. (2021) under accession number GSE135811 in Gene Expression Omnibus. After filtering low-quality reads and adapters, sequences were mapped into the Nile tilapia reference genome (ASM185804v2). CircRNA prediction was performed for each RNA dataset with the circRNA in silico prediction tools CIRI2. Differential expression of circRNAs between the groups was assessed using circMeta (Chen L. et al., 2020), and the host genes of circRNAs were predicted using circParser (Artem et al., 2020).

Results

A total of 7,862 circRNAs were identified from a muscle RNA-seq dataset (n=6) using the CIRI2 algorithm. Among them, 26 circRNAs were present in both wild fish and their progeny undergoing domestication (Fig. 1). Further analysis revealed 39 differentially expressed (DE) circRNAs. Several DE circRNAs originate from host genes known to be involved in domestication, such as *MHC class I* and *glutamate receptor-interacting protein 2*. Furthermore, a number of DE circRNAs orthologues were found to be conserved between many fish species. Taken together, our findings reveal a potential role for circRNAs in fish domestication.

ANTIOXIDATIVE ACTIVITIES, PHENOLIC COMPOUNDS AND MARINE FOOD ALLERGENS IN THE MACROALGAE *Saccharina latissima* PRODUCED IN INTEGRATED MULTI-TROPHIC AQUACULTURE SYSTEMS

C. Rebours*, J. Mildenberger and J.K. Stangeland

Møreforsking AS, Borgundveien 340, 6009 Ålesund, Norway
E-mail: Celine.Rebours@moreforsking.no

INTRODUCTION

The concept of "Integrated Multi-Trophic Aquaculture" (IMTA) has been given great interest in recent decades and is one of several strategies to increase biomass production from the sea by reducing the environmental impact of fish farming and by increased production of low-level trophic organisms such as macroalgae. However, due to lack of data and scientific evidence, appropriate food regulations are lacking for IMTA to guide the production of macroalgae and their application as food products. Macroalgae are however recognized to have valuable bioactivities including antioxidative activity. Due to variations in bioactivities between species, geographic location and season, characterization of the quality of specific IMTA products will be important for further marketing purposes. Besides valuable compounds, macroalgae can also contain elements with unwanted effects such as allergens. Thus, there is a growing concern from the food industry and food safety authorities regarding the potential occurrence of contaminating marine allergens in seaweed food products. As seaweed is produced in the ocean, allergens of marine species, such as crustaceans, molluscs or even fish might find their way into the production line and these hazards must be monitored to evaluate the risk for allergenic incidents and the need for appropriate labelling for future food products. Here, the occurrence of marine food allergens as well as total phenolic compounds and antioxidant activity have been assessed in *S. latissima* produced in three different locations in 2020 in the vicinity of salmonids farms in Norway.

MATERIALS AND METHODS

In 2020, 10 kg of seaweed was collected at three different Norwegian IMTA farms located at three different sites (Bjønnspjotneset, Dyrholmen Vest, Furholmen) owned respectively by Osland Havbruk AS, Sulefisk AS and Engesund Fiskeoppdrett. The seaweed was washed, freeze dried and ground. Extractions and analyses were conducted in triplicates. For analysis of phenolic compounds and antioxidants, seaweed samples were dissolved at 25 mg/ml in dH_2O or MeOH:dH_2O (4:1), incubated in an ultrasonic water bath (Branson 2200, 40kHz) for 30 min where indicated, and filtered. Phenolic compounds were measured by the Folin-Ciocalteu method[1,2]which can replace synthetic ones due to their potential implications for health problems in children, have gained significant popularity. Therefore, the antioxidant potential of extracts obtained from three brown macroalgae (Ascophyllum nodosum, Fucus vesiculosus and Bifurcaria bifurcata with gallic acid (Sigma Aldrich G7384) standard curve and undiluted samples. Antioxidative activity was assessed by ORAC assay, according to the BioTek Application Note 2006[3]cosmetics, supplements and pharmaceutical agents has become of particular interest. This is the result of the evidence demonstrating the relationship of reactive oxygen/nitrogen species (ROS. Samples were diluted to 25 μg/ml (1:1000) for MeOH extracts and to 5 mg/ml (1:5) for water extracts.

For allergen detection, ELISA kits for the antigens fish parvalbumin, mollusc tropomyosin or crustacean tropomyosin (Demeditec DEFISE1, DEMOLE1 and DECRUE1) were used. Dried and grinded seaweed (0.2 g, exact weight) was dissolved in 20 ml extraction buffer, filtered, and diluted 2-times to limit matrix effects.

RESULTS

The content of phenolic compounds was in a range of 1-2 mg GAE/g dry weight for all three locations and all three extraction methods. Antioxidative capacity was significantly increased when extracted in aqueous methanol as compared to water extracts in all samples. In the methanol extracts, the seaweed from Osland contained the significantly highest antioxidative activity with 1665.1 ± 39.4 μmol TE/g, followed by Sulefisk with 1243.2 ± 68.9 and Engesund with 630.9 ± 31.5 μmol TE/g. The difference in ORAC values between Osland and Sulefisk was not consistent for all extraction methods, while the sample from Engesund had the overall significantly lowest values. The treatment in an ultrasonic water bath did not have a significant effect on the content of phenolic compounds or antioxidant capacity but decreased the viscosity of water extracts.

(Continued on next page)

Further, the seaweed samples were tested for the established food allergens crustacean, mollusc and fish. Values for crustacean tropomyosin were for all samples above the lower detection limit of 20 ppm in the assay (corresponding to 0.2 mg/kg sample) and ranged from 0.442 ± 0.05 mg/kg for Osland to 1.005 ± 0.39 mg/kg at Sulefisk. The measured values were not significantly different between the three IMTA sites, although the lowest values were all detected in the samples from Osland. The mollusc tropomyosin concentrations in the seaweed samples were numerically above, but very near the lower detection limit of 10 ppm in the assay or 0.1 mg/kg sample. Fish allergens, provided as cod concentrations, were below the lower detection limit of 4 ppm in the assay (or 40 mg/kg sample) for the seaweed samples from Sulefisk and Engesund. The concentration measured in the samples from Osland was above, but near the detection limit. Osland was also the location with the highest fish production in 2020. According to literature, cod contains parvalbumin at 2 mg/g4,5 with higher concentrations in muscle6. Based on this, 40 mg cod per kg as the detection limit would translate to 0.08 mg parvalbumin per kg.

CONCLUSIONS

Products with relatively high market value such as food and feed ingredients are predicted to play an important role in creating value from Norwegian-grown seaweed and kelp[7]industry and public authorities have been committed to develop a Norwegian bio-economy based on cultivated seaweed, focusing on cultivation and processing of the biomass. This review reports on the status of seaweed aquaculture in Norway, supported by production data collected since the delivery of the first commercial cultivation permits at sea in 2014. Although novel product developments are currently limited, future industrial perspectives based on cultivated biomass are being discussed. Upscaling from experimental cultivation schemes to commercial production requires a thorough assessment of the risks and benefits associated with seaweed aquaculture, as well as the development of a regulative framework adapted to this industry. Issues associated with upscaling the macroalgal production that needs to be addressed includes (i. This work confirmed the presence of phenolic compounds and antioxidative activity in *S. latissima,* produced in IMTA systems, in a similar range for all assessed locations and comparable to previous studies, indicating that this species and production method can play a role for the development of natural food additives, functional food or health products from seaweed. The here reported bioactivities should be further investigating to fully understand the potential and limit of using *S. latissima* as functional ingredients in food or feed formulas.

Our analyses of *S. latissima* bulk samples with commercial sandwich ELISA kits for known food allergens have shown acceptable detection limits, linearity and recovery. Only crustacean allergens could be detected in all tested locations in this study, while mollusc tropomyosin was very near the detection limit, thus assumed as not detectable. Cod parvalbumin was detected slightly above detection limit only in one location. In the context of realistic incorporation in final food products and resulting daily ingestion, the presence of contaminating marine species in seaweed raw products does not seem to be critical, but should be further followed through seasons, locations and productions as more processed products are developed.

INTRODUCTION

Strategic development and research actions are needed to realize the Norwegian government's long-term aim for a predictable and sustainable growth within the aquaculture industry[1]. Fish farming in Norway is dominated by sea cage farming of salmonid species (Atlantic salmon and rainbow trout). In recent years, the industry has experienced an augmentation in production volumes per farm while the number of farm locations has decreased[2]. This augmentation of production leads to increased feed use, and subsequently to augmented release of nutrients and organic particles released into the marine environment[3,4]. These nutrients and organic particles released from aquaculture represent a possible resource for new biomass cultures, but also a risk to the environment and sustainability of the fish production. Thus, improved resource and energy utilization must be investigated in order to transform the wastes into a resource for producing other organisms at other trophic levels with potential for creating high value products[5]. In Norway, IMTA systems could also be a way to increase seafood production in areas already occupied by/allocated for salmonid aquaculture.

MATERIALS AND METHODS

The data were collected through a desktop study of peer-reviewed and 'grey' literature to identify the reported IMTA research and industrial activities and investigate the incentives already in place to develop this technology in order to outline the upscaling potential of each technological approach in Norway.

RESULTS

Various research initiatives, both nationally and internationally, have been addressing IMTA related questions and are contributing to a gradual development of the sector, including the transition from research to commercial scale IMTA systems. In Norway, the IMTA research activities currently focus on increasing the knowledge about new potential aquaculture species and appropriate organism for co-culturing based on their trophic levels and complementary functions in the ecosystem, as well as their economic value or market potential. However, most studies on IMTA have so far been based on experimental designs with limited biomass of extractive species not yet allowing for thorough evaluations of biological and economical pros and cons of implementing salmon based IMTA as a production strategy.

There is still a reluctance to this concept of ecological engineering in Norway reflected by the lack of research on IMTA and development of new technologies for integration of species at lower trophic levels with today's intensively fed monocultures of fish. At present there is uncertainty about the potential use of bivalves in IMTA, while macroalgae and deposit feeders seems more promising and are the scope for research environments and industry.

Seaweed has demonstrated having a high capacity for absorption and metabolism of inorganic nutrients excreted by fish aquaculture, integrating seaweed cultures in IMTA and seems promising for further upscaling of IMTA in Norway while producing valuable products of marine origin[6]. However, based on the current production technology, the seaweed value-chain will require extensive innovation and economies of scale to become energy competitive[7,8] and to be competitive as a biomass source for the production of fish feed ingredients[9]. Further research should investigate the predictive environmental impacts of a fully developed seaweed value-chain and account for the emissions and multi-functionality of the system (e.g. lost biomass, impact on biodiversity, ecosystem services).

The particulate excess from salmon aquaculture can also be regarded as a food source for filter feeders in an IMTA system. Whereas feed waste constitutes only 3-5% of the feed distributed, most of the particles originate from feces production. Fish feces has a low nutritional value, but this food source still can support the growth of bivalves such as blue mussels in nutrient limited areas. Thus, to the best of our knowledge it has not been investigated whether running a whole cultivation cycle of mussels or scallops in IMTA with salmon in Norway yields higher bivalve biomass at harvest compared to monoculture production. Nevertheless, collected sludge from production of larger smolts in land-based systems before deployment at sea can be further fed as substrate and utilized by deposit feeders (e.g. polychaetes, sea cucumber) and currently presents one of the new opportunities for developing IMTA in Norway[10].

(Continued on next page)

CONCLUSIONS

Upscaling of pilot experiments with new sophisticated technological solutions and systems at industrial scale is a prerequisite for the quantification of the potential for bioremediation services and increased biomass production of the low-trophic species in IMTA in Norway. Although the aquaculture regulations are intended to secure a sustainable industry, they have not yet been fully adapted to suit the emerging integrated systems. Norwegian aquaculture activity is thoroughly regulated, and spatial issues related to minimum distance between aquaculture farms, co-location of species at different trophic levels, and zoning strategies has been used as main management tools to control disease transfer. Therefore, restrictions on co-location of multiple species on the same site and the limited environmental, economic and societal pressures and incentives from the industry and the public are important challenges to the develop commercial IMTA in Norway.

Introduction

Eco-certification programs provide eco-certified status to aquaculture farms that meet a set of sustainability criteria based on the assessment of a third-party auditor. These programs are certifying an increasing volume of farmed seafood and claim to address both environmental and social issues in the sustainable development of aquaculture, but their success in creating positive sustainability outcomes remains uncertain.

Tröster & Hiete (2018) provide a definition of success for eco-certification that includes four dimensions of sustainability: problem solving effectiveness is the ability of eco-certification to address the issues it is intended to address, behavioural effectiveness is change in the activity of the eco-certified producer, process effectiveness is the uptake of eco-certification by producers, and constitutive effectiveness is the acceptance of certification amongst stakeholders. While each of these types of effectiveness are necessary for the overall success of eco-certification, problem solving and behavioural effectiveness are required to improve sustainability without limiting eco-certification to creation of a 'market for sustainable seafood' only (Ponte, 2012) (Figure 1). Given the growth of aquaculture and the increasing volume of eco-certified farmed seafood, this review provides an overview of research on the effectiveness of eco-certification, in particular, producer-level effectiveness, which is necessary if eco-certification is to create positive ecosystem-level outcomes.

Approach

A scoping review was used to review and assess the status of research literature on the success of aquaculture eco-certification. Tröster & Hiete's (2018) four dimensions of effectiveness were used to categorize types of research on the effectiveness of eco-certification and summarize findings. Research literature related to producer-level effectiveness was further reviewed and themes related to challenges in the application of eco-certification to aquaculture sustainability issues were identified. Where relevant, the way in which these challenges are addressed by eco-certification in other resource sectors were also reviewed to discuss potential approaches for improving producer-level effectiveness of aquaculture eco-certification.

Results and Discussion

Evaluating the effectiveness of eco-certification is challenging due to difficulty identifying appropriate non-certified farms (counterfactuals) for comparison with certified farms (Blackman & Rivera, 2011). However, there has been increasing interest in this topic in recent years, including research on the potential producer-level effectiveness of aquaculture eco-certification based on analysis of eco-certification criteria and processes, which has provided insight into specific shortfalls. These shortfalls include advancing an incomplete definition of sustainability, risking future improvements by labelling farms as sustainable, and not accounting for the potential far-field effects of aquaculture or local context in the application of eco-certification criteria.

Recommendations for addressing these shortfalls include (1) applying an ecosystem services framework to the selection and development of eco-certification criteria, (2) differentiating the level of compliance or stringency of criteria between and/or within eco-certification schemes, (3) using benchmark criteria and requirements for improvement over time, (4) including more criteria related to the far-field effects of aquaculture on the ecosystem, and (5) recognizing the role of local context in achieving sustainability outcomes.

While several recommendations for the improvement of eco-certification criteria are identified, it is important to consider the implications of these recommendations for *process effectiveness*, since as compliance criteria become more stringent and complex, producer participation can be expected to decline (Kalfagianni & Pattberg, 2013). For example, while moving beyond farm scale is necessary if eco-certification is to include an ecosystem perspective of sustainability, producer capacity to address increasingly complex eco-certification criteria may affect the willingness of farmers to embrace eco-certification.

Introduction
Animal health related issues are nowadays the major constraint for aquaculture expansion and sustainability (Adams 2019). Besides vaccination, prophylactic measures such as the incorporation of immunostimulants and prebiotics in feeds (Meena et al. 2013; Song et al. 2014), have also been used to prevent disease outbreaks. To enhance fish disease resistance and general health, diets are often supplemented with β-glucans, which are compounds with known beneficial effects in fish innate immune response (Guzmán-Villanueva et al., 2014). β-glucans show repeating patterns on their structure that are recognized in the gut by cell pattern recognition receptors (PRR), leading to the activation of the host´s innate immune cells enhancing its immune response (Dalmo et al., 2008). The present work aimed to evaluate the effects of both short- and mid-term feeding diets supplementated with microalgae (*Phaeodactylum tricornutum*) extracted β-glucans on gene expression, oxidative stress biomarkers and plasma immune parameters in gilthead seabream (*Sparus aurata*) juveniles.

Material & Methods
A practical commercial-like diet was used as control (CTRL), whereas 3 others based on CTRL were further supplemented with a constant concentration of β-glucans, derived from *Saccharomyces cerevisiae* (diet MG1000) and different extracts of *P. tricornutum* (diets Phaeo21 and Phaeo37). Diets were randomly assigned to quadruplicate groups of 95 gilthead seabream (initial body weight: 4.1 ± 0.1g) that were fed to satiation three times a day for 8 weeks in a pulse feeding regimen. Therefore, fish were fed the different experimental diets intercalated with the CTRL dietary treatment every 2 weeks. After 2 and 8 weeks of feeding, 3 fish/tank were sampled for blood and tissues collection.

Results & conclusion
All groups showed equal growth performance and no significant changes in plasma innate immune status. Nonetheless, seabream fed β-glucans supplemented diets showed an improved anti-oxidant status compared to those fed CTRL at both sampling points. Furthermore, diet Phaeo37 seems to induce an immune tolerance effect in the gilthead seabream gut, causing a general down-regulation of immune related genes, without compromising systemic immune response. In conclusion, results suggest that the dietary administration of a *P. tricornutum* 37% enriched-β-glucans extract might be relevant in a context of gut inflammation due to its immune tolerant and anti-oxidative effects.

FATTY ACID PROFILE COMPARISON OF THREE MARINE BY-CATCH FISH SPECIES AVAILABLE IN INDIAN WEST-COAST WATERS WITH THREE INDIAN FOOD FISH

Steffi Reji*, Phibi Philip Naduvathu, Aldon Baby, R. Anandan and S. Bharathi.

Introduction

The total capture fisheries production of India in 2019 was about 13.7 million tonnes (NFBD, 2020) of which 3.56 million tonnes was contributed by marine sector (CMFRI, 2019). In 2011, trawl fisheries contributed to around 50% of the total marine capture production and the low valued bycatch contributes to around 25% to the total trawl fisheries production in India (Dineshbabu *et al*, 2013). *Canthidermis maculata*; an epi-pelagic (1-110m), reef associated fish (Lieske and Meyer, 1994), *Gephyroberyx darwinii*; a meso-pelagic (200-500 m) deep-sea fish (Maul, 1990) and *Satyrichthys adeni* a demersal (58-300 m), deep sea fish are found to constitute a good quantity of by-catch discards from deep sea trawlers operating at off south west coast of India. Relatively lower flesh content, lack of consumer demand and market, smaller size at catch of fish are the major reasons behind discarding. New studies can reveal new utility of by-catch but discarding bycatch is complete wastage of natural resources and can cause environmental concerns too. Nutrient profiling of these by-catch fish is the primary step to find some utility that can lead to by-catch or waste utilisation. Most of the deep-sea fish stocks remain underexploited and harvesting of these fish resources can increase the capture fish production. Shifting the effort towards exploiting deep sea fish stocks shall reduce the exploitation pressure on other pelagic fish stocks allowing them to recover. In this regard the work tried to analyse and compare the chemical composition and fatty acids profiles of three marine fish species *viz Canthidermis maculata, Gephyroberyx darwinii* and *Satyrichthys adeni* with three available Indian food fish *viz Channa striata, Systomus serana* and *Gerres subfasciatus*.

Materials and methods

The fish muscles were homogenized well in a blender to prepare the fish samples for nutritional analyses after filleting and skinning. The moisture content, total nitrogen, crude fat and ash content of the samples were carried out according to the standard procedures of Association of Official Analytical Chemists (AOAC, 2005). Fatty acid methyl esters were derived from the samples through lipid extraction suggested by Folch *et al* (1957), followed by saponification and esterification (Metcalfe *et al*, 1966). The sample were then injected and run in Gas Chromatography (Perkinelmer clarus 580) to derive the fatty acid profile. Analyses were triplicated and the results were expressed as mean ± standard deviation.

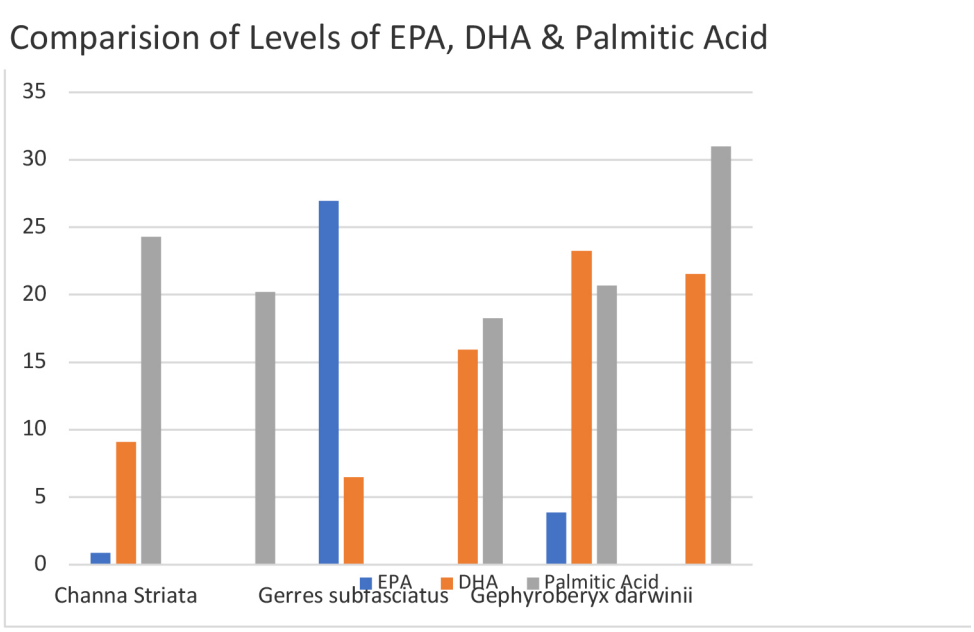

Fig 1: Comparison of levels of EPA, DHA and Palmitic Acid in *Channa striata, Systomus serana, Gerres subfasciatus, Canthidermis maculata, Gephyroberyx darwinii* and *Satyrichthys adeni*

(Continued on next page)

Results and Discussions:

The crude protein content expressed in percentage of *Canthidermis maculata, Gephyroberyx darwinii* and *Satyrichthys adeni* were found to be 21.99%, 19.97% and 20.99% respectively which were comparable with the crude protein content of the food fish *viz Channa striata* (17.97%), *Systomus serana* (21.93%) and *Gerres subfasciatus* (22.01%). The significant protein level implies that it can be a good raw material for fish meal production. Levels of docosahexaenoic acid (DHA) in the total fatty acid level of *Canthidermis maculata*, *Gephyroberyx darwinii* and *Satyrichthys adeni* were 15.94%, 23.23% and 21.52% respectively which were significantly higher than the levels in the food fish. The level of palmitic acid (in brackets) in *Canthidermis maculata* (18.26%), *Gephyroberyx darwinii* (20.68%) and *Satyrichthys adeni* (30.98%) were comparable with that of the food fish *viz Channa striata* (24.28%) and *Systomus serana* (20.20%). Among the six fish, significant levels of eicosapentaenoic acid (EPA) were only found in *Gephyroberyx darwinii* (3.87%), *Channa striata* (0.89%) and *Gerres subfasciatus* (26.98%). Caproic acid was found in in significant level in *Canthidermis maculata* (59.70%) and *Satyrichthys adeni* (14.64%). The significant levels of DHA, EPA and palmitic acids (see figure 1) in the marine fish can be extracted to be used as food or feed additive, nutrition supplements, pharmaceutical products, emollient or surfactant in cosmetics etc.

ANTIOXIDANT SYNERGY OF MEDITERRANEAN HERBS AND ALGAL POLYSACCHARIDES: POTENTIAL IN THE DEVELOPMENT OF FUNCTIONAL BEVERAGES

M. Repajić[a*], A. Dobrinčić[a] and V. Dragović-Uzelac[a]

[a]Faculty of Food Technology and Biotechnology, University of Zagreb, Pierottijeva 6, 10 000 Zagreb, Croatia
Email: maja.repajic@pbf.unizg.hr

Introduction

Herbal extracts and algae contain a wide range of bioactive molecules with positive effects on human health. However, their application in the production of functional beverages is still insufficient despite the fact that various plant species and their potential use as ingredients in different categories of functional beverages have been explored.

Salvia officinalis and *Thymus serpyllum* are aromatic herbs from the Lamiaceae family native to the Mediterranean area. Due to their high antioxidant capacity, which is directly correlated with a high content of various polyphenolic and volatile compounds (Mrkonjić et al., 2021), they present a valuable source for the production of functional beverages. On the other hand, green alga *Ulva lactuca* is an important source of sulfated polysaccharide ulvan, while brown algae *Fucus virsoides* and *Cystoseira barbata* are important sources of sulfated polysaccharide fucoidan. All of these polysaccharides show a wide range of biological activities such as antioxidant, anti-inflammatory and antitumor, however they are strongly dependent on chemical composition of polysaccharides.

In order to test the possibility in the development of functional beverage on the basis of selected Mediterranean herbs extracts enriched with algal polysaccharides, the aim of this research was to evaluate antioxidant capacity of *S. officinalis* and *T. serpyllum* extracts, polysaccharides of *U. lactuca*, *F. virsoides* and *C. barbata* and their mixtures.

Materials and methods

S. officinalis and *T. serpyllum* were purchased from Suban Ltd. (Strmec, Croatia), while *U. lactuca*, *F. virsoides* and *C. barbata* were harvested from coastal region of Zadar (Croatia) in February 2020. *S. officinalis* and *T. serpyllum* (2 g) were each extracted with ddH_2O (100 mL) using ultrasonic bath at 50 °C/30 min. Obtained extracts were analysed for total polyphenols using Folin-Ciocalteau method (Repajić et al., 2018) and mixed in 1:1 ratio for further experiment. Conventional polysaccharide extraction was performed at 80 °C/3 h using 0.1M H_2SO_4 (Dobrinčić et al., 2021). Extracted polysaccharides were analyzed as follows: total sugars by colorimetric phenol-sulfuric acid method (Dubois et al., 1956), L-fucose concentration by colorimetric assay with L-cysteine (Dische and Shettles, 1948), sulfate content was quantified after acid hydrolysis (1M HCl at 105 °C for 5h) by turbidimetric $BaCl_2$-gelatin method (Dodgson and Price, 1962) and uronic acid content was measured with modified sulfamate/m-hydroxydiphenyl colorimetric method (Filisetti-Cozzi and Carpita, 1991). In order to evaluate antioxidant synergy of Mediterranean herbs and algal polysaccharides, three different amounts of polysaccharides (0.25, 0.5 and 1 g) from each alga were mixed with 10 mL of herbal extract. The ability of prepared extracts (herbal extract, algal polysaccharides and their mixtures) to scavenge the DPPH radical was assessed spectrophotometrically.

Results

Content of total sugars in all three algal polysaccharides ranged from 57.28 to 61.21%, while sulfate group content ranged from 33.55 to 41.86%. *U. lactuca* polysaccharides had significantly lower content of fucose and uronic acid, while *C. barbata* polysaccharides contained the highest fucose content. The highest content of uronic acid was found in *F. virsoides* polysaccharides. Herbal extracts contained 27.00 (*S. officinalis*) and 15.03 mg GAE g^{-1} (*T. serpyllum*) of total polyphenols and their DPPH radical scavenging activity was 242.03 and 215.9 mg L^{-1}, respectively. Furthermore, mixture (1:1 ratio) of these extracts showed DPPH radical scavenging activity of 230.53 mg L^{-1}, while DPPH radical scavenging activity of *U. lactuca*, *F. virsoides* and *C. barbata* polysaccharides was 43.51, 67.64 and 71.14 mg L^{-1}, respectively. Addition of polysaccharides into the herbal extract increased DPPH radical scavenging activity (280.03 to 299.9 mg L^{-1}) regardless of the algal species and the amount added. However, increase of polysaccharides addition from 0.25 to 1 g increased scavenging activity in *F. virsoides* and *C. barbata* herbal mixtures, but not in herbal mixture of *U. lactuca*.

(Continued on next page)

Discussion and conclusion

Various biological activities of algal polysaccharides are often associated with their chemical composition, e.g. high levels of L-fucose, high degree of sulfation and low levels of contaminants such as uronic acid and protein (January et al., 2019). However, significant discrepancies in structural properties makes it impossible to precisely relate the bioactivity of polysaccharides with just one structural property but rather a combination of several properties. Green algae *U. lactuca* is a source of ulvan whose major monosaccharide unit is L-rhamnose, while L-fucose is predominant monosaccharide in brown algae polysaccharides. Lower fucose and sulfate group content, despite low level of uronic acid, could explain lower DPPH radical scavenging activity of *U. lactuca* polysaccharides. On the other hand, *S. officinalis* and *T. serpyllum* extracts contain various polyphenols which are known as strong antioxidants. The chemical structure of polyphenols varies upon number of aromatic rings and hydroxyl substituents which enable polyphenols to scavenge free radicals and reacting oxygen species through direct reaction with free radicals and from the chelation of free metals (Leopoldini et al., 2011).

Obtained results revealed a synergistic action of polyphenols from Mediterranean herbs and algal polysaccharides by which antioxidant activity of herbal extracts increased with the addition of algal polysaccharides, even in low amounts. These observations present an excellent base for the further development of functional beverages enriched with natural antioxidants.

Introduction

Bioactive peptides are small amino acid chains with valuable properties (beyond their nutritional value), including antioxidant, mineral-binding, immunomodulatory or antimicrobial activities. They can be obtained from protein-rich by-products and included in aquafeeds, contributing to circular economy and waste reduction. In this work, we hypothesised that including blood hydrolysates (BH) in sustainable plant-based aquafeeds could promote fish robustness, increase the economic value of animal blood (which is often discarded) and minimize waste, contributing to a circular economy. Additionally, BH may address the *T. maritimum* infections that occur in aquaculture farms, with high impact on fish health, well-being and aquaculture production.

Methods

Three fractions of swine BH obtained by autohydrolysis (AH) or enzymatically were selected. AH was oven dried, whilst the enzymatically obtained BH were further submitted to a micro- (MF) and nanofiltration (NF) and the respective retentates freeze-dried. Dried hydrolysates were then included in five isolipidic and isoproteic diets for European seabass: a fishmeal (FM) based diet (positive control, PC), a commercially-based diet where 50% of FM was replaced by vegetable proteins (negative control, NC) and three diets where 3% of each BH was added to the NC. Diets were assigned to triplicate groups of 71 European seabass juveniles (initial weight 12.3 ± 1.4 g), fed three times daily until apparent satiation in a recirculating saltwater system (RAS). Growth, nutrient utilisation and whole-body, liver and muscle composition were evaluated after 12 weeks. Plasma was also collected from 9 fish per treatment for evaluation of immune parameters. At the end of the trial, ten fish per tank were infected with *Tenacibaculum maritimum* (3.5×10^5 cfu/mL), in a two-hour water bath, and mortality was assessed for 8 days. A digestibility trial was carried out with the remaining fish from the growth trial in a Guelph system, for evaluation of macronutrient and mineral digestibility. All diets were supplemented with 200 mg of Y_2O_3 per kg, as an inert marker.

Results

Dry matter apparent digestibility coefficient (ADC) was significantly lower in hydrolysates-containing diets compared to the PC; NF did not differ from the NC. Protein ADC was generally high (>91%) and both MF and NF had similar values to the PC and NC diets. MF and AH had a significantly lower lipid ADCs when compared to PC and NC, while the NF only differed from the PC. Mineral ADC values of the PC, NC and NF did not differ statistically. AH diet led to a significantly lower iron ADC value compared to the controls. Calcium ADC was significantly lower for MF and AH diets, when compared to all other diets. MF also displayed lower copper and potassium ADC.

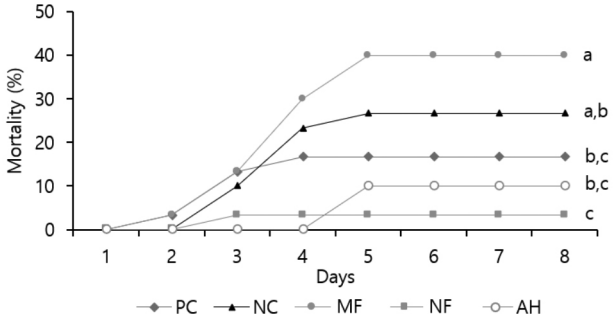

Figure 1 - Mortality rate of seabass fed the experimental diets for 12 weeks and challenged with *T. maritimum*. Different letters indicate significant differences among treatments.

(Continued on next page)

Fish fed PC had the highest final weight, followed by NC and NF that had similar final weights. Specific growth rate (SGR) and feed conversion ratio (FCR) of fish fed NF showed no significant differences from those fed PC and NC. Diet MF induced the lowest final body weight and highest FCR.

Despite no significant differences among treatments regarding final body composition, lipid and energy retention and gain were lowest in fish fed MF, which also had the lowest condition factor. No differences were found in muscle and liver lipid content.

Innate immunity markers were evaluated in the plasma. Peroxidase was increased by the MF diet, but lysozyme was significantly lower in fish fed this diet, compared to all other treatments. Regarding the infectious challenge, NF had the lowest mortality rate that differed significantly from the NC and MF groups (figure 1).

Conclusions

Results clearly show that the NF diet was able to significantly reduce European seabass mortality after exposure to a very common pathogen in fish farms (*T. maritimum*). It should be noted that the higher pathogen resistance was achieved without affecting fish growth compared to a commercially-based diet (NC). Contrarily, MF diet reduced nutrient digestibility and fish growth; this diet also led to decreased plasmatic lysozyme, which supports the lower resistance towards disease that was evidenced in the bacterial challenge, as this diet led to the highest mortality. In conclusion, the enzymatically obtained blood hydrolysate further submitted to a nanofiltration (NF) has a high potential to be included in aquafeeds for European seabass, corresponding to a new and effective way to reduce fish susceptibility to *T. maritimum*.

Introduction

In aquaculture farms, fish are subjected to several stress situations, including high farming densities, periodic handling, routine procedures or even changes in temperature, oxygen and other environmental parameters. All these stressors may induce oxidative stress by causing an imbalance between the generation of reactive oxygen species (ROS) and the scavenging activity of antioxidants [1]. The accumulation of ROS may damage biomolecules such as proteins, lipids or nucleic acid, impairing growth, immune response and flesh quality [2]. Bioactive peptides, small amino acid chains with properties including antioxidant, mineral-binding, immunomodulatory or antimicrobial activities, can be obtained from protein-rich by-products, making them attractive ingredients for inclusion in aquafeeds within the context of a circular economy. Thus, supplementation of diets with functional ingredients able to modulate fish oxidative stress has been considered in this work, using bioactive peptides included in swine blood hydrolysates (BH). We have investigated the potential of the dietary inclusion of BH to improve European seabass (*Dicentrarchus labrax*) oxidative status after air exposure.

Methods

Three fractions of swine BH obtained by autohydrolysis (AH) or enzymatically were selected. The enzymatically obtained BH were further submitted to a micro- (MF) or nanofiltration (NF). Dried hydrolysates were then included in five isolipidic and isoproteic diets for European seabass: a fishmeal (FM) based diet (positive control, PC), a commercial-based diet where 50% of FM was replaced by plant proteins (negative control, NC) and three diets where 3% of each BH was added to the NC. Diets were assigned to triplicate groups of 71 European seabass juveniles (initial weight 12.3 ± 1.4 g), and fed to apparent satiation in a recirculating saltwater system (RAS). After 12 weeks, 9 fish per treatment were either immediately sampled or air-exposed for 1 minute and let to recover for 6 hours prior to sampling. Plasma and liver were collected to evaluate oxidative stress indicators.

Results

Plasmatic cortisol and lactate were elevated for all diets after the air exposure although differences among diets were not found. Glucose levels were unaffected by either diet or stress. Regarding oxidative stress markers in the liver, lipid peroxidation (LPO), measured by TBARS, tended to increase after air exposure. Considering the non-stressed fish, MF diet led to the lowest LPO levels, being significantly lower than the AH, but without differing significantly from the remaining diets. In stressed fish, the dietary impact on LPO levels was limited. Protein oxidation, evaluated by carbonyl content, decreased in stressed fish, irrespectively of the dietary treatment. Liver catalase was significantly lower in the NC, NF and AH compared to the PC, and increased after stress in all treatments. Glutathione peroxidase was unaffected by diets or stress condition. Fish fed MF had a significantly higher superoxide dismutase activity than those fed PC and AH diets and was reduced in all stressed fish compared to the non-stressed ones.

Conclusions

The stress response triggered by air exposure involved an increase in cortisol levels, which was followed by an increment in plasma lactate; however, the tested BHs could not enhance plasma response to stress. Regarding liver oxidation markers, the stress challenge increased LPO, as ROS can accumulate in the liver under oxidative stress. Carbonyls decreased post-stress, likely due to a feedback interaction with the radicals produced during LPO, which acted to reduce protein oxidation. The NF, composed of smaller peptides than the other BH, may modulate European seabass antioxidant defences by lowering catalase levels without increasing LPO, suggesting this diet could be providing exogenous antioxidants to counteract ROS-induced oxidative stress.

(Continued on next page)

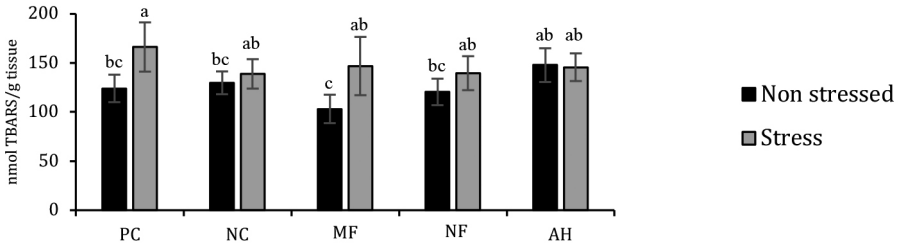

Figure 1 - Lipid peroxidation (LPO) in the liver of fish sampled before (non-stressed) or after (stress) 1 minute air exposure, and after feeding the experimental diets for 12 weeks. Values presented as mean ± standard deviation (n=9). Different lowercase letters indicate significant differences for Diet x Stress after a two-way ANOVA ($p<0.05$).

BIOFORTIFIED FISH PRODUCTS FOR CONSUMERS WITH NATURAL IODINE, SELENIUM AND FATTY ACIDS: IMPACTS ON FISH PHYSIOLOGY

Laura Ribeiro[1]*, Marisa Barata[1], Ravi Araujo-Luna[1], Vera Barbosa[1], Narcisa Bandarra[1],Florbela Soares[1], Cátia Marques[1], Jorge Dias[2], António Marques[1], Pedro Pousão- Ferreira[1]

[2]SPAROS - SPAROS, Lda., 8700-221 Olhão, Portugallribeiro@ipma.pt

Introduction
Tailor-made fortified seafood products can contribute to overcome one third of global population nutritional deficiencies, particularly on iodine, selenium and iron (1). Therefore, eco-innovative biofortified diets in iodine (macroalgae), selenium (yeast), EPA and DHA (microalgae), were enhanced with levels of these essential nutrients within the legal limits for consumers (2) and tested with gilthead seabream (*Sparus aurata*). These nutrients are known to interfere in vertebrates important metabolic and physiological functions, thus affecting both humans and fish. Iodine is an essential mineral for thyroid function (metabolism), selenium is involved in different and important enzymatic reactions of different pathways (deiodinases, oxidative stress, digestive enzymes, etc) and EPA and DHA are essential for membranes formation, lipid metabolism, synthesis of important bioactive molecules, among others. Therefore, biofortification of farmed fish products must assure that levels used in diets do not interfere with fish physiological functions, to avoid compromising fish health and welfare. The aim of this study was to assess the effect of the biofortified diets on different aspects of seabream physiology namely on digestive physiology, blood analysisand liver condition.

Material and Methods
Trial was carried out at IPMA's aquaculture research station in Olhão, for 3 months, using gilthead seabream (2). Fish were fed four experimental diets manufactured by SPAROS, one based on commercial formulation (CTRL), and three enriched diets (B1, B2 and B3) supplemented with different blends of iodine-rich macroalgae (0.40% in B1 and B2; 0.80% in B3) and selenized yeast (0.015% in B1 and B2; 0.035% in B3). At the end of the trial six fish were anesthetized, blood collected from caudal vein, and afterwards sacrificed to collect intestine and liver samples for analysis. Histological sections of intestine and liver stained with H-E were made to analyse tissue structure andintegrity. Aminopeptidase and alkaline phosphatase activities were determined using specific substrates. Liver fatty acid profile was determined by GC-FID. EPOC multiparameter blood reader (Siemens Healthcare) was used for blood analysis (haematocrit, haemoglobin, pH, pCO_2, pO_2, K^+, glucose and lactate). Plasma was used for total lipids, triglycerides, and phospholipids determination using clinical diagnostic kits from SPINREACT (Spain), whereas enzyme immunoassay kits from IBL(Germany), were used for quantitative determination of triiodothyronine and free triiodthyronine (fT3).

Results
The histological structure of gilthead seabream intestine and the number of mucous cells scattered on the villi epithelium ($P>0.05$) were similar among the different dietarytreatments. The activity of digestive enzymes was differently affected by the diet, since fish fed B2 diet exhibited higher aminopeptidase activity ($P<0.05$), whereas alkaline phosphatase was higher for fish fed CTRL and B3 diets. Liver histological structure of fish was similar regardless the diet. Liver fatty acid profile exhibited few differences among treatments, where higher levels of n-3 fatty acids reflected the biofortification process.

Blood analysis of gilthead seabream indicated that parameters varied within similar intervals of values. Still, pH, oxygen and glucose were higher on fish fed B1 diet ($P<0.05$). Similar values were observer for the analysed plasmatic parameters (lipid metabolism and thyroid hormones) among treatments, although FT3 level tended to increase in the biofortified diets.

Discussion
Physiological biomarkers values observed for gilthead seabream fed biofortified diets were largely similar when compared to control diet. Biofortified diets induced different physiological responses by gilthead seabream for the different parameters studied. The different composition of biofortified diets, manufactured with different ingredients and doses, might have triggered biological pathways differently, resulting in different physiological responses by fish. Integrating some of the physiological biomarkers (alkaline phosphatase activity and FT3 levels) with zootechnical parameters (2), suggeststhat B3 diet enhanced fish metabolism but with low energy efficiency, due to the higher FCR and lower weight attained at the end of the trial.

Overall the biofortification of fish farmed products for consumers is possible withoutcompromising fish health and welfare.

(Continued on next page)

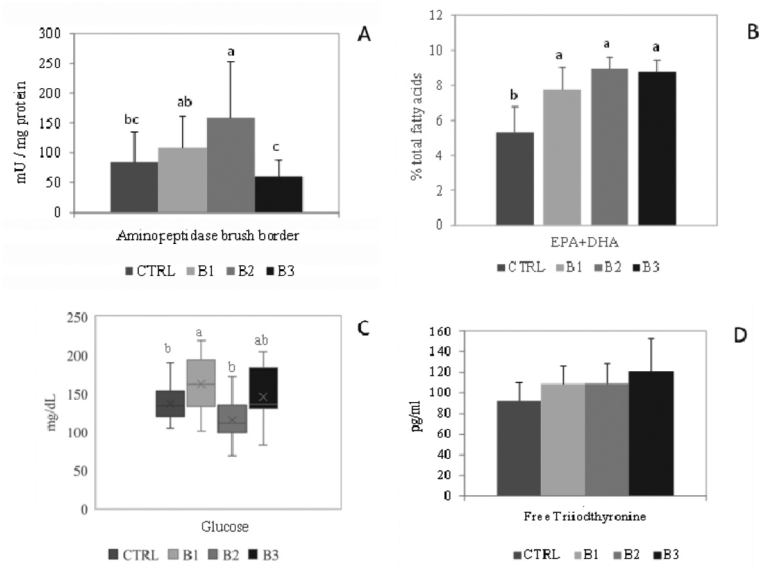

Figure 1 – Different physiological biomarkers measured on different tissues of *Sparus aurata* fed experimental diets; A - aminopeptidase activity on intestine; B- EPA+DAH on liver; C – & D – plasmatic levels, respectively of glucose and free triiodothyronine.

Introduction

The Iberian southwest coast possesses important and strategic zones for biodiversity conservation that are under the umbrella of different environment conservation instruments such as Natura 2000, RAMSAR, Special Protection Areas (SPA and National Parks. Traditionally these were sources of local socio-economic profits, such as extensive/semi-intensive aquaculture in earthen ponds using old salterns (1). Currently, their low profitability resulted in the neglect of the ponds and loss of biodiversity since, due to sedimentation, they become unproductive diked areas. Although intensive production systems are known to be responsible for biodiversity loss, recent studies acknowledge the importance of low-intensive land-use systems as important elements for large-scale conservation programs (2). It is, therefore, important to understand the environmental effects of land use for the conservation of biodiversity, and its relation to ecosystem services.

Project approach

The idea behind AQUA&AMBI project (phase 1 and phase 2) was to develop tools and knowledge to support decision on the management of wetlands, and to increase the profitability of these wetland by implementing ecological approaches to aquaculture systems. A multidisciplinary approach was adopted combining expertise from natural and social scientists, from various cross-border institutions of Portugal and Spain.

During phase 1, AQUA&AMBI 1 contributed for the creation of a Geographic Information System that enabled the recognition of areas with different legal protection levels, as well as their compatibility with territory uses, activities and occupation. Main ecosystem services provided by aquaculture were assessed, whit special focus on those related to ornithological biodiversity. Also public consultation, to ascertain scores of the natural capital associated with threatened biodiversity and to generators of ecosystem services (conservation of avifauna and natural oyster banks), was performed to establish basis for future conservation programs.

The actual phase 2 of the project, AQUAAMBI 2 (Fig. 1) will bring out information to support coastal spatial planning, assess the role of aquaculture and salt production in the carbon balances, identify new species for production and/or with biotechnological importance, and ecological approaches to aquaculture production like organic and integrated multi-trophic farming. The technologies and knowledge obtained within the project will be transferred to stakeholders in specific actions.

Expected results

The information obtained with AQUA&AMBI will allow the development of innovative methodologies to enhance the productive identity of these spaces and their dynamism as an engine of socio-economic development and a factor of competitiveness for other regions. In addition, the collective linked to the sea sector has been enriched with tools to access new opportunities that generate employment and economic growth and increase opportunities for transition to sustainable aquaculture activities.

Overall, the concept of AQUA&AMBI is to contribute to preserve and even enhance biodiversity thru optimization of profitability of abandoned areas under the actual legal framework and the spreading knowledge and use of ecological approaches to aquaculture production.

Introduction

Global aquaculture is growing at a fast rate and is a fundamental sector as source of healthy food and nutrients for humans (FAO, 2018). All fish are rich in macronutrients, vitamins, and minerals and are our main source of long-chain omega-3s. This characteristic associates fish consumption with numerous health benefits, distinguishing itself from other agri-food products. The aquaculture industry, particularly of carnivorous fish, still depends on fishmeal (FP) and fish oil (OP) obtained from wild fish, standing a huge and urgent sustainability challenge. The partial replacement of FP and OP by plant ingredients is already a common practice in the industry. However, concerns arise about the effects of FP and OP substitutions on the nutritional value of fish muscle and on the content of concomitant beneficial nutrients for humans, as plant ingredients used instead are devoid of the aforementioned n-3 LC-PUFA. Therefore, it is essential to investigate strategies to overcome this problem, since one of the main goals of aquaculture is to guarantee the consumer the supply of omega 3, recommended by the World Health Organization to promote health. OmegaPeixe project aims at mitigating this problem through the production of differentiated fish with a high content of omega-3 LC-PUFA, focusing on species of great relevance and value in Southern Europe: European seabass and turbot. For this strategy to have a real impact, this innovative product must be viable on the market, which means that the increase in costs per kg of fish produced should be inferior to the price increase that the consumers are willing to pay for a high-quality product, rich in omega 3s. In order to revisit the market's acceptance of differentiated aquaculture products, a comprehensive consumer survey was carried out nationally and in the relevant European countries, considering the general consumer segment, but also the BIO products sector.

Objectives

To carry out a comprehensive consumer survey, both nationally and in relevant European countries, a questionnaire was developed with the main purposes of:

1. Assess the consumer's willingness to pay for omega 3 fortified aquaculture fish.
2. Assess the level of consumer confidence in aquaculture products.
3. Identify trends in fish consumption.

Material and methods

The online questionnaire was designed to allow the collection of information about the target audience - socio-economic characterization data, consumption data for fish and aquaculture products, availability to pay for value-added products, level of confidence and preference for aquaculture products. The questionnaire was disseminated by the project promoters, through their commercial and institutional contact networks, as well as through social networks. Additionally, entities relevant to consumers (e.g., DECO, Portuguese Nutrition Association, Portuguese Cardiology Association, FIPA), aquaculture sector entities (e.g., FAO, Portuguese Aquaculture Association, DOCAPESCA, European Aquaculture and Technology Platform), and NGOs (e.g., WWF, Quercus, ZERO) were approached to participate in the dissemination of the questionnaire, so that it was as comprehensive as possible. The answers were collected for 6 months, and then the collected information was statistically treated in order to develop the product study report.

This questionnaire was developed according to Hill[1]. Pre-tests of 20-30 quizzes were undertaken and a final sample size of 385 valid questionnaires were considered as the minimum number, in order to undertake a multivariate analysis and decreasing the error. Questions were simple, short and without conjunctions or disjunctions, for a better understanding of the respondent. Types of quantitative and qualitative responses were obtained, and the response scale was chosen in even number to better understand the trends. Moreover, questions were elaborated based on the indications and objectives of the OmegaPeixe project and previous surveys carried out in reference documents such as scientific articles[2,3] and publications by UE[4] and FAO[5].

The collected data will be treated using SPSS Statistics, by applying a Multivariate Analysis so that the hypotheses and relationships between the variables can be evaluated.

Results

The collection of survey responses is still ongoing. Results will elucidate the perception of consumers about aquaculture products, their positioning regarding their wild counterparts, and identify trends in fish consumption. Furthermore, the survey will establish how much consumers are willing to pay for a high-quality product, rich in omega-3s.

Introduction

Fish consumption has increased over the past decades due to high nutritional value, but the large scale of the world population and the fast growth rate may lead to collapse the stocks in the sea, and there is a need to increase production in aquaculture. Despite the evolution of sustainable strategies and the implementation of new technologies in aquaculture, it has started to become more intensive, resulting in increased disturbances throughout the fish production process, making them more susceptible to disease outbreaks (Ariel & Olesen, 2002). Monogenean ectoparasites, such as *Calceostoma glandulosum*, can be found on the gills of hosts as well as on its skin and fins. One of the main environmental factors influencing parasite life cycle (egg production and free-living larvae (*oncomiracidium)* hatching) is the temperature (Turgut, 2012). Thus, the main objective of this study was to understand how this abiotic parameter could influence egg production and viability, embryo development and, finally, what are the optimum values for hatching.

Methods

Monogenea eggs were collected from cotton strips which were placed in the *Argyrosomus regius* broodstock tanks at EPPO (Aquaculture Research Station of Olhão). During the trial, five average sea water temperatures were recorded 13ºC, 14ºC, 16ºC, 17ºC, 22ºC and 24ºC. Egg viability was also performed for each temperature. Therefore, the eggs collected from the tanks were counted and classified according to Militz *et al* (2014). All eggs showing *oncomiracidium* with developed eye opercula were removed from the collecting substrate, with a needle. Then transferred to a Petri dish and after to six-well incubation plates, forming a stock of 100 larvae, by placing 10 eggs in 3ml of UV-filtered seawater. Five different controlled incubation temperatures of 17ºC, 19ºC, 21ºC, 23ºC and 25ºC were then used, with a photoperiod of 12:12 (day/night), to understand which would provide the fastest hatching rate in the first 48 hours. The water in the wells was carefully renewed by about 1/3, every day. The cultures were observed daily at the same time, recording the day of hatching of the larvae.

21	41	56
23	42	100
25	35	50

(Continued on next page)

Results

Along the trial it was observed that the number of eggs produced had oscillations, since at colder temperatures, such as 13ºC, egg production was almost non-existent and gradually increased at 14ºC, 16ºC and 17ºC, with the latter temperature presenting maximum values, decreasing gradually when the water reached 22ºC and the minimum was to 24ºC. Egg viability was also influenced by this factor as observed by the number of viable and hatched eggs with the rise of temperature values. With respect to egg incubation, where the conditions were complete controlled, a similar pattern for the hatching rate was observed, and the optimum value for total hatching, after 48 hours, was 23°C.

Discussion

In this study, *C. glandulosum* eggs hatching rate was found to be affected by fluctuations in water temperature, and a significant decrease in egg production was observed in the transition from autumn to winter, where minimum values were reached (13ºC), and then a significant increase at the beginning of spring (14ºC – 16ºC). Parasites, besides showing optimum values for egg production, exhibit a range in which they have the capacity to survive and produce eggs. In the case of *C. glandulosum* the range that this species is able to tolerate is situated between 14ºC and 25ºC. The viability of *C. glandulosum* eggs is also affected by temperature. Therefore, the number of hatched eggs decreased equally, as well as the embryonated eggs. This can be confirmed by Zhang *et al* (2021), as he states that when eggs are exposed to very low temperatures, outside the tolerable limits of the parasite, hatching fails completely, which may bring problems for the embryo that may eventually die, making the eggs unviable. On the other hand, when the temperature drops to levels, still within the range that the species can withstand, the eggs can be preserved and when this factor reaches optimal values the development of the embryo returns, since it has energy reserves and important lipids that facilitate larval longevity (Brazenor *et al*, 2020). To conclude, it was observed that *C. glandulosum* has a tolerable limit for temperature, particularly between 14ºC and 25ºC, demonstrating that, outside this range, the production and hatching of eggs is extremely low or does not occur. It was also possible to observe that the increase in temperature may be beneficial to a greater proliferation of this parasite, which may cause disease outbreaks.

Introduction

Gammarids are aquatic invertebrates that have been identified as promising candidates for their use in aquaculture. Gammarids have good growth performance, tolerate high densities and, importantly, can be fed on a wide range of sidestreams from bioindustries [1,2]sustainable nutrient sources for utilisation as dietary ingredients. Exploring the potential of under-utilised resources from other industries is imperative to replace finite natural resources, such as fish meal. Marine gammarids may be an excellent source of essential fatty acids; however, their aquaculture using formulated diets remains untested in terms of survival, growth and nutritional value of the cultured product. Here, juveniles of 2 marine gammarid species, Gammarus locusta and Echinogammarus marinus, were maintained in controlled feeding experiments with 2 marine diets (Ulva spp. and Fucus spp.. While marine gammarids contain relatively high levels of long-chain ($C_{20–24}$) polyunsaturated fatty acids (LC-PUFAs), physiologically essential compounds required for normal growth and development of vertebrates [3], it is unknown whether the LC-PUFA levels of gammarids grown on low LC-PUFA containing substrates can be maintained. Conversions of short-chain fatty acids (FAs) into LC-PUFAs in animals is determined by the complement and function of genes encoding enzymes that catalyse these multistep pathways [4]. Our main goal is to elucidate the LC-PUFA biosynthetic pathways in gammarids in order to identify species with high capacity to convert short-chain FAs available in sidestreams into LC-PUFAs that ultimately could allow obtaining a high nutritional value biomass. Specifically, this study aimed to characterise molecularly and functionally three genes encoding elongation of very long-chain fatty acid (Elovl) proteins, termed as *elovl4*, *elovl6* and *elovl1/7*-like, from *Echinogammarus marinus*.

Materials and methods

To obtain the full-length sequences of the *E. marinus elovl4*, *elovl6* and *elovl1/7*-like open reading frames (ORFs), BLAST searches were carried out on the Transcriptome Shotgun Assembly (TSA) of the *Gammarus* BioProject (PRJNA497972). The ORFs were identified and then isolated by PCR using *E. marinus* complementary DNA (cDNA) as template, with primers containing specific restriction sites for further cloning into the pYES2 vector. The *E. marinus* Elovl4, Elovl6 and Elovl1/7-like were functionally characterised by heterologous expression in yeast. Transgenic yeast containing the different *E. marinus elovl* ORFs were grown in the presence of a series of exogenously supplemented polyunsaturated fatty acid (PUFA) substrates to test their elongation capacity. After 2 day incubations, yeast were harvested and washed prior extraction of total lipids. An aliquot of total lipids was used to prepare fatty acid methyl esters for analysis by gas chromatography. Conversions of PUFA substrates to the corresponding products were calculated by the proportion of substrate FA converted to elongated FA product(s) as [areas of all products with longer chain than substrate/(areas of all products with longer chain than substrate + substrate area)] × 100.

Results

The molecular analyses showed that all the *E. marinus* Elovl sequences had the distinctive characteristics of fatty acyl elongases, including a histidine box (HXXHH). Interestingly, Elovl4 and Elovl1/7-like, but not Elovl6, contained diagnostic amino acids preceding the histidine box that are characteristic of PUFA elongases. Consistently, the functional characterisation results showed that the *E. marinus* Elovl4 and Elovl1/7-like are indeed PUFA elongases, since they elongated PUFA substrates ranging from C_{18} to C_{22}. However, the *E. marinus* Elovl6 only showed activities towards C_{18} PUFA substrates (Table 1).

Discussion and conclusions

The research described in this work demonstrates that gammarids possess at least three distinct elovl genes, namely elovl4, elovl6 and elovl1/7-like, with putative roles in the biosynthesis of LC-PUFAs. Molecular and functional characterisation of the set of elovl sequences from the marine gammarid E. marinus revealed that gammarids' Elovl4 and Elovl1/7-like are PUFA elongases with affinity towards PUFA substrates ranging from C18 to C22, and account, by themselves, for all the elongation reactions required for LC-PUFA biosynthesis from C18 biosynthetic precursors [5]. On the contrary, the gammarid Elovl6 sequence contained characteristics typically found in non-PUFA elongases [6] that, along with its elongation capacity being restricted to C18 PUFA substrates, indicated that this enzyme does not play major roles in LC-PUFA biosynthesis in gammarids. Elovl4 was the sole Elovl found in gammarids with the ability to produce PUFAs of up to 26 carbons. Overall, the present study provides insight into the endogenous machinery enabling gammarids to bioconvert dietary fatty acids into high value LC-PUFAs.

Introduction

The fast and remarkable growth of global aquaculture in the recent years has created new economic and ecological challenges [1]. With regard to fish farming, such challenges have been mostly linked to guarantee the supply of raw materials used for feed formulation in order to reduce the current usage of finite resources such as fishmeal and fish oil. Gammarids, particularly their biomasses, have prompted interest as alternative sources for feed formulation due to their nutritional profile. Recent studies have reported the ability of gammarids to grow on a wide range of sidestreams while accumulating relatively high levels of long-chain (C_{20-24}) polyunsaturated fatty acids (LC-PUFA) [2,3], physiologically essential compounds for normal growth and development of vertebrates [4]. Diet and temperature have been suggested to modulate the abundance of LC-PUFA in aquatic invertebrates [5]. Here, we aimed to elucidate the effects of three diets (the seaweed *Fucus* sp., carrot leaves, coconut flesh) and four different temperatures (5, 10, 15, and 20°C) on LC-PUFA profiles of *Gammarus locusta*, a marine gammarid with capacity for trophic upgrading when grown in low-LC-PUFA diets [3].

Materials and methods

Offspring (42 days post hatch) from laboratory cultured *G. locusta* were starved for 2 d at 10°C to allow gammarids to empty their gut. Gammarids (20) were placed in 1 L buckets and cultured at the corresponding diet vs. temperature combination during 21 d. The combinations of three different diets, namely the seaweed *Fucus* sp., carrot leaves, coconut flesh, and four different temperatures (5, 10, 15, and 20°C), were tested. At the end of the experiment, gammarids (3-4 replicates per condition) were collected, rinsed twice in ddH_2O, and freeze-dried before analysis. Total lipids and fatty acids (FA) were analysed from gammarid samples, as well as experimental diets. Principal Component Analysis (PCA) was used to analyse and visualise the relations between the experimental conditions and FA profiles of gammarids. Moreover, Analysis of Variance (two-way ANOVA) was used to test the effect of temperature and diet on the *G. locusta* FA profiles and potential interactions between both factors.

Results

FA analysis of diets showed that coconut is rich in saturated fatty acids (SFA) in comparison to *Fucus* sp. and carrot leaves. Regarding LC-PUFA, *Fucus* sp. showed moderate levels of arachidonic acid (ARA, 11.96%) and eicosapentaenoic acid (EPA, 4.81%), and lower levels of docosahexaenoic acid (DHA). Both coconut and carrot leaves diets lack LC-PUFA. FA analysis of *G. locusta* showed that temperature did not significantly influenced the composition of gammarids irrespectively of the diet. However, the *G. locusta* FA profiles varied with diets. Statistical analysis revealed that diet is the leading factor accounting for the *G. locusta* FA profiles ($p < 0.05$). Interestingly, gammarids fed on *Fucus* sp. showed the highest content of total lipids among all dietary treatments, and a fairly similar FA profile to that of wild type specimens [3]. Furthermore, *G. locusta* fed on carrot leaves and coconut showed levels of DHA similar to those fed on *Fucus* sp. diet.

Discussion and conclusions

The study demonstrates that diet is the main modulator of FA composition in *G. locusta* when compared to temperature. Our analyses also revealed the presence of DHA, albeit in small proportions, in gammarids fed on either coconut or carrot leaves, regardless of the presence of this LC-PUFA in these sidestreams. These results suggest that *G. locusta* might have some endogenous capacity enabling the production of certain LC-PUFA from precursors present in diets devoid of these essential compounds. Therefore, gammarids can contribute to trophic upgrading of aquatic food webs by the production of physiologically essential FA such as EPA and DHA from primary sources. Thus, it is fundamental to fine tune the culturing conditions for LC-PUFA production in *G. locusta* regarding the optimisation of such biosynthetic mechanisms. We conclude that cultured gammarids fed on either *Fucus* sp. or carrot leaves are promising candidates culturing marine gammarids from which high nutritional value biomasses can be processed for their use as ingredients for aquafeeds.

HOW UNIQUE OR COMMON ARE MICROBIAL COMMUNITIES IN BIOFILTERS? A TALE OF STATE-OF-THE-ART LONG-TERM MONITORING OF INDUSTRIAL RECIRCULATING AQUACULTURE SYSTEMS

D. Ribičić[a*], S. W. Dahle[a], K. Attramadal[b], T. Busche[c] and R. Netzer[a]

Introduction

At present, microbiological analyses used for detection of microorganisms in biofilter are mainly limited to the detection of total bacteria, nitrifiers or certain potentially problematic representatives. Although nitrifying microorganisms are a very important component for the performance of a biofilter in RAS, these are not the only microorganism group in such a complex ecosystem. In this study, we have employed 16S rRNA gene amplicon sequencing on samples derived from five different full industrial scale RAS over a period of fifteen months to elucidate microbiota dynamics during standard production period and to investigate how different or common are microbial communities in different RAS systems. This study obtains data at an unprecedented immensity and longitudinal depth reported so far.

Materials and methods

Biofilters of five different RAS farms farming Atlantic salmon (*Salmo salar*) have been monitored over a period of fifteen months. Monitored farms, and corresponding biofilters, exhibit different designs, but also characteristics. Samples from each biofilter were collected bi-monthly and in triplicates. DNA was extracted, amplified (V3-V4 16S rDNA region), and sequenced using Illumina MiSeq platform. Obtained sequences were treated using Quantitative Insights Into Microbial Ecology 2 (QIIME2) pipeline. Downstream statistical analysis was performed in R using dedicated packages for microbiome analysis and multivariate statistics.

Results and discussion

Biofilters showed differences in regard to alpha diversity (Simpson and Shannon index). As seen from figure 1A. the smallest variations in diversity were observed for biofilters in farms A and C. Also, biofilters A and C showed significantly higher Simpson and Shannon diversity when compared to microbial diversity observed in biofilters B, D and E. This is also an indication that the most stable bacterial communities can be found in biofilters A and C. Principal Coordinate Analysis (PCoA) of microbial communities revealed unique microbial fingerprint for each of biofilters (Figure 1B). The clustering distance coincides also with geographical locations of the respective RAS farms, meaning that biofilters A and C are to be found on completely opposite sides of Norway, while biofilters B, D and E are geographically much closer. It has been hypothesized that each RAS biofilter (and RAS in general) has the potential to establish a unique microbial composition or "fingerprint" due to different operational procedures, components or design[1]. Exact explanation for the differences in microbial community, as for within and between biofilters, are rather inconclusive here as many different variables could have accounted for that. All farms investigated for this study are very different in biofilter design, capacity, maturity, day-to-day operations, disinfection methods and frequency, and even the fish rearing stages. However, there is an indication that geographical origin of water used to fill the systems and uniqueness of RAS itself could have played a substantial role as a driving force for shaping microbial community composition and subsequent maturation, as observed in Figure 1B and Figure 1C.

Most dominating phyla were Proteobacteria with relative abundance ranging from 38.1% up to 55.3% (Figure 1C). Proteobacteria were followed by Bacteroidetes, with 13.8% to 28.2% in relative abundance. Other phyla that showed abundances larger than 2 % were Plantomycetes, Cloroflexi, Verrucomicrobia, Actinobacteria, Acidobacteria, Nitrospirae, Chlamydiae, Chlorofexi and Gemmatimonadetes. Similar observations were obtained by Huang et al.[2] and Ruan et al.[3] where most dominant phyla in monitored biofilters were Proteobacteria, followed by Bacteroidetes, Nitrospirae, Planctomycetes, Actinobacteria, Chlorofelxi and Verrucomicrobia. Although beta-diversity analysis showed rather unique microbial composition between biofilters, there is an indication that certain microbial groups are omnipresent in monitored biofilters. To investigate this further, we have screened for common microbiota of all five biofilters. Interestingly few genera found to represent core microbiota are already well-known nitrifiers, i.e., Nitrospira and Nitrosomonas. For the other taxa found within the core microbiome, literature overview shows that these microbes are commonly found in wastewater and activated sludge, but also other RAS biofilters, where they demonstrated ability for the hydrolysis and utilization of complex carbon sources.

(Continued on next page)

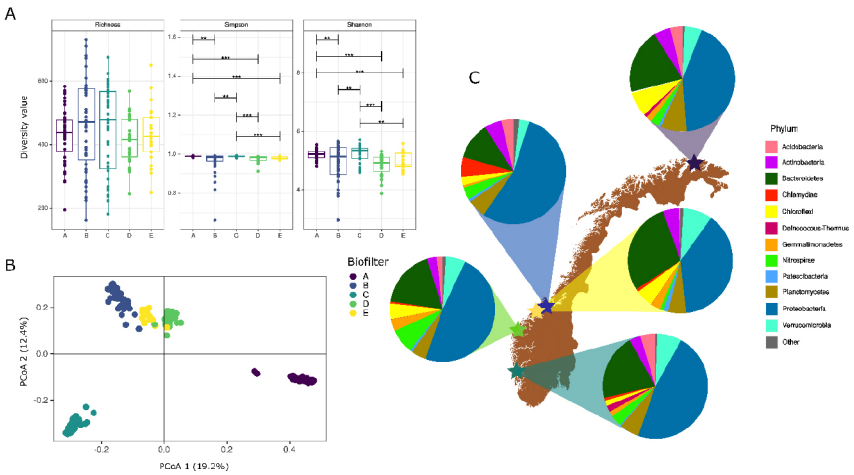

Figure 1. Alpha diversity represented as total observed number of ASVs ("Richness"), Simpson and Shannon diversity metric (A). PCoA plot based on unweighted UniFrac distance metric (beta-diversity) A map of Norway with indicated positions of five RAS and community composition at Phylum level for each of the biofilter represented as pie-charts (C).

Conclusions

In this study we have conducted deep and comprehensive mapping of microbial communities and their dynamics in biofilters of five full scale commercial RAS cultivating Atlantic salmon. Large differences in microbial communities and heir dynamics could be observed between monitored biofilters. Although, microbiologically different, core common microbiota could be established, with known nitrifiers representing it amongst other taxa.

A NON-LETHAL APPROACH UPON *Sparicotyle chrysophrii* BURDEN PREDICTION IN GILTHEAD SEA BREAM (*Sparus aurata)*

E. Riera-Ferrer[1], I. Estensoro[1], R. del Pozo[1], M.C. Piazzon[1], P. Moreno-Estruch[2], A. Sitjà-Bobadilla[1], O. Palenzuela[1]*

[2] Culmarex SAU, Murcia, Spain

Introduction

Sparicotyle chrysophrii is a polyopisthocotylean monogenean (Microcotylidae) parasite of gilthead sea bream (*Sparus aurata*) (GSB). It attaches to the gills and it can cause Sparicotylosis, which often involves severe anaemia and white-gill syndrome. The disease is ubiquitous across sea cages in the Mediterranean and it causes direct and indirect economic losses to the GSB farming sector. *S. chrysophrii* infection intensity determinations are necessary for appropriate application and coordination of farms' health management plans, aiming at keeping parasite presence below threatening thresholds. In the farms, these counts are tedious and time-consuming. Parasite loads are usually extrapolated from partial counts, e.g., of a number of gill arches from one or both sides. However, different protocols and indexes are used by the industry.

In previous studies, we have demonstrated the hematophagous nature of *S. chrysophrii* and its direct role in GSB anaemia. The aim of the current study is to explore for a fast, non-lethal approach to predict the parasitic burden of affected GSB using haematological parameters. Therefore, a large data set on infection intensity and parasite distribution, as well as biometrical and haematological data from laboratory experimental infections and from commercial cages, have been gathered and analysed.

Materials and methods

Fish sampling, Hematological data and Parasite Counts

Fish kept under experimental (N = 150) and farming conditions (N = 388) were euthanized and bled from the caudal vein. Haematocrit values were recorded after standard microhematocrit capillary tube centrifugation, and haemoglobin values obtained using the HemoCue ® Hb 801 System. Gill arches were dissected and either inspected thoroughly under stereomicroscopes, or processed by a high-throughput method based on an incubation of the gill arches in a diluted formalin solution, followed by concentration and final counting of parasites in a Sedgewick-Rafter chamber. The number and type of life stages (juveniles and adults) were registered and the performance of both counting methods compared to assess the total parasite burden.

Sparicotyle chrysophrii distribution

A Kruskal-Wallis H test was performed in order to analyse the distribution of adults, juveniles and the total parasite population throughout the gill arches.

Haematology analysis

Haematocrit and haemoglobin values were correlated using Pearson correlation coefficient and the R^2 value was calculated.

Prediction models

Partial counts sensitivity was assessed for farm data (N = 2 fresh gill arches per fish counted with scope) and laboratory data (N = 6 remaining arches processed for Sedgewick-Rafter counts) from commercial GSB cages. Several generalised linear models (GLMs) including haematocrit and haemoglobin variables were explored in order to predict the number of *S. chrysophrii* adults in affected GSB. All the statistical analyses, were conducted using R Statistical Software (version 3.6.1; R Foundation for Statistical Computing, Vienna, Austria).

Results

Sparicotyle chrysophrii distribution

Parasite presence in the different arches presented a non-normal distribution in the different arches of the left and right gills. No significant differences were found in neither adult, juvenile, nor total parasite counts among the different gill arches. Moreover, no significant differences were found in total parasite counts between the left and right gill arches.

$$N_{adults} = \exp\left(5.884 + (Hb \times -0.294) + (Hct \times -0.056)\right)$$

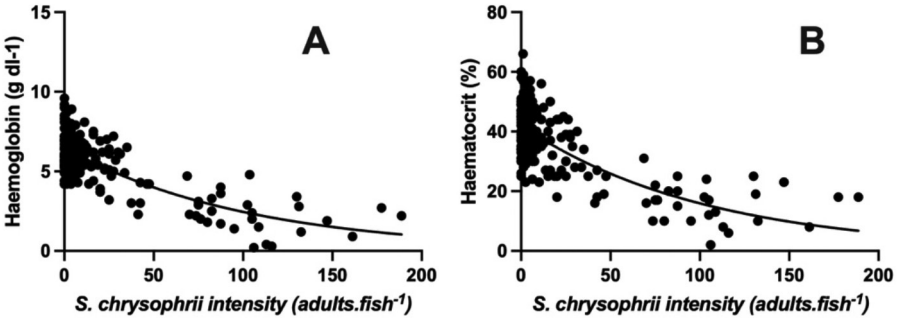

Figure 1. Exponential regression plot between infection intensity and haematological parameters (A: Haemoglobin, B: Haematocrit)

Haematology analyses

Correlations between haematocrit and haemoglobin values were highly significant in experimental, farm and in combined experimental and farm data.

Prediction models.

Different iterations were explored with subsets of data extrapolated from total or partial counts. Significant differences were found in the predicted burden values calculated from partial count data from two and six gill arches, being the latter the most reliable. Correlations between adult parasite load and haematocrit and between adult parasite load and haemoglobin values were highly significant for data from experimental and farming conditions (Fig. 1). For our entire dataset, a negative binomial regression model was obtained:

Discussion and Conclusions

No bias associated to specific gill arches of GSB could be found in the distribution of juveniles or adults of *S. chrysophrii*, and therefore, extrapolation of the total parasite load can be performed from parasite counts in a limited number of arches. However, the sensitivity of the partial counts in two gill arches was significantly inferior, showing up to 66.67% of false negatives in the earliest stages of infection. A high-throughput method was developed for *S. chrysophrii* counting from GSB gill arches, which delivers highly sensitive and reliable intensity values. Haemoglobin and haematocrit values proved to be reliable parameters, which are strongly correlated with the parasite load in GSB infected with *S. chrysophrii*. Furthermore, haematological data will allow the assessment of parasite burden in a fast and non-lethal manner by means of the prediction models developed.

Introduction

Florfenicol (FLO) is a synthetic amphenicol antibiotic that exerts broad spectrum antibacterial activity against Gram-negative bacilli, gram-positive cocci and other atypical bacteria. Moreover, FLO is a highly lipophilic drug providing thus high concentrations to treat intracellular pathogens. The pertinent literature on the use of FLU in aquaculture indicates that the drug has promising properties in fish. In this study, the absorption and depletion of FLO in European seabass following a multiple oral dosing, were investigated. Minimum inhibitory concentration tests (MIC) were also carried out against some important bacterial pathogens of European seabass.

Materials and methods

European seabass kept at 24ºC, received a medicated diet with FLO (10 mg/kg fish) for 7 consecutive days. Blood samples were taken from 10 individuals in each time point from 2 to 24 hours and days 2, 3, 4, 5, 6 and 7. Following the completion of the treatment, 10 fish were killed and muscle plus skin samples were obtained for 5 consecutive days. An HPLC method with fluorescence detection was used for FLO measurements in plasma and muscle samples of individual fish at each time point. The MIC values of FLO were also determined for bacterial fish pathogens isolated from diseased European seabass in Greece including *Aeromonas veronii bv sobria*, *Vibrio anguillarum strain*, *V. harveyi, Photobacterium damselae* subsp. *damselae*, *P. damselae* subsp. *piscicida* and *Edwardisiella anguillarum*.

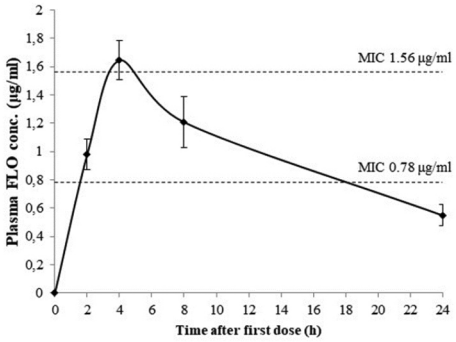

Fig. 1. Mean plasma concentrations of FLO (10mg/kg fish) during first treatment day.

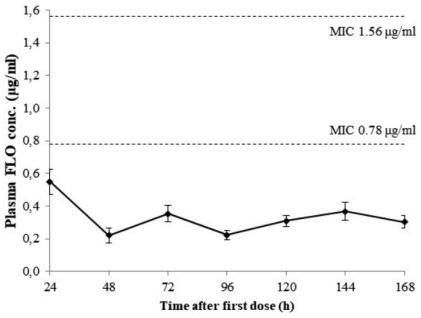

Fig. 2. Minimum plasma concentrations of FLO after multiple oral administrations at 10 mg/kg per day for seven consecutive days.

(Continued on next page)

Results

Maximum plasma concentrations of FLO in European seabass revealed values around 1.5 μg/ml at 4h post feeding during the first day (Fig.1), while during the seven-day therapy, mean plasma concentrations of FLO showed no statistical differences between 24h time intervals (Fig. 2).

Based on the muscle plus skin FLO levels (including the amine), withdrawal times for FLO were calculated to be less than 3 days post treatment. The MIC values of FLO were measured to be 0.78 μg/ml for *A. veronii* bv *sobria*, *P. damselae* subsp. *piscicida* and *E. anguillarum* and 1.56 μg/ml for *V. anguillarum, V. harveyi* and *P. damselae* subsp. *damselae*. Based on the MIC values alone, none of the tested strains can be considered as resistant to FLO in the current trial.

Conclusions

FLO is readily absorbed and rapidly eliminated from European seabass edible tissues. A PK/PD evaluation of FLO properties as a time-dependent bacteriostatic antibacterial, fits to a predictive model of Tc>MIC where Tc is the percentage of the inter-dosing interval during which the serum/plasma concentration exceeds the *in vitro* MIC against the target bacterium. Considering the above model, FLO could be a potentially efficient 'off label' antibacterial against some bacterial pathogens of European seabass tested herein. A double FLO dosing, administered twice a day may aid to obtain higher circulatory daily drug levels in European seabass, but this remains to be experimentally verified.

Background:
Just like in any other activity there are bad examples that spoil the aquaculture industry and good examples that must be followed. It's important to distinguish both and drift the industry towards the good practices to achieve sustainability.

Technology is able to improve aquaculture's practices and sustainability by aiming its focus in fish health and welfare. In turn, it will influence all the outcomes of the industry reaching increasingly better results and higher quality products.

Real case example:
How can a startup play a sustainability role in the industry?

SEAentia is a Portuguese aquaculture start-up, which aims to produce top quality fish in the most sustainable manner by combining novel aquaculture engineering with scientific research. SEAentia will pioneer in meagre (*Argyrosomus regius*) production from hatchery to commercial size in a sustainable and environmental-friendly RAS production system where animal health and welfare is a major concern.

We aim to become an international reference in aquaculture by exploring new species with great marketing potential and consumer acceptability. This will only be possible by combining new farming methods with novel technology and scientific knowledge, thereby contributing to address the global challenge of sustainably feeding the growing human population with high-quality, traceable and biosecure products.

SEAentia is paving its way to thrive, grow and lead by example.

GUT HEALTH IMPORVEMENT IN EUROPEAN SEABASS *Dicentrarchus labrax* FED ENZYMATICALLY PROCESSED SOY PROTEIN

R. Robles[1], L. Bermúdez[1], S. Husballe-Rasmussen[2].

1Testing Blue S.L. C/Holanda, 26.Puerto Real.11510. Cádiz. Spain.
2 Hamlet Protein A/S. Saturnvej 51, 8700 Horsens, Denmark.

Introduction

Aquaculture production is projected to reach 109 million tons in 2030. The need for high quality protein is increasing particularly to feed high-value species such as shrimp, marine fish and salmonids. The search for alternative protein sources of high quality is on and supported by decades of academic and private research in aquaculture nutrition around the globe.

Bioprocessing, fermentation or enzymatic treatment are some of the processes developed to increase the utilisation efficiency of soybean in fish. Enzymatic hydrolysis decreases the content of anti-nutritional factors (ANFs) and promotes nutrient utilization. An enzyme-treated soy protein (ESP; HP AquaSure) produced from dehulled and fat-extracted soybean meal has an average crude protein content of 52%, and a reduced ANF content of 2.0 mg/g trypsin inhibitor activity (TIA) and 10^3 ppm β-conglycinin.

This study reports on the evaluation of ESP in a feeding trial for the European seabass *Dicentrarchus labrax*.

Materials and methods

The trial has been carried out at the facilities of Testing Blue S.L. (Cádiz, Spain). ESP has been tested at 10 % inclusion level in two formulations: ESP M0 and ESP P0; in the first case ESP replaced soybean meal (SBM) in the formula and in the case of ESP P0, soy protein concentrate (SPC) was replaced. Both diets were evaluated against a Control diet including SBM and SPC. The formulations were made according to the current practice of using a mixture of vegetable protein sources in fish feeds (Table 1). Fishmeal has been included at 25% in all the diets.

European seabass fingerlings of 7.30±0.08 g average individual body weight were stocked in a RAS (recirculating aquaculture system) equipped with 12 units of 150 litre-tank and the appropriate solid separation system and water treatment and biofiltration. Each diet has been tested in 4 replicate tanks. The trial lasted 12 weeks. Histology (intestinal damage index and ratio IP/EP) and oxidative stress (LPO, CAT and GSH:GSSG) were evaluated at the end of the trial. Faeces production was also measured during the last week of the trial.

Results

No issues related to palatability was found during the trial. Feed intake was very similar for the three diets. Production results (Figure 1) namely specific growth rate (SGR) and feed conversion rate (FCR) were very similar among the three diets and no significant difference was found among diets (ANOVA $p>0.05$).

Replacing SBM by ESP resulted in 6% increase in the hepatosomatic index whereas replacing SPC resulted in 8% lower hepatosomatic index. For each ESP diet, there was no significant difference with the Control. No significant difference among diets was found in the eva luation of three oxidative stress biomarkers in the intestinal tissue. In the case of the histopathological evaluation of the intestinal epithelium, ESP sustains a better condition in the intestines of the seabass fed ESP products compared with the Control diet with an average 25% lower damage score. The ratio IP/EP for the ESP M0 and P0 were 7 % and 2 % higher than the IP/EP ratio for the Control diet. These results indicate a healthier intestinal epithelium and greater surface area for nutrient absorption in sea bass fed the ESP diets (Figure 2).

Another remarkable finding of the trial was the significantly reduced volume ($p< 0.00032$) of faeces produced by the ESP P0 diet compared with the Control diet. ESP M0 and P0 had a 2.6% and 9% lower faeces production than the Control (Figure 3). This result points to the potential advantage of using feeds including ESP to reduce the amount of solid waste in RAS.

Introduction

The turn towards renewable energy sources has increased the European production of biodiesel from vegetable oils, leaving glycerol (also known as glycerine) as a valuable by-product. In the EU catalogue of feed materials, "Glycerol" is described as "Product of biodiesel production (methyl or ethyl esters of fatty acids), obtained by trans-esterification of oils and fats of unspecified vegetable and animal origin" with subsequent refining via distillation or ion exchange chromatography. Although at a higher cost, refined glycerol (glycerol >98% DM; methanol <0.2%), shows much lower levels of impurities than crude glycerol.

In the living organisms, glycerol is a precursor for synthesis of triacylglycerides and of phospholipids in the liver and adipose tissue. Additionally, when the body uses stored fat as a source of energy, glycerol can be converted to glucose by the liver and provides energy for cellular metabolism. At a metabolic level, glycerol must be converted to the intermediate glyceraldehyde 3-phosphate before it can enter the pathway of glycolysis or gluconeogenesis (depending on physiological conditions). Glycerol has been evaluated as a dietary energy source for several farm animals, including various fish species. However, little is known about the potential use of glycerol in shrimp feeds. A study was undertaken to assess the effect of dietary biodiesel-derived refined glycerol (from rapeseed oil) on the overall growth performance, nutrient retention and digestibility in whiteleg shrimp (*Penaeus vannamei*).

Methods

The trial comprised 3 dietary treatments: a control diet (CTRL) containing among others 15% by-products fishmeal, 30.5% solvent-extracted soybean meal and 25% whole wheat; and two additional diets with refined glycerol at 5 and 10% (GLY5 and GLY10, respectively). Glycerol was incorporated at the expenses of wheat and a slight upward adjustment of soybean meal to guarantee isonitrogenous conditions. All other ingredients were kept constant. Diets were extruded and were isonitrogenous (CP: 38% DM), isolipidic (CF: 7.5% lipid) and isoenergetic (GE: 19.4 MJ/kg DM).

Homogenous groups of 45 shrimp (IBW: 2.55 g) were stocked in 500 L tanks. Each experimental treatment was tested in quintuplicate tanks over 50 days. Rearing tanks were supplied with recirculated seawater (salinity: 19.4; temperature: 28.1 ± 0.5°C; dissolved oxygen >7.2 $mg \cdot L^{-1}$). Additionally, at the end of the trial the apparent digestibility of protein and energy of the various diets was measured by the indirect method with feeds containing 0.02% yttrium oxide and feces collected by siphoning. Data were treated by a one-way ANOVA and when appropriate, means were compared by the Student's-Newman-Keuls test. Statistical significance was tested at 0.05 probability level.

Results and discussion

After 50 days of experimental feeding, the final body weigh ranged between 12.97 and 13.65 g, which represents a 5-fold increase of their initial weight. No significant differences were found in terms of survival, final body weight and SGR among treatments ($P>0.05$). However, shrimp fed with the GLY5 and GLY10 diets showed a significantly higher FCR, feed intake and a significantly lower PER than those fed the CTRL diet ($P<0.05$).

Conclusions

Data from this study indicates that refined glycerol used at 5 and 10%, and incorporated at the expenses of wheat, does not compromise weight gain criteria in whiteleg shrimp. However, glycerol inclusion tends to have a detrimental effect on FCR. This lower feed utilization could not be associated to a lower digestibility of protein or energy. This suggests that glycerol, in comparison to wheat, may present a lower efficiency at a metabolic level. Further studies, comprising a detailed assessment of the metabolic fate of glycerol in shrimp are warranted.

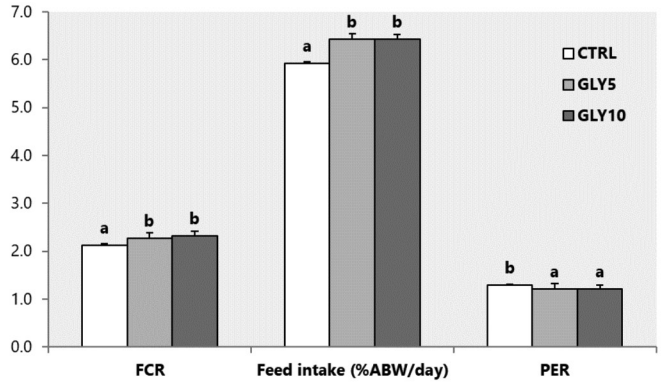
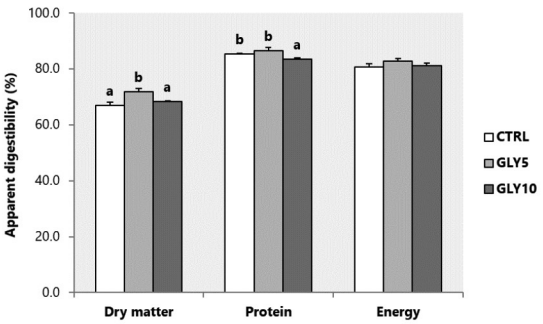
(Continued on next page)



The whole-body composition of shrimp in terms of moisture, ash, protein, lipid and energy was not significantly affected by dietary treatments (P>0.05). Similarly, the whole-body retention of protein, lipid and energy was not significantly by dietary treatments (P>0.05).

The apparent dry matter digestibility of GLY5 was significantly higher than that of CTRL and GLY10 (P<0.05). Additionally, diets CTRL and GLY5 showed also a significantly higher digestibility than diet GLY10 (P<0.05). Energy digestibility was not affected by dietary treatment (P>0.05).



SPONTANEOUS SPAWNING OF THE BLACK SEA-CUCUMBER *Holothuria forskali* (DELLE CHIAJE, 1823) IN CAPTIVITY. PRELIMINARY RESULTS OF FERTILIZATION, EGGS INCUBATION AND LARVAL REARING

C. Rodríguez (*), J.M. Martínez, C. Lobo and F. Aguado-Jiménez.

Spanish National Research Council. National Center Spanish Institute of Oceanography. Oceanographic Centre of Santander. "El Bocal" Marine Aquaculture Station. Monte-Corbanera, 39012, Santander, Spain
E-mail: cristina.rodriguez@ieo.es

Introduction

Holothuria forskali (Delle Chiaje, 1823) is a native species in the Cantabrian Coast (Spain) that can also be found in the North East Atlantic Area and Mediterranean Sea. It is a detritivore species that feeds mainly at night. This gonochoric species has an annual reproduction cycle with a synchronous spawning for male and female in spring in the Atlantic Area (Tuwo and Conand, 1992). *H. forskali* is an interesting species from an aquaculture point of view, not only as a gastronomic product, but also for its bioremediation potential in integrated multitrophic (IMTA) configurations. Therefore, breeding control in captivity is basic for its integration in IMTA systems. With this aim we planned to create a stock of breeders obtaining them from their natural environment.

Material and methods

In April 2021, coinciding with the end of the reproductive season of the species in the Atlantic, 33 *H. forskali* adults were collected at La Maruca´s Beach (Cantabrian Sea, Spain: 43°28'47"N 3°50'11"W) during low tide (seawater temperature at 12.9 °C). Specimens were transferred in a 20 L cooler to the hatchery of the "El Bocal" Marine Aquaculture Station of the Oceanographic Spanish Institute of Santander (Cantabria, Spain). At all time, the sea-cucumbers were carefully handled to avoid expulsion of Cuvierian tubules which would induce stress.

Specimens were weighted (wet weight) and placed in a rectangular tank (3 m long x 1 m wide and an average depth of 0.25 m: aprox.600 L) with flowing seawater at 13 °C.

Unexpectedlly, two hours after arrival at our facilities, a spontaneous spawning event occurred, and 5 specimens (3 males and 2 females) began to release their gametes (Fig. 1). Naturally fertilized eggs were rapidly removed from the tank with 20 μm sieve and washed with seawater. Also, eggs and sperm were collected directly from the gonopore of those specimens that remained releasing their gametes naturally, and artificial fecundation was performed in a flask. Egg diameter was measured in one hundred fertilized eggs.

Swiftly and with the available means, egg incubation and larval rearing was planned. The seawater used for embryonic rearing was filtered at 1 μm and sterilized with a UV light system. Eggs were incubated at 14 °C (±2 °C) in 1 L flask with soft aeration and natural photoperiod.

Once embryonic development was completed, lyophilized *Nannochloropsis gaditana* at a final concentration of 3.10^3 cell $.mL^{-1}$ was used to feed the larvae.

Results

The mean weight of the specimens collected was 120.24 ± 33.50 g. No mortality was recorded after acclimation to captivity. The average diameter of the fertilized eggs was 156.37 ± 7.35 μm. Embrionic development started with elevation of the fertilization envelop and expulsion of the polar bodies (Figure 2). The morula stage took place 3 days after fertilization (DAF), early auricularia 4 DAF and mid auriculatia 5 DAF

After mid auricularia larval stage, larval rearing collapsed. Until that moment, embryonic development was slower than as Laguerre et al. (2020) described it. This could be due to our lower water temperature.

FREEZE DRIED MICROALGAE: THE NOVEL OFF-THE-SHELF STANDARD IN BIVALVE AND CRUSTACEAN HATCHERIES AND NURSERIES?

L. Roef[1], M. Muys[1] , M. Wille[2], V. Vermeylen[2], C.T. Giang[3], J.D. Lima[4], M. Michiels[1]

Mailing address: luc.roef@proviron.com

Introduction

Although microalgae are indispensable in aquaculture when feeding mollusks and crustaceans during the larval stages, microalgae production within hatcheries and nurseries is still a major bottleneck. Many hatcheries struggle to combine microalgae culture with the core business of farmed animal production. The general experience with microalgae culture systems is one of variable product quality, 'crashes', culture upsets, contaminations, and most important, a general inability to culture the microalgae species that are most desirable as aquaculture feed. Even a brief 'crash' of the algal cultures can result in the loss of a large investment in the animals. These problems can be overcome with a reliable year-round external supply of high-quality freeze-dried (FD) microalgae.

Proviron has developed, engineered and patented a proprietary closed photobioreactor system for reliable indoor cultivation of freeze-dried microalgae, named ProviAPT (Proviron Advanced Photobioreactor Technology), that is particularly suited for the mass production of high quality algae biomass for aquaculture purposes. Rigorous control and standardization of all operational parameters within narrow boundaries, results in the production of pathogen-free freeze-dried microalgae featuring a stable and high quality. In contrast to fresh and frozen algae products, the application of freeze-dried microalgae allows for easy global distribution from a centralized production site and logistics hub and results in a higher flexibility due to the prolonged shelf life up to 3 years.

In the current presentation, a variety of feeding trials are reported that validate the performance of freeze-dried microalgae as an off-the-shelf solution, compared with the live algae alternative. Studied organisms include shrimp (*Litopenaeus vannamei*) larvae, oyster (*Crassostrea gigas*) and manila clam (*Venerupis philippinarum*) spat, ... An array of blends of different species of freeze-dried microalgae, as well as live microalgae were investigated. Furthermore, an automated algae dosing unit (ADU) was developed and tested to guarantee a continuous supply of microalgae to the larvae tanks. Using this ADU, different feeding regimes were investigated.

Table 1. Survival at the postlarval stage, growth performance of different tested organisms on a diet c omposed of FD algae.

Case	Organism	Diet	Survival rate (%)
1	*P. vannamei* larvae	FD *T. pseudonana* + FD *T. chuii*	61,5
		FD *C. muelleri* + FD *T. chuii*	50
		live *C. muelleri* + live *T. chuii*	44.9
		live *T. pseudonana* + live *T. chuii*	76,5
2	*C. gigas* larvae	70% live + 30% freeze dried algae	64,2
		50% live + 50% freeze dried algae	52,8
		70% live + 30% freeze dried algae	48,3
		100% live algae	32,3
		100% freeze dried algae	30,2

(Continued on next page)

Materials and methods

Larval cultivation of *L. vannamei* took place in a RAS set-up in a temperature- and light-controlled room. *N*auplii were stocked in 100-L cylindroconical PVC tanks at a density of 100-150 larvae. L^{-1}. Microalgae were dosed at ~10^5 cells/mL, while artemia were fed starting from zoea 3. Four microalgae feeds were formulated using Provirons ThalaPrime P, ChaetoPrime and TetraPrime FD microalgae and applied in triplicates: (1) FD *Thalassiosira pseudonana* and FD *Tetraselmis chuii*; (2) FD *Chaetoceros muelleri* and FD *T. chuii*; (3) live *C. muelleri* and live *T. chuii;* and (4) live *T. pseudonana* and live *T. chuii*.

Pediveliger larvae of Crassostrea gigas were fed 5 diets consisting of varying amounts of live and freeze dried algae. From day 1 to 6 diets contained the species *Nannochloropsis* sp., *Tisochrysis lutea* and *Chaetoceros muelleri* at 33,3% each. From day 7 onwards *Tetraselmis chuii* was added to the diet (25% each). All diets thus contained the same algae species at the same proportions, but with different percentages of the live algae being replaced by their freeze dried counterparts (NannoPrime, IsoPrime, ChaetoPrime and TetraPrime C). Algae were added at 2.500 cells per larvae at pediveliger stage up to 80.000 cells at setting.

Results and discussion

Table 1 gives an overview of the results of two case studies in which FD algae were used to replace or complement live algae diets.

For shrimp larvae, the use of diets consisting only of freeze dried microalgae resulted in a promising relative survival rate between 50 and 62%, with values that were slightly higher (ChaetoPrime) or slightly lower (ThalaPrime) compared to the live microalgae control treatment. For *Crassostrea gigas*, a diet composed of only freeze dried algae fed from pediveliger stage on resulted in settling rates of 30,2% comparable to a diet consisting of only live alga (32,3%), be it with a delay of one day (18 versus 17 days). A clear synergistic effect was noted however when using diets consisting of a mixture of live and dried algae. A diet of 70% live + 30 % freeze dried algae resulted in setting at day 14 with a survival rate of 64,2 %.

These results demonstrate for the first time that the complete replacement of live algae with FD algae is possible for a variety of organisms in aquaculture. The synergistic effect between live and freeze dried algae that is noted may further increase performance. The use of FD algae could become the novel standard in hatcheries, reducing the costs related to live algae cultivation, while improving reliability and feed quality.

Results on shrimp larvae and oyster are collected as part of the BlueMarine^3.Com project funded by the Flemish government through Flanders Innovation and Entrepreneurship (VLAIO) and is facilitated by the Blue Cluster program.

MARKET INTERGRATION WITHIN THE VALUE CHAIN

K.H. Roll

University of South Eastern Norway
Raveien 215
3184 Borre, Norway
krr@usn.no

In this article, we will investigate the market integration between high value aquaculture species (salmon and tuna) and lover value spices that are used as input to the aquaculture industry (sardine and anchovy). Sardine and anchovy are low value species, where a large share of it landing traditionally has been utilized as bait for higher value fish (such as tuna) or reductions used as in ingredient in the feed for aquaculture (such as salmon), in addition to human consumption. To investigate how the price of the small pelagic spices are integrated with the price of higher values spices, where it is utilized as bait and feed, we are conducting a traditional Johansen market integration analyses. For the analyses we aggregate trip level landings and revenue data to monthly price indexes, testing for Law of One Price (LOP) and price leadership

Understanding how small pelagic species are related to this market would be a next step in understanding how the fish markets are related, since the small pelagic are an important input factor in the farmed salmon market. Understanding how the different small pelagic are related are also interesting it itself. While a number of studies has investigated the market integration between different spices of whitefish fish (Asche et al 2004), between wild and farmed fish (Bjørndal and Guillen 2016), there has been little focus and the market interaction between the small pelagic. A few exceptions to however exist: Mulazzani et al (2012) investigate spatial interaction for the European anchovies and sardines and Pincinato and Asche (2018) presents a market integration and price transmission analysis for the Brazilian sardine market, comprising the fresh and canned sardines' segments.

A PROXY TO CARRYING CAPACITY FOR MEDITERRANEAN AQUACULTURE

Introduction
Over the last two decades, the European fish farming industry has been experiencing a progressive stagnation in production levels due to the rare of suitable areas for aquaculture because of the confluence of maritime space uses. Therefore, the planning and management of aquaculture areas aims to play a key role in their successful sustainable development. In this sense, its management should take into account not only the selection of the allocated zones for aquaculture (AZAs) if not the application of carrying capacity studies (Sanchez-Jerez *et al*., 2016; Macias *et al*., 2019; Weitzman *et al*., 2021). Therefore, in this study is intended to develop a mathematical model for the calculation of carrying capacity, integrating productive, ecological and socio-economic factors, which can be used by public administrations to regulate aquaculture activity in the open sea on the Spanis Mediterranean cost.

Material and Methods
This study used a modified Delphi approach structured in three rounds. It started with the formation of a network of contacts through semi-structured interviews and ended with two rounds of questionnaires discussed in sectoral roundtables and workshops with experts to obtain a consensus on the value of the maximum allowable production (baseline production) and the different factors involved in increasing or reducing it.

Results and Discussion
During the first round, the experts identified a total of 39 indicators classified according to their type of carrying capacity (technical-productive, environmental, social and economic) and their degree of importance. After the first round, 18 of the 39 indicators were excluded from the study and in addition, 3 new ones were also identified, bringing the total of 11 factors as possible estimators of carrying capacity. After a consensus analysis by the Delphi expert panel, Round 2 ended with a model proposal based on a baseline production and 8 factors carrying capacity estimators, together with their respective ranges and weighting values. Due to its high restrictive power and observing the possible inconsistencies of the model, Round 3 ended with a final readjustment of the model (Table 1) in order to provide a new tool for the Spanish fish farming, available for producers and administrators for the innovative management of the Spanish aquaculture since its formulation is based not only on ecological, but also on social and economic aspects selected and defined by marine aquaculture stakeholders.

This project is carried out with the collaboration of Fundación Biodiversidad, of the Ministerio para la Transición Ecológica y el Reto Demográfico, through Pleamar Program, cofinanced by FEMP. We thank the collaboration of the three companies that gave us access to their facilities.

Introduction

Three high-mortality epidemics of infectious hematopoietic necrosis (IHN) occurred in farmed salmon populations in British Columbia (BC), Canada from 1992 to 1996 (St-Hilaire et al., 2002), 2001 to 2003 (Saksida, 2006), and in 2012 (Garver & Wade, 2017). Wild Pacific salmon were hypothesized to be the source of IHN virus to farmed populations (Saksida, 2006; Garver & Wade, 2017). Since the 2012 epidemic, IHN has been well controlled through vaccination on salmon farms. In 2010, a Viral Disease Management (VDMP) was developed by BC salmon companies to rapidly and effectively minimize infection transmission and prevent spread to more distant Management Zones (MZ); however, to date the effectiveness of VDMP practices in mitigating IHN epidemics has not been evaluated (Garver & Wade, 2017)"autho r":[{"family":"Garver","given":"K"},{"family":"Wade","given":"J"}]},"label":"page"},{"id":628,"uris":["http://zotero.org/users/2112239/items/XYAPA36R"],"uri":["http://zotero.org/users/2112239/items/XYAPA36R"],"itemData":{"id":628,"type":"article-journal","abstract":"I investigated a recent infectious haematopoietic necrosis disease (IHN. We used an epidemiological simulation model to evaluate a hypothetical, waterborne spread of IHN virus among a susceptible population of farmed salmon in BC, after initial introduction into a single farm site. The purpose of the modelling was to evaluate existing viral management practices and to inform decision-making of regulatory agencies about spatial planning of future marine sites.

Material and methods

The simulation model (Romero et al. 2021) is spatially-explicit and allows modelling of 3 components of waterborne spread of IHNv in marine sites: within net-pens (a SEIR model as used for COVID-19 in humans), among net-pens (based on infection prevalence and a user-specified probability of transmission), and spread to distant sites, the probability of which decreases with increasing seaway distance. For distances of >15km, there is almost zero probability of waterborne IHNv spread between sites (Foreman et al. 2015). Data used to inform the model were production and location details of all 84 active farm sites in 2019, distributed across 10 MZs in BC. Expert opinion was used for number of net-pens per site, number of fish per net-pen, baseline daily fish mortality at the net-pen level, and mitigation measures for IHN. For each of the 10 MZs, different scenarios were explored to evaluate the combined effectiveness of disease surveillance and detection, depopulation procedures and vaccine use in reducing IHNv transmission. For every scenario, a single net-pen was selected as the infection source ("index") for the simulated IHNv incursion. This index pen was randomly sampled from the farm site with the lowest average seaway distance to other sites in the same MZ.

Results

The simulated waterborne IHN transmission is highly influenced by the mitigation measures implemented and the spatial distribution of farms within a MZ. IHN spreads mostly to farms closer to the "index", as lower seaway distances between farms corresponds to a higher probability of waterborne transmission (Figure 1). IHN spread varies between different MZs, as a consequence of the spatial distribution of farm sites within the MZ (Figure 2); the between-farm spread of IHN increases with the level of spatial clustering of farm sites within the MZ.

Discussion

The IHNv model demonstrated the ability to describe spatio-temporal patterns of IHN epidemics and assess the effectiveness of different mitigation strategies. This can be adapted to other aquatic-farmed species and pathogen spread in seawater by adjusting the open-source modelling framework (https://github.com/upei-aqua/DTU-DADS-Aqua). Particle tracking data from numerical circulation models (e.g., FVCOM) can be incorporated in the model to provide a stronger basis for assessing hydroconnectivity between sites.

USE OF DIFFERENT SUSPENDED COLLECTORS FOR EUROPEAN FLAT OYSTERS (*Ostrea edulis*), CONTROL OF RECRUITMENT AND PRODUCT QUALITY IN A LONGLINE FARM OF THE MIDDLE ADRIATIC

Roncarati A., Mosconi G., Palermo F.A., Cocci P.

URDIS - School of Biosciences and Veterinary Medicine, Camerino University, Italy

Introduction

The flat oyster juveniles from the wild has always represented an important source of income for fishermen of the Marche region. Unfortunately, in recent years, there has been a sharp decline in the recruitment of spat which is arousing serious concern among operators and public administrators. The main causes include excessive exploitation of the flat oyster banks of natural areas, the decrease of benthic ecosystems and the lack of efficient management of marine areas. A limited amount of food available to bivalve specimens could affect the energy reserves able to guarantee a normal reproductive rhythm as well as changed conditions of the marine environment. In this situation, *Ostrea edulis* juveniles could have serious health risks coming from parasites such as *Bonamia* and *Marteilia* (Cocci et al., 2020; Colsoul et al., 2021). In Italy, flat oyster farming generally begins with a half-size product, taken from natural banks, not submitted to grading. The main technique is based on growing the oysters, introduced in trays in the suspended system, with attachment to long lines, from 20–25 mm until they reach market size.

In this study, the efficiency of different collectors suspended in the water column of the longline farm was evaluated and the collected specimens were reared in trays.

Materials and Methods

The trial was performed at a long-line shellfish plant located 5.5 km from the coast of Porto Recanati (43°26'42.76" N–13°43'45.33" E). Sea depth ranged between 12 and 13 m, and the sea floor was mostly sandy. The main long-line rope was 4 m below the surface of the water. The sea current was quite strong (9–12 cm/s) and continuous.

Three different types of collectors were used: Chinese hats; lantern nets with white plastic strips; lantern nets with cupped oyster shells. In July, all the collectors were attached to the longline system at a depth of 3 m under the sea level. At different times, the devices were periodically monitored until the harvest occurred in March.

Results and discussion

The best performances were obtained by the lanterns filled with white plastic trips followed by the lanterns with shells and the Chinese hats. As concerns the substrate composed by the white strips, this type of collector showed the easiness to remove the oysters in agreement with other papers reported (van der Brink et al., 2020).

The activities carried out promoted the enhancement of the bivalve farming; the need to respect the environment, thanks to the application of good practices for the rearing of bivalve molluscs which were focused on the correct management of the seabed in correspondence of longline shellfish farm, were in a perspective of sustainable farming.

OPTIMIZING A RAINBOW TROUT BREEDING PROGRAM WITH GENOMIC SELECTION

Chantal Roozeboom[1]*, Antti Kause[2] , Mark Camara[1], Hans Komen[1], John W.M. Bastiaansen[1]

Introduction

Traditional breeding programs use pedigree-based estimated breeding values for selective breeding to improve the performance of farmed fish species. However genomic selection can increase genetic gain. Genomic selection is routine in Atlantic Salmon, Tilapia and shrimp (Ødegård et al., 2014; Yoshida et al., 2019; Zenger et al., 2019), but has not been routinely implemented in breeding programs for important European cultured species such as rainbow trout, Gilthead seabream and European seabass. Breeding companies that are interested in implementing genomic selection benefit from optimizing the structure of breeding programs to maximize genetic gain (Sonesson & Ødegard 2016). Parameters to be optimized include selection intensity, mating strategy and the number and ratio of fish used for sib-testing and as selection candidates in the nucleus. Using stochastic simulations, we optimize these parameters and explore the selective genotyping strategy for a rainbow trout breeding program under restricted inbreeding to assess the potential impact of implementing genomic selection. .

Materials and Methods

A breeding program for rainbow trout was designed based on answers to questionnaires send to breeders. We used this pedigree-based breeding program design as the reference design. With this reference design, 10 generations of selection were implemented using stochastic simulation in R software. The simulated traits were tagging weight, weight in nucleus, gutted weight at sea, visceral percentage, fillet percentage and survival at sea. The traits gutted weight at sea, visceral percentage, fillet percentage and survival at sea were measured in the production environment on sibs of the selection candidates held in the nucleus. The reference design consisted of 200 full-sib families of 100 individuals produced each generation from 100 male and 100 female parents in a 2:2 mating design. Twenty five fish per full-sib family were pre-selected for the nucleus and 15 fish for the production environment. Selection was based on a multi-trait selection index of traditional, pedigree-based estimated breeding values (EBVs). We also simulated this reference design with genomically estimated EBVs (GEBVs). To optimize the reference design with genomic selection, we simulated scenarios with varying 1) numbers of selected sires and dams, 2) mating ratios, and 3) ratios of pre-selected fish assigned to the nucleus and production environment. Additionally, we simulated different genotyping strategies, namely genotyping with lower density SNP panels and genotyping only a part of the selection candidates. Twenty replicates were simulated for each scenario.

Results

Compared to traditional, pedigree based selection, genomic selection resulted in higher genetic gains for all traits and a lower rate of inbreeding (Table 1). Selection response is improved by decreasing the selected proportion in genomic selection to 0.02 from 0.05 in the reference design, for the same level of inbreeding. Changing the mating ratio did influence the rate of inbreeding, but the effect on genetic gain was small. The optimal mating ratio was the 2:2 mating ratio from the reference design. The reference design for the ratio of fish preselected for the nucleus or sea produced the highest genetic gain. The optimized design (reference design with genomic selection and a selected proportion of 0.02) resulted in an increase of 14.6%, 15.2%, 5.5%, 11.1% and 30.0% of genetic gain for the traits weight in nucleus, gutted weight at sea, visceral percentage, fillet percentage and survival compared to the reference design with genomic selection.

Table 1 Results of the simulations

	ΔG and ΔF in reference design	**ΔG and ΔF in reference design with GS**	**ΔG and ΔF in optimized design with GS**
Weight in nucleus	95.5 grams	121.7 grams	139.5 grams
Gutted weight at sea	136.9 grams	203.6 grams	234.6 grams
Visceral percentage	-0.23 points	-0.36 points	-0.38 grams
Fillet percentage	0.28 points	0.45 points	0.50 points
Survival at sea	0.026 points	0.05 points	0.06 points
Rate of inbreeding	0.75%	0.47%	0.72%

(Continued on next page)

Genotyping with a lower density SNP panel resulted in decreased genetic gains compared to genotyping with a high density SNP panel. Genetic gains from using a low density SNP panel in the optimized GS design were still higher than from the pedigree-based selection in the reference design. Selectively genotyping 50% or less of the selection candidates resulted in comparable or lower genetic gains, respectively, compared to the genetic gains in the reference design.

Discussion and Conclusion

Applying genomic selection while keeping the design the same resulted in higher genetic gains because genomic selection exploited both the between and within family variance. Pedigree-based selection does not exploit within-family Mendelian sampling for traits measured on sibs only. The rate of inbreeding was reduced due to implementing genomic selection in the reference design, since genomic selection results in higher differentiation between sibs in the nucleus.

The optimal design for genomic selection should balance a high genetic gain with an acceptable rate of inbreeding. Due to the decreased rate of inbreeding, the selected proportion could decrease substantially without the rate of inbreeding increasing above 1%. The effect of the mating ratio on inbreeding was found to be more important than the effect on genetic gain. Additionally, optimizing the genotyping strategy significantly reduced the cost of genotyping while the cost in genetic progress was limited.

Introduction

There is a trend towards increased concern for the welfare of animals under human care, and this concern has expanded to include the welfare of farmed fish. However, at present, the necessary operational welfare indicators (OWI) and implementation protocols required to monitor and safeguard the welfare of farmed fish are lacking. Operational Welfare Indicators (OWI) in aquaculture are measures that can be used to assess welfare status in individual animals or groups of animals, made practical and operational on commercial aquaculture facilities (Martins *et al*. 2012).

The objective of this procedure was to develop a scheme to certify the welfare of Gilthead seabream (*Sparus aurata*) and to perform a pilot run to verify its feasibility.

Methodology

The approach taken is based on the five freedoms in an attempt to follow a methodology already developed to certify farmed terrestrial animals including mammals and birds. This methodology was selected for two reasons; firstly, it has been developed over the years by experts in the field of animal welfare from all over Europe and it has been validated for different farmed animal species, secondly it can be easily applied in a farmed fish welfare certification scheme.

To garantee animal welfare, different principles need to be covered. These principles include good feeding, good housing, good health, and appropriate behaviour and must be valid throughout the animal's entire life (Veissier and Evans 2007). Butterworth *et al*. (2009) conducted a literature review and identified a set of 12 welfare criteria (11 in the case of seabream). These criteria were then grouped under the four principles mentioned above. The welfare criteria must be applicable to all farmed species (in our case all farmed fish) and they should be grouped under the four wider principles. Measures to assess these criteria corresponded to 21 potential OWIs. Each OWI was then plotted on a small chart and a final calculation method was proposed for each OWI, then given specific weight to get a criterion and finally a principle punctuation. All 4 principles are assumed the same specific weight (0.25) in the final calculation (Figure 1).

Results

A test run was performed using 2 tanks with 180g -200 g seabream to verify the feasibility of the scheme. In general, the pilot testing went well, although some parameters have to be reviewed. The list of OWIs to be reviewed include novel object test for a group of fish and swimming behaviour. Score analysis is undergoing.

DESCRIPTION OF THE FEEDING BEHAVIOUR OF MULLET (*Mugil cephalus*) WITH FEED DEMAND IN RAS

Roque A*. and Duncan N.

IRTA 43540 Spain
*email: Ana.Roque@irta.cat

Introduction

In addition to the sustainability of the diet formulation, feed is the most expensive part in the culture of finfish species and careful feed management will greatly increase sustainability and reduce polluting environmental effects and waste. In the wild, different species of fish feed on prey such as phytoplanckton or zooplankton (Wassef and Eisawy, 1985; Andrade et al., 1996).

Demand feeding has been demonstrated to improve growth rates, improve food conversion ratio (FCR), reduce variation in size and reduce aggression in Atlantic salmon (Noble et al., 2007, 2008). In seabass improved growth and lower FCR was observed in both studies conducted in cages (Azzaydi et al., 1998) and tanks (Azzaydi et al., 2000), whilst in salmon results in different cages all improved growth and FCR. Some benefits of self demand system include ability to test the individual s capacity for differentiating between types of feed. Indeed, a feed demand system allows to study fish demand feeding behaviour and motivation (levels, rhythms, alteration) and to correlate it with physiological variables, individual growth and SGR. Present study investigated the the levels and rhytms of mullet (*Mugil cephalus*) maintained in a RAS with freshwater.

Material and methods

Experiment ran from October to January in 4 tanks, tanks were connected in pairs to a recirculation system (IRTAmar®). All tanks were fitted with a dark net to avoid stress and fish jumping from the tank. The system ran in freshwater at 21ºC and the photoperiod was 12h L:12h D. Each tank contained 80 mullet, 45,4 ± 2.9 g wet weight. Each tank had 2 automatic feeders in oposed positions. For the first fortnight, feeders were programmed to deliver a 3% of the biomass divided in 8 feeds per day so that fish knew where the food would appear. After this period the programme was changed to autodemand where 0.95 g would fall with each demand. The food fell from the feeder within 0-5 seconds after the demand when the pendulum was triggered. Tanks were left like this for 8 weeks to ensure fish knew how to use the feeders and the description of feeding behaviour corresponds to a further 4 weeks.
Fish were weighed and sampled at the beginning and end of the experiment.

Results and discussion

Results showed fish consummed an average of 0.27g per day and fed mainly during the day hours. Total average growth was for 28 days was 7.55g. The demand on the tanks varied and the demand on one tank was lower than the others. On average mullet demanded food 52.8 ± 3 times per day. The majority of the demands occurred when there was day light (between 6 am and 7 pm). A total of 2681,25 g was demanded during the night period and a total of 3998.5 g was demanded during the day period. One tank made its demands preferably during the night. No left over food was observed in the tanks. The estimated FCR for this period was 2.76 which was higher than what should be expected to omnivorous fish.

Performance in the tanks was different and there were preferences towards using one or the other feeder of tank.

In conclusion, fish learnt how to use the feeders, wasted no food but the growth performance was not very efficient.

Introduction

Fish cultured in intensive farming conditions may develop severe skeletal deformities that affect both their external morphology and welfare. In the case of commercially important fish species, such as the gilthead seabream (*Sparus aurata*), this is a matter of great concern and a major factor that affects production costs, downgrades hatcheries' production and fish market value. Among the solutions proposed to improve the skeletal deformities of aquaculture fish, the supplementation of their diet with natural compounds or extracts that stimulate skeletogenesis is increasingly seen as an economically sound approach to improve the competitiveness of the aquaculture industry and fish health. Extracts from marine origin are already being used as fish diet supplements, as they are a valuable source of important nutrients, but recently, some were also found to contain osteogenic and mineralogenic compounds. To explore their potential to improve farmed fish skeletal status, we supplemented a commercial fish diet with ethanol extracts of microalgae strains commercially available in Portugal and shown to be rich in bone anabolic compounds, and fed gilthead seabream juveniles with these experimental diets. Morphological and hematological parameters, and skeletal status were then evaluated.

Material and Methods

Gilthead seabream (*Sparus aurata*) juveniles of 4.8±0.7 g were fed *at libitum* 3 to 4 times a day with a commercial diet (Sparos, Lda.) supplement with ethanolic extracts of *Skeletonema* sp. (at 1%) or *Tetraselmis* sp. (at 0.5%) until they tripled their weight. Fish were housed at the Estação Piloto de Piscicultura de Olhão (EPPO/IPMA) in 250-L rectangular tanks with water renewal of approximately 350 L per hour and a temperature of 25.3±1.0ºC. At the end of the trial, growth parameters such as total length and weight, and welfare/stress parameters such as cortisol levels and blood analytes (including gases such as oxygen and carbon dioxide, Na+, K+, Ca++, Cl-, glucose, lactate and creatinine) were determined to assess the innocuity of the algal supplement. The occurrence of skeletal deformities was evaluated through X-ray imaging, while bone mineral composition was determined from ashed vertebrae by microwave plasma atomic emission spectroscopy. To better understand the putative effect of the supplementation in the mechanisms underlying bone formation and status, several well-established bone markers were selected, and their expression determined by qPCR in fish vertebrae.

Results

Regarding fish growth performance indicators, dietary treatments had no impact on feed conversion rate (FCR), although a slight increase was observed for fish fed with the diet supplemented with *Skeletonema* sp. extract. The total length was not significantly altered in fish fed supplemented versus control diets, but a positive effect was observed on the weight of the fish fed the diet supplemented with *Tetraselmis* sp., which consequently show a moderate increased condition factor. The analysis of several haematological parameters revealed that food supplementation with microalgae extracts does not influence fish physiological status or stress levels, except for the increased in pCO_2 levels, which may indicate a higher cellular activity. In terms of bone parameters, the vertebrae of fish fed with the diet containing *Skeletonema* sp. extract showed a higher phosphorous content, although the optimal balance between calcium and phosphorous was maintained in the vertebrae of fish fed supplemented diets. The analysis of the type and severity of the skeletal deformities revealed that most of them are associated with the caudal fin complex, independently of the treatment, but that the incidence is reduced when fish are fed with the diets containing extract of *Skeletonema* sp. (deformity charge (df) = 1) or *Tetraselmis* sp. (df = 1.17) when compared to the control diet (df = 1.36). The expression of several bone marker genes was also altered upon dietary treatment, as it is the case of the osteoblast markers *sp7* and *col1a1*, that are, respectively, up and downregulated for fish treated with *Skeletonema* sp., and osteoclast marker *acp5*, that is upregulated for fish fed with *Tetraselmis* sp. Interestingly, the expression of the glutathione peroxidase *gpx1* was increased in the vertebrae of fish treated with both extracts, suggesting an activation of antioxidant mechanisms by both experimental diets. Overall, the data gathered in this study points out to a general improvement of fish skeletal status upon dietary treatment with microalgae extracts containing bone anabolic compounds, without compromising, and possibly improving, fish growth performance indicators.

Funding

This study was funded by the Portuguese Foundation for Science and Technology (FCT) through the project UIDB/04326/2020 and by the European Maritime and Fisheries Fund (EMFF/FEAMP) through the National Operational Programme MAR2020 and project OSTEOMAR MAR-02.01.01-FEAMP-0057.

EFFECTS AND AMELIORATION OF NATURALLY OCCURRING AND EXPERIMENTALLY INDUCED MYCOTOXICOSES IN JUVENILE NILE TILAPIA *Oreochromis niloticus*

Introduction

Toxigenic filamentous fungi are common contaminates of agricultural crops. These fungi produce low molecular weight secondary metabolites commonly known as mycotoxins. Although contamination by these fungi frequently occurs in areas with a hot and humid climate (i.e. conditions favorable for fungal growth), they can also be found in temperate conditions.[1] Climate changes events are likely to influence toxigenic fungal spatial growth and the inherent risk of crop contamination.[2]

Mycotoxins are nearly ubiquitous in a variety of plant origin commodities, animal feeds and human foods causing serious health conditions to man and animals with severe economic consequences to the related industries.

Scientific literature describes mycotoxins-related pathologies in aquatic species since the 1960's and acute outbreaks are documented globally for the different species by common toxins throughout the years. Recently, similar to other livestock industries, more awareness is given to the chronic and sub-clinical effects of mycotoxins in aquaculture. Chronic mycotoxicoses are often due to moderately naturally contaminated raw materials used in untreated aquaculture feeds that do not exhibit signs of molding themselves and upon consumption do not evoke clear and specific clinical signs in the animals.

Ochratoxin A (OTA) is the most important member of the ochratoxins group concerning both human and animal health. It is produced by different species of *aspergillus* and *penicillium* fungi.[3] Beyond its direct effect on the consuming animal it also shows high levels of carry-over through the food chain from the contaminated animal feed through the animal's tissue to the consumer.[4] Maximum levels for OTA both for animal feeds and human foods are set in the European union[5] and regulatory efforts are also being applied by various authorities such as the FDA and other national bodies.

Several commercial products to counteract the negative effects of mycotoxins on livestock have been developed and described. A major limitation to a successful application of detoxifying products are their selectivity towards the mycotoxin while maintaining required nutritional components such as vitamins and minerals. Additionally, data on the product suitability and efficacy for aquatic organisms at their various developmental stages is often missing.

In two *in vivo* trials, the effects of naturally occurring mycotoxins and experimentally OTA-contaminated diets were evaluated in Nile tilapia (*Oreochromis niloticus*) in addition to the efficacy of detoxification and bioprotection solution using proprietary mitigation product was assessed.

Materials and methods

The experiment composed two trials lasting eight weeks long each. In both, juvenile, male-monosex population of Nile tilapia were housed in 24 recirculating aquaculture system (RAS) tanks.

In the first trial, the fish were divided in two groups, one receiving non-supplemented and naturally contaminated tilapia diet formulated according to industrial standards, and the other group received the same diet with addition of the mycotoxin detoxifying product at inclusion rate of 2.5 mg/kg.

In the second trial, a new group of fish was divided into 3 groups receiving control diet, artificially contaminated with OTA at 500 μg/kg inclusion rate and the same OTA contaminated diet with supplementation of 2.5mg/kg of the detoxifying product.

(Continued on next page)

Performance (zootechnical) parameters were evaluated before during and after each of the feeding trial periods. Additionally, immune and health markers were evaluated at the end of each trial and fish survival rate and response to additional immersion bacterial challenge using *Streptococcus agalactiae* was also included in the second trial where the OTA supplemented diet was used.

Results and discussion

In the experiment, significant weight and FCR differences were observed. Survival rate was also negatively affected by the natural presence of mycotoxins(Table 1). Furthermore, the experimental inclusion of OTA 500$\mu g*kg^{-1}$ in the diet exacerbated the negative effects and significantly reduced the specific growth rate and survival before and following the bacterial challenge. Supplementation of the detoxifying product with it's bioprotective component improved the performance parameters.

Toxin	**Value** $\mu g*kg^{-1}$
Total Fumonisins	121.03
Zearalenone	75.82
Type B trichothecenes	98.57
Type A trichothecenes	2.88
Ochratoxin	1.24
Ergot alkaloids	0.63

Table 1 Mean mycotoxin level of the naturally contaminated diet in the first experiment

The objective of the study was to evaluate the effects and offer an efficient and economical solution for mycotoxicosis both as chronic, naturally-occurring contamination and as acute intoxication in Nile tilapia. The different combinations of mycotoxin challenges proved to have detrimental effects in certain evaluated parameters and at the same time, the mycotoxin detoxifying product demonstrated to counteract those effects.

The problem of mycotoxins in aqua feeds is expected to increase in coming years due to environmental concerns such as climate changes, overfishing and sustainability concerns. These already bring advances in feed formulation such as the use of alternative ingredients and increase of plant material to replace proteins and oils from marine sources. Awareness, surveillance and detoxification strategy are the key factors for successful outcome of this challenge in aquaculture.

Introduction

Aquaculture is a very fast-growing food-producing sector and due to intensive fish farming practices, infectious disease can cause heavy loss to farmers. Fish have considerably higher exposure to pathogens than non-aquatic vertebrates and the outbreak of diseases is not merely related to the causing agents (Martin and Król, 2017). In fact, outbreaks of fish diseases commonly occur when fish are stressed due to a variety of factors associated with the aquaculture environment and management procedures such as high stocking densities, transport or handling. For this reason, an optimal immune function of farmed fish is important to protect them from infections and, in this context, there is also an increasing consumer demand for environmentally-friendly and animal-friendly alternative to the extensive preventive use of antibiotics.

Organic acids (OA) and botanicals (or phytogenic compounds) are widely used in terrestrial animals and they gained an increasing interest also in aquaculture. OA are well known for their antimicrobial power, as well as phytogenic compounds. Some botanicals have also been proven to exert antioxidant and anti-inflammatory properties, strengthening the immune-response of fish.

The aim of the study was to determine the effect of AviPlus®Aqua (Vetagro SpA), a microencapsulated blend of OA (sorbic and citric acid) and nature-identical compounds (NIC, thymol and vanillin), on Atlantic salmon parr (*Salmo salar* L.) immune-response, during an inflammatory challenge.

Materials and methods

Three hundred Atlantic salmon specimens of an average weight of 5.4 g were randomly distributed into 6 tanks (50 fish per tank) at SPAROS Lda (Portugal). The following diets were tested in triplicate tanks: 1) control (CTR), 2) AviPlus®Aqua 1500 ppm (D1500). Fish were fed for 92 days and then subjected to an inflammatory challenge by injecting them intraperitoneally (i.p.) with either 100 μl of UV-killed Yersinia ruckeri (Yr) (CTR+, D1500+) or Hanks' Balanced Salt Solution (HBSS) (CTR-, D1500-). Upon injection, fish were redistributed into new tanks according to diet and injection stimuli. Four- and 24-hours post-injection, fish injected with UV-inactivated Yr (n=3 per replicate tanks, n=9 per diet) or HBSS (n=3 per replicate tank, n=9 per diet) were subjected to moderate anesthesia and a sample of blood was collected by puncture of the caudal vein with a heparinized syringe. Serum was collected to study humoral parameters such as reactive oxygen species (ROS), total peroxidase activity (PA), and nitric oxide (NO). Moreover, plasma bactericidal activity against *Vibrio harveyi* was assessed according to Graham et al. (1998) with some modifications (Machado et al., 2015). Data were analyzed with a two-way analysis of variance, with diet inclusion and injection type (Yr and HBSS) as variables.

Results

At a basal state (prior to inflammatory challenge), in comparison to the non-supplemented control treatment, fish fed diets supplemented with 1500 mg/kg AviPlus® Aqua showed a higher plasma antibacterial activity ($P<0.05$).

Four- and 24 hours after injection, fish fed the D1500 diet continued to show a significantly higher plasma bactericidal activity (Fig. 1). No differences were found about plasma ROS concentration but plasma levels of NO and PA were significantly higher in fish fed the D1500 diet than those fed the CTRL diet, at both time points (Fig. 1).

Conclusion

In conclusion, Atlantic salmon parr fed a diet supplemented with 1500 mg/kg AviPlus® Aqua for 92 days showed an enhanced capacity to cope with an inflammatory condition.

(Continued on next page)

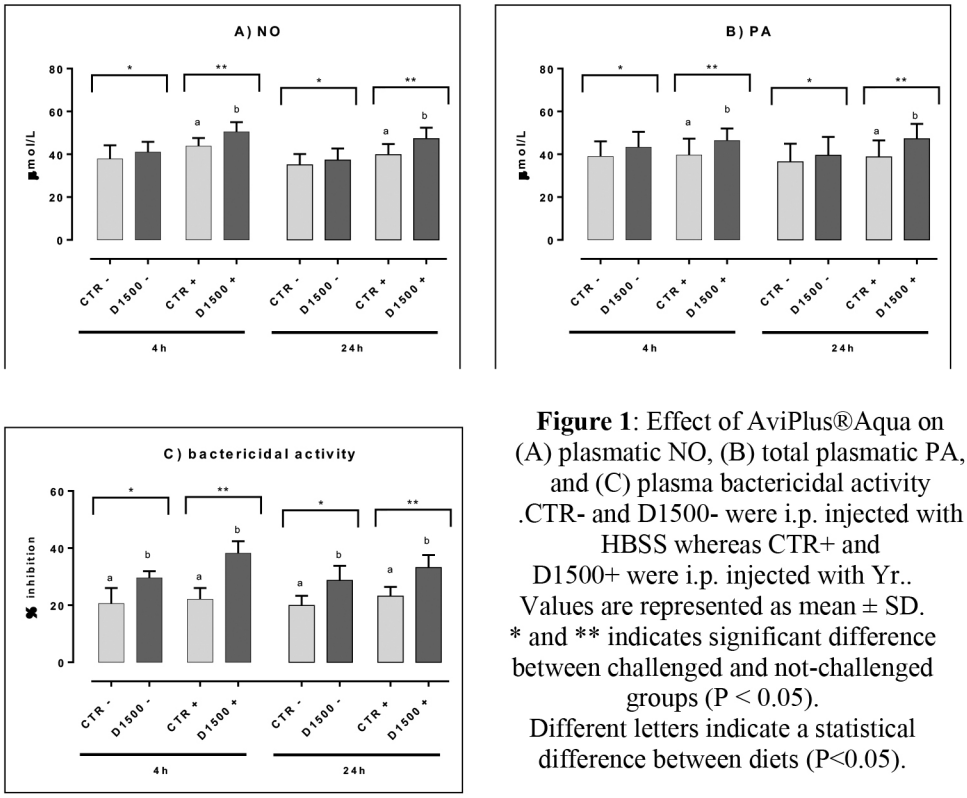

Figure 1: Effect of AviPlus®Aqua on (A) plasmatic NO, (B) total plasmatic PA, and (C) plasma bactericidal activity .CTR- and D1500- were i.p. injected with HBSS whereas CTR+ and D1500+ were i.p. injected with Yr.. Values are represented as mean ± SD. * and ** indicates significant difference between challenged and not-challenged groups ($P < 0.05$). Different letters indicate a statistical difference between diets ($P<0.05$).

The melanocortin system is a complex neuroendocrine signaling mechanism involved in numerous physiological processes in vertebrates, including pigmentation, steroidogenesis and metabolic control. In humans, five melanocortin receptors (MCR) have been cloned, identified and shown to have a wide distribution throughout the body and likely many diverse functions. It has also been shown that a high degree of identity and conservation in structural characteristics and pharmacology exists between Mcrs from fish and mammals. However, in fishes, the number, affinity, specificity, tissue distribution and physiological roles are far from defined and appear to be species-specific. A clear example is the Mcr2 subtype. In humans, it is well known that Mc2r is expressed in the adrenal gland and controls steroidogenesis and in fact the same function has also been described in fish. However, the fact that Acth (a melanocortin agonist) may have a role in regulating fish pigmentation and that Acth acts on Mc2r, the involvement of Mc2r in fish pigmentation might be a possibility. Using CRISPR/Cas9 genome engineering tools we have generated “loss-of-function” mc2r mutant fish. We demonstrate that Mc2r , apart from controlling steroidogenesis, also has a direct role in regulating fish pigmentation.

ADVANCES AND OPPORTUNITIES IN SCIENCE COMMUNICATION: TIPS, TRICKS AND LESSONS LEARNED FROM PARTICIPATION IN GOJELLY H2020 PROJECT

Introduction

Applied sciences directly address societal challenges by forming collaborative networks. Consequently, scientists that are involved in these collaborations need specific skills and expertise (Rotter et al., 2021). In addition, a lot of top-down structures have been introduced in recent years, such as science communication, quadruple helix approach and the concept of the responsible research and innovation. There is a visible gap between the academic training and exercising science in practice, where these overarching skills that are needed in tackling scientific hypotheses, entering new research areas, obtaining scientific funding and collaborating are self-trained. A field which has been gaining increasing importance is science communication, which, especially in top-priority societal challenges (in recent years especially impacted by (micro)plastics pollution and recently also with the COVID-19 pandemics), needs special consideration. The talk will focus on (micro)plastics pollution and the unexpected interest for communicating the progress and results of one of the projects that tries to provide a solution to microplastic pollution, GoJelly (https://gojelly.eu/). The main aim of the project is to use one nuissance (increasing jellyfish blooms and the presence of non-indigenous jellyfish species) to solve another emerging problem, microplastic solution. The potential of wild harvesting or jellyfish aquaculture were also assessed during the project, thus addressing important environmental protection and sustainability bottlenecks.

Concepts and terminology

Collaborative networks are dynamic structures that are assembled based on the funding opportunity or emergence of a specific topic (Rotter et al., 2021). They typically have a limited duration, e.g. a predetermined time goal for providing concrete results. The most common collaborative networks are organized to target specific funding calls, promising innovative solutions with a realistic market-entry potential in future. One such example, the Blue Growth Horizon 2020 call (BG-07-2017: Blue green innovation for clean coasts and seas) identified chemical pollution as well as increasing jellyfish blooms as increasing problems in the oceans, seas and coasts. To address this problem, an international transdisciplinary consortium was formed with the aim of addressing one problem (microplastic pollution) using an unlikely source for a solution (jellyfish mucus). The idea behind the proposed solution was so novel and innovative, that it was convincingly financed. But, surprisingly, the solution was convincing and innovative also for an unexpected stakeholder category: the media, which typically represent a proxy for the general public. Indeed, since the formal approval of the project, the consortium members have been featured in many national, regional and global media.

The issue of microplastic pollution has been in the recent years recognized as a top priority area by the general public, the policy makers, the media as well as the scientific world. However, while scientists are still trying to evaluate the adverse effects of microplastics pollution on the environment, food and humans, the public and policy makers are eager to finally use the potential solutions.

In this perspective, the issue of microplastic pollution is an excellent example of transdisciplinary scientific collaboration, science communication, involvement of public and NGOs, efforts for legislation change, including the close collaboration with policy makers and finally offering approaches that can be used in practice and in future commercialized by small & medium enterprises as well as the industry.

The talk will present some introduction to the terminology and what scientific communication has done to catalyse this area of research. As the project is entering its final stage, the timing is right to deliver some basic concepts, project impact, lessons learned and provide tips and tricks that will enable to better shape the future generation of innovators and provide them with know-how to become efficient science communicators.

(Continued on next page)

Conclusion

The case of microplastic pollution and the GoJelly project is a great example of how the scientific community should operate. It is not self-sufficient, and industry, policy makers and the general public should all be involved to maximize the outputs. This is the concept of quadruple helix, which will also be presented.

Overall, we feel that there is a lack of »behind the scenes capacity building« presentations such as ours which we believe it will be well appreciated within the scientific and industrial community.

DATA ASSIMILATION APPROACH TO SUPPORT DAY-TO-DAY DECISION PROCESS: FORECASTING FISH WEIGHT DISTRIBUTION IN A LAND-BASED RAINBOW TROUT (*Oncorhynchus mykiss*) FARM

Edouard Royer [(1)*], Damiano Pasetto[(1)], Roberto Pastres [(1),(2)]

2) Bluefarm, s.r.l., Venice, Italy
E-mail: edouard.royer@unive.it

Introduction

Ecological intensification of aquaculture sector aims at improving productivity of the aquaculture farms while reducing environmental impact and ensuring fish welfare. In order to overcome the various challenges of this paradigm shift the GAIN H2020 project dedicated a non-negligible part of its work to the Precision Fish Farming (PFF) framework (Fore et. al., 2018), testing among other things some real-time biomass monitoring systems in farming conditions. One of the case studies was led in a rainbow trout farm in Preore (Trento, Northern Italy), where several cohorts of fish were monitored during several months using a weight monitoring system. Here we focus on the development of a reliable forecast system of population growth where model results and parameters are updated in real-time through the assimilation of the weight measurements. The data assimilation procedure improves then the short-term forecasts of the population distribution which is of huge interests for farm management.

The research leading to these results has received funding from the European Union's H2020 Framework Programme for Research and Innovation, under Grant Agreement No. 773330.

Methodology

Data Assimilation (DA) algorithms are being currently used in many scientific fields, e.g. mechanics, oceanography, meteorology, as they allow one to combine model output and field data as long as they are collected, avoiding the full re-calibration of the model. The purpose of DA is two-fold: i) to correct the prediction of output variables, based on the information provided by new data; ii) to improve the estimation of the un-observed state variables, which may include also model parameters. Most DA procedures describe the system state variables as stochastic variables which distribution changes in time in accordance with the differential equations governing the system; the system measurements are crucial to reduce the uncertainty on this distribution and possibly correct its mean value.

In the last decade, several fish biomass monitoring system were designed and commercialized, mainly destinated to salmon production as a consequence of high turnovers, and thus investments margins of this market. To our knowledge, no similar system was designed for land-based flow-through farming, and we then decided to use the Biomass Daily (BD) commercialized by Vaki Ltd in a trout farm in Northern Italy. In parallel of the installation and test of the device, we build a growth model able to forecast growth performance of individuals, based on temperature and feed ration. Trying to best take benefit of both elements, we implemented a DA approach that integrates daily measurements of the population into the model, in order to improve the reliability of daily population weight distribution forecast. The individual-by-individual representation of the whole population was replaced by a cohort approach based on the super-individual concept (Scheffer et al., 1995). The initial weights of this super-individuals, and the number of fish each one of them represents, where defined from the initial distribution of the population measured by BD. Daily feed ration, food composition, and water temperature were daily downloaded from the farmer's management system.

Results and discussion

Results show that the system allows to correctly predict daily fish weight distributions, providing thus an interesting additional level of information to the farmer that used until now only daily average weight predictions. On one side daily average weight is fully in line with the farmer's predictions and with the BD measurements. On the other side, the daily weight distribution fits with the BD observations, and is in line with the intermittent samples made by the farmer. This method could be of high relevance for farmer's days-to-day decision process as its results allow one to more accurately quantify some key parameters for farm management as feed quantity, oxygen supply, economical value of the biomass, but also the need for cohorts to be divided or moved to a larger raceway.

MONITORING THE DEVELOPMENT AND MITIGATION OF SOYBEAN MEAL INDUCED ENTERITIS (SBMIE) IN TWO DIFFERENT STRAINS OF RAINBOW TROUT *Oncorhynchus mykiss* OVER A LONG-TERM FEEDING TRIAL

Marina M. Rubio Benito*, Nicholas Romano, Kenneth Overturf, and Vikas Kumar

Aquaculture Research Institute, Department of Animal, Veterinary and Food Sciences, University of Idaho, Moscow, ID, 83844, USA
mrubiobenito@uidaho.edu

Introduction

Plant protein sources have been largely studied for their potential in replacing fish meal (FM) as the main source of protein in aquafeeds. Specifically, soybean meal (SBM) has been widely used at high inclusion levels to improve sustainability and affordability of fish feeds. However, carnivorous species like rainbow trout (*Oncorhynchus mykiss*) are susceptible to feeds formulated with high inclusions of SBM, exhibiting reduced growth rates and distal intestinal inflammation or enteritis. Mitigation of SBM-induced enteritis (SBMIE) may be done by dietary supplementation of L-glutamine (Gln) as it has shown encouraging results in species like turbot, sturgeon, and carp in terms of improved intestine morphology, decreased pro-inflammatory gene expression and improved antioxidant enzymatic activity.

The goal of this study was to evaluate the potential mechanisms by which Gln might exert a protective effect on reducing inflammation and restore barrier function in two different commercial strains (A and B) of rainbow trout over a 30-week long-term experimental period.

Materials and methods

Diets: three experimental diets (isonitrogenous: 40% crude protein and isolipidic: 20% lipid) were formulated including a FM diet (control), a SBM diet (30% inclusion level), and a SBM-Gln diet (1.5% L-Alanyl-Gln supplemented).

Animals: 2,250 fish from two different commercial strains of rainbow trout (strain A = 1,125 and strain B = 1,125) initially weighing 24.3 ± 1.0 g, were randomly distributed into 18 350-L tanks (125 fish/tank) in a recirculating aquaculture system (RAS). During the trial, fish were fed to apparent satiation for 30 weeks. Fish were sampled five times at 6, 12, 18, 24 and 30 weeks for growth performance and intestinal tissue samples from three fish per tank were taken for histology and SBMIE molecular markers analysis, and for glutamate quantification.

Histology: distal intestine tissue samples from three fish per tank were fixed in Bouin's solution and dehydrated using a graded series of alcohol baths and infiltrated with paraffin wax. A total of four cross sections from each sample were cut at 5 μm. Sections were then stained with hematoxylin/eosin (H/E).

Statistical analyses: data was assessed for normality using the Shapiro-Wilk normality test and variance homogeneity using the Bartlett test of homogeneity of variances. Significant differences were analyzed using one-way and two-way ANOVA followed by Tukey's multiple comparison test.

Results

Weight gain at four out of five sampling points is presented in Table 1. Differences in weight gain of strain A were detected at 18 weeks by one-way ANOVA analysis, being significantly higher in fish fed the SBM diet ($p = 0.02$) as compared to FM. However, two-way ANOVA revealed no impact of diet, strain, or their interaction on weight gain and FCR at any sampling point up to 24 weeks. Histology analyses of distal intestine after 6 and 12 weeks of dietary exposure showed significant differences ($p < 0.05$) in terms of villi length and width at all dietary treatments, and inflammation was reduced in the SBM-Gln group in both strains (Fig. 1). Distal intestine gene expression analyses are underway for the inflammatory markers: TNF-α, NF-ϰB, IL-8, IL-10; barrier function markers: MLCK, ZO-1, occludin; as well as brush border transporters: FABP2, and SLC1A5. Distal intestine samples were also collected to evaluate glutathione peroxidase enzymatic activity and for glutamate quantification.

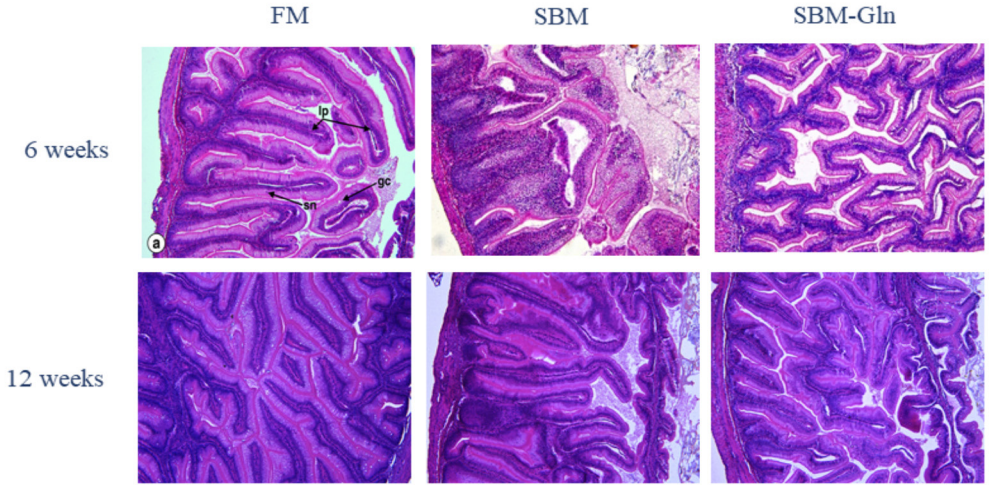

Fig. 1. Histopathology of distal intestine of trout A strain after 6 and 12 weeks. 200X magnification.

Conclusion

Growth performance in terms of weight gain showed no differences across treatments and strains; moreover, weight gain was not negatively impacted in fish fed the SBM diet as was expected, with strain A showing slightly higher values in this dietary group overall throughout the trial and especially at 18 weeks. Nonetheless, histology results show morphological alterations of the distal intestine such as widened and shorter villi in both strains. Interestingly, it apppears that SBMIE was lessed at 12 weeks in both strains, possibly indicating the fish are adapting to dietary SBM. Final growth performance results from 30-week sampling point as well as gene expression analyses and glutamate quantification in the distal intestine will help elucidate the molecular mechanism underlying Gln driven SBMIE mitigation.

HETEROTROPHIC VS AUTOTROPHIC PRODUCTION OF MICROALGAE. BRINGING SOME LIGHT INTO THE EVERLASTING COST CONTROVERSY

Jesús Ruiz [1]*, Rene H. Wijffels [2,3], Manuel Dominguez [1], Maria J. Barbosa [2]

Introduction
Heterotrophic or autotrophic? This is the continuous question industry faces when microalgae production is the endeavor. Without a doubt, production cost may be among the reasons to come to a decision. Surprisingly, still today specialists have not reached a consensus on which is the most economical option.

To shed some light on the issue, the current work thoroughly analyses costs for heterotrophic and autotrophic cultivation of microalgae at industrial scale. Our work follows a similar procedure as the one we previously developed to explore costs of autotrophic production (Ruiz et al., 2016). These cost studies on heterotrophic and autotrophic production follow analogous methodologies, and they both share some of the fundamental points, such as location or biomass capacity. These facts indicate that a reliable comparison can be performed.

Methods
We developed a model to perform a Techno-economic assessment of microalgae production in fermenters under heterotrophic conditions. Biomass capacity of the projected facility is 6.094 ton·year^{-1} measured as dry weight. It is identical to the autotrophic production in our Article Towards industrial products from microalgae for Flat Panels in Spain (Ruiz et al., 2016), which enables comparisons.

Studied species: Chlorella sp. is used as cell factory. This is the most studied heterotrophic microalga and its performance exceeds most of other microalgae under these conditions. The cultivation is performed in batch process with a biomass productivity of 4.81 g·l^{-1}·d^{-1} (this is an average from 23 tests on Chlorella sp. in glucose, which ranged between 31.86 and 0.15 g·l^{-1}·d^{-1}).

Results

After comparing the value from our heterotrophic base case (4.00 €·kg^{-1}) and the base case of autotrophic production in flat panels (3.50 €·kg^{-1} (Ruiz et al., 2016)) we can sustain that heterotrophic carbon nutrition of microalgae is costlier (Figure 1). However, it depends on the production system, as our previous study also reveals that photosynthetic production in tubular photobioreactors or open ponds can reach a cost above 5.20 €·kg-1 (Ruiz et al., 2016). Thus, although we can claim that autotrophic culture in flat panels would be cheaper than heterotrophic production, the latter is not always the most expensive option.

Conclusions
The results show a comparable cost for heterotrophic and autotrophic production of microalgae at industrial scale. Nevertheless, although large-scale cultivation in fermenters and open ponds came true, existing facilities based on photobioreactors are still relatively small. Microalgae need a leap forward in production scale to become a competitive novel feedstock for biobased products. A facility producing thousands of tons of biomass per year could benefit from the economy of scale, overcoming most cost restraints.

Introduction

Commercial aquafeeds are usually high in lipids, since this ingredient is the main source of dietary energy and essential fatty acids for fish. However, an excess of fat can generate an increase in the amount of lipid bodies and adipose tissue, which has a negative impact on animal welfare, as well as in terms of the fillet quality (Salmerón et al., 2018). Since bile salts (BS) act as lipid emulsifiers and contribute to the digestion and absorption of fat (Swann et al., 2011), they have been tested as additives in fish diets, showing an improvement in growth performance, in efficiency of feed utilization and in the oxidative state (Ding et al., 2020; Mansour et al., 2020). Their supplementation in diets has also contributed to elucidate their regulatory role on lipid digestibility, lipase activity, adiposity and, cholesterol and bile acid (BA) levels in fish (Gu, Bai & Kortner, 2017). Likewise, in a nutritional trial conducted by Xiong et al. (2018), grass carp were fed diets supplemented with different BS and, as a result, it was observed that, especially the ones containing primary BS (i. e., sodium taurocholate), could modify the BA profiles in the gall bladder and change gut microbiome. These variations in the BA profile were attributed to a change in the intestinal epithelium permeability induced by gut microbiota, which would lead to a higher reabsorption (Xiong et al., 2018). Previous studies have revealed that BA can act as regulators of gut microbiome community structure, but also that the intestinal microbiota would be responsible for the regulation of the BA pool size and composition through mechanisms such as BS deconjugation (Ridlon et al., 2014). Based on this information, the objective of this work was to test whether by adding bile salts in diets with a high saturated fats content it was possible to improve the health and quality of gilthead sea bream (*Sparus aurata*), and its regulating effect on growth performance, feed utilization, oxidative stress, adiposity, fatty acids profile, and gut microbiome.

Materials and Methods

A 90-day feeding trial was carried out in which juvenile *S. aurata* (initial body weight: 44.05 ± 4.08 g) were fed with three experimental isoproteic (44 %), isolipidic (22.6 %) and isoenergetic (21.4 MJ/kg) diets: a "control", with a high content of saturated fats, and two others with a composition similar to the previous one but supplemented with a blend of BS (sodium taurocholate and deoxycholic acid) at different levels of inclusion (0.06 % and 0.12 %). During the trial, monthly sampling to monitor fish growth in terms of weight (g) and standard length (SL) was performed. At the end, the specific growth rate (SGR) and the feed conversion ratio (FCR) were calculated, as well as the hepatosomatic index and the perivisceral fat index. Oxidative stress in liver was measured through its total antioxidant capacity (TAC), lipid peroxidation (LPO) (through the concentration of MDA), and enzymatic activity of catalase (CAT), glutathione reductase (GR) and superoxide dismutase (SOD). Microscopic observation of histological sections of the liver and foregut allowed to evaluate the overall condition and accumulation of fat in these tissues. In addition, the *villi* height, thickness of the musculature, height of enterocytes and density of goblet cells in the intestinal mucosa was evaluated, as well as its level of inflammation. The serum levels of cholesterol, triglycerides, alkaline phosphatase, GTP transaminase, GOT transaminase, albumin, globulins, and total proteins of the fish were measured. Fatty acid profiles of muscle and liver were analysed using gas chromatography. From DNA extracted from scraping the interior walls of the intestine, Next-Generation Sequencing (Illumina - MiSeq platform) using specific primers for the V3-V4 hypervariable regions of 16S rRNA genes was performed and RDP database was used for classifying the OTUs, identifying the composition of the gut microbial communities.

Results and Discussion

At the end of the nutritional trial, growth results showed that fish fed the diets with a BS inclusion of 0.06 % and 0.12 % were respectively 2.4 % and 2.1 % heavier than those fed the control diet ($P < 0.05$). In addition, a trend towards an increase in SGR was observed in both groups with respect to the control, obtaining significant differences in those fed the diet with 0.06 % BS ($P < 0.05$). This is in accordance with the results obtained by Ding et al. (2020). Furthermore, the inclusion of BS in diets reduced the level of perivisceral fat. In particular, PVI was 3.01 ± 0.28 % in the control group and 2.58 ± 0.19 %

(Continued on next page)

and 2.67 ± 0.19 % in fish fed the diets with 0.06 and 0.12 % BS, respectively ($P < 0.05$). On the other hand, the addition of BS in the diet did not affect the hepatosomatic index and FCR values ($P > 0.05$). Although *a priori* the antioxidant status of the liver did not vary between the groups, a lower CAT activity was detected in the diet with an inclusion of 0.06 % of BS (63.76 ± 15.87 nmol min^{-1} mg $protein^{-1}$) with respect to the control group (96.88 ± 5.62 nmol min^{-1} mg $protein^{-1}$) ($P < 0.05$). This could be part of a response to less oxidative stress in fish fed these diets. Histological results showed lower levels of hepatic and intestinal fat accumulation in fish fed with the 0.06 % BS diet. These results are in accordance with data from the perivisceral fat index; both results showing that the addition of BS reduces adiposity, possibly thanks to their role as fat emulsifier and in lipid metabolism (Swann et al., 2011). There were no differences in the rest of the histological and serum parameters, which remained within the range of the normal values for the species, indicating an optimal health condition. In conclusion, the addition of BS in diets with high saturated fats content is capable of modulating growth efficiency, accumulation of perivisceral, hepatic and intestinal fat and, in part, oxidative stress in *Sparus aurata*, which would lead to an improvement in the health and quality of the fish. Results of fatty acid profiles, BA profiles and gut microbiota will also be discussed.

EFFECT OF AN ESSENTIAL OIL DERIVED FROM *Capsicum sp.* AS A DIETARY SUPPLEMENT ON BODY ADIPOSITY, HEALTH AND QUALITY OF GILTHEAD SEABREAM

Alberto Ruiz Hernández*, Karl B. Andree, Dolors Furones, Enric Gisbert [1]

[1] IRTA, Aquaculture Program, Sant Carles de la Ràpita, Spain

Introduction

In aquaculture, lipids are frequently used as the main source of energy and essential fatty acids for fish. However, high-fat diets can generate an increase in the amount of lipid bodies and adipose tissue, which generates a negative impact on animal welfare and on production due to its effect on the half-life and organoleptic properties of the product (Salmerón et al., 2018). In this context, according to recent studies feed additives can modulate fish body adiposity (Zhou et al., 2018), being essential oils (EOs) a good candidate, given the existing antecedents on the modulating role of some of them in lipid metabolism (Firmino et al., 2021). Some studies have suggested that these compounds can influence the kind and amount of secretion produced by the intestinal mucosa, which allows an improvement in digestion and absorption of some nutrients, such as lipids, by the microbiota (Sutili et al., 2018). The use of EOs as animal feed additives is booming due to its innumerable properties, including their capacity to promote growth performance, to modulate the gut microbiota, to inhibit bacterial resistance and virulence factors and to induce the immune response, as well as the anti-inflammatory and antioxidant activities (Sutili et al., 2018).

Capsicum is as a genus of angiosperm plants belonging to the Solanaceae family, native to America, cultivated worldwide for their chili pepper fruit, whose natural extractives, oleoresins and EOs are generally recognized as safe (GRAS) for their intended use in food (Rogers et al., 2018). In mammals, *Capsicum* has been shown to increase thermogenesis and whole-body energy expenditure, to boost fat oxidation, to decrease triglyceride storage and to reduce body fat, to a great extent thanks to the action of capsaicinoids, which also have been shown to prevent inflammation and associated diseases, like cancer and heart disease (Varghese et al., 2017). However, there are not many studies using *Capsicum* as aquafeed supplement (Abdalla and Agouz, 2014; Parrino et al., 2020), so its effects on fish health and production remain still partly unknown. Based on the above, the objective of this work is to test whether by adding an EO based on *Capsicum sp*. in diets with a high saturated fats content it is possible to regulate the adiposity of gilthead sea bream (*Sparus aurata*) and to test its consequences in terms of health and quality.

Materials and Methods

Juvenile *S. aurata* (initial body weight: 44.07 ± 4.24 g) were fed during 90 days with three isoproteic (44 %), isolipidic (22.6 %) and isoenergetic (21.4 MJ/kg) diets with a high content of saturated fats and increasing concentrations of a based-on *Capsicum sp*. essential oil: 0 % ("control"), 0.1 and 0.15 %. During the trial, fish growth in terms of body weight (BW, g) and standard length (SL, cm) was monthly monitored. At the end, the specific growth rate (SGR), the feed conversion ratio (FCR), the hepatosomatic index (HSI) and the perivisceral fat index (PVFI) were measured. To determine oxidative stress in liver, the activity of glutathione reductase (GR), catalase (CAT) and superoxide dismutase (SOD) were measured, as well as lipid peroxidation (LPO) (through concentration of MDA) and total antioxidant capacity (TAC). Hepatic metabolism was also monitored through the enzymatic activity of glutamic oxaloacetic transaminase (GOT), glutamic pyruvic transaminase (GPT) and lactate dehydrogenase (LDH) in liver. Histological sections of the liver and gut allowed to evaluate fat accumulation, and other physiology parameters in gut (*villi* height, thickness of the musculature, density of goblet cells, height of enterocytes and presence or absence of inflammation). Furthermore, total proteins, globulins, albumin, triglycerides, cholesterol, GOT, GPT and alkaline phosphatase in serum were measured.

(Continued on next page)

Results and Discussion

Fish fed the diets with an inclusion of 0.1 and 0.15 % of based on *Capsicum* EO were respectively 2.78 % and 3.24 % heavier than those fed the control diet ($P < 0.05$). In addition, an increase in SGR with respect to the control was observed in both groups fed the diets supplemented with EO ($P < 0.05$), which is in accordance with the results obtained by Parrino et al. (2020) in rainbow trout. Although addition of *Capsicum* EO did not affect the FCR and HSI, PVFI decreased from 3.01 ± 0.28 % (a) in the control group to 2.32 ± 0.37 % ($P < 0.05$; b) and 2.68 ± 0.28 % ($P > 0.05$; ab) in fish fed the diets with 0.1 and 0.15 % EO, respectively. Furthermore, in histological observation, less fat accumulation was appreciated in the groups fed with the EO diets than in the control. This would be indicative that the EO derived from *Capsicum sp*. can reduce the adiposity of gilthead sea bream. Having into account the fact that a reduction of hepatic fat accumulation was only observed in the diet with the lower inclusion of EO, together with the PVFI results, everything seems to indicate that the most effective dose of *Capsicum* EO to meet the purpose of reducing body fat in *S. aurata* would be 0.1%. No differences were observed in the rest of measured parameters, indicating that the EO had no harmful effect for the health and quality of the fish, although it has been proven in freshwater fish that, under certain conditions, dietary supplementation with *Capsicum* can ameliorate blood parameters (Parrino et al., 2020) and even their reproductive performance (Abdalla and Agouz, 2014).

Reduction of fish meal is an important goal of the aquaculture industry but its replacement by plant-proteins have often a negative impact on the content of amino acids such as methionine and taurine. The aim of this study was to evaluate meagre juvenile response to different levels of dietary methionine and taurine. To achieve this, three diets were formulated: D1 diet had low methionine supplementation and a deficiency of this AA estimated in 25 % and a supplement of 1 % taurine; the D2 and D3 diets had a methionine content 18 % above the estimated requirement and were supplemented with 1 % and 2 % taurine, respectively. The diets were tested in juvenile meagre (initial weight: 12.0 ± 1.6 g) for eight weeks. Fish were held in 1500 L fibre tanks at a density of 0.08 fish /L. Survival varied between 95 and 100 %. The results showed that meagre fed the D1 diet had lower specific growth rate (2.2 to 2.5), lower feed efficiency (0.9 to 1.2) and higher FCR (1.1 to 0.8) as well as a lower activity of the ALAT enzyme. Furthermore, a higher recruitment of muscle fibres was observed (46 compared to 36 %) as well as a higher fibre density (1019 compared to 870 fibres/mm^2). In conclusion, this study shows that methionine supplementation in plant-based formulations is crucial to overcome the reduction of fish performance and growth associated to fish meal replacement of meagre diets. Moreover, taurine supplementation was not able to mitigate the effects of methionine deficiency.

There is a continuous effort to find an alternative to fish meal (FM), not only from a sustainability perspective but, as well, because of the high cost it represents. Considerable research has been carried using plant-feedstuffs, but the results have been far from ideal. In recent years, insect meal (IM) has been tested as an alternative ingredient to partially replace FM. IM shows several advantages, such as its antimicrobial properties and its more sustainable and economic production. In this experimental trial, three diets were tested in meagre juveniles of approximately 10 g. In the first treatment, FM was replaced by 20 % of IM (INS20), in the second treatment, FM was replaced by 10 % (INS10) and the control (C) treatment had no IM. The results showed that the inclusion of 20 % IM had a negative impact on fish final weight, specific growth rate and food conversion ratio (Fig. 1). However, these differences in growth were not reflected in changes in the mean fibre area and density or in several markers of protein degradation. In fact, the inclusion of 10% IM in the diets, rather than 20%, seems to induce a higher proteolytic activity in the hepatic and muscle tissues of meagre juveniles. The overall digestive enzyme activity in meagre was not significantly affected by the level of incorporation of the IM in the diets. Nevertheless, differences were found for the total activity of aminopeptidase (lower in INS20) and for alkaline phosphatase intestinal maturation index (higher in the control group). In relation to the intestine histomorphology, fish fed the C and INS10 diet showed changes in the enterocytes with hyper vacuolization and nucleus misplacement whereas fish fed the INS20 diet showed a more regular and normal sized vacuolization.

Introduction and objectives

The interest of the native European clam *Ruditapes decussatus* for aquaculture is increasing (da Costa et al., 2020). Spat of this species is usually utilized to restocking harvested natural populations (Borrell et al., 2014). A detailed knowledge of the performance in hatcheries and an adequate management of the species' genetic diversity are essential to develop a science-based management of clam fisheries and aquaculture. Adequate levels of genetic diversity in the hatchery stock depends on the contribution of a large number of parents, but this often is not the case in bivalves (Borrell et al., 2014). Moreover, *R. decussatus* is characterized by the existence of three races, which could be maintained by endogenous barriers to gene flow (Cordero et al, 2014; Arias-Pérez et al., 2016). Applying microsatellites as genetic markers to the progeny of a cross between clams of Atlantic and West Mediterranean races, we have studied three topics which are important for clam production and conservation of genetic resources: 1) male and female contributions to offspring after conditioning and spawning induction in the hatchery; 2) testing for genetic barriers between the two races; and 3) growth rate differences among families and populations.

Materials and Methods

Sixty wild clams were sampled in Cambados (NW Spain, Atlantic Ocean), and Mar Menor (SE Spain, Mediterranean Sea) in spring 2016. Hatchery methods were as described (Markaide et al., 2021). Equal numbers of good-quality eggs and sperm from four males and four females from each locality were chosen for performing mass fertilization at the IRTA facilities. In the winter of 2017, a subset of 250 offspring was transferred to the IATS facilities, where they were individually tagged and measured for shell dimensions. Three months later (June 2017) clams were again measured and then sacrificed. Individual growth rate was assessed as $GR = (X_f - X_0)/ X_f$, where X_0 stands for initial shell length or height, and X_f stands for final shell length or height. DNA was extracted from a piece of gill from parents and offspring by standard minicolumns. The genotypes of the parents and each offspring were scored for 6 microsatellites (Borrell et al., 2014). Parentage assignment was carried out using the software Cervus 3.0 (Kalinowski et al., 2007).

Results & Discussion (I) : parental contributions and race genetic barriers

Parentage analysis allowed ascription of 249 offspring to their parents at 80% confidence, including 134 at 95% confidence. All parents contributed to the offspring but at very different proportions. Females mothered an average of 31 ± 10 offspring (mean ± S.E.)(range 4-90), and three females alone mothered 78% of all progeny. Males fathered an average of 31 ± 7 offspring (range 7-72), and the two most fertile males fathered 51% of the progeny. These results indicate that individual reproductive success of *R. decussatus* is low in the hatchery for both males and females, and a very large broodstock would be necessary to keep the genetic variability at the level of the wild stock.

Results & Discussion (II) : genetic barriers

Atlantic females mothered 54% of the progeny, and Atlantic males fathered 42%. The proportion of offspring of hybrid (Atlantic x Mediterranean) origin was 51%. These results are indicative of equal fertilization and survival rates of pure and hybrid crosses (P=0.90, two-tailed Fisher exact test), and demonstrate an absence of important reproductive barriers between the two races.

Results & Discussion (III): growth rate.

Shell length and shell height varied widely among sibs, as is usual in bivalves (Markaide et al., 2021). Growth rate (GR) could be measured in 170 animals. GR in length varied between 0.00 and 0.47 among individuals, and GR in height varied between 0.00 and 0.36. In both cases GR was normally distributed. Differences in growth rate across families were nonsignificant (ANOVA, $P > 0.05$). Average GR of hybrid clams was slightly higher than that of pure-bred clams for both shell length and shell height, but variances were very large and, therefore, the observed differences were non-significant (ANOVA, $P< 0.05$). These results suggest the occurrence of heterosis for growth in interracial crosses of *R. decussatus*.

FISH TRANQUILIZATION, ANESTHESIA AND EUTHANASIA IN AQUACULTURE

Nick Saint-Erne, DVM, Certified Aquatic Veterinarian

World Aquatic Veterinary Medical Association - Phoenix, Arizona USA
Email: nsainterne@gmail.com

Introduction

Tranquilization aids in shipping live fish and in handling fish during physical examination, for biopsy sampling or for breeding purposes such as egg and milt stripping during artificial spawning. Anesthesia and analgesia are required for surgical or invasive procedures. Surgery can be performed on anesthetized fish to implant transponders or for research purposes, and to repair wounds, remove skin and fin tumors, or to remove abdominal masses. Sometimes euthanasia is needed to perform diagnostic testing and necropsies, to end the suffering of a sick or injured fish, or for research or other purposes. Each of these techniques can be accomplished with fish by adding anesthetic medications to the water, and sometimes by injection or oral administration of anesthetics. Food fish have specific limitations to medications that can be used with them, and withdrawal times for approved medications must be observed.

Tranquilization and Anesthesia Techniques

Many chemicals have been used to induce tranquilization (sedation) or anesthesia (unconsciousness) in fish. All have some element of risk, but when used carefully they have successfully induced sedation or anesthesia. Anesthetic agents used in lower doses produce tranquilization, and at higher doses they are used for anesthesia purposes. Care must be taken not to overdose the fish, or leave them anesthetized too deeply for too long of time. It is recommended to start with a lower dose and add more as needed if using a new drug or working with an unfamiliar species of fish. Monitor the heart rate, blood oxygen concentration, and operculum (gill cover) motion during anesthesia to ensure fish is not too deeply anesthetized.

Most fish anesthetics are added to clean, well-oxygenated water in a suitable glass or plastic container. The water is thoroughly mixed to ensure all the chemical is dissolved and dispersed evenly. The anesthetic solution should be the same temperature and pH as the water from which the fish was taken. Use a thermometer to monitor the water temperature during anesthesia, and if an oxygen meter is available, also monitor the dissolved oxygen concentration of the anesthetic solution. An aquarium air pump with an air stone should be placed into the water to circulate it to maintain adequate oxygen level, especially with a large fish. The water should be tested to ensure all the water quality parameters are in the correct range for the fish species.

A pulse oximeter can be clipped onto the caudal fin of large fish, near the tail base, to monitor the pulse and blood oxygen concentration. Electrocardiogram (ECG) monitors can also be used in large fish by attaching the monitor clips to hypodermic needles placed into the muscles on either side of the body by the pectoral fins. This will create a 2-lead ECG that will show the heart rate of the fish. It is important to get a baseline heart rate and monitor for slowing, rather than to see if the heart stops, as the heart in fish can continue to beat after the fish is dead!

When placed into the container with the anesthetic in the water, the fish will gradually begin to lie on its side and the respiratory rate will slow as the chemical induces anesthesia. In some cases, there may be an excitatory stage, so the anesthetic chamber may need to be covered to prevent fish from jumping out. After the fish is anesthetized in the anesthetic bath, it can be removed from the water for short-term examination or diagnostic procedures. If the fish is removed for longer procedures, anesthetic solution can be dripped across the gills through an IV bag and drip line, by hand with a syringe, or with a recirculating water pump or aquarium filter powerhead. Have oxygenated fresh water on hand to syringe across the gills if the plane of anesthesia becomes too deep. Keep the body moist if out of the water for examination or surgery. Use ophthalmic ointment on the eyes to keep them from drying. Monitor the respiration rate (operculum movements) to assess the depth of anesthesia.

(Continued on next page)

Stages of Anesthesia in Fishes

Stage	Plane	Description	Signs
0	0	Normal	Swimming actively, equilibrium normal
I	1	Light sedation	Reduced motion, ventilation decreased
I	2	Deeper sedation	Motionless unless stimulated
II	1	Light anesthesia	Partial loss of equilibrium
II	2	Deep anesthesia	Total loss of equilibrium
III	1	Surgical anesthesia	Total loss of reactivity when stimulated
III	2	Deep surgical anesthesia	Decrease in respiratory and heart rates
IV	1	Medullary collapse	Cessation of respiratory movements
IV	2	Cardiac arrest	Death

Recuperation after anesthesia is accomplished by transferring the fish into a container of fresh, well-aerated water without any anesthetic. It is helpful to move the air pump and air stone to the recovery container to continue to aerate the water. Never leave a fish unattended while it is under anesthesia. Some large fish tend to jump during induction or recovery from anesthesia. Moving the fish gently in a forward direction will aid the flow of fresh water across the gills, hastening anesthesia release from the gills. Do not slosh the fish back and forth in the water. Once there are steady operculum movements let the fish rest and gradually recover in a quiet, dim environment. The longer a fish is under anesthesia, the longer it will take to recover from the anesthetic. Monitor the fish until it has regained its equilibrium and is swimming normally and can be transferred back into the aquarium or pond.

Euthanasia

Humane death can be induced in fish by immersing them in an anesthetic solution, usually ten times the normal anesthetic concentration is used, and leaving them in the solution until respiration and heart beats cease. It is recommended to wait at least an hour after respiration has stopped to confirm death. Secondary methods of euthanasia, such as pithing, can be performed after the fish is anesthetized to ensure death.

Introduction

Aquaculture is the fastest growing animal food-producing industry. Intensified production systems and climate change, facilitate the occurrence of disease outbreaks due to the favoring of stressed and immuno-compromised animals. Therefore, a suitable environmentally friendly solution is the use of feed additives with immunomodulatory properties that may be used as functional feeds to improve disease resistance (Dawood et al., 2021). A wide spectrum of phytogenics have been studied in aquafeeds due to their growth promoting, antimicrobial, immunostimulant, antioxidant and anti-inflammatory properties (Reverter et al. 2021). In this study, we have evaluated a feed additive rich in triterpenic compounds and polyphenols (AQUOLIVE®, NATAC Biotech SL, Spain) on the systemic immune response and disease resistance of Atlantic salmon (*Salmo salar* L.) smolts.

Materials and Methods

Atlantic salmon parrs were kept in tanks of 450 L connected to a water recirculation system (IRTAmar®) at an initial density of 2 kg m^{-3}. Water temperature, pH and oxygen levels during the trial were 12 ± 0.1 °C, 7.4 ± 0.3 and 9.6 ± 0.2 mg/L. After 47 days, fish were smoltified during 10 days and transferred to 35 ppt, and kept at similar water temperatures than the parr phase during 76 days. Photoperiod was 24 h light and 0 h darkness. Two experimental diets were tested: D1, control diet (40% protein; 22.15% fat; 21.60 energy MJ/kg); D2, control diet supplemented with the feed additive AQUOLIVE® at 0.15% inclusion. This feed additive was obtained from olive tree containing 10% of olive bioactive compounds (8.0% triterpenic acid and 2% polyphenols). At the end of the trial, in order to investigate the immunomodulatory properties of the phytogenic tested against a bacterial infection, an *in vivo* challenge with *Aeromonas salmonicida* was performed (4 tank replicates; 8 fish per tank). In addition, total RNA was extracted from the head kidney (HK) of individual fish (n = 18 fish per dietary treatment) and its transcriptomic profiling analyzed by means of a microarray platform (Krasnov et al., 2011).

Results and Discussion

At the end of the trial (133 days), no differences in body weight were observed between fish fed the diet containing 0.15% AQUOLIVE® (252.3 ± 9.2 g) and the control group (240.2 ± 19.3 g). The transcriptomic profiling of the HK from smolts fed the control and AQUOLIVE® diets revealed a total of 1,027 differential expressed genes (DEGs). Among them, 805 DEGs were up-regulated (UP) and 222 genes were significantly down-regulated (DOWN). Furthermore, the ClueGO platform (Bindea et al., 2009) was used to identify the biological processes (BPs) linked to the above-mentioned DEGs. The enriched BPs were mainly associated with immune pathways. Particularly, "leukocyte activation" (34 UP and 14 DOWN genes), "granulocyte activation" (26 UP and 11 DOWN genes) and "neutrophil degranulation" (25 UP and 11 DOWN genes), indicating that the BPs identified were the primary actors of the innate immune response promoted by the tested functional additive in this lymphoid organ. In the case of granulocyte, neutrophils are one of the three types of granulocytes identified in fish, whereas neutrophilic granulocytes are the most abundant in salmonids (Rønneseth et al., 2006). As their main function is arriving first at the site of the infection and having a central role in host tissue protection by killing and degradation of microorganisms; therefore, neutrophils are an essential part of the innate immune system whose main activities are to phagocyte pathogens and stimulate lymphocytes and other immune cells (Secombes and Wang, 2012). Thus, the results of our functional analysis regarding leukocyte activation, granulocytes and neutrophils, in particular, might suggest and increased specific immune capacity promoted by the tested functional diet.

(Continued on next page)

Among others BPs identified, the the "i-kappaB kinase/NF-kappaB signaling" pathway was evidenced. Nuclear factor kappa B (NF-κB) pathway is a nuclear transcription factor involved in the regulation of several cytokines, chemokines, antimicrobial peptides, and interferon-stimulated genes, being crucial for a multitude of important immnulogical transcriptional programs, including inflammatory responses to antigens by innate immune cells (Dorrington et al., 2019).

Results from the transcriptomic profiling of the HK were validated in an *in vivo* pathogenic challenge with *A. salmonicida* (intraperitoneal injection of 10^7 CFU/mL). The bacterial challenge lasted 15 days and at the end of the assay, cumulative survival was higher in fish fed the AQUAOLIVE diet (96.9 ± 6.4%) than in fish from the control group (60.7 ± 13.5%).

Conclusions

These results indicate that the dietary supplementation of the functional feed additive AQUOLIVE® at level of 0.15% enhanced the systemic immune response in Atlantic salmon smolts as the combined analysis of the HK transcriptomic profiling and results from the *A. salmonicida* challenge indicated.

Introduction

Aquaculture intensification and sustainability has led to new industrial challenges, among them the need of reducing the use of antimicrobials. Phytogenics are good candidates for this purpose, as they may enhance fish growth, health and welfare due to their antimicrobial, immunostimulant, antioxidant and anti-inflammatory properties (Reverter et al. 2021). In this study, we have evaluated a feed additive rich in verbascoside and triterpenic compounds like ursolic acid on the systemic immune response and disease resistance of Atlantic salmon (*Salmo salar*) smolts.

Materials and Methods

Atlantic salmon parrs were kept in tanks of 450 L connected to a water recirculation system (IRTAmar®) at an initial density of 2 kg m^{-3}. Water temperature, pH and oxygen levels during the trial were 12 ± 0.1 °C, 7.4 ± 0.3 and 9.6 ± 0.2 mg/L. After 47 days fish smoltified during 10 days and were then transferred to 35 ppt during 76 days. Water temperature was maintained similar than the parr phase and photoperiod was 24 h light and 0 h darkness. Two experimental diets were tested: D1, control diet (40% protein; 22.15% fat; 21.60 energy MJ/kg); D2, control diet supplemented with a medicinal plant leaf extract (MPLE) at 0.1% inclusion. This feed additive was obtained from sage (*Salvia officinalis*) and lemon verbena (*Lippia citriodora*) containing 10% ursolic, 3% triterpenic compounds, 2% verbascoside and <1% polyphenols (NATAC Biotech SL, Spain). At the end of the trial, in order to investigate the immunomodulatory properties of the phytogenics tested against a bacterial infection, an *in vivo* challenge with *Aeromonas salmonicida* was performed (4 tank replicates; 8 fish per tank). Total RNA was extracted from the head kidney (HK) of individual fish (n = 18 fish per dietary treatment) and its transcriptomic profiling analyzed by means of a microarray platform (Krasnov et al., 2011). Differences in somatic growth between both diets (control; 0.1% MPLE) were evaluated by means of a *t*-test.

Results and Discussion

At the end of the trial (133 days), significant differences in body weight were observed between fish fed the diet containing 0.1% MPLE and the control group (271.5 ± 9.2 g vs. 240.2 ± 19.3 g, respectively; $P < 0.05$). This weight increase is in agreement with previous studies evaluating the same phytogenic in seabream (Salomón et al., 2020) and they might be attributed to the potential growth-promoting effects of polyphenolic compounds like verbascoside. In addition, FCR values were lower in fish fed the MPLE diet (1.09 ± 0.05) than in smolts fed the control diet (1.25 ± 0.08) ($P < 0.05$). The transcriptomic profiling of the HK from smolts fed the control and MPLE diets revealed a total of 1,178 differential expressed genes (DEGs). Among them, 802 DEGs were up-regulated and 376 genes were significantly down-regulated. Furthermore, the ClueGO platform (Bindea et al., 2009) was used to identify the biological processes (BPs) linked to the above-mentioned DEGs. The enrichment analysis indicated that the BPs were mainly associated with immune pathways. Particularly, "leukocyte activation", "neutrophil mediated immunity", "lymphocyte activation involved in immune response", among others, indicating that the identified BPs were the primary actors of the innate immune response promoted by the tested functional additive in this lymphoid organ.

These results support those obtained from an *in vivo* pathogenic challenge with *A. salmonicida* (intraperitoneal injection of 10^7 CFU/mL). The bacterial challenge lasted 15 days, and at the end of the assay, the cumulative survival was higher in fish fed the MPLE diet (90.6 ± 6.4%) than in the control group (60.7 ± 13.5%). This is relevant, since the additives tested might be used as sustainable and environmental-friendly treatment strategy for fighting fish diseases, through an increased systemic immune capacity. Moreover, the tested additive regulated other BPs like "stem cell differentiation" and "antigen processing and presentation of antigen via MHC class II". These results are important since leucocytes develop

(Continued on next page)

from a common cell origin, the multipotent hematopoietic stem cell (Øverland et al., 2010). Besides, MHC class II in fish granulocytes has been suggested to play a key role in the ability to present antigens (Øverland et al., 2010). Collectively, these results led to an increased capacity in terms adaptive immunity, thus capable to generate immunological memory.

Furthermore, the "iNF-κB signaling" and "exocytosis" pathways were evidenced. This is of special relevance since the nuclear factor kappa B (NF-κB) pathway is involved in the regulation of several cytokines, antimicrobial peptides, and interferon-stimulated genes, being crucial for a multitude of important immunological transcriptional programs, including inflammatory responses to antigens by innate immune cells (Dorrington et al., 2019). In addition, exocytosis is recognized by its important role in the immune response participating in neutrophil function, in the cell-mediated cytotoxicity and finally, in the immunological synapses among cells (Faurschou and Borregaard, 2003).

Conclusions

The present results from the combined analysis of the HK transcriptomic profiling and from the *A. salmonicida* challenge indicate that the dietary supplementation of the functional feed additive MPLE at the level of 0.1% promoted somatic growth, improved feed efficiency and enhanced the systemic immune response in Atlantic salmon smolts.

Introduction

Aquaculture will supply the majority of aquatic dietary protein by 2050, playing a relevant role in food security and supply, and poverty alleviation (Stentiford et al., 2020). In this context, Atlantic salmon (*Salmo salar* L.) production has increased strongly in recent decades thanks to the expansion in the northern Europe and in North and South America with Norway and Chile as the mains world producers (FAO, 2020). This fast and continued growing in the salmon industry has side effects. Under intensive culture conditions, fish may be exposed to several environmental and husbandry related stimuli that may have a potential noxious or stressful effect. All these factors have negative impacts on fish welfare and overall performance. In addition, a higher susceptibility to disease has been observed since reduced immune response allows pathogens to act with greater efficiency with an impact in the industry causing sanitary crisis and economic losses (Tort, 2011). Therefore, the development of functional feeds focused on their growth promoting, antimicrobial, immunostimulant, antioxidant, anti-inflammatory and sedative properties has been encouraged during the last decade (Reverter et al., 2021). In the current study we evaluated the transcriptomic profile of the intestine in Atlantic salmon smolts fed a functional diet rich in triterpenic compounds and polyphenols (AQUOLIVE®, NATAC Biotech SL, Spain) obtained from olive fruit (*Olea europaea* L.) extract on the local immune response of smolts.

Materials and Methods

Atlantic salmon parrs were kept in tanks of 450 L connected to a water recirculation system (IRTAmar®) at an initial density of 2 kg m^{-3}. Water temperature, pH and oxygen levels during the trial were 12 ± 0.1 °C, 7.4 ± 0.3 and 9.6 ± 0.2 mg/L. After 47 days, fish were smoltified during 10 days and transferred to 35 ppt, and kept at similar water temperatures than the parr phase during 76 days. Photoperiod was 24 h light and 0 h darkness. Two experimental diets were tested: D1, control diet (40% protein; 22.15% fat; 21.60 energy MJ/kg); D2, control diet supplemented with the feed additive AQUOLIVE® at 0.15% inclusion. This feed additive was obtained from the fruit olive containing 10% of olive bioactive compounds (8.0% triterpenic acid and 2% polyphenols). In addition, total RNA was extracted from the intestine of individual fish (n = 18 fish per dietary treatment) and its transcriptomic profiling analyzed by means of a microarray platform (Krasnov et al., 2011).

Results and Discussion

At the end of the trial (133 days), no differences in body weight were observed between fish fed the diet containing 0.15% AQUOLIVE® (252.3 ± 9.2 g) and the control group (240.2 ± 19.3 g). The transcriptomic profiling of the gut from smolts fed the control and AQUOLIVE® diets revealed a total of 2,200 differential expressed genes (DEGs). Among them, 1564 DEGs were up-regulated (UP) and 636 genes were significantly down-regulated (DOWN). Furthermore, the ClueGO platform (Bindea et al., 2009) was used to identify the biological processes (BPs) linked to the above-mentioned DEGs. Considering the close relationship between diet and gut condition and the consequences on the organism and overall health, evaluating the interactions between dietary ingredients and the intestine is of special relevance due to the wide array of functions that have been associated to the gastrointestinal tract (Calduch-Giner et al., 2016). This is of special relevance when evaluating functional feed additives that are supposed to promote health and nutrition in farmed animals (Dawood et al., 2021). Among the most representative BPs enriched obtained from the intestine of the Atlantic salmon were the following: myeloid leukocyte activation (7.95%), response to organic substance (10.23%), regulation of metabolic process (12.5%), cellular response to cytokine stimulus (17.05%), protein localization to endoplasmic reticulum (17.05%) and establishment of protein localization to endoplasmic reticulum (22.73%). Therefore, this positive regulation of the aforementioned BPs might suggest to a more metabolically active intestine due to greater protein synthesis, which could lead to a stimulation not only of the innate immune response, but also adaptive, although they are needed further research to confirm this hypothesis.

(Continued on next page)

Conclusions

These preliminary results indicate that the dietary supplementation of the functional feed additive AQUOLIVE® at level of 0.15% promoted transcriptional innate and adaptive immune responses in gut, especially through the modulation of those processes involved in leukocyte activation, cellular response to cytokines, among others.

Introduction
Marine fish culture is an emerging industry in the Western South Atlantic coast. Two species are currently commercially produced in Brazil, the cobia *Rachycentron canadum* (Sampaio et al 2010) and the grouper *Epinephelus* (Mello et al, 2018). Nevertheless, there is a continuous search for prospective species.

Sciaenidae fish are produced in North America and Europe, aquaculture production for red drum (*Sciaenops ocellatus*) reachs 77,000 ton, while meagre (*Argyrosomus regius*) 37,500 ton (FAO 2021), thus suggesting other large Sciaenidae species, such as endangered Southern black drum (*Pogonias courbina*) would also have good aquaculture potential.
This is the first report of successful mass production of juvenile Southern black drum *P. courbina*.

Materials and Methods
Twenty adult fish were captured during the winter 2019 (from July to September) at Cassino Beach, in Southern Brazil (32°S-52°W), and immediately transferred to the Laboratory of Marine Fish Culture at FURG. They were measured, tagged, and stocked in a 15 ton tank, attached to a RAS. Water temperature and photoperiod at the hatchery mimicked the conditions in the wild. Broodstock were hand fed daily on frozen fish, squid, and shrimp.

Live feed was provided to the larvae, including microalgae (*Nannochloropsis oceanica*), rotifer (*Brachionus plicatilis*), and *Artemia sp* (nauplii and metanauplii). Rotifer and *Artemia* metanauplii were enriched using commercially available lipid emulsions rich in HUFA (Red pepper – Bernaqua). During cofeeding, up to weaning, larvae were offered commercial diets (Win Fast – Sparos and NRD – Inve).

Larvae were reared in 300 L tanks attached to a RAS. Continuous light was provided during larviculture, temperature was kept at 26°C and salinity was set to 30‰.

Results
Four months after the last broodstock were stocked in the hatchery, during January 2020, naturally fertilized eggs of *P. courbina* were obtained for the first time. At the time of spawning water temperature was 26°C and photoperiod was equal to 14 h light and 10 h darkness. The precise moment of spawning was not determined, but in the morning, embryos often had already reached the 180° stage, hatching took place between 9 and 12PM. Newly hatched larvae measured 1.9 mm.

Exogenous feeding started 48 h after hatching, larvae were fed exclusively on rotifers for 5 days, when Artemia nauplii was introduced. Rotifers were discontinued 11 dah and Artemia nauplii 13 dah, when larvae were fed only enriched Artemia (Figure 1). Co-feeding with dry diets began 15 dah and larvae were fully weaned 22 dah. One month after hatching larvae reached 29 mm and weighed 270 mg. Survival up to metamorphosis was between 75 - 90%.

Discussion and conclusion
One of the first steps towards the introduction of a new species for aquaculture is to accomplish its controlled reproduction in captivity (Mylonas et al 2010). Wild caught broodstock of Southern black drum readily adapt to captivity and were conditioned to spawn volitionally.

Larviculture of teleost fish is dependent of live food, but their larvae should be readily be weaned into dry diets, therefore reducing the need for live prey production and the high costs associated to production of rotifers and purchase of *Artemia* cysts (Campoverde et al, 2017).

Larviculture of Southern black drum larvae is faster than most species. Larvae were fully weaned as soon as 22 dah. Survival was also high, up to 90% upon completion of metamorphosis.

The successful mass production of striped drum juveniles suggests it may be a prospective species for aquaculture in South America.

INFLUENCE OF EXTREME CLIMATIC EVENT ON LOCAL FISH LANDING DUE TO MASSIVE ESCAPES IN WESTERN MEDITERRANEAN SEA

P. Sanchez-Jerez*[1], D. Fernandez-Jover[1], J.M. Valero-Rodriguez[1], Jose L. SanchezLizaso[1], I. Sola-Macia[1], D. Izquierdo-Gomez[2], P. Arechavala-Lopez[3], F. Romero[1], and K. Toledo-Guedes[1]

Introduction

The acceleration of climate change has exacerbated existing environmental problems in the Mediterranean Basin that are caused by the combination of changes in land use, increasing pollution, and declining biodiversity (MedECC, 2018). One of the connections between extreme events due to climate change and the effects on marine ecosystems are fish escapes from aquaculture facilities. As it is complicated to determine the extent and duration of the presence of escapes in coastal areas, local fisheries can be a proxy to assess the relevance of this impact at the mesoscale level. The objective of the work was that to assess if the magnitude of the storms should be reflected in the local fishermen's landings in the fish market. The duration of landings above average landings was also assessed in relation to the distance to the aquaculture facilities and cultivated species.

Material and Methods

We analyzed the temporal trends of daily fishing landings from 30 fish markets along the Spanish Mediterranean coast using official data from the Ministry of Fisheries of the Government of Spain of meagre (*Argyrosomus regius*), seabass (*Dicentrarchus labrax*) and seabream (*Sparus aurata*) from 2018 to 2021. On the other hand, the events of storms with waves higher than 1 m in the areas where aquaculture is most intensively developed were analyzed. The SIMAR simulation model based on oceanographic data from the oceanographic buoy measurements of *Puertos del Estado* (Government of Spain) and atmospheric data was used to obtain the significant wave height for the positions of the most significant aquaculture facilities. The data were filtered to obtain representations of storms with waves higher than 1 m.

Results and Conclusions

During the studied period, four storms with waves greater than three meters were identified between 2019 and 2021. The most significant event was storm Gloria in January 2020, with waves greater than 4 m (Figure 1). The landings from the fish farms were clearly correlated with the intensity and duration of the storms, increasing between 10 and 100 times the average catches of each species. A clear relationship was also detected between the distance to the facilities and regional and temporal differences in the cultivation of each species. For example, in La Villa Joisa there was an important peak in meagre catches (Figure 2), followed by seabass, the main species cultivated in the area. Of course, the effect of each fleet in its area of influence is related to its fishing effort capacity and the type of fishing gear used. The relevance of Gloria is reflected in the magnitude of the catches and their duration over time. Therefore, catches in local fisheries may be a suitable proxy for estimating the impact of escapes from aquaculture in coastal environments, which are clearly related to extreme oceanographic events. Strategic plans for aquaculture development should be able to forecast and take into account the future climatic projections and local oceanographic conditions. It should not be forgotten that other extreme events can act negatively synergistically with global warming as strong storms or torrential rains, which in turn should be taken into account in spatial planning plans for aquaculture. On the other hand, fish escaping from net pens have always been considered a major source of ecological issues and local artisanal fisheries have proved the ability to mitigate escape events by recapturing escapees (Izquierdo-Gomez and Sanchez-Jerez 2016).

CHARACTERISATION OF GENES ESSENTIAL FOR PATHOGENESIS OF FISH ADAPTED *S. Agalactiae*

Morena Santi*, Adam Blanchard, James Leigh and Sharon A. Egan

School of Veterinary Medicine and Science, University of Nottingham
Email:morena.santi@nottingham.ac.uk

Introduction

Streptococcus agalactiae or Group B Streptococcus (GBS), is a highly infectious zoonotic pathogen, responsible for streptococcosis in fish, meningitis and septicaemia in humans and mastitis in cattle. In fish, it manifests as septicaemia, resulting in high morbidity and mortality in a number of wild and farmed species, in particular tilapia, sea bass and rainbow trout. Next-generation sequencing (NGS) associated with transposon mutagenesis of a comprehensive mutant library allows the genome-wide measurement of individual genes involved in the fitness of a bacteria growing in different conditions, enabling the identification of conditionally essential genes by negative selection consisting of an estimated 1.1 million transposon mutants and we have used genomic DNA from this mutant pool, and Illumina nucleotide sequencing to prime from the transposon and sequence into the adjacent target DNA. With this method, which we have called TraDIS (transposon directed insertion-site sequencing. This can provide important information to determine bacterial pathogenesis, key genes linked to virulence and host adaptation and to discover potential drug targets or vaccine candidates.

Materials and methods

The temperature sensitive plasmid, pGh9:IS*S1*, was used to generate a mutant population of *S. agalactiae* 01173 by random integration. This bacterial mutant population was grown in 3 separate growth conditions related to pathogenesis in fish tilapia serum, bacterial media containing either hydrogen peroxide or antimicrobial peptides, and bacterial media used as a comparative control. Harvested DNA was processed by inverse PCR, NGS sequenced and processed through PIMMS a bioinformatic pipeline to identify and quantitate transposon insertions present in the bacterial genome.

Results

Comparative sequence analysis was performed on approximately 100,000 individual mutants for each condition using the PIMMS transposon analysis platform. Among the conditionally essential genes, 3 were shared between growth conditions, *atpB*, *atpC* and *dltX*. A*tpB* and *atpC* are part of ATP synthase or ATPase operon, involved in the regulation of internal pH and the production of ATP, while *dltx* is involved in d-alanylation of teichoic acids important for charge-based regulation of the cell envelope and resistance to the effects of positively charged host immune factors. Other conditionally essential genes were shared only between two of the three conditions including the heat shock protein *dnaK* and protease *clpX*. DnaK is key for the regulation of accurate protein folding whilst clpX removes misfolded or damaged proteins.

This study highlights the potential use for transposon mutagenesis to rapidly identify potential vaccine targets for bacterial aquaculture related disease allowing this growing industry to become more sustainable for food production.

ACUTE AND SUBCHRONIC TOXIC EFFECTS OF MICROPLASTICS AND COPPER, ALONE OR COMBINED, IN BLACKSPOT SEABREAM (*Pagellus bogaraveo*) LARVAE

Introduction

Microplastics (MPs) comprise a major percentage of marine litter, being nowadays an environmental issue of global concern. It has been demonstrated that MPs can adsorb, for example, heavy metals, which can affect their bioavailability in aquatic biota and lead to biological adverse effects. Their presence in the marine ecosystems can impact commercial fisheries and aquaculture industries, posing serious risks for fish productivity and a potential constraint for food security. In this context, it is crucial to clarify the risks inherent to MPs, with or without other pollutants, to fisheries and aquaculture, to understand how species development may be affected and the aquatic organism's fitness compromised. Considering the above, the present study aimed to evaluate the effect of MPs, associated with copper (Cu), another contaminant of high concern, in the later larvae development of the economically and ecologically important species, the blackspot seabream (*Pagellus bogaraveo*). For this, in the present study, newly hatched blackspot seabream larvae were exposed to MPs, with or without Cu, for 10 days, to evaluate its effects on survival, growth, oxidative damage, antioxidant activity and expression of antioxidant and neurotoxicity-related genes.

Materials and Methods

The experiments were conducted with 120 newly hatched blackspot seabream larvae, randomly distributed through 500 mL glass beakers and incubated under semi-static conditions (16 ± 1 °C and a photoperiod of 12 /12 h light: darkness). Larvae were initially exposed, from 3 days post-fertilization (dpf) until 6 dpf, to a control (filtered natural seawater), MPs (0.3 mg/L of red fluorescent particles of 1-5 μm), five concentrations of Cu (Cu10, 10 μg/L; Cu30, 30 μg/L; Cu90, 90 μg/L; Cu270, 270 μg/L; and Cu810, 810 μg/L) and five binary mixtures of MPs and Cu (Cu10+MPs; Cu30+MPs; Cu90+MPs; Cu270+MPs; and Cu810+MPs). Three replicates were established for each group. To evaluate the acute effects of MPs and Cu, alone or combined, pools of larvae were sampled at 6 dpf, for gene expression and biochemical parameters analysis. The remaining larvae of the control, MPs and the two lowest concentrations of Cu and Cu+MPs groups, remained continuously exposed until 12 dpf, to evaluate the subchronic effects of sublethal doses of MPs and Cu on their development. At 12 dpf, pools of larvae were also sampled for gene expression and biochemical/metallothioneins analysis. Body length and the ingestion of MPs by larvae was also assessed at 12 dpf. For gene expression, RNA was isolated and the expression levels of the antioxidant enzymes (*cat* and *gst*) and neuronal (*pcna* and *ache*) genes were evaluated by quantitative real-time PCR (qPCR). The biochemical biomarkers, namely reactive oxygen species (ROS), lipid peroxidation (LPO), superoxide dismutase (SOD), catalase (CAT), glutathione-S-transferase (GST), reduced (GSH) and oxidized states (GSSG) of glutathione levels, lactate dehydrogenase (LDH), acetylcholinesterase (AChE) and metallothioneins (MT), were determined according to standardized protocols. The obtained data were then statistically analyzed.

(Continued on next page)

Results and Discussion

The acute exposure, induced a decreased survival and a time- and dose-dependent sensitivity to Cu, reaching a 72-h LC_{50} of 92 μg Cu/L. Interestingly higher mortality was observed in the Cu+MPs than in the Cu alone groups, although the differences were not statistically significant. At 6 dpf, ROS levels were not affected by the treatments, however, in the Cu270+MPs group, a significant increase in SOD activity was observed ($p<0.05$), indicating a cellular response against ROS. Nevertheless, the induction of oxidative damage in larvae exposed to high Cu concentrations was not prevented since an increase of LPO levels was observed in both Cu270 ($p=0.018$) and Cu270+MPs ($p<0.0001$) groups. Also, the CAT and GST activities decreased in all exposed groups ($p<0.001$), suggesting an imbalance of the antioxidant system, which may have contributed to the induction of oxidative damage and higher mortality, observed in the higher concentrations groups. However, the *cat* and *gst* genes did not support the cellular biomarkers, since the expression of these two genes was not affected by the treatments ($p>0.05$).

Blackspot seabream larvae ingested the plastic particles, along with the food. Indeed, after the subchronic exposure, an accumulation of plastic particles was observed, particularly, in the gastrointestinal tract. These observations point out the potential negative impacts on normal absorption and food digestion. Despite this, no significant effects of MPs, alone or combined with Cu, were observed in the body length of larvae. Considering the potential induction of oxidative stress by the treatments, it was observed an increase of the ROS levels in the MPs and Cu30 exposed larvae ($p<0.05$), followed by a decrease of CAT activity in all exposed groups ($p<0.0001$). In turn, the GST activity increased in the MPs, Cu30 and Cu30+MPs groups ($p<0.05$), suggesting that MPs and Cu, alone or combined, induce oxidative stress, with larvae responding with the subsequent activation of the antioxidant enzyme system to prevent oxidative damage. Indeed, no oxidative damage was observed in larvae, since LPO levels did not suffer significant changes. The results of the present study indicate the involvement of different cellular mechanisms and signalling pathways to prevent oxidative stress.

Overall, this study contributes to current research providing information on the mechanisms involved in the toxicological effects of MPs, as well their interaction with heavy metals in fish early life stages. In turn, it highlights that precautionary measures should be applied to reduce the entry of MPs in aquaculture systems to ensure aquatic organisms health and human food safety.

Introduction

The occurrence of fish bacterial diseases is one of the biggest challenges of world aquaculture intensification. Photobacteriosis is a septicemic disease caused by *Photobacterium damselae* subsp. *piscicida* (*Phdp*), affecting a wide range of marine species and leading to relevant economic losses. Although several studies have yet been performed regarding the pathogen features and virulence factors, few information about the host defence mechanisms activated after infection is available. The present study aimed to evaluate gilthead seabream (*Sparus aurata*) innate immune response to infection with *Phdp*.

Materials and methods

A time-course study was performed at CETEMARES (Politécnico de Leiria, Peniche, Portugal) facilities with 72 seabream juveniles (9.8 ± 2.2 g). After 2 weeks of acclimation, 12 fish were sampled before infection (time 0). The remaining animals were randomly selected and intraperitoneally (i.p.) injected with 100 μl PBS (placebo group) or 100 μl of exponentially growing *Phdp* (10^6 CFU mL^{-1}; infected group) and distributed as a complete randomized design in 6 recirculating seawater systems (i.e. triplicates *per* experimental condition). Two animals per tank (n = 6 *per* treatment) were sampled at 3, 6, 9, 24 and 48 h after i.p. injection. Fish were euthanized with 2-phenoxyethanol (0.5 mL L^{-1}) and blood samples were collected for haematological procedures. The remaining blood was centrifuged for plasma collection and innate humoral parameters (i.e. peroxidase, protease and antiprotease activities) were evaluated. Liver and head-kidney were also collected for oxidative stress (lipid peroxidation, total glutathione content, catalase, superoxide dismutase and glutathione-S-transferase activities) and gene expression analyses. Head-kidney total RNA isolation was performed with NZY Total RNA Isolation kit and first-strand cDNA synthesized with NZY First-Strand cDNA Synthesis Kit. Gene expression of innate immune selected genes was analysed by RT-qPCR and normalized by Pfaffl method using EF-1α as housekeeping gene. Although both placebo and infected groups were analysed, significant differences were mainly registered on infected groups against unstimulated animals and therefore are highlighted for a better understanding of host response to *Phdp* infection.

Results

Infection produced a host anaemic state since haemoglobin concentration and mean corpuscular haemoglobin concentration decreased in infected animals 48 h after bacterial challenge. Also total erythrocyte levels decreased 9 h after infection, while haematocrit presented lower values 48 h post-infection. In contrast, total peripheral leucocytes produced few differences throughout the time course. Circulating neutrophil and monocyte numbers augmented since the first hours of infection compared to non-infected animals. Regarding humoral responses, infected animals presented increased antiproteases activity 48 h post-infection. Hepatic oxidative stress biomarkers resulted on increased lipid peroxidase and glutathione-S-transferase 9 hours after pathogen inoculation, whereas catalase produced a later but similar variation. Moreover, hepatic total glutathione decreased 24 hours after bacterial challenge. Molecular findings go along with the cellular, humoral and oxidative stress results, with increased expression of interleukin1β, interleukin-34, interleukin-10 and major histocompatibility complex I, which are recognized genes related to inflammatory response and phagocytic processes. Also genes related to the iron metabolism such as haptoglobin and transferrin increased mRNA expression during infection, sugesting haemolysis and presenting a possible mechanism from host to avoid the bacterial uptake of iron.

(Continued on next page)

Discussion and conclusion

The outputs of this study include several pathways that contribute for a steady immune response. Cellular mechanisms are driven by peripheral monocytes and neutrophils that migrate for the infection site and release antioxidant and antibacterial substances trying to cope with the infection. Inflammation develops through a balanced production of anti and pro-inflammatory cytokines that result on a sustained but directed response. It is also remarkable the selective differentiation of macrophages through the interleukin-34/colony stimulating factor 1 receptor route and the increase of transferrin production that might be considered preferred routes to avoid bacterial survival and proliferation.
A broad view of the host mechanisms involved on other bacterial infections are essential for the definition of health biomarkers that can be suitable for an early disease detection.

Introduction

Infectious bacterial fish diseases remain a major challenge for aquaculture development. Although antibiotics are an important tool for disease treatment, their damaging effects on the environment and public health have led to increased restrictions to their use in aquaculture. Quorum-Sensing (QS) is a regulatory mechanism closely related to the expression of virulence factors contributing to the pathogenicity of fish diseases. Hence, disruption of bacterial QS, known as Quorum-Quenching (QQ) is being proposed as a possibility to fight aquaculture diseases dissemination [1]. *Bacillus* spp. are sporeforming bacteria with recognizable biotechnology applications including as a source of natural antimicrobial molecules, such as QQ molecules. Indeed, we recently isolated from the gut of three marine fish species, *Bacillus* spp. capable of inhibiting the growth and biofilm formation of 14 different fish pathogens and with *in vitro* QQ capacity [2]. Alongside with other probiotic health-promoting characteristics, *Bacillus* spp. are also known for their immunostimulatory effects enhancing the host's innate and adaptive immunity against fish pathogens [3].

Here, we screened the QQ capacity of the extracellular components of our collection of *Bacillus* spp., previously isolated from the gut of different marine fish species and tested their ability to degrade AHLs QS-signals produced by important fish pathogens, their protective effects in an *in vivo* model when challenged with *E. tarda* and their putative modulation of the fish immune system.

Materials and Methods

We took advantage of 200 Fish isolates (FI) isolated from the gut of different fish species (*Sparus aurata*, *Dicentrarchus labrax*, and *Diplodus sargus*) [2, 4] to explore their QQ potential, by testing the ability to degrade AHLs QS molecules using CV026 biosensor. FI with extracellular QQ activity were tested for AHL enzymatic degradation of 30 μM of 3-Oxo-C6-HSL and evaluated for their QQ capacity against AHLs QS-signals produced by *Aeromonas* spp., *Vibrio* spp., *Photobacterium damselae*, *Tenacibaculum maritimum*, *Edwardsiela tarda,* and *Shigella sonnei* using a well-diffusion method and CV026 biosensor. The fish isolates' protection against *E. tarda* infection was performed using zebrafish larvae (*Danio rerio*). Larvae were treated once with the lyophilized extracts of FI314, FI436 and FI464 after mouth's opening (7dpf), for 2h at 28°C. The treated 10 dpf larvae were challenged by immersion with *E. tarda* at $1x10^8$ CFU mL^{-1}, and cumulative mortalities were registered between 16-24hours post-infection.

To elucidate the immune-modulatory properties of the QQ strains, head–kidney leucocytes from gilthead seabream were isolated and treated for 24h with extracts of FI314, FI436 and FI464 before stimulation with *E. tarda* ($5x10^6$CFU/mL). Different innate immune parameters – viability (propidium iodide), respiratory burst activity and phagocytosis – were evaluated using flow cytometry. Simultaneously, expression of immune-relevant genes (Hsp70, Cox-2, IL-1β, IL-6, IL-10 and Tnfα) were measured using real-time PCR.

(Continued on next page)

Results

We found out that ~12% of our fish-gut *Bacillus* spp. were able to interfere with synthetic AHLs signalling molecules. We further selected 10 isolates as producers of extracellular putative AHL-lactonase enzymes. Conjugating the QQ genomic profile, QQ bioactivities and molecular identification FI314, FI436 and FI464 were tested for their QQ capacity against natural AHLs produced by fish pathogens. We observed that *A. veronii* and *E. tarda* produce AHLs molecules detectable by *Chr. violaceum* biosensor, that were degraded when subjected to the extracellular extracts of fish-gut isolates FI314, FI436 and FI464. Moreover, when compared to the control (non-treated zebrafish larvae infected with *E. tarda*), FI extracellular compounds from FI314, increased the average survival rate of challenged larvae by 43% ($p<0.01$), and strains FI436 and FI464 increased the survival rate upon challenge by 50% ($p<0.001$).

Although, *Bacillus* spp. extracellular extracts did not stimulate the respiratory burst activity and cell viability, they remarkably increased pathogens' phagocytosis when the seabream leukocytes were exposed to *E. tarda*. Statistical analysis revealed that all extracts significantly increased ($p<0.001$) the engulfment of *E. tarda* 1h post-infection. In cells treated with the extracellular extracts, we observed an up-regulation of the immune genes associated with inflammation, including IL-1β, IL-6 and Cox-2, indicating a stimulus of the immune system. FI314 extracellular extract significantly increased the expression of IL-1β ($p=0.04$), IL-6 ($p=0.005$) and Cox-2 ($p=0.021$) and, FI436 and FI464 significantly increased IL-6 expression ($p=0.047$ and $p=0.009$, respectively).

Conclusions

Taken together our experiments revealed three promising fish-gut *Bacillus* spp. that produce extracellular molecules capable of quenching aquaculture pathogens' communication, protect fish from *Edwarsiella tarda* infection in an *in vivo* model and improve the immune system of gilthead seabream. Thus, the extracellular molecules from FI314 (*B. subtilis*), FI436 (*B. vezelensis*) and FI464 (*B. pumilus*) may be promising tools for disease control in aquaculture.

Funding: RAS, NP and NM are recipients of a PhD grant (SFRH/BD/131069/2017, SFRH/BD/138187/2018, SFRH/BD/137919/2018, respectively) from FCT; CRS has a scientific employment contract supported by national funds through FCT. Introduction

Meagre (*Argyrosomus regius*) is a migratory marine species with widespread distribution in the Mediterranean and eastern Atlantic and receiving currently special attention due to the need of species diversification in Mediterranean mariculture (Fernández-Alacid *et al*, 2019, Duncan *et al,* 2013; Parisi *et al,* 2014). In what concerns to its captive rearing performance, demonstrates a low feed conversion ratio (FCR — 0.9 - 1.2) (Monfort, 2010), high fecundity index of 380 780 ± 167 577 eggs kg^{-1} (Mylonas *et al*, 2013) and high growth rates (1.45 ± 0.02 % day, at 26°C) (Kounna *et al*, 2021). Because of its meat quality and consumer acceptance (Grigorakis *et al,* 2011; Duncan *et al,* 2013), is considered a promising species with the potential to become one of the most cultivated species in the Mediterranean region. However, the characteristics of its meat and growth performance will depend on the farming conditions and the respective production system.

The present study aims to evaluate the nutritional quality and biochemical profile of meagre (*Argyrosomus regius*) reared on a recirculation aquaculture system (RAS).

Material and Methods

This study was conducted in a marine indoor RAS at SEAentia (Peniche, Portugal), which is highly optimized to offer the best growth conditions of meagre, and in MARE - Polytechnic of Leiria (Peniche, Portugal) where samples processing and analysis were performed. Juvenile meagre with a mean body weight of 57.12 ± 8.39 g were sampled after 20 days being fed with a tailor-formulated fishfeed (SPAROS, Olhão, Portugal). Muscle samples from both fillets of ten individuals (n=10) were collected and kept at -80°C. After their lyophilization, samples were analyzed for: (i) total protein by the Kjeldahl method (AOAC, 2016); (ii) lipid content (Folch, Lees & Stanley, 1957), (iii) ash (incineration at 500°C, for 12 hours) and (iv) fatty acids profile by gas chromatography (GC-FID).

Results and Discussion

The author is working on this section, to further present the obtained results.

Introduction

Meagre (*Argyrosomus regius*) is a migratory marine species with widespread distribution in the Mediterranean and eastern Atlantic and receiving currently special attention due to the need of species diversification in Mediterranean mariculture (Fernández-Alacid *et al*, 2019, Duncan *et al,* 2013; Parisi *et al,* 2014). In what concerns to its captive rearing performance, demonstrates a low feed conversion ratio (FCR — 0.9 - 1.2) (Monfort, 2010), high fecundity index of 380 780 ± 167 577 eggs kg^{-1} (Mylonas *et al*, 2013) and high growth rates (1.45 ± 0.02 % day, at 26°C) (Kounna *et al*, 2021). Because of its meat quality and consumer acceptance (Grigorakis *et al,* 2011; Duncan *et al,* 2013), is considered a promising species with the potential to become one of the most cultivated species in the Mediterranean region. However, the characteristics of its meat and growth performance will depend on the farming conditions and the respective production system.

The present study aims to evaluate the nutritional quality and biochemical profile of meagre (*Argyrosomus regius*) reared on a recirculation aquaculture system (RAS).

Material and Methods

This study was conducted in a marine indoor RAS at SEAentia (Peniche, Portugal), which is highly optimized to offer the best growth conditions of meagre, and in MARE - Polytechnic of Leiria (Peniche, Portugal) where samples processing and analysis were performed. Juvenile meagre with a mean body weight of 57.12 ± 8.39 g were sampled after 20 days being fed with a tailor-formulated fishfeed (SPAROS, Olhão, Portugal). Muscle samples from both fillets of ten individuals (n=10) were collected and kept at -80°C. After their lyophilization, samples were analyzed for: (i) total protein by the Kjeldahl method (AOAC, 2016); (ii) lipid content (Folch, Lees & Stanley, 1957), (iii) ash (incineration at 500°C, for 12 hours) and (iv) fatty acids profile by gas chromatography (GC-FID).

Results

Muscle proximate composition showed: 19.8 ± 0.6% of protein; 3.5 ± 1.1% of total lipid content; 1.2 ± 0.1% of ash and 75.2 ± 1.3% of water content. Analysis of fatty acids showed the most abundant n-3 fatty acids were eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) with a percentage of abundance of 8.21 ± 0.33% and 13.76 ± 0.79%, respectively. Linoleic acid was the most abundant n-6 fatty acid (8.77 ± 0,28%). The value of hypocholesterolemic and hypercholesterolemic fatty acids ratio was 2.3 ± 0.0. Both atherogenicity index (AI) and thrombogenicity index (TI) were also assessed showing respective values of 0.5 ± 0.0 and 0.3 ± 0.0. Muscle fillets composition presented a ratio n-3/n-6 of 2.4 ± 0.1.

Discussion and Conclusion

Our study showed that SEAentia's meagre has a high quality fillet due to a low fat and high protein profile. Moreover, it showed a very healthy fatty acids profile. This fact shows that meagre is a suitable species for RAS production, having been proven that SEAentia's RAS production system and operations are adequate for meagre growth, guaranteeing its flesh quality.

Introduction

The European seabass (*Dicentrarchus labrax*) is one of the most extensively cultured species in European aquaculture productions. Environmental effects on the well-being of organisms and especially in teleost have been demonstrated within a broad range of studies. In particular, the temperature is known to control every biological function in such organisms [1], especially during early larval development, and can have both direct effects, such as on the growth rate, the development of skeletal deformities, but also indirect effects, such as on sex differentiation and the final sex ratio of the populations in fish with temperature-dependent sex determination system (TSD). Previous studies in the European sea bass have shown the existence of TSD [2, 3]although suspected in several species, is thought to be evolutionarily unstable and has been proven in very few cases. In the European sea bass, temperature is known to influence the sex ratio. We set up a factorial mating, producing 5.893 individuals from 253 full-sib families, all reared in a single batch to avoid any between-families environmental effects. The proportion of females in the offspring was 18.3%, with a large variation between families. Interpreting sex as a threshold trait, the heritability estimate was 0.62 +/- 0.12. The observed distribution of family sex ratios was in accordance with a polygenic model or with a four-sex-factors system with environmental variance and could not be explained by any genetic model without environmental variance. We showed that there was a positive genetic correlation between weight and sex (r(A. Besides the significance of sex control in aquaculture influenced by environmental factors, embryonic and larval stages represent one of the most critical periods to ensure high performance and superior quality in the subsequent developmental phases of the life cycle. Key developmental events occur early in development and are influenced by external parameters such as stress, temperature, salinity, and photoperiod. Any failure may cause malformations, developmental delays, poor growth, and massive mortalities.

Here we report the influence on miRNAs at three different temperatures during the European sea bass development.

Material and methods

Ethical approval for the study was obtained by the relevant Greek authorities (National Veterinary Services) under the license No 255368 (ΑΔΑ: 6Λ4Σ7ΛΚ-ΩΜΥ). Samples of larvae were collected at the following developmental stages: mouth opening, flexion, all fins, and metamorphosis, and total RNA extraction was carried with the use of the Nucleospin miRNA kit (Macherey-Nagel, Duren, Germany) following the manufacturer's instructions. miRNA libraries were generated using the NEBnext multiplex Small RNA Library Preparation and sequenced over 4 lanes on the Illumina NextSeq sequencing platform at the Microchemistry laboratory of Forth, Crete, Greece. Samples at the same developmental stages were also collected for eye development evaluation and were preserved in 4% formaldehyde:1% glutaraldehyde until histological analysis. For skeletal deformities evaluation, during the samplings, which were conducted at the flexion and the metamorphosis stages, specimens were anesthetized with ethylene glycol-monophenylether (Merck, 0.2–0.5 ml l_ 1), fixed individually in phosphate-buffered 5% formalin, and stored in the dark at room temperature before staining.

Results

In total, 654 million sequencing reads were obtained, with an average of 13 million reads per sample. A correlation matrix based on read counts was generated (Fig.1a) was generated. Expression profiles of all stages at 15°C, 17°C, and 20°C were assessed (Fig.1b). Stages are ordered according to their respective developmental time course confirming correct staging during sampling.

Temperature differences were detected mainly between 15°C versus 20°C (203) and 17°C versus 20°C (145) in the metamorphosis stage. The flexion stage reveals to be of special interest since no differential expression was detected between the temperature 15°C and 20°C but between 15°C and 17°C (321) as well as between 17°C and 20°C (299). The same phenoma has been observed in the development of rod cells in the eye as well as in the lower jaw elongation.

(Continued on next page)

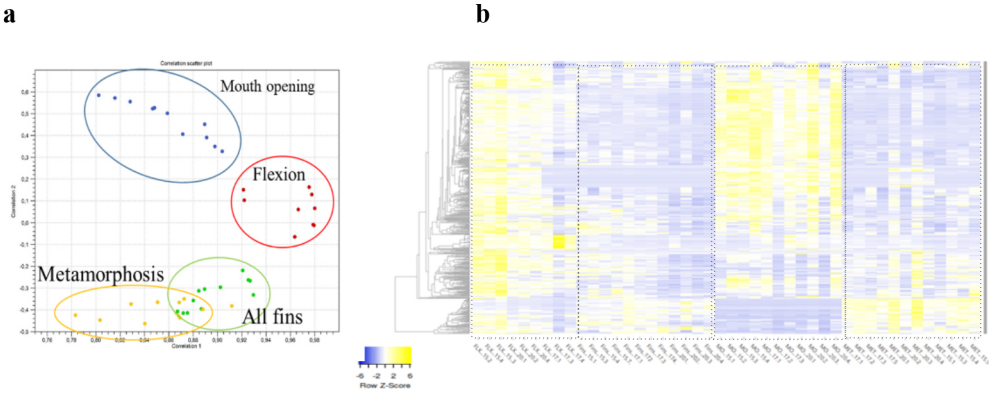

Fig. 1a Correlation matrix of obtained miRNA expression matrix. **1b** Heatmap showing the expression profile of all miRNAs of all stages at 15°C, 17°C and 20°C.

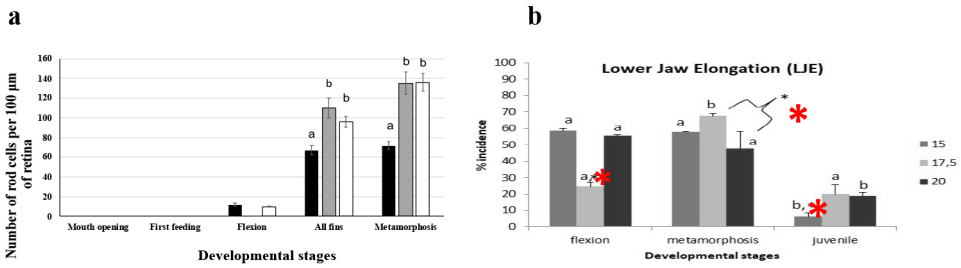

Fig.2a Mean (±SEM) number rod cells in the different developmental stages at the three different temperatures. **b** Mean (± SEM, n=2) incidence (%) of Lower Jaw Elongation deformity in response to rearing temperature. The existence of significant differences is indicated by * (=P<0.05). Different letters indicate significantly different means (between sampling times within temperature groups.

Discussion and conclusions

The present study showed clearly the importance of miRNA concerning temperature changes in early developmental stages. The main stages being influenced by temperature are the metamorphosis as well as the flexion stage. Identified miRNAs are found to be largely regulating genes belonging to the immune response. This finding may indicate that changes in temperature influences the immune system. The particularity of the flexion stage may comprise the first indications that during this stage the gender may be determined since identified miRNAs are found to regulated sex-determining genes. Future research will be focused on the evaluation by functional studies of expressed differentially miRNAs according to temperature changes and their putative target.

Introduction

Gilthead sea bream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*) are the most important marine farmed fish in the Mediterranean. In recent years, different companies have initiated breeding programmes and the proportion of genetically improved stocks has increased.

Understanding population structure and genetic diversity within and between wild (*W*) and farmed (*F*) populations is of paramount importance to develop optimal strategies for the conservation of *W* populations and to achieve sustainable aquaculture production of Mediterranean seabream and seabass. In particular, the success of any breeding programme critically depends on the way in which the base population of breeders is built and on the control of inbreeding (or equivalently, the effective population size, N_e) once selection programmes are running. Also, although little is known on escapees from seabream and seabass farms, they pose an ecological risk of transferring diseases to wild fish and may cause undesirable genetic effects in native populations due to interbreeding.

Recently, a combined 60K SNP array for both species has resulted from the collaboration between the EU projects MedAID and PerformFISH and is an essential tool for genetic studies for estimating N_e and relationships between populations (Peñaloza et al. 2021). The objectives of this study were to i) identify the extent of *W* and *F* population stratification within species considering the geographic origin of individuals; and ii) assess the genetic status of *W* and *F* populations through the estimation of current N_e.

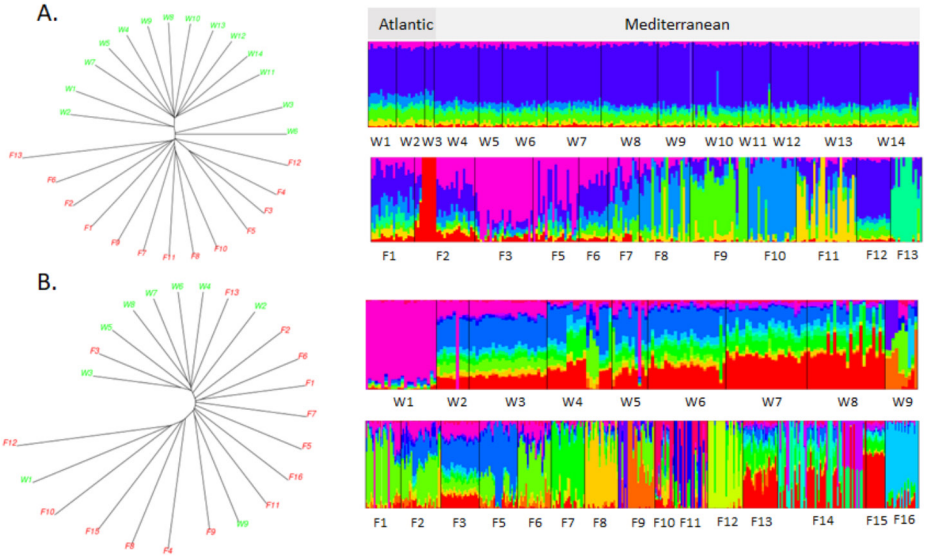

Fig.1. Evolutionary dendrograms (left) and admixture plots (right) for seabream (A) and seabass (B) populations analysed. Populations are numbered in accordance to the geographic proximity from West to East (*W*: in green in the dendrograms; *F*: in red in the dendrograms).

(Continued on next page)

Material and Methods

Samples were collected from *W* and *F* populations of both species from East to West Mediterranean. Three populations of seabream from the Atlantic were also sampled. For seabream, SNP genotypes were available for 462 individuals sampled from 14 *W* and 12 *F* populations. For seabass, SNP genotypes were available for 516 individuals collected from 9 *W* and 15 *F* populations. After quality filtering the total number of SNPs available for analysis was 25,319 (seabream) and 22,507 (seabass). Population structure was assessed through (i) Principal Component Analysis (PCA) using the software PLINK (Purcell et al. 2007) and a R script; (ii) distant-based clustering methods using an R-package; (iii) ancestry clustering using ADMIXTURE (Alexander and Lange, 2011); and (iv) pairwise F_{ST} using Metapop2 (López-Cortegano et al. 2019). Current estimates of N_e were obtained from linkage disequilibrium between independent SNPs as implemented in the software NeEstimator (Do et al. 2014).

Results

Results from PCA did not show a clear differentiation between *W* and *F* populations, and showed a considerably dispersion within and between populations. However, clustering methods and F_{ST} revealed a clear differentiation between *W* and *F* populations. Despite the little differentiation among *W* populations, Atlantic/Mediterranean (seabream) and West/East Mediterranean (seabream, seabass) patterns were detected (Fig. 1). In general, N_e was large (> 1000) for *W* and small (< 100) for *F* populations of both species, with some exceptions. Farmed populations were more heterogeneous and presented in many cases critical values of N_e. Average F_{ST} was lower between *W* (0.020 for seabream, 0.047 for seabass) than between *F* (0.033 for seabream and 0.051 for seabass) populations.

Discussion

In general, our results are in line with those obtained in the EU AquaTrace project (https://cordis.europa.eu/project/id/311920/reporting/es) that used a much more limited number of SNPs to explore population structure and genetic variability of wild and farmed populations of both species (about 1,200 for seabream and 2,700 for seabass). They also suggested that wild populations are more similar among them and present higher genetic variability than farmed populations, and that there are subtle levels of population structure in both species. The low differentiation between wild populations indicates that considerable gene flow exists, facilitating sampling decisions when base populations are established. These results also indicate that there are no specific requirements for conservation of wild populations. The low N_e estimated for some farmed populations highlight the need of applying measures to increase this size to ensure the sustainability of the breeding programmes. Finally, since farmed populations differ from wild populations, escapees from farms should be avoided and only wild broodstock should be used if fish stocking were done. In summary, this report evidence the high potential of the genomic tool developed by the MedAID project (i.e., the MedFish SNP array) for establishing and monitoring breeding programmes in aquaculture. This is the first time a population genetic analysis in these species has been carried out with such a high number of SNP markers.

Introduction

Until a couple of years ago, the flat oyster (*Ostrea edulis*) population was thriving in the Limfjorden (Denmark), with a sustainably regulated fishery with landings up to 320t (2018/2019) and the identification of new populations. Although, the pathogen *Bonamia ostrea* had been detected from national surveys in flat oyster individuals in 2014 in aquaculture sites and in 2017 in the wild, no mass mortality events had been observed. But in late 2019, fishermen reported the first event of mass mortality in some fishing areas. *Bonamia* outbreaks are known for causing up to 70-90% mortality of flat oyster populations. It was not the first time since the recolonization of the Limfjorden 170 years ago by flat oysters that *Bonamia* had been detected. During this period, millions of flat oysters from several places in Europe were imported to supplement the local population for exploitation. These imports potentially have led to genetically mixed populations, and were the cause of the first introduction of *Bonamia* in the Limfjorden in 1980 from an oyster batch from France. The infected oysters were removed, however, no surveys were conducted until 1996 when a national monitoring program started, lasting until 2018. During 1996-2014, no *Bonamia* was detected and the Limfjorden was declared *Bonamia sp*. and *Marteilia refringens*-free.

After the 2019 mass mortality event, we conducted a new sampling program and found that *Bonamia* was present and spreading to new areas. At the same time, specimens were sampled for genetic diversity. Simultaneously, the sole flat oyster hatchery in Denmark implemented a new strategy to produce *Bonamia*-free spat and preserve high genetic diversity in the offspring: i) implementation of new biosecurity measures, ii) establishment of broodstock with new tested specimens from areas where *Bonamia* had not been detected, iii) collaboration with fishermen for mass mortality monitoring, and iv) a genetic program for establishing the broodstock genetic diversity, effective population size (Ne) and effective number of breeders (Nb). In parallel, alongside the reliable spat production protocol already developed for aquaculture, new protocols for spat-on-shell production for restoration were developed in the hatchery.

Material and methods

Molecular methods were used for screening of the oysters samples from the wild and in the hatchery: a duplex Real Time PCR method for *Bonamia* sp and *Marteilia refringens* (Canier et al. 2020). Oysters from the broodstock were anesthetised (Suquet et al. 2010) for gill sampling for both genetic diversity, effective number of breeders and pathogen analysis prior entering the hatchery and post reproduction. The population structure of the Limfjorden's flat oyster along its distribution range will be studied using low-coverage whole genome sequencing data. Western Europe and Scandinavian populations are included in this DNA-sequencing dataset, which will permit "global-to-local" scales of comparison. Using seventeen microsatellite markers, we gathered genotypic information for the entire broodstock (of 2019, 2020, and 2021) and assigned offspring with high confidence.

Results and discussion

The presentation will describe the different tools put in place to produce *Bonamia*-free spats, ensure genetic diversity of the broodstock, monitor wild oyster population genetic diversity, mapping of wild population biomass fluctuation and *Bonamia* infestation, and consolidate and develop hatchery protocols. Ensuring harvesting of new *Bonamia*-free broodstock in the Limfjorden is challenging due to the rapid spread of the disease and the chronic nature of the pathogen. Biosecurity measures and repeated screenings are necessary to maintain disease-free hatchery compartments. The effective number of breeders (Nb) and effective population size (Ne) are important parameters for a sustainable spat production especially for restoration. The developed protocols for spat-on-shell production for restoration was successful and scalable to large production. Finally, with the new construction of a large-scale commercial hatchery including a quarantine, biosecurity measures and high water quality and treatment, the establishment of a secure *Bonamia* free compartment in the Limfjorden is tangible.

Introduction

Jellyfish blooms and their consequences have been of increasing interest over the last decades, often highlighting challenges for local economies (Purcell et al., 2015). More recently, studies started investigating new opportunities and the potential use of jellyfish for a great variety of purposes such as human consumption, aquaculture feed, cosmetics, or microplastic filter (Torri et al., 2020; Prieto et al., 2018). For example, *Aurelia aurita*, has been presented as a crispy product with a potential gastronomic interest (Pedersen et al., 2017). This new marketing of jellyfish drives the interest in jellyfish culture and the possibility to produce fast-growing biomass for economic purposes. Understanding jellyfish ecology is crucial to determine optimal culture conditions as studies have shown that there are differences between closely related species (Hubot et al., 2017). In this context, the present study tested the effect of different temperature and salinity regimes on the rearing success of *Aurelia solida*.

Material and Methods

Mesocosm experiments investigated the simultaneous effects of temperature and salinity on the rearing of the jellyfish *Aurelia solida*. Experiments were performed on two different life stages, polyps and ephyra, at the mesocosm system (MOSS) and laboratory facilities at the Madeira research unit of MARE – Marine and Environmental Research Centre, located at Quinta do Lorde Marina, Madeira, Portugal. Temperature and salinity (S) levels represented values typically found for the species across their distributional range and covered temperatures between 10 and 28°C and salinities of 20 up to 40. Survival, asexual reproduction of polyps and growth of ephyra were monitored for several weeks to determine successful rearing conditions for *A. solida*.

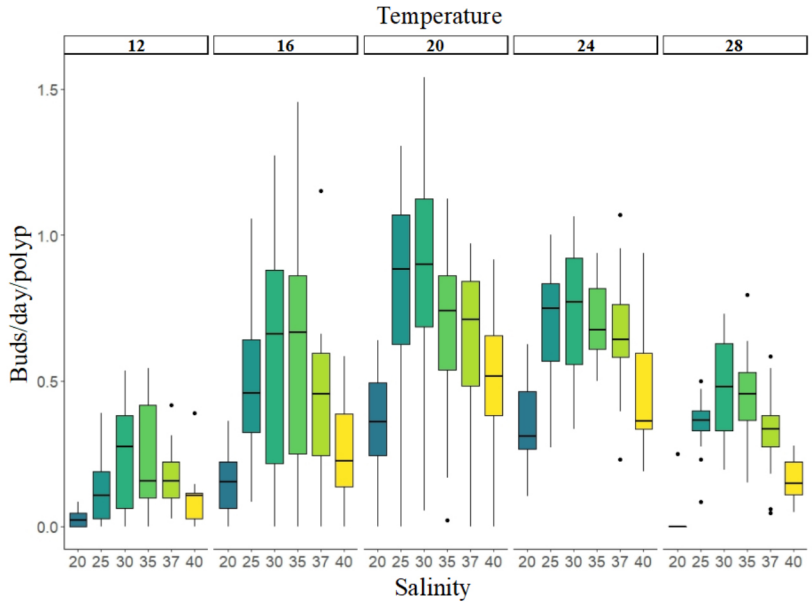

Fig. 1. Daily bud production of *A. solida* polyps kept at 30 different combinations of temperature (12, 16, 20, 24, and 28°C) and salinity (20, 25, 30, 35, 37, and 40).

(Continued on next page)

Results

Survival of the *A. solida* polyps was generally high (83-100%) in almost all treatments. Only the combination of the highest temperature (28°C) and lowest salinity (20), resulted in 0% survival. Polyps showed asexual reproduction in all combinations but produced the most at 20°C and 30S (Figure 1). Strobilation occurred mainly at 16°C and 35S.

Ephyrae kept at lower temperatures (10 and 15°C) showed the highest survival rates. However, preliminary results suggest that the highest growth rates were reached at 20°C in combination with 20 and 35S.

Discussion and Conclusion

The best conditions for asexual reproduction in *A. solida* polyps was at intermediate temperatures (20°C) and lower than marine salinities (25 and 30). In contrast, although ephyrae growth was highest at intermediate temperatures as well (20°C), it increased at lower salinities (20). Comparing these results to studies on other *Aurelia* species, we can see differences in optimal rearing conditions regarding temperature and salinity depending on species: *Aurelia aurita* showed highest budding rates at higher temperatures (28°C; Pascual et al., 2015), and *Aurelia labiata* showed higher budding rates at lower temperatures (7 and 10°C; Purcell, 2007). These comparisons highlight the need for laboratory studies for individual species to advance our current understanding on best rearing conditions for the particular species in order to optimize jellyfish culture.

Introduction

Marine sponges are one of the most important sources of bioactive compounds used in medicine, industry and as nutraceuticals. As sessile organisms, sponges have developed chemical defense mechanisms to avoid covering by algae, bacteria and infectious microorganisms (Thoms et al., 2006). The Mediterranean sponge species *Chondrosia reniformis* is of special interest due to its high collagen content (Swatschek et al., 2002). However, a large amount sponge biomass is required to obtain a high yield of collagen. To avoid overharvesting of natural sponge resources special culture techniques need to be developed. However, to date no land-based cultivation and high mass production of *C. reniformis* has been possible due to their sensitivity to transportation and high demands on aquaculture conditions (Nickel and Brümmer, 2003).

The present study aims to determine optimal conditions in recirculating aquaculture system (RAS) to allow *C. reniformis* fragments to grow and create a sustainable source of sponge biomass with commensurate maximized collagen production.

Materials and methods

C. reniformis were obtained by SCUBA from the coast of the Conero Promontory (Italy) in the Adriatic Sea and subsequently raised in a recirculation aquaculture system at the Alfred Wegener Institute, Bremerhaven (Germany).

In a first experiment sponge fragments were cut into fragments and glued on an artificial substrate before the effect of nutrient content, light and water drain position on sponge attachment, survival, growth and collagen content were examined at specific intervals. They were fed a mixture of commercial liquid diet and microalgae.

In a second experiment, feeding strategies and feed types were tested. Sponge fragments were fed with either the commercial liquid diet for filter feeders or a novel formulated diet. Sponges were fed once a day for four weeks, then at increased feeding frequency for another four weeks after sacrificing half of the respective fragments. Attachment, fragment growth, survival rate and collagen content were measured at the end of the experiment. Fragment growth was measured photographically. Collagen content was detected by the company KliniPharm GmbH. Collagen was dissolved by alkaline hydrolysis and the solution was analyzed by quantitative color reaction (Roti®-Quant Universal).

Results

In the first experiment, fragments remained attached and after a week began to encrust the substrate. Mean fragment growth curves measured in cm^2 initially increased, but decreased again after one to two months. Mortality was 26.1% in total. Best survival rates were detected under blue light and tank drain at the bottom. Nutrient content (ammonia, nitrite, and nitrate) fluctuated markedly throughout the experiment. Collagen content ranged from 5% to 25% with twenty percent of samples having less than 10% collagen.

In the second experiment, attachment and survival rate was high with 81% and 91%, respectively. Nutrient levels remained low throughout the experiment. A bespoke *C. reniformis* diet was used (diet 1). On average sponge fragments fed with diet 1 had a higher collagen content than those fed with diet 2 (commercial diet) (Fig. 1). After four weeks fed once a day sponge collagen content ranged from 11% to 30% with sixty percent of samples having less than 20% collagen. After another four weeks fed at increased feeding frequency sponge collagen content ranged from 19% to 80% with half of samples exhibiting a collagen content above 30%.

Discussion and conclusion

To avoid high mortality rates of sponge fragments the aquaculture system has to provide stable values of abiotic factors. To increase the possibility of physical adaptation to the new hydrodynamic patterns, moving of fragments during experiments was avoided, hence, measurements of growth rely on two values (at the start and end of experiment).

(Continued on next page)

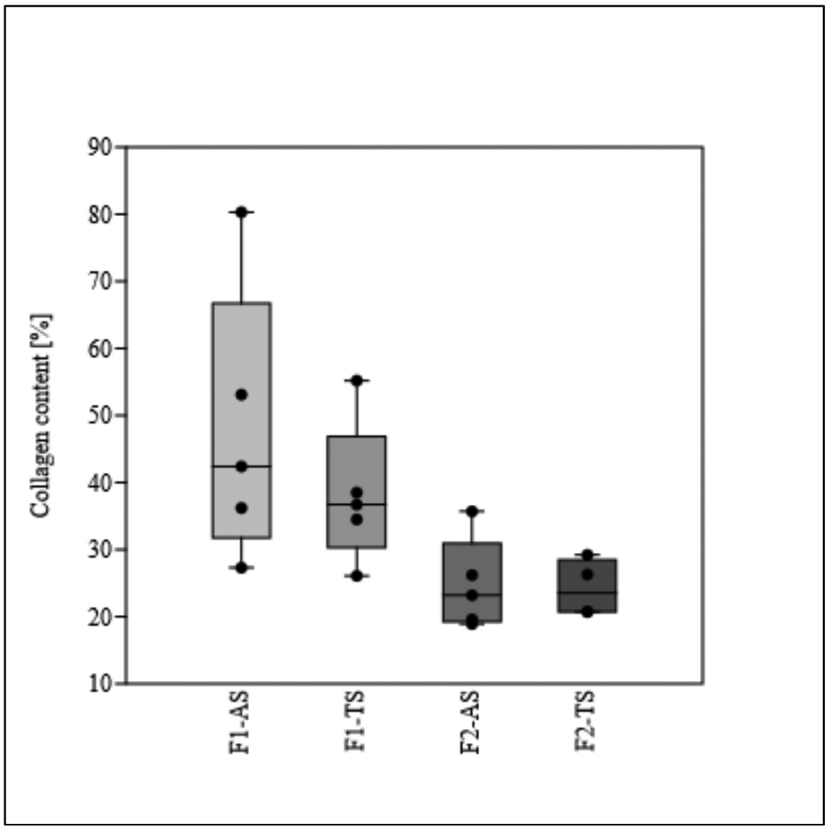

Fig.1 Boxplot of collagen content [%] (F1 = diet 1, F2 = diet 2, AS = artificial substrate, TS = bowl made of clay)

One of the important parameters for successful land-based aquaculture is an optimal feed supply and nutrient content. Additionally, sponge growth is dependent on the amount of feed supplied; high loads of feed can lead to blockage of the ostia and too low feed supply in starving of sponge fragments (Wilkinson, 1983).

In conclusion, an aquaculture system with optimized rearing conditions including stable nutrient water retreatment processes and an optimal feed is essential for survival, attachment, growth, amount of collagen content.

Email: Melanie.schiffer@awi.de

Background
Marine sponges are highly valuable sources of bioactive compounds with pharmaceutical potential. Over 55% of almost 300 pharmacological marine products at different stages of clinical exploration are of sponge origin. Among these sponges *Chondrosia reniformis* and *Axinella polypoides*, two Mediterranean sponge species, are of special interest due to the high concentration (> 30%) of type I collagen in the sponge biomass and a broad-spectrum of antibiotic activities, respectively.

One major constraint regarding the industrial application of bioactive substances from marine sponges is a sufficient supply of sponge biomass to process the purified compound. However, removal of large quantities of biomass from the marine habitat might have major ecological consequences. Land-based aquaculture represents an interesting economic alternative to grow marine sponges for production of bioactive compounds. Optimal species-specific conditions for cultivation can be employed in closed recirculating aquaculture systems (RAS) providing sustainable and reliable production and allowing location-independent production of sponge biomass.

Objectives
The aim of the project MedSpon is to develop and establish an aquaculture process for *C. reniformis* and *A. polypoides*, with knowledge from mariculture, by successfully breeding sponge fragments to serve as a source of secondary metabolites. MedSpon will drive the supply of new secondary metabolite sources through convenient recirculating aquaculture system (RAS) conditions for sponge fragments, creating a sustainable, optimised, source of sponge biomass. Strong wild populations of the target species will be studied at Italian field sites, to assess habitat specifications and provide information for mass production in RAS under controlled conditions. Abiotic factors and nutrition will be tested to create optimal rearing conditions for bioactive content. Formation potential of bioactive compounds and associated microbial communities with different sponge species/rearing conditions will be verified to create the maximal bioactive content with highest quality.

Task
For the experiments, the abiotic factors such as temperature, light, flow and nutrient content in RAS will be adapted to the conditions of the native habitat. The sponge individuals of the two species will be cut into similarly sized fragments and are allowed to attach to a clay pot as substrate. Preliminary work has developed a self-designed novel formulated diet for the species *C. reniformis*. Therefore, experiments will concentrate on different feeding strategies. For experiments with fragments of the species *A. polypoides* the parameters light (different spectra), temperature, flow and the filter system will be changed in experimental approaches. Furthermore, three different feeds will be offered to the fragments. Molecular methods (Amplicon sequencing) will be used to determine the symbiont composition in each of the two sponge species in relation to the factors tested in the experiments.

Project consortium
Polytechnic University of Marche, Italy: UNIVPM will co-operate with other partners providing samples for sponge aquaculture ex-situ and produce sponge biomass from sponge aquaculture in-situ to optimize sponge aquaculture in eutrophic and oligotrophic areas. With sound experience in experimental sponge cultivation in-situ and in habitat restoration, UNIVPM activities will be transversal to the other partners.

Alfred Wegener Institute (AWI), Germany: The tasks of AWI will be the detection and adaption of special suitable conditions in a land-based recirculating aquaculture system for cultivation and reproduction of the sponge species with the aim of building up a sustainable source of sponge biomass with a maximized yield of target metabolites.

SpongiPharm EPE, Greece: Possessing the necessary preparatory and analytical laboratory infrastructure, SpoPha will establish primary antibiotic screening of the sponges and their extracts. Sponge candidates will then be identified, and living sponge samples forwarded to the consortium partners for in-vitro sponge culture further developments.

KliniPharm GmbH: KP will discover novel antibiotic principles in sponges. Most interesting is an enzyme based antibiotic activity, e.g. in *Axinella polypoides*, unknown in animals. It blocks the growth of many bacteria of the WHO list of priority pathogens for research and development of new antibiotics.

FROM AQUACULTURE TO AQUACULTURE: PRODUCTION OF THE FISH FEED ADDITIVE ASTAXANTHIN FROM AQUACULTURE SIDESTREAMS IN *Corynebacterium glutamicum*

Ina Schmitt*, Florian Meyer, Nadja A. Henke, Petra Peters-Wendisch and Volker F. Wendisch

Genetics of Prokaryotes, Faculty of Biology & CeBiTec, Bielefeld University, Bielefeld, Germany
E-Mail: ina.schmitt@uni-bielefeld.de

Circular economy holds great potential to minimize the use of finite resources and reduce waste formation by the creation of closed-loop systems. Turning biotechnological production chains into sustainable, circular processes offers the possibility to contribute to climate protection and global waste reduction.

Aquaculture generates nutritious side streams from residual fish feed and fish excrements that may be used for bacterial fermentation processes. Fermentation processes are established in the biotechnological industry creating value from products such as food and feed amino acids or non-animal protein.

Corynebacterium glutamicum is used in the million-ton-scale fermentative amino acid production (Wendisch, 2020), but has also been engineered for production of functionalized amines, diamines, organic acids, alcohols or isoprenoids (Mindt et al., 2020). *C. glutamicum* naturally synthesizes the yellow C50 carotenoid decaprenoxanthin and was engineered for the production of the red C40 carotenoid astaxanthin (Henke et al., 2016; Henke & Wendisch, 2019). Carotenoids exhibit antioxidative and ROS quenching properties. They are used as supplements for animal feed in salmonid and shrimp aquaculture, in poultry farming and as food colorants.

C. glutamicum grows on a number of carbohydrates and has been engineered to utilize several alternative growth substrates to enable a flexible feedstock concept (Wendisch et al., 2016).

C. glutamicum is a very suitable production host for the circular bioeconomy as large scale processes are established and can be scaled and due to its flexibility regarding utilization of various feedstocks and the ease of metabolic engineering towards a broad spectrum of target products.

In this study, we aimed to utilize an aquaculture side stream (AQ) for production of astaxanthin. Previously, we have engineered *C. glutamicum* for overproduction of astaxanthin (Henke et al., 2016; Henke et al., 2018; Henke & Wendisch, 2019). Here, we studied if *C. glutamicum* can utilize components present in AQ. First, AQ did not inhibit growth of *C. glutamicum*. Second, AQ could replace a number of components of the mineral salts medium used to support growth of *C. glutamicum*, e.g., phosphorus, calcium, chloride, magnesium and sulfate ions as well as biotin and trace elements. Third, we could show that the standard growth medium supplemented with AQ even enhanced production of the native decaprenoxanthin as well as production of astaxanthin. The AQ improved astaxanthin production was scaled-up to 2 L bioreactor fermentations.

Thus, we have gained a proof-of-principle for production of astaxanthin from aquaculture sidestreams for use as feed additive in aquaculture, e.g. of salmonids or shrimp. We will discuss the potential and limitations of this aquaculture based approach to circular economy.

[2]WMR - Wageningen Marine Research, P.O. Box 77, 4400 AB Yerseke, The Netherlands

To reduce fishing on wild mussel beds Dutch mussel growers increasingly obtain mussel seed (juvenile mussels) through so-called seed mussel collectors (SMCs). A major disadvantage of the current SMC-systems is the increase in costs compared to the traditional fishing of mussel seed from natural reefs. In this study, we tested whether biodegradable (starch-based) socks filled with cockle shells can provide a cost-efficient and sustainable alternative to the regular nylon seed collectors.

While mussel seed is normally harvested from the SMCs and then seeded separately onto culture plots, these biodegradable SMCs can be harvested and seeded in their entirety. We hypothesized that leaving the mussel seed attached to the biodegradable SMC when seeded, will reduce losses caused by predation and hydrodynamic forces. Therefore, mussel seed may be seeded at an earlier and smaller stage and the mussel production will increase.

To examine how the seeding method in combination with seeding time will influence mussel production, a field experiment was carried out on a subtidal culture plot in the Dutch Oosterschelde estuary. Mussels were transplanted in three configurations namely, (1) attached to the intact biodegradable SMC, (2) attached to the biodegradable SMC but with a cut open sock and (3) detached from the SMC and only seeded with loose shells. This experiment was deployed in July when the average mussel seed length was around 1 cm and in August when length was around 2 cm. In addition, a laboratory experiment was conducted to better understand the predation rate by shore crabs and sea stars when mussels are seeded in these three configurations.

After nine months mussel production of the mussels seeded in August was significantly higher when mussels were still attached to the intact biodegradable SMC. Seeding of mussels at an earlier stage, with smaller mussels, was not feasible because of high predation rates by crabs.

Our results show that biodegradable shell-socked SMCs promises to be an effective method to increase mussel production. The next step will be to scale up and examine how different seeding configurations will influence mussel production.

EUROPEAN SEABASS (*Dicentrarchus labrax*) ALLERGENICITY AND FISH QUALITY AFTER EDTA SUPPLEMENTATION

D. Schrama[1,2,*], C. Raposo de Magalhães[1,2], Annette Kuehn[3], S. Engrola[2], P.M. Rodrigues[1,2]

[1]Universidade do Algarve, Campus de Gambelas, Faro, Portugal

Introduction

Allergies to fish are a significant public health concern throughout the world and show sensitization prevalence's of up to 2.9% in the general population [1]. The main fish allergen is β-parvalbumin; a small and highly stable muscle protein, and responsible for 95% of the allergic responses. Fish parvalbumins are highly conserved proteins, which bind bivalent ions, like calcium or magnesium. Previous works showed that EDTA is a calcium chelator and might reduce the IgE-binding capacity of the main fish allergen, due to a structural rearrangement resulting in an apo-form. The objective of this study was to diminish the allergenic potential of European seabass through the supplementation of EDTA in fish diets.

Methodology

Twenty-two European seabass juveniles with an initial body weight (IBW) of 174 ± 1.29 g were reared in 500L conical tanks for 98 days. Four different experimental diets were tested (in triplicates) namely, Control (CTRL, commercial diet without EDTA supplementation), 1.5, 3 and 4.5% of EDTA supplementation in the commercial diet, which will be referred as EDTA1.5, EDTA3 and EDTA4.5, respectively. Fish were reared under optimal environmental (dissolved oxygen above 5 mg L^{-1}) and natural photoperiod conditions. Fish were fed twice a day by hand, *ad libitum*. All fish were lethally anaesthetized with tricaine methanesulfonate (MS-222) and sampled for biochemical and quality analysis. Proteins from muscle samples were used for allergenicity quantification by sandwich IgE-ELISA using serum from fish allergic patients.

Results

At the end of the trial, the fish final body weight (FBW) was not significantly affected by any of the diets (Table1). However, feed conversion ratio (FCR) was negatively affected by the EDTA4.5 diet when compared to CTRL (one-way ANOVA, followed by post-hoc Tukey, $p<0.05$).

Fish quality, muscle pH and *rigor mortis* index were measured during the first 72 h *post-mortem*. Muscle pH decreased with time without showing significant differences between the experimental diets. Fish reached almost a full *rigor* index 24 h *post-mortem* with significant differences at T1 (1 hour *post-mortem*) and T48. As mentioned, supplementation with EDTA would induce the apo-form of parvalbumin, a less allergenic structure due to the blocking of the functional epitopes of the protein. The analysis of IgE-reactivity using fish allergic patients' serum (n=6) showed no significant differences in the modulation of parvalbumin and therefore supplementation with EDTA up to 4.5% seems not to reduce the allergenicity of European seabass.

Conclusion

Dietary EDTA supplementation preserved fish quality as edible food product. IgE-ELISA showed that the supplemented chemical into fish feed was unable to modulate fish allergenicity.

As future works a different rearing technique will be tested to reduce the allergenic potential of European seabass. Also, different *post-mortem* treatments will be studied in the two mean Mediterranean species, European seabass and gilthead seabream.

Table1. Growth performance parameters of European seabass fed the experimental diets (CTRL, EDTA1.5, EDTA3, EDTA4.5).

Diet	FBW (g fish $^{-1}$)	FCR
CTRL	367 ± 12	1.50 ± 0.09*
EDTA1.5	363 ± 15	1.64 ± 0.03
EDTA3	345 ± 16	1.64 ± 0.05
EDTA4.5	339 ± 13	1.67 ± 0.05*

FBW – Final body weight, FCR – feed conversion ratio. Data are represented by mean ± standard deviation.
* Significant differences by one-way ANOVA followed by post-hoc Tukey ($p<0.05$)

Introduction

Energy evaluation of fish-feeds and ingredients is mostly done on digestible energy (DE) basis. Calculation of the optimal dietary DE content assumes a constant energy utilization efficiency of DE for growth (k_{gDE}). However, k_{gDE} alters with dietary macronutrient composition (Schrama *et al*., 2012; Glencross *et al*., 2017; Rodehutscord and Pfeffer, 1999). With the current and future diversification of ingredients use in fish-feeds, more carbohydrates will be included resulting in more variation in macro-nutrient composition. Energy evaluation on net energy (NE) basis can overcome the shortcomings in DE evaluation. For implementing a NE system for fish, the energy utilization efficiencies of each macro-nutrient (protein, fat and carbohydrate) needs to be estimated. This study assessed the variation in these energy utilisation efficiencies of digested protein, fat and carbohydrates between different fish species: tilapia, trout, African catfish, barramundi, carp, striped catfish and snakehead.

Materials and methods

For this study, the outcome of a meta-analyses on tilapia and trout (Schrama et al., 2018) and four separate experiments on African catfish (71.6 g), carp (28.9 g), snakehead (29.1g), and striped catfish (29.1 g) were used. The experiments had a 4×2 factorial design with three replicates per treatments. In each experiment, four diets were formulated with 2 carbohydrates levels (low vs high) and 2 fat levels (low vs high) and applied at 2 feeding levels. This design aimed to achieve the large contrast in the intake of digested protein, fat and carbohydrates. Data about digestibility and energy balance were collected to conduct the multiple regression between energy retention (*i.e*., growth response) and the intake of digested protein, fat and carbohydrates.

Results

Average over feeding levels and dietary fat levels, increased dietary carbohydrates level decreased the final body weight of African catfish, carp, striped catfish and snakehead by 29, 13, 16 and 10 g, respectively (Table 1). By conducting the multiple regression between retained energy and digested protein, fat and carbohydrates intake, the energy utilisation efficiencies were quantified (Fig 1). Digested fat is used most efficiently compared to digested protein and carbohydrates among studied fish species. The largest variation was found in the utilisation efficiency of digested carbohydrates for growth (Fig 1). The utilisation efficiencies of digested fat were less variable between species than that of digested protein.

Discussion and conclusion

The limited growth by increasing dietary starch on African catfish, carp, striped catfish and snakehead is similar to observations on barramundi (Glencross et al., 2017), Nile tilapia (Schrama et al., 2012) and rainbow trout (Rodehutscord and Pfeffer, 1999). The energy utilisation efficiencies of digestible protein and fat are comparable between studied fish species. This indicates that the ability to use protein and fat for growth is comparable between studied fish species. The energy utilisation efficiencies of digested protein was highest in African catfish, compared to other studied fish species, which needs further studies to explain. The largest variation in the energy utilisation efficiency of digested carbohydrates indicates the large difference in the ability to use carbohydrates for growth in the studied fish species. African catfish, carp and striped catfish can handle the digested carbohydrates efficiently while this ability is limited in barramundi and snakehead.

Introduction

European pikeperch (*Sander lucioperca*) is a popular food fish and a promising aquaculture species in Europe (Dil 2008, Baekelandt et al. 2018). It is however highly sensitive to environmental and handling stressors in aquaculture (Dalsgaard et al. 2013, Baekelandt et al. 2018)building, and operating intensive land-based RAS for different species. This study compiles and assesses published literature along with un-published hands-on experiences with rearing different species in RAS in the Nordic countries, including Atlantic salmon (Salmo salar. This limits the intensification of its farming in recirculating aquaculture and aquaponic systems. These are production modes of growing interest for this species and of sustainable intensification of its cultivation (Steinberg et al. 2018). Plant bioactive compounds can be effective feed ingredients that reduce stress and improve fish growth and immunity, but few specific compounds have been identified and tested on pikeperch. Furthermore, plants also release exudates into the medium surrounding their roots, but their influence on an aquaponic system has not been studied to date.

The European INTERREG Research project PERCIPONIE is dedicated to the development of perciculture in aquaponic systems. One of the objectives of the project is to identify bioactive compounds emitted by plants cultivated in aquaponics, or as a food additive with beneficial effects on the growth and immunity of pikeperch. Other objectives of PERCIPONIE are to develop the fish polyculture in aquaponics and to model the dynamics of an aquaponic pilot system. Based on a cross-border consortium of partners, the project brings together stakeholders from research as well as the aquaculture industry for scientific excellence and applicability of results. The collaboration with regional aquaponic companies ensures technical and economic suitability for application.

Materials and Methods

The results of the first project stage will be presented.

A systematic review of the literature from the fields of botany and aquaculture research, is conducted in order to i) identify molecules of interest for the growth and immunity of fish and the families of plants which produce these molecules of interest, either in their tissues or in the form of root exudates, ii) target plants of agronomic interest and / or having a potential positive effect on fish health as a food additive through bioactive molecules, iii) select plant species according to their suitability for hydroponics and iv) assess the compatibility of plants with the range of aquaponic systems involved in the project (from controlled environmental conditions and low species diversity to variable abiotic factors and a wide range of plant species). The results will feed into the other experiments of the PERCIPONIE project and will provide new information on understudied dynamics of aquaponic systems.

BASQUE MICROALGAE CULTURE COLLECTION (BMCC): HUNDREDS OF MICROALGAE STRAINS FOR BIOTECHNOLOGY PURPOSES

S. Seoane*, J. Bilbao, A. Llorente, E. Blanco-Rayón

Ecology of Marine and Estuarine Plankton Group, Department of Plant Biology and Ecology, Faculty of Science and Technology, University of the Basque Country (UPV/EHU), Leioa, 48940, Spain
sergio.seoane@ehu.es

The Basque Microalgae Culture Collection (BMCC) (www.ehu.es/bmcc) is a new microalgae collection recently registered in the World Federation of Culture Collections (WFCC). Sited in the Science and Technology Faculty of the University of the Basque Country (UPV/EHU) (Spain), it possesses more than 700 cultures of microalgae, including species from almost all the taxonomic groups. The major groups in the collection are diatoms, dinoflagellates, haptophytes and chlorophytes, but others such as cyanobacteria and cryptophytes are also well represented. The strains have been isolated from marine, brackish and freshwater ecosystems and it is possible to find pelagic and benthic species. Most of the strains are from the Basque Country (estuaries, coast and reservoirs), but there are maintained strains from all over the world.

The BMCC has recently taken part in different projects related to marine bioprospecting, such as MARBIOM and Algaberri projects. The aim of the MARBIOM project is the discovery of new anti-cancer substances, and it involves the University of Almeria and Pharmamar S.A., among others. Extracts from different strains are being tested in order to find compounds that help to beat this disease. Regarding the Algaberri project, its goal is to obtain compounds that can be used in anti-obesity and anti-neurodegenerative treatments. In this project, the BMCC collaborates with AZTI Company and some research groups of the University of the Basque Country.

The existence of culture collections, with its characterization and maintenance, needs many resources and it is a time-consuming task, but on the other hand, it provides an inestimable source for biotechnology projects to start experiments, saving the time required for the isolation, culturing and characterization of the species.

Bacillus subtilis SPORES ARE EFFICIENT VEHICLES FOR ORAL VACCINATION OF FISH AGAINST VIBRIOSIS

Introduction

Vibriosis, a hemorrhagic septicemia caused by members of the gram-negative genus *Vibrio*, is one of the most prevalent diseases of cultured fish, shrimps and bivalves (1). *V. anguillarum*, the etiological agent of classical vibriosis in warm- and cold-water fish species, is particularly problematic, leading to high mortalities and economic losses in aquaculture (1). Although commercial vaccines have been developed against vibriosis, these are mainly injectable ones, requiring individual handling of fish, which is laborious, time-consuming and may induce stress-related mortalities (2). Present vaccine trend developments focus on alternative methods for mass delivery of antigens, including oral and immersion vaccination (2). Oral vaccine administration incorporated in feed seems to be the preferable method as it reduces fish stress and costs to the minimum and is feasible for larvae and juveniles vaccination (2). Oral vaccines are thus highly demanded by the aquaculture sector, but till today most previous attempts to obtain effective oral vaccines in fish have failed.

One possible strategy is the use of bacterial spores, extremely resistant structures with wide biotechnological applications (3), that survive passage through the gastrointestinal tract. Bacterial spores, in particular those of *Bacillus subtilis,* have been shown to behave as mucosal vaccine adjuvants in mice models (4), but, to date, such technology has not been applied against gram-negative fish bacterial diseases.

To fulfil this gap, we used *B. subtilis* spores as a delivery vehicle for the presentation of the OmpK immunogenic protein, an antigen shared among several *Vibrio* species and evaluated its efficacy in increasing survival of larvae from the model zebrafish (*Danio rerio*) and of juveniles from an economically important aquaculture species, the European seabass (*Dicentrarchus labrax*).

Materials and Methods

The genes encoding for the OmpK protein and the green fluorescence protein (GFP) were PCR amplified containing an N-terminal 6Histines-Tag and cloned into p1CSV-CotY-N and p1CSV-CotY-C plasmid vectors (5), resulting in a translational fusion to the crust protein CotY either C-or-N-terminally. Integration at *B. subtilis* 168 chromosome through a double-crossover recombination event, resulted in the chloramphenicol resistant strains CRS218 (CotY-H6-GFP), CRS219 (H6-GFP-CotY), CRS220 (CotY-H6-OmpK) and CRS221 (H6-OmpK-CotY). Spores of WT *B. subtilis* 168 and its congenic derivatives were obtained after induction of sporulation by nutrient exhaustion in DSM and purified following standard procedures. The display of the target proteins at the surface of the recombinant spores was evaluated by western blot with a commercial anti-His-Tag antibody. Strains carrying the GFP fusions were also observed under a fluorescence microscope.

The vaccination potential of OmpK-carrying spores was first evaluated in zebrafish larvae reared at 28 ºC in 6-wells plates containing egg water. At 6 dpf (days post-fertilization), larvae were treated for 2h with spores suspensions (10^8 CFU mL^{-1}) of each recombinant strain carrying the OmpK-CotY fusions, or from the parental *B. subtilis* 168 strain. At 9 dpf larvae were challenged by immersion with 3×10^8 CFUs mL^{-1} of *V. anguillarum* or 1×10^8 CFUs mL^{-1} of *V. parahaemolyticus*. Cumulative mortalities were registered between 16-24h, and dead larvae removed and safely discarded. The experiment was independently carried out 3 times.

(Continued on next page)

Next, the vaccination potential of OmpK-carrying spores was also evaluated in European seabass. Triplicate groups of 40 European seabass juveniles, were fed diets containing 1×10^9 spores Kg^{-1} feed of either CRS220 (OmpK-diet), CRS218 (GFP-diet) or from the parental *B. subtilis* 168 strain (CTR, control-diet). After 30 days, 10 fish from each tank of the GFP-diet and of the CTR diet were used for blood collection and subsequently used for anti-GFP antibodies detection in fish serum, using an indirect ELISA approach. Simultaneously, 60 fish from tanks of the OmpK-diet and of the CTR diet, were challenged by injection with *V. anguillarum* ($1x10^6$ CFU/fish), while the remaining fish from the same treatments were injected with PBS. Fish survival was followed during 7 days, with dead and moribund fish showing signs of infection daily removed and sacrificed. At the end of the challenge, the remaining fish were euthanized with an overdose of anesthetic. Survival curves were plotted using the Kaplan-Meier method and pairwise comparisons between treatments were performed with nonparametric log-rank test, at 0.05 significance level, in GraphPad Prism version 9.

Results

Both OmpK and GFP proteins were successfully displayed at the surface of the *B. subtilis* spore, although more efficiently in the C-terminal versions. Importantly, zebrafish survival upon challenge with *V. anguillarum* and *V. parahaemolyticus* was increased in magnitudes of 50 to 90% respectively, when previously vaccinated with OmpK-carrying spores. Further, we detected anti-GFP-antibodies in the serum of European seabass fed diets containing GFP-carrying spores and increased European seabass survival by 30% when challenged with *V. anguillarum* if previously fed with a diet containing OmpK-carrying spores.

Conclusions

Overall our results indicate that *B. subtilis* spores can be efficient antigen carriers for oral vaccine delivery in fish.

Introduction

Mycobacterium marinum is the causative agent of Mycobacteriosis, a fish bacterial disease characterized by granulomatous inflammation in multiple organs, with a mortality rate that can range between 30-100% (1). Mycobacteriosis outbreaks have important effects on commercial fish production, in particular that of European seabass (*Dicentrarchus labrax*), a fish species of high economic interest. Mycobacteriosis is also an important infectious disease in zebrafish (*Danio rerio*), associated with severe losses in research facilities. Because no satisfactory vaccine or treatment is available, once a population of fish is infected, the most likely scenario is euthanasia of the entire group. Thus, it is imperative to develop an efficient strategy to prevent mycobacteriosis infections. One possibility is the use of bacterial extracellular vesicles (EVs), which are spherical bilayered structures naturally liberated from the outer membrane of Gram-negative bacteria. Bacterial EVs have been progressively used as carriers of immunogenic antigens (2). An example is the commercially-available EV-based vaccine Bexsero® against *Neisseria meningitidis* serogroup-B15 in humans (3).

Materials and Methods

First, EVs derived from the non-pathogenic and environmentally friendly cyanobacterium *Synechocystis* sp. PCC 6803 wild-type and congenic derivatives Δ*tolC*, Δ*tolC*/Δ*spy*, *ΔfucS* (with distinct vesiculation phenotypes), ranging between 50 and 500 μg LPS mL^{-1}, were tested for their effects on 3 days post fertilization (3 dpf) zebrafish larvae survival. LPS isolated from the same bacterial strains were used for comparison while commercial LPS from *Pseudomonas aeruginosa* (known to induce zebrafish mortality) was used as control. Survival curves were plotted using the Kaplan-Meier method and pairwise comparisons between treatments were performed with nonparametric log-rank test, at 0.05 significance level, in GraphPad Prism version 9. In addition, at days 1 and 5, total RNA was extracted from pools of 5 embryos of each replicate (n=3) from EVs treatments, for analysis of transcript levels of pro-inflammatory cytokines interleukin 1 beta (*il1β*) and tumor necrosis factor (*tnf1α*) and of anti-inflammatory cytokine interleukin 10 (*il10*), by RT-qPCR, using established oligonucleotides. Next, European seabass juveniles were randomly assigned to duplicate groups of 12 fish, and injected with engineered cyanobacterial EVs loaded with the reporter GFP in the following scheme: either one injection with 824 μg EVs containing 16.48 μg GFP; or two injections, separated by 15 days, each with 412 μg EVs containing 8.24 GFP. As controls, one injection of 16.48 μg GFP alone; or PBS were included. At days 15 and 30 after injection, 6 fish from each tank were euthanized for blood collection, plasma extraction and subsequently used for anti-GFP antibodies detection in fish serum, using an indirect ELISA approach.

(Continued on next page)

Results

Neither cyanobacterial EVs from any of the cyanobacterial strains used, nor isolated cyanobacterial LPS, induce significant mortality in zebrafish larvae under the tested conditions. Thus, while 45 μg mL^{-1} *P. aeruginosa* LPS triggered severe mortality (>80%) after 24 h, isolated EVs concentrations of up to 500 μg mL^{-1} from *Synechocystis* may be used without significantly reducing larvae survival even after 5 days of incubation. Accordingly, and in contrast to LPS from *P. aeruginosa* that induced significant upregulation of inflammatory markers at sub-lethal concentration of 35 μg mL^{-1}, EVs isolated from *Synechocystis* strains were shown not to induce significant inflammatory response. Further, we detected anti-GFP-antibodies in the serum of European seabass injected with EVs containing GFP, and no harmful effect could be detected on fish after a 30 days trial.

Conclusions

Our results support that *Synechocystis* EVs structural components are biocompatible with fish even at high concentrations. Cyanobacterial EVs are thus good candidates to be used as carriers of immunogenic antigens in zebrafish and with potential to be used in aquaculture species such as the European seabass. Future work will engineer EVs with heterologous *M. marinum* antigens, and evaluate these as delivery vehicles to immunize zebrafish and European seabass against *M. marinum*.

Introduction

The aquaculture industry is one of the fastest growing industries of its sector, mostly due to the incremental demand of fish production. However, this generates resource management issues mainly in the use of fish meal (FM), which becomes both ecologically and economically unsustainable. To respond to this issue, novel dietary ingredients are being studied to formulate aquafeeds with suitable dietary profiles for each species. With a high protein and lipid contents, a balanced amino acid profile and a recent authorization for the incorporation in aquafeeds in the European Union, insect meal (IM) positions itself as a strong candidate for FM substitution. Introduction of novel ingredients, however, can impact over the fish immune status and/or growth performance. One of the known effects of introducing novel dietary ingredients is the potential to generate gut microbial communities shifts which are recognized to impact on fish growth, metabolism, and immune status (Ringø et al. 2015; Ringø et al. 2018; Serra et al. 2021). In fact, prebiotic effects have been attributed to IM, with these being commonly associated with the increase of dietary chitin, a structural polysaccharide present in the insects exoskeleton (Perry et al. 2020) However, information about the potential gut microbiota shifts occurring as a consequence of dietary IM inclusion are scarce (Perry et al. 2020). Thus, this study aims to assess the effect of three different IM, namely, *Hermetia illucens* larvae meal (HM), *Tenebrio molitor* larvae meal (TM), and *H. illucens* exuviae meal (HEM) on European seabass gut microbiota modulation.

Materials and methods

To access gut microbiota modulation due to dietary IM, five isoproteic (45%) and isolipidic (18%) diets were used: a control diet (CTR); a diet similar to the CTR with 5% commercial chitin (CHIT5), and three diets with 25% inclusion of HM25, TM25 and HEM2, respectively. The experimental diets were randomly assigned to 5 groups of 15 fish with an initial mean body weight of 53.7 ± 2.67 g. The trial was conducted in a recirculating aquaculture system equipped with 100 L water capacity tanks, thermo-regulated to 22.7 ± 0.3 °C. Fish were fed by hand twice a day, 6 days per week, until apparent visual satiation for 8 weeks. The allochthonous (digesta) and autochthonous (mucosa) communities were aseptically collected, had their DNA extracted and were subjected to a 2-step PCR barcoding of the V4 region of the 16S rRNA followed by Illumina Miseq sequencing (paired-end mode; 2× 300 bp). Amplicon pools were extracted from the raw sequencing data using the FASTQ workflow in BaseSpace (Illumina), demultiplexing was performed with the python package demultiplex (Laros JFJ, github.com/jfjlaros/demultiplex) and barcodes, linkers and primers were trimmed off using BBDuk (BBTools, sourceforge.net/projects/bbmap). DADA2 R package version 1.14.1 (https://www.r-project.org/, R 3.6.2) was used for demultiplexing amplicon sequencing variants (ASVs). Taxonomy assignment was based on SILVA taxonomy database (release 138). Amplicon sequence libraries were analysed using the vegan (v2.4.3) and phyloseq (v1.30.0) packages of the software R. DESeq2 (v1.26.0) implemented in phyloseq was used to determine statistical significant differences in ASV abundances between diets and/or sites. Finally, quantitative PCR of the conserved *chiA* gene was used to assess if the observed microbial shifts were accompanied by a genomic shift towards chitinase-encoding genes.

Results

Overall, the European sea bass gut microbiota was dominated by the phylum Proteobacteria, followed by Firmicutes, Actinobacteria and Bacteroidota. A beta-diversity analysis of the allochthonous and autochthonous communities revealed a stronger impact of the sampled site (digesta versus mucosa) when compared with the impact of the tested diets on community composition, with digesta communities being more diverse than their mucosal counterparts. Nevertheless, an overall impact of diet on the composition of the European sea bass gut microbiota (p=0.004, r^2=0.244, PERMANOVA) could also be observed. While the mucosa-associated microorganisms were more resilient to dietary changes, digesta-associated communities were significantly altered upon HM-based diets leading to an increase in several families belonging

(Continued on next page)

to the Firmicutes and Actinobacteria phyla, with HEM25 presenting a stronger influence. Although genomic potential for chitinolytic activity is recognized for bacteria in both phyla, our results showed that only HEM25 was able to promote a shift towards chitinase-encoding taxa, mainly due to the increase of the *Paenibacillaceae* family, which was not found to significantly increase in HM25. When screening our samples for the presence of chitinase A gene (*chiA*) using primers targeting a conserved region of ChiA, we detected *chiA* in the digesta of fish in all diets, but fish fed the HEM25 diet had significantly higher copy numbers of *chiA* compared to fish fed any of the other diets ($p=0.0077$, ANOVA). These results show an increased *chiA*-driven chitonolytic potential of the European sea bass digesta microbiota fed a HEM25 diet. In conclusion, our results showed a metabolic shift in fish gut microbiota towards chitin-degrading microorganisms due to dietary IM inclusion.

Introduction

In aquaculture, finding alternative ingredients to fish meal (FM) is urgently needed, since the depletion of fish wild stocks has led to a decrease in FM availability, thus increasing FM price. Plant feedstuffs (PF) may partially replace FM in aquafeeds (Tacon et al. 2011). However, PF use has its own drawbacks. In terms of resources management, PF are in direct competition with human food and have a high demand for land and water for production. Moreover, the presence of anti-nutritional factors, and, imbalanced amino acid profile, diminishes its effectiveness as an FM substitute in aquafeeds (Gatlin et al. 2007; Henry et al. 2015). Insect meal (IM), recently authorized for use in aquafeeds, positions itself as a promising aquafeed commodity due to its high protein content, balanced amino acid profile and high lipid contents. However, insects are also rich in chitin, a structural polysaccharide present in the insect's exoskeleton, whose non-digestibility has been linked with lower fish performance and nutrient digestibility (Henry et al. 2015; Gasco et al. 2019). To overcome the chitin impairments of IM inclusion in aquafeeds, IM can be submitted to chemical or enzymatic treatments to promote chitin breakdown before being added to diets, but these processes have high costs, low yield, residual acidity, and may result in serious environmental pollution (Harish Prashanth and Tharanathan 2007). Alternatively, probiotic (PRO) bacteria, knowing to possess chitinase activity (e.g. *Bacillus subtilis*, (Askarian et al. 2013)), could be a solution. As such, this proposal aims to isolate, from European sea bass gastrointestinal tract, PRO bacteria capable of producing chitinases to improve the use of high IM-containing diets, supporting cost-effective fish growth without compromising welfare and health status.

Materials and methods

Based on the adaptability of gut microbial communities, chitin-containing diets were fed to promote microbial shifts towards chitin-metabolizing bacteria. Five isoproteic (45%) and isolipidic (18%) diets were formulated: a control diet (CTR); a diet similar to the CTR with 5% chitin supplementation (CHIT5); and 3 other diets with 25% inclusion of either *Hermetia illucens* (HI) larvae meal (HM25), *Tenebrio molitor* larvae meal (TM25) or HI exuviae meal (HEM25). After 8 weeks feeding trial, whole guts were aseptically excised and squeezed to collect the digesta contents. To select for aerobic bacterial sporeforming isolates, serial dilutions were prepared and heat-treated before inoculation on Luria Bertani (LB) medium (Nicholson 1990). The potential PRO were comprehensively screened *in vitro*, concerning their putative PRO traits, namely: sporeforming ability; chitinolytic activity; antibiotic resistance; haemolytic activity; and gut-survival aptitude.

Results

From the obtained microorganisms, from each diet and dilution, colonies presenting different morphologies were randomly selected for further analysis, resulting in a total of 363 isolates. Sporulation ability was confirmed by phase-contrast microscopy of cultures submitted to nutrient exhaustion by cultivation on DSM. These isolates were sequentially gauged for their chitin metabolization ability, resulting in a group of 40 isolates with promising chitinolytic activities. The remaining 40 isolates were subjected to full taxonomic identification followed by haemolytic activity characterization narrowing the isolate number to 20. Antibiotic resistance screening of the 20 candidates revealed that all isolates, but one, were resistant to at least one of the tested antibiotics and, as such, total chitinolytic activity was determined for all 20 isolates. Within these, the 4 isolates presenting the highest chitinolytic activity were selected and assessed regarding their gut-survival aptitude and total chitinolytic activity in gut-like conditions. All the selected isolates performed well in the tested conditions with 2 isolates performing better than the rest, namely FI645 and FI658. The best PRO candidates will be subsequently evaluated *in vivo*, considering their potential to modulate fish gut microbiota, aiming to improve chitin utilization in IM-based diets.

Introduction
The gut microbiota plays a central role in fish health and performance. Gut microorganisms perform or facilitate a series of digestive, metabolic, and immune-stimulating processes vital for host fitness (1). Imbalances in the gut microbiota composition, a process called dysbiosis, are linked to the development of multifactorial diseases (1,2). Aquaculture practices, such as fish transportation, are often associated to an increase of fish stress, morbidity and mortality, and have the potential to generate gut microbial community shifts, with an impact on fish growth, metabolism, and immune status (2,3). Here, we examined whether the gut microbial population of Senegalese sole juveniles was changed by an acute stress (standardized 30 min transportation), and if such changes could recover, when fish were fed diets fortified with antioxidants and β-glucans, known as effective immunostimulants in fish production (4).

Materials and methods
Triplicate groups (80fish/tank) of Senegalese sole juveniles (5g) were fed three diets, formulated and manufactured by SPAROS, with high-quality ingredients: CTRL, rich in high quality fish, squid and krill meals; CTRLox, CTRL supplemented with natural antioxidants (i.e. vitamins and curcumin); and CTRLas, CTRL supplemented with antioxidants and β-glucans. A fourth commercial diet was used as positive control. Each diet was administered in 8 daily meals and fed to apparent satiety. Animals were fed the experimental diets for 7 days and submitted to an acute stress by a standardized 30 min transport. Fish were then returned to the experimental tanks and fed the same dietary treatments for additional 7 days. After this period, all fish were fed the commercial diet for the last 7 days of the experiment. Fish were sampled at the beginning (time 0), prior transport (time 7), 7 days following transport (time 14) and at the end of the feeding trial (time 21). At each sampling point, intestines of 5 fish per tank were aseptically excised, and pooled into one sample to overcome inter-fish variation and assess differences between dietary groups. DNA extraction and polymorphism analysis of 16S rRNA genes by Denaturing Gradient Gel Electrophoresis (DGGE) and by Next-Generation Sequencing (NGS) using the Illumina´s MiSeq platform (paired-end mode; 2× 300 bp), was essentially performed as previously described (5).

Results
The Senegalese sole gut microbiota was dominated by the phylum Tenericutes, followed by Proteobacteria, Firmicutes, and Actinobacteria. Although the tested experimental diets did not promote significant changes in the gut microbiota diversity indices, a reduction on microbial richness and microbial diversity was seen after the acute stress induction. Regarding differently abundant genera, the experimental diets CTRLas and CTRLox significantly reduced the % of *Cellulosilyticum* spp. *(p<0.001)*, a poorly characterized genus of cellulolytic, acetic acid producing anaerobic sporeforming bacteria; and of *Vibrio spp*. *(p=0.011)*, a more diverse genus, that includes species widely distributed in aquatic and marine habitats, many of which are considered opportunistic bacterial pathogens for fish (e.g. *V. scophthalmi , V. anguillarum, V. vulnificus*) causing Vibriosis.

Introduction

An adequate nutritional strategy acquires a great importance enhancing the potential of selective breeding programs on aquaculture production (Callet *et al.,* 2017). The substitution of FM and FO by alternative and more sustainable ingredients may affectfish growth, welfare and health (Montero and Izquierdo, 2010), impairing the geneticallyselected traits. Functional additives have shown the ability to reduce this effect in commercial based diet formulas (Giannenas *et al.,* 2012) by enhancing growth performance (Hoseinifar *et al.,* 2015), welfare (Serradell *et al.*, 2020), and health (Torrecillas *et al.,* 2019). The objective of the present study was to evaluate the potential of different functional additives to attenuate stress response and antioxidant status on a selected genotype comparatively to non-selected European sea bass (*Dicentrarchus labrax*) juveniles fed a low FM and FO diet.

Material and methods

Four isoenergetic and isonitrogenous diets with a low FM and FO content (10% and 6% respectively) supplemented with a 0.05% galactomannan oligosaccharides (GMOS), a 0.02% of two different mixtures of essential oils (PHYTO 1 and PHYTO 2) and acontrol diet (with no supplementation) were fed to two European sea bass genotypes,high grow genetically selected (HG) (by EMG breeding company since several generation with SYSAAF advice), and non-genetically selected (UN). The experimental diets were fed for 72 days (6 days/week, 3 times/day). Afterwards, fish were subjected toan oxidative stress challenge by bath with hydrogen peroxide (H_2O_2) at a final concentration of 50 ppm for 1 hour. At the end of the feeding trial (t=0h), and along the*in vivo* challenge test (2h, 4h, 24h after the exposure) plasma cortisol concentrations (ng/mL) as well as the relative gene expression of different genes in gill, including genesrelated with the antioxidant fish capacity as *sod, cat, gpx*, mitochondrial function genesas *Na-K-ATPase, ucp1*, *ucp* 3, *nd5* and proinflammatory genes as *interleukin-1β*, *nf- Kβ*, *tnf- α*, *cyb*, *coxi* and the proapoptotic *caspase-9* were evaluated.

Results

HG fish presented a significant ($p < 0.05$) lower basal circulating plasma cortisol level than UN fish at t= 0h before the *in vivo* challenge test, with concentrations ranging between 280.1 ± 80.9 ng/ml and 387.7 ± 84.1 ng/ml for HG and UN fish groups, respectively. Unless no significant, HG fish presented an improved acute stress response in relation to higher plasmatic cortisol concentration than UN fish (2h post exposure). HG fish fed Control and GMOS presented an increase in cortisol concentrations of 3.2 and 2.7 fold times in relation to their basal levels, while those HG fish fed PHYTO 1 and PHYTO 2 diets presented an increase of 2.5 and 2.2 fold times respectively in relation to their basal level. Similarly, UN fish fed Control and GMOS diets, despite presented a higher basal circulating cortisol levels than HG fish groups, the exposure to the stressor induced an increase of cortisol level of 1.8 and 1.7-fold (2h post exposure) in relation to basal levels, while UN fish fed PHYTO 1 and PHYTO 2 diets presented an increase on plasmatic cortisol concentrations (2h post exposure) of 1.6 and 1.4-fold in relation totheir basal level. Twenty-four hours after the exposure to the stressor (t=24h) fishbelonging to both genotypes (HG and UN) presented a reduction on circulating plasma cortisol values regardless the dietary treatment fed. At t=2h after oxidative stress, UNfish showed higher ($p < 0.05$) gill relative gene expression of *sod, cat* and *gpx* than HG fish. When fish were fed the functional diets (PHYTO 1, PHYTO 2 or GMOS), both HG and UN fish presented an up-regulation of *cat* relative gene expression 2h after H_2O_2 exposure. In contrast, those fish fed the

(Continued on next page)

Control diet showed higher *cat* relative gene expression values at t= 4h after oxidative stress. *Interleukin-1β* relative gene expression values were up-regulated ($p < 0.05$) in UN fish after oxidative stress in relation to *interleukin-1β* basal relative gene expression values (t=0h). At t= 2h after exposure, UN fish fed the functional diets presented an up-regulation ($p < 0.05$) of the gene expression levels compared to fish fed the Control diet. At t=4h fish fed the Control diet presentedan up-regulation on *interleukin-1β* gene expression values similar to those presented by fish fed the supplemented diets.

In summary, multi-traits EMG selected European sea bass genotype has a higher capacity of response against oxidative stress than UN fish, in relation to a more efficient acute response in terms of cortisol production two hours after H_2O_2 exposure. The recovery of basal levels for HG groups seems also to be more efficient in selected groupsthan in unselected populations, regardless of the diet fed. The use of functional diets up- regulated UN fish antioxidant gene expression, especially *cat,* after the oxidative stress challenge.

AQUACULTURE IN THE DUTCH NORTH SEA: TECHNICAL PRESENTATION OF TWO CONCEPTS

Jorrit-Jan Serraris[1], Kika Jonker[2], Linda Kemp[1]

(1) Maritime Research Institute Netherlands (MARIN). P.O. Box 28, 6700 AA, Wageningen (Netherlands)
Email: j.w.serraris@marin.nl, (2) kmmjonker@gmail.com

Introduction

More and more offshore wind parks are being developed in the Dutch North Sea. Multi-use of the space between the wind turbines is foreseen for nature reinforcement and development, production of renewable energies, mariculture and passive fishing activities.

Inspired by the international aquaculture industry the present paper presents an investigation into the application of aquaculture within Dutch offshore wind parks. The paper touches upon relevant aspects of aquaculture and focusses on the technical aspects.

Background

The feasibility of aquaculture within Dutch offshore wind parks depends on many aspects, including: government and legislation: which activities are allowed within offshore wind farms and which fishing techniques can be applied; biological: which fish species are suitable for cultivation in the Dutch North Sea; ecological: what is the impact on the ecosystem; economical: what will be a viable business case; communal: who will work in the aquaculture industry and what is the communal impact; fish welfare: how to guarantee the welfare of the fish; technical: what are the design conditions for aquaculture systems in the Dutch North Sea and what are robust designs?

Ref [1] gives insight in governmental, ecological and economical aspects. Ecological, biological and economic viability of potential species for aquaculture are described in detail in Ref [2].

The present paper adds to the exploratory research from the technical viewpoint by means of presentation of two potential aquaculture concepts. The suggested systems are patent-free; we encourage further development of these concepts by others.

Technical design

Selected site: Borssele II
Environmental conditions and design loads

Suggested concept

Concept I: closed net pen: philosophy, design, loads, mooring
Concept II: Seabed based large fish cage: philosophy, design, loads, mooring

Figure 1: Concept I: Closed net pen within offshore wind park

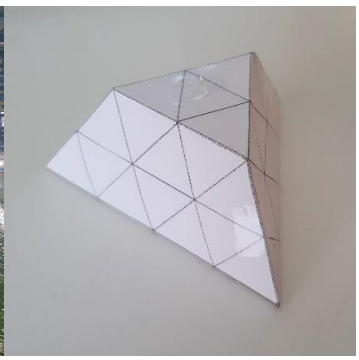

Figure 2: Concept II: seabed based large fish cage

(Continued on next page)

Conclusions and recommendations

The present research indicates the technical feasibility of the two suggested systems. Further technical developments are recommended on: determination of the environmental loads; improvement of the design; logistic operations including installation, operation and maintenance. Furthermore multidisciplinary research is required to develop the concepts further including governmental, ecological and economical research aspects.

THE POTENTIAL FOR COMBINED PRODUCTION OF SALINITY TOLERANT TILAPIA AND SHRIMP IN BRACKISH WATER PONDS IN INDONESIA

Priadi Setyawan[1,2*], Mark Camara[1], John Bastiaansen[1], and Hans Komen[1]

[1]Animal Breeding and Genomics, Wageningen University and Research

Introduction

The potential area for brackish water aquaculture in Indonesia is about 2.25 million ha of undeveloped and marginal land concentrated along the coast of Java Island, which contributed 614,518 ton in 2017 with the total value of around 1,59 billion USD. Total production is spread between traditional (216,791 ton), semi-intensive (360,617 ton) and intensive (37,109 ton) farming systems, and consists mostly of smallholder shrimp farmers operating low input traditional and semi-intensive systems.

Shrimp farming occupies around 53% of Indonesian aquaculture production in brackish water (1.15 million ton in 2017) second only to tilapia (1.27 million ton) (MMAF 2018). However, in recent years mass mortality and farm failures have made shrimp farming a high-risk industry, and resulted in the abandonment of land and ponds in many traditional shrimp farm areas. Consequently, many small-scale farmers are looking for alternative crops to secure their livelihoods. Promising alternatives are rotational cropping or co-culture of tilapia and shrimp.

Tilapia farming is predicted to become a key industry in Indonesia (Phillips et al. 2015). Fisheries extension officers in many areas in North Coast Java report that the number of tilapia farmers in brackish water ponds is rapidly increasing, and milkfish production declined from 747,445 tons in 2016 to 701,319 ton in 2017 (MMAF 2018). However, tilapia in high salinity ponds have lower growth rates, survival, and reproduction (Popma and Masser 1999, Cruz-Suarez et al. 2006, Bœuf and Payan 2001, Cnaani and Hulata 2011). The prevalence and economics of these systems have not been studied sufficiently to determine whether they are economically viable and sustainable. economically viable and sustainable.

The objective of this study was to review the current status of combined tilapia and shrimp farming in Indonesia as a foundation for more in-depth economic analyses and to identify challenges, barriers, and opportunities that must be addressed in the near future.

Materials and methods

We conducted a survey of farmers in four provinces on Java Island (Banten, Central, East, and West) and to determine the current practices related to shrimp and tilapia farming in brackish water. 224 farmers were asked a series of questions about which species they farm, the systems they use, and the income they generate. To describe the patterns and trends, we summarized the number of farmers who earn low, medium and high incomes as percentages for each of provinces. We categorized the farming systems implemented in each province as monoculture, polyculture, mono-rotation, and poly-rotation and present these data as percentages. We also summarized the types of water aeration, pond lining systems, the use of commercial feed, the feeding rate and type of tilapia farmed as percentages.

Results

Our survey results show those farming practices vary between regions, and that polyculture and rotational farming systems are much less common in Banten than other regions of Java. We also found that the use of commercial feed and feeding rates varies between regions, with Banten farmers completely reliant on commercial feed, East Java farmers least reliant on commercial feed, and Central and West Java intermediate. More than half of farmers in Central Java, West Java and East Java applied commercial feed at less than 3% of fish biomass per day, while 56.3% of farmers in Banten applied a higher rate of 3-5% biomass per day.

Furthermore, the income levels of farmers vary between regions. Most farmers in Java Island (46.4-61.1%, depending on the province) are low-income earners. Medium income earners account for around a third, and less than a quarter of the farmers surveyed are high income earners. This regional variation could be affected by many factors that need to be analyzed in further study.

(Continued on next page)

Discussion and conclusions

Recurrent shrimp farming failures caused by disease outbreaks have resulted in an important shift in farming systems in brackish water ponds in Indonesia. Shrimp monoculture is now only practiced in the most suitable areas, and a majority of shrimp farmers have shifted to tilapia or low-density shrimp production in polyculture systems. Farmers are implementing a variety of production rotational and polyculture systems in Central, East and West Java, but much less so in Banten. It seems that the lowest percentage of ponds in production driven their farming system.

However, despite the advantages, farming tilapia in abandoned brackish water shrimp ponds faces some challenges and obstacles. Currently available salinity tolerant tilapia strains show large variation in growth and survival, and further work is required to 1) develop an optimised breeding strategy to improve growth rate and survival of tilapia grown in shrimp ponds under fluctuating and unpredictable salinities, and 2) assess and compare the economic viability of various shrimp-tilapia farming systems.

Small scale shrimp tilapia farmers in all four provinces are dominated by low-income earners who practised low input production system which presumably ended up in a low productivity trap. Government support is needed to promote them to be more productive through providing a better financial access and supporting irrigation system, road, electricity, and other infrastructures in brackish water area.

Introduction

Considerable efforts have been made in the past years towards closing the European eel life cycle in captivity (Tomkiewicz et al., 2019), including enhanced environmental conditions for embryonic and larval culture (Politis et al., 2017, 2018). Still, effects of pH fluctuations on eel early life stages remain unknown. Fish embryos and larvae are expected to be particularly sensitive to pH changes, as organs for pH regulation are not fully developed (Ishimatsu et al., 2008). The aim of this study was to evaluate the sensitivity of eel embryos to fluctuations in pH/CO_2 and identify the developmental timing and functionality of related regulatory pathways.

Materials and methods

Following a standardized gamete production and fertilization protocol (Tomkiewicz et al., 2019), European eel embryos were moved to three custom designed RAS units supplying upwelling incubators. Embryos were incubated at optimal temperature and salinity and at three different PCO_2/pH conditions: (1) control-PCO_2 (400 µatm CO2, pH 8.1), (2) high-PCO_2 (1000 µatm, pH 7.7) and (3) extreme-PCO_2 (3000 µatm, pH 7.0). Embryonic survival was assessed at 4, 24, and 48 hours post-fertilization (hpf). Samples of embryos were taken at 24 hpf for morphological measurements, and at 24 and 48 hpf to determine the expression levels of 11 target genes: hsp70 and hsp90, involved in physiological stress/repair response; aqp1 and aqp3, which are water and solute transporters; nkcc1a, ncc and car15, involved in acid-base regulation; crfr1 and crfr2, that mediate in responses to stress; and GABAAα6b and GABAAα12, related to inhibitory neurotransmission.

Results

Survival was similar for all pH/CO_2 conditions at 4 hpf. At 24 hpf and onwards, survival significantly declined at extreme PCO_2 compared to the control and high PCO_2 treatment (Fig. 1A). The egg diameter at 24 hpf was smaller at high and extreme PCO_2 with a related reduction of the perivitelline space (Fig. 1B). The expression of aqp3, hsp70, crfr2 and ncc significantly increased from 24 to 48 hpf, although they were not affected by the pH/PCO_2 treatments. Conversely, crfr1, GABAAα6b and GABAAα12 expression, decreased over time for all treatments. Finally, the expression levels of aqp1, hsp90, car15, and nkcc1a genes were similar across treatments and developmental times.

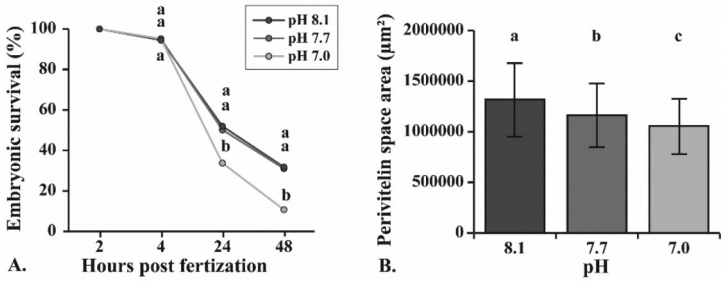

Figure1. Survival (A) and perivitelin space area (B) of European eel embryos incubated at control, high and extreme-PCO_2 conditions.

(Continued on next page)

Discussion

At increased pCO2 levels, egg swelling was impaired resulting in a reduction in egg size. Here, high concentrations of H^+ may have an inhibitory effect on colloidal processes leading to a reduction in water uptake during perivitelline space formation (Eddy & Talbot, 1983). This could negatively affect the embryos ability to osmoregulate and therefore lead to increasing mortality as was observed for the high and extreme PCO_2 conditions. Such stressful conditions, are expected to lead to upregulation of heat shock proteins (Roberts et al., 2010). In European eel embryos, hsp70 and hsp90 expression was unaffected by changes in PCO_2, even though these genes are upregulated in response to salinity and thermal stress in early larval stages (Politis et al., 2017, 2018). Similarly, crfr1 and crfr2 transcription levels, genes also involved in stress response, were not affected by acidification. Expression of crfr2 increased in all treatments from 24 to 48 hpf, whereas crfr1 showed an opposite trend. This is similar to what was observed for zebrafish embryos, which relates to their inability to synthesise cortisol until after hatching (Alderman & Bernier, 2009). On the other hand, the expression of acid-base regulatory genes was similar for all treatments. Here, nkcc1 and CA15 expression remained constant, but ncc increased towards 48 hpf suggesting an important role in osmoregulation in late developmental and early larval stages. In conclusion, the underlying mechanisms investigated in this study, seem to be under development during early embryonic ontogeny and thus not yet matured to regulate a molecular response to acidification. Nevertheless, these findings show that exposure to high PCO_2 conditions can impair normal development in this species and should be controlled in order to optimize European eel culture.

Introduction
Hypervacuolization and a whitish appearance of the pyloric caeca due to excessive lipid accumulation in the tissue are the main symptoms of the lipid malabsorption syndrome (LMS)[1]. LMS frequently affects Atlantic salmon *(Salmo salar L.)* fed with plant-based feeds containing high lipid level concomitant with low choline. Choline, free or as part of phosphatidylcholine, is required for lipoprotein assembly and secretion, and therefore essential for lipid transport[1]. The requirement for post-smolt Atlantic salmon fed with a plant-based diet containing 29% lipid has been estimated by Hansen et. al[2] to be around 3.4 g/kg. However, choline requirement most likely vary with production conditions, environmental and dietary factors. Fish at later stages of development need increasing level of lipids in the diet, and therefore, higher level of choline may be necessary to secure an adequate lipid transport. The results to be presented are part of an experiment conducted to evaluate how choline requirement in Atlantic salmon is affected by dietary lipid level and possible interaction with environmental temperature.

Materials and methods
Four choline deficient plant-based diets were formulated differing in lipid levels: 16%, 21%, 26% and 31%, respectively and fed to Atlantic salmon raised in fresh water at two different environmental temperatures: 8 and 15 degrees. Duplicate tanks of fish were used for each treatment.

Following an 8-week feeding trial, six fish from each tank were sacrificed and body measures taken. Thereafter, the fish were opened, and the organ package removed. Liver and intestines were separated from the other organs and cleaned of external lipid. Weights of liver, and the intestine separated into the pyloric region, mid and distal intestine sections were weighed and sampled. Tissue samples from all the fish were processed to perform gene expression analyses. Additional samples were processed to evaluate histological changes and steatosis level. Enterocyte vacuolization was scored according to their morphological appearance and graded as normal, mild, moderate, marked and severe (Fig.1). To conduct further chemical and digestibility evaluations, feed and feces were collected to be analyzed for dry matter, ash, crude protein, lipid and starch. The digestibility of the macronutrients was assessed by using Yttrium oxide as internal marker. Plasma was collected and stored for evaluation of plasma biomarkers of nutritional status: glucose, free fatty acids, cholesterol and total triacylglycerides.

Results
Growth performance was, as expected substantially, higher in fish raised at 15 degrees compared to those raised at 8 degrees, whereas no significant effect of dietary lipid level was observed.

The histological examination showed a significantly higher degree of vacuolization in the pyloric caeca of fish fed higher lipid levels compared to those fed lower lipid levels. Suggesting a clear dose response effect (Fig.2).

In parallel, the profiling of targeted genes involved in lipid uptake and transport, cholesterol metabolism, phosphatidylcholine and fatty acid synthesis, revealed a similar pattern.

However, preliminary results show that gene expression is highly influenced by the lipid level, rather than by the environmental temperature.

Other results of the experiment are under evaluation and will be presented at the conference.

Conclusions
The results obtained so far indicate that choline requirement is mainly affected by the lipid level, whereas the temperature effects show a less clear picture. Further data analyses will be conducted to achieve a clearer overall conclusion.

Introduction

Nutritional requirements of fish are classically determined through dose-response trials under controlled settings and generally defined as the nutrient amounts required to cover basal/maintenance costs plus whatever required to achieve a certain growth (or nutrient retention). Despite the cumulative knowledge acquired on the nutritional requirements of fish (see, e.g., NRC 2011), there is the possibility that, as fish traits change due to (e.g.) genetic improvement programs, fish nutritional requirements may be affected, eliciting the need to revise nutritional guidelines accordingly.

It is challenging to quantify the genetic improvement in feed utilisation and growth efficiency across years. As a complementary approach, it is possible to analyse annual trends of data on fish traits, with a "year effect" being used as a proxy of the "genetic effect" on fish traits. In particular, we assume that, if genetic improvement has affected fish traits in a meaningful way, one should be able to observe these changes along time, as genetic improvements accumulate.

We performed a meta-analysis of rainbow trout growth trials (from both published peer-reviewed sources and in-house trials) covering the 1979-2019 time period to determine: a) whether there is evidence of changes in important fish traits (e.g. feed intake rates, maximum growth capacity, growth efficiency) along time; b) what possible changes in nutritional requirements should we expect as a consequence of these changes in fish traits.

Materials and methods

For the analysis, information on a total of 24 rainbow trout growth trials (representing 172 tanks/cages/units) was collected from either scientific literature or in-house trials of SPAROS Lda, covering the time span between 1979 and 2019. This effort focused on sources which provided explicit information on growth, water temperature, feed intake and diet composition. When available, information on whole body composition was also collected from each source. For each period between measurements, aggregate estimates of relevant factors and responses (year, average temperature, average body weight, average growth, average feed intake, average digestible energy intake, average digestible protein intake, average energy gain, average protein gain) were calculated, resulting in a dataset with 534 points used for downstream analysis. Meta-analysis was performed by modelling relevant fish traits as a function of the factors (or transformed factors) using least-squares and quantile linear regression. Additional information about time-dependent trends of important traits (growth, FCR, fillet yield, viscerosomatic index) in rainbow trout, provided by Luke and obtained using an independent genetic trend analysis of the Finnish national breeding program, was also used to support this analysis (Kause et al. 2021).

Results

The results do not show strong evidence of year effects (and, thus, potential genetic improvement effects) on feed intake levels or maximum growth rates. Instead, there is a progressive improvement over time in traits related to growth efficiency (i.e. minimum FCR, maximum protein and energy retention efficiencies).

This improvement in growth efficiency is consistent with the independent estimates of the genetic improvement of rainbow trout traits in Luke's breeding program (red points/lines in Figure 1, Kause et al. 2021), which have been estimated avoiding the confounding effects of nutritional factors.

Discussion and Conclusion

Overall, the results support the notion that, at least in rainbow trout, genetic improvements have led to cumulative changes in traits that can affect fish nutritional requirements. We discuss the possible impacts of these trait changes on nutritional requirements and optimal feed formulations.

(Continued on next page)

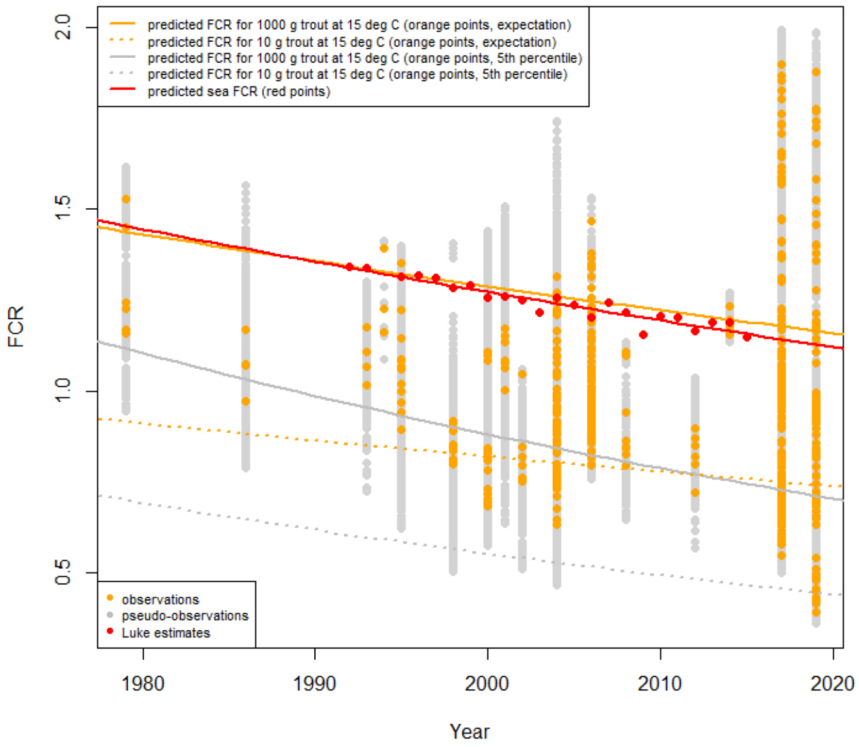

Figure 1 – Scatter plot showing measured FCR values as a function of year. Orange points represent measurements used for the analysis, grey points represent pseudo-measurements obtained by interpolation (not used for analysis), and red points represent Luke's estimate of genetic improvement. The effect of year on rainbow trout FCR estimated by Luke (red line) is consistent with the effects estimated in the current analysis (other lines).

Introduction
Macroalgae are natural sources of functional proteins and carbohydrates, carotenoids, phenolic compounds and vitamins. The use of macroalgae in fish diets has improved trends in fish growth, physiology, stress resistance, immune system, and fillet muscle quality. Nevertheless, very few macroalgae species have been investigated as potential components in finfish diets, reviewed in (Kamunde et al., 2019; Wan et al., 2019). Due to the variable nutritional content of macroalgae, a previous characterization of their properties is essential.

Methods
Here, we performed a characterization of biological activities in seven macroalgae species naturally occurring in the southwest region of the Portuguese coast: the brown algae: *Cystoseira sp*., *Fucus vesiculosus, Sargassum vulgarae*; the red algae: *Asparagopsis armata*, *Sphaerococcus coronopifolius*, *Plocamium cartilagineum* and the green algae: *Codium vermilara*. The algae were collected by diving and were dried in the shadow at room temperature. Ethanolic extracts were prepared (100mg/ml) and further characterized by evaluation of total phenolic content and *in-vitro* antioxidant activity, by determining superoxide, DPPH and NO scavenging activity. *In-vitro* evaluation of anti-diabetic, anti-inflammatory and antioxidant capacity was done by measuring inhibitory activities of the extracts on the enzymes: lipoxygenase, acetylcholinesterase, tyrosinase, xanthine oxidase, α-glucosidase and α-amylase.

Results
Brown algae, namely *Fucus vesiculosus,* and *Sargassum vulgarae*, demonstrated to have the highest phenolic content (Fig. 1A) and antioxidant capacity (Fig.1B).

Brown algae also revealed an enhanced enzyme inhibitory activity when compared with green and red algae, especially anti-diabetic effects, by inhibiting α-amylase and glucosidase enzymes as shown by the very low IC50 values (Fig 2). Anti-inflammatory activity by inhibition of lipoxygenase and acetylcholinesterase was prevalent in all extracts although at higher concentrations.

Conclusions
Extracts of seven species of naturally occurring marine macroalgae of in the southwest coast of Portugal were characterized for the first time regarding their antioxidant capacity and anti-enzymatic activity. There was individual variability regarding antioxidant levels but the brown algae *Fucus vesiculosus, Sargassum vulgarae* and *Cystoseira sp*., presented the highest levels of phenolic content and antioxidant capacity. *Fucus vesiculosus* and *Sargassum vulgarae* showed also good levels of anti-enzymatic activity in all analysis performed especially anti-diabetic activity by inhibiting α-amylase and α-glucosidase. Supplementation of finfish diet with these algae or algae extracts may bring benefits for the aquaculture industry and constitute a valuable functional ingredient in fish feeds.

Introduction

The effects of climate change have been observed all over the world, specifically on coralreefs, which may have an irreparable impact on biodiversity and ecosystem services in theoceans. When they are under stress, the photosynthetic corals can lose theirendosymbionts, (dinoflagellates from the genus *Symbiodinium,* usually known as zooxanthellae) being this process described as mass coral bleaching. Climate change havebeen associated with the rise of sea surface temperature and the occurrence of marine heatwaves. The frequency at which marine heatwaves occur has increased over the last few decades, resulting in a higher frequency at which coral bleaching events occurs. As aconsequence, coral species most susceptible to these events suffer irreversible damage, aszooxanthellae represents a substantial part of their nutrition, which can lead to coral degradation and, in more extreme cases, to their death, shifting the structure of coral reefs.However, in addition to autotrophic nutrition, provided by the products of photosynthesis,photosynthetic corals can also feed by heterotrophy, and are consequently classified as mixotrophic animals. According with several studies, this feeding strategy can contributeto corals resilience to stress.

Methodology

In this context, the aim of this study was to evaluate the response to heat stress of mini colonies of *Palythoa sp*. (subclass Hexacorallia; order Zoantharia) after four months of culture without (NF) and with (F) feed supply. Immediately after this period the thermal stress test was performed: two groups (25NF and 25F) remained with the culture temperature (25±1°C) while other two groups (30NF and 30F) were exposed to a gradualwater temperature increase during 24 hours until reaching 30±1°C. This temperature wasmaintained during eight days. Fed corals were compared with corals without feed supply,in order to evaluate the diet effect in a scenario of thermal stress. To support this experimental assay, an evaluation of photobiology parameters, oxidative and thermal stress biomarkers, oxidative damage, and energy reserves was carried out. No mortality was recorded during the experimental assay.

IMPLEMENTATION OF A MACROALGAE SUPLEMENTED FEED FOR SENEGALESE SOLE (*Solea senegalensis*) REARING

Introduction
Macroalgae offer nutritional added value in fish diet, since they were shown to have beneficial effects in fish growth, physiology, stress resistance, immune system, and fillet muscle quality and have been successfully introduced in feed for farm animals (Kamunde et al 2019; Wan et al, 2019; Nazarudin et al, 2020). Nevertheless, the use of macroalgae in the production of Senegalese sole have never been tested and the potential effects on growth, reproduction and skeletal development are still to be determined. The aim of this study was to assess the benefits to Senegalese sole performance by incorporating dry algae, rich in phylloquinone and antioxidants, into a semi-humid diet specifically formulated and optimized for *S. senegalensis* rearing.

Methods
After establishing a macroalgae panel, previously characterized for their phylloquinone and antioxidant content, we selected *Plocamium cartilagineum*, *Sargassum vulgare* and *Cystoseira sp*. for incorporation (5% dw) into *S. senegalensis* feed. The dietary experiment was carried out during alevin 3 stage (mean weight 16g) and was carried for 4 months. The main parameters determined included growth, bone quality and acute stress resistance.

Results
Fish showed a good acceptance of the new diets and during the experimental period of 117 days increased over 3-fold in wet weight. Survival was not affected by dietary supplementation with the selected seaweeds. Algae supplementation had a small effect on growth parameters: final weight amongst groups was similar and feed efficiency and survival rate were not affected (Table 1). The condition factor (K%) was lower in *Sargassum vulgare* fed groups ($p<0.05$) and daily weight gain was smaller for *Cystoseira sp.* and *Plocamium cartilagineum* groups ($p<0.01$) but overall, the specific growth rate (SGR%) was not influenced by macroalgae supplementation in the diet.

Analysis of bone quality was determined by vertebral mineral content and revealed a decrease in the levels of calcium and especially phosphorus in the fish fed with *P. cartilagineum* supplemented diet (Table 2). Fish fed with *S. vulgare* supplemented diet also showed a slight decrease in phosphorous levels, but not in calcium. Nevertheless, these differences were not reflected in less radio-dense bone as diagnosed by X-Ray analysis (data not shown).

Stress resistance was performed by air exposure challenge, which led to an acute stress response characterized by an increase in the cortisol levels in all groups (Figure 1). Nevertheless, the timing and dimension of the response was different for each diet, while the *P. cartilagineum* fed group followed a similar response to the control diet group, the amplitude of the cortisol peak at 1.5h was significantly smaller ($p<0.001$). *Cystoseira sp.* fed group reached the cortisol peak at 1h while recovery to pre-stress levels occurred at 1.5h, sooner than control group. *S. vulgare* fed group displayed the highest stress response with cortisol peak occurring at 1h and continuing to rise at 1.5h. By 3h post-stress all groups had reached basal levels of cortisol except *S. vulgare* ($p<0.0001$). The secondary response to stress was evaluated by plasmatic glucose and lactate levels. *Cystoseira sp.* group displayed an earlier increase in glucose levels (at 0.25h, $p<0.05$), while *S. vulgare* fed diet displayed an increase at 3h in both glucose ($p<0.001$) and lactate levels ($p<0.0001$). *P. cartilagineum* fed group had levels of glucose and lactate similar to control group at all timepoints.

Conclusions
Supplementation of macroalgae rich in phylloquinone and antioxidants showed no deleterious effects on growth, feed efficiency parameters and survival. On the other hand, bone quality of *Solea senegalensis* fed with *P. cartilagineum* and *S. vulgare* enriched diet may be affected since phosphate content was reduced. Regarding acute stress response, *Cystoseira sp,* enriched diet allowed for a faster recovery of the stress condition, while *P. cartilagineum* supplemented diet led to a decrease of cortisol levels. Further studies at molecular and histological levels will provide further insights on the mechanisms giving rise to these distinct physiological stress responses. As it stands the benefits/drawbacks of using these macroalgae in *S. senegalensis* diet need further experiments and will be reinforced by analysis of immune response and nutrient content in the fish.

Introduction

Senegalese sole (*Solea senegalensis*) is a highly valuable flatfish species in the aquaculture of SouthernEuropean countries. Aquaculture produced fish are potentially subjected to stress and pathogens due to several environmental factors. *S. senegalensis* is especially vulnerable to diseases such as Pasteurellosis or Flexibacteriosis (Toranzo et al., 2005). Previous studies reported that macroalgae can be used as an antioxidant additive, and are natural sources of liposoluble vitamins, such as vitamins K1, E and A, which are known to improve immune competence (Kraan, 2013). With this work we propose to increase health and well-being of *S. senegalensis* under aquaculture conditions, by using diets supplemented with macroalgae as natural sources of liposoluble vitamins and antioxidants, in this way promoting higher resistance to disease outbreaks and avoiding the use of antibiotics and other treatments.

Methods

The experiment was carried out at Ramalhete Marine Station Facilities at the University of Algarve (Faro, Portugal) in a RAS system (temperature: 17-19ºC; salinity 36ppt; photoperiod 14h light:10h dark; dissolved oxygen above 85% saturation level). Fish (weighing on average 16.22±0.9g wet weight) were maintained for 9 months and feed with a commercial diet supplemented with 5% dry algae: *Plocamium cartilageneum*, *Cystoseira sp*., *Sargassum sp*. and a control diet supplemented with 5% wheat (Sparos, Lda, Olhão, Portugal). At the end of the trial a challenge with *Photobacterium damselae* sub. *piscicida* was performed in IPMA/EPPO (Olhão, Portugal). For that, 19 fish from each experimental diet (weighing on average 66.2±26.9g wet weight) were subdivided into 3 groups and received $5x10^8$ CFU/ml of *Photobacterium damselae* sub. *piscicida* through intraperitoneal inoculation (0,1ml). Another 18 (3x6) fish from the control diet were divided into 3 subgroups and received a saline control inoculation. Mortality was recorded daily.

Results

This study intended to evaluate the effects of dietary macroalgae inclusion in the resistance to pathogens, namely mortality, in sole.

Statistical analysis showed no significant differences between group diets in each sampling time. Nevertheless, *P. cartilageneum* and *Cystoseira sp*. enriched feed had slightly better results in the mortality assay at 120h (95,24% vs 100%).

Conclusions

Algae supplementation in fish diet has the potential to improve resistance to disease outbreaks. Here supplementation with 5% *Plocamium cartilageneum*, *Cystoseira sp*. and *Sargassum sp*. showed no significant effect in resistance of *S. senegalensis* juveniles to *Photobacterium damselae* sub. *Piscicida*. However other algae or higher algae incorporation rates should be tested to determine the potential benefits of macroalgae as natural sources of bioactives for dietary enrichment.

Introduction

Scientific interest for photosynthetic corals has been steadily rising due to climate change, but also because these organisms are increasingly cultured for marine conservation purposes, bioprospection and the aquarium trade (Leal et al., 2013). Nevertheless, the intricate physiology of these organisms is still not well known. Furthermore, photosynthetic corals are unique in the animal kingdom, on the one hand, due to the sheer simplicity of their tissues, and on the other hand due to the complexity of several different symbionts sharing the same organism. The increasing awareness in these organisms has been fostering the scientific community interest, and numerous studies have been developed, namely toxicological trials in which the use of organic solvents is customary. The work described here sheds light on the physiologic response to one of the more commonly used solvents, methanol, of three distinct coral species (*Montipora digitata*, *Sarcophyton glaucum* and *Zoanthus* sp.). These species represent the major groups of cultured photosynthetic corals (*Scleractinia, Alcyonacea, Zoantharia*), providing crucial insights regarding the physiology of cultured corals.

Materials and methods

Coral specimens were collected in the Indo-Pacific and acclimated for one month in standardized modular systems (Rocha et al*.,* 2015). After acclimation, colonies were fragmented and randomly assigned to different methanol concentrations (from 0.01 mL L-1 to 2.9 mL L-1) for 96 h. After the trial, we assessed the antioxidant response (catalase activity – CAT, glutathione s-transferase activity – GST and total glutathione – tGSH), the lipidic peroxidation – LPO and the photosynthetic activity using rapid light curves (maximum electron transport rate – ETRmax and maximum quantum yield – F_v/F_m). Data were analysed in R (2021) with a principal component analysis – PCA.

Results

The principal component analysis clearly shows separate groups representing the different species. The PC1 is sufficient to separate the species and is responsible for the variation within the *Montipora digitata* group. The antioxidant response and lipid peroxidation are the variables that contribute more to the PC1 explaining 40.58% of the variation. The PC2 is responsible for the variation within the groups, more notably within the zoanthid but also within the *Sarcophyton glaucum*. The photosynthetic indicators, F_v/F_m and ETRmax, are the variables that contribute the most to the PC2, which explains 20.03% of the total variation.

Discussion

The response of the zoanthid is stronger in photosynthetic indicators. This behaviour is intriguing given the fact that zoanthids usually prioritize autotrophy over heterotrophy (Leal et al., 2017), and consequently, conserving the photosynthetic apparatus was expected, although not observed. The response of *Montipora digitata* is reflected mainly throughout the antioxidant response. This reaction is typical to several other organisms when faced with chemical stressors (*e.g.* Rodrigues et al. 2015). Finally, the *Sarcophyton glaucum* response is somewhat less expressive than the other species. Nonetheless, the response is more variable throughout the photosynthetic apparatus. Given the results, our study highlights the need to consider the physiological intricacies of apparently similar organisms that are often entitled to the same living being. The oversimplification of the *Anthozoa* class hinders the unfolding of the physiology of these organisms, which is the cornerstone to better understand these organisms, and ultimately better culture techniques.

Introduction

AquaVitae (AV) is a research and innovation project funded by the European Union's Horizon 2020 program. AV's overall objective is to introduce new, and expand existing, low trophic species products and processes to marine aquaculture value chains across the Atlantic. Diversification of macroalgae production is paramount if macroalgae are to reach their full potential for the provision of food, feed, and biomass for many other applications. Therefore, species of macroalgae not yet fully exploited commercially but with recognised potential were investigated to optimise production conditions.

Codium tomentosum is a valuable source of food and biomass, which is currently cultivated at a pilot scale in land-based aquaculture. Cultivation is carried out through biomass fragmentation followed by vegetative propagation in tumble culture, which may result in reduced genetic diversity and reduce technology options for its cultivation.

To develop a new hatchery protocol based on sexual reproduction to produce seedlings of *C. tomentosum* it is essential to understand the basic reproduction biology of the species. Sexual reproduction in the *Codium* genus is performed through zygotes resulting from the gamete fusion. The zygote germinates into a diploid germling, a siphonous filament, which eventually develops into the adult thalli. The peak of sexual maturation for *C. tomentosum* has been reported to be reached in winter, but no comprehensive analysis on the seasonal reproductive status of the species has been done until now. Moreover, the control of the life cycle under artificial culture conditions is challenging and has not been achieved so far.

This study aims to evaluate the effect of the season and culture conditions such as light intensity and spectrum, nutrient concentration, and water movement on the reproductive status, and early stages of development of *C. tomentosum*. The ultimate goal is to define optimized culture conditions for sexual reproduction, which will form the basis for the future establishment of hatchery protocols for seedling production.

Material and methods

Specimens of *Codium tomentosum* were collected from two natural populations from Northern Portugal: Aguçadoura shore (41° 26′ N, 8° 47′ O), located in **Póvoa** de Varzim, and Viana- Norte (41°41'49.3"N, 8°51›03.4»W), located in Viana do Castelo. The biomass has been collected monthly or bi-monthly since January 2020 for evaluation of seasonal variation in the reproductive status.

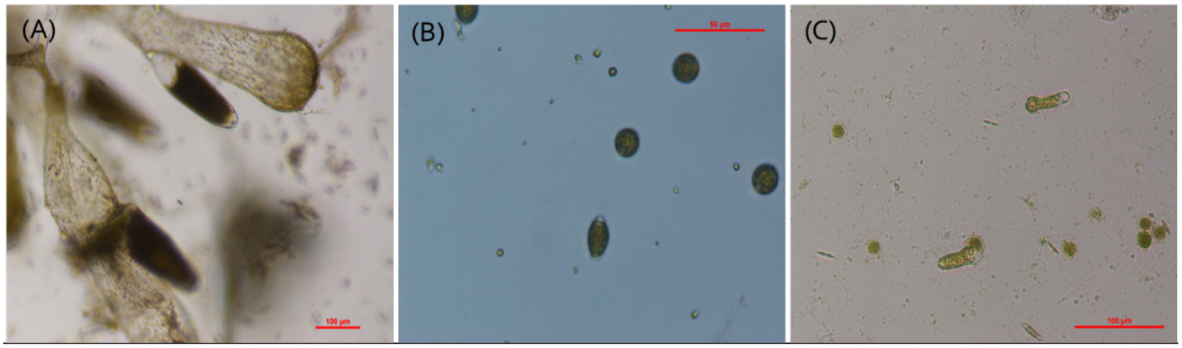

Figure 1. (A) Utricles with gametangia; Scale bar = 100 μm (B) Male and female gametes 24 hours after release; Scale bar = 50 μm. (C) Zygotes started to germinate forming filamentous germlings (4 days in culture); Scale bar = 100 μm. Pictures by Gonçalo S. Marinho

(Continued on next page)

The species identification, observation of reproductive structures, gamete release, zygote formation, and early stages of development were followed through microscopic observation. Images were recorded with a coupled camera, and post-processed (e.g. measurements) using ImageJ software.

The effect of the light spectrum (white, blue, green, and red) and intensity (20, 40, and 60 **µmol** m^{-2} s^{-1}), nutrient medium concentration (PES, PES/2, PES/10, and natural seawater), and water movement on the early stages of development of *C. tomentosum* was investigated.

Results

The absence of mucron in the apical part of the utricles indicates that the biomass collected from natural populations corresponds to *C. tomentosum*, and not the co-existing invasive *C. fragile*.

The presence of reproductive structures, gametangia (Figure 1A), which are indicative of the reproductive status of the specimens, was observed in the samples collected in January and March 2020, they were absent in the samples collected in May and June 2020, and then were observed again in the samples collected from August 2020 to March 2021. The reproductive status was further confirmed by the liberation of gametes, zygote formation and germination.

Both male and female gametes were successfully released and identified (Figure 1B), and after a few days in culture, the development of a zygote could be observed. After approximately 3 to 7 days each zygote germinated into a filamentous germling (Figure 1C). The germlings obtained from the specimens collected in the winter months (December 2020 and January 2021) presented a faster development than those obtained from specimens collected in any other month. Nevertheless, even after some months in culture, the formation of adult thallus could not be observed.

Regarding the culture conditions, the filamentous germlings had a faster development when exposed to a light intensity of 20 μmol m^{-2} s^{-1}, compared to 40 or 60 μmol m^{-2} s^{-1}, regardless of the light spectrum applied. Moreover, the green, red, and white light spectra resulted in faster development than the blue. The germlings performed better when grown in PES medium at normal concentration compared to those grown at lower concentrations (PES/2 and PES/10), or natural seawater alone. Moreover, preliminary results suggest that water movement promotes the development of the germlings compared to cultures kept without movement. The germlings developed (in length) for several weeks, and after some weeks some branching could be observed. However, even after some months in culture, the formation of adult thallus could not be observed.

Discussion

The results showed that *C. tomentosum* from the studied natural populations is reproductive most of the year with exception of a short period in spring-early summer, which matches a period in which an immature new generation of *C. tomentosum* is emerging for the rocky substrate to form the upright adult thallus replacing almost entirely the former one. This study will continue for another year to confirm the observed pattern.

Culture conditions that promote the development of germlings have been identified with respect to light intensity and spectrum, nutrient concentration, and water movement. Nevertheless, even after some months in culture, the development of upright adult thallus was not achieved. This suggests that the culture conditions required to induce the morphogenesis of germlings to form the spongy thallus may not be the same that favor the development of the filamentous germlings. Further multifactorial trials will focus on the specific condition required to induce the morphogenesis and thereby obtain seedlings of *C. tomentosum*.

Acknowledgments

This study/AquaVitae project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No 818173.

DYNAMICS OF HARMUL ALGAE BLOOMS IN OFFSHORE AQUACULTURE AREAS BY OCEAN COLOUR REMOTE DETECTION

C. Silveira [1,*], P. Goela[2], S. Cristina[2]

[1] Universidade do Algarve [2] CIMA– Centre for Marine and Environmental Research of the University of Algarve, Campus de Gambelas, Faro, Portugal
*E-mail: catissilveira@gmail.com

Introduction:
Phytoplankton are unicellular organisms, primary producers and are the base of the marine food web are also important for the feeding of bivalves crustaceans, as well as larvae of commercially crustaceans and fish. Phytoplankton blooms are regular and seasonal in many marine areas, but in some situations, they can cause negative impacts, involving serious economic losses for aquaculture, fishing and tourism operations and have major environmental and human health impacts. These impacts can be caused by diatoms such as *Pseudo-nitzschia* spp., dinoflagellates such as *Dinophysis* spp. and other harmful algal blooms (HABs), which can produce toxins that include Diarrhetic Shellfish Poisoning (DSP), Amnesic Shellfish Poisoning (ASP) and Paralytic Shellfish Poisoning (PSP), due to the consumption of contaminated bivalves. The aim of this study was to detect the dynamics of HABs in offshore aquaculture areas using ocean colour satellite remote sensing.

Materials and methods:
Chlorophyll-a satellite images adquiredfrom the SW coast of Portugal has been collected from the sensors Moderate Resolution Imaging Spectroradiometer, aboard the Aqua satellite (MODIS-AQUA) and Visible Infrared Imaging Radiometer aboard the Suomi National Polar-orbiting Pathership (VIIRS Suomi-NPP) and crossed with algal bloom events in the region of study reported in literature (Danchenko et al., 2019) and from monitoring data from IPMA (Portuguese Institute for Sea and Atmosphere) in the L7a and L7c zones. It has been also made a remote sensing reflectance (R_{rs}) spectral shapes analysis were 3x3 pixel matrices were extracted from different coordinates between 2 km and 12 km of distance from the coast in both L7a and L7c zones.

Results:
Variations of Chlorophyll-a concentration during the occurrence of HABs in 2014
Ocean colour remote sensing was able to detect a bloom forming in the beginning of July, reaching 2.96 $mg.m^3$ of Chlorophyll a which started to fade after de 9th of July (Fig. 1). According to the literature (REF), on July 14, 2014, it was observed a bloom of *Dinophysis caudata* and *Dinophysis acuminata*, with a concentration of 520 cells L^{-1}. For the same day, the presence of *Gymnodinium catenatum* was also reported, with 2480 cells L^{-1}, which has resulted in the harvest banning of *Mytilus edulis*, for the 14/07/2014, in zone L7a. IPMA data (Site) shows that on July 16, for the L7a zone, the concentrations of *Pseudo-nitzschia* were 10800 cells L^{-1} and of *Dinophysis* was 240 cells L^{-1}.

Spectral analysis of phytoplankton communities during the occurrence of blooms
The R_{rs} (l) spectra extracted from 16.08.2014 (Fig.2a) and the R_{rs} (l) from 24.08.2014 (Fig.2b), which are the closest dates to the day of collection by IPMA, reveals differences in the spectral shapes, which may indicate a change in the phytoplankton community in the region close to aquaculture area in the region of study.

Discussion:
This study shows a DSP and ASP bloom initiated after a high Chorophyll a blooms detected with the use of ocean colour images and data. Further studies are needed to confirm that changes in spectral differences are due to ASP and DSP producing communities and not to other optical constituents in the water column.

CIRCULARITY AND WASTE VALORISATION FROM A (RAS) FISH FARMERS PERSPECTIVE

Paul-Daniel Sindilariu*, Jan Giebichenstein[1]

* Next Tuna GmbH, Londoner Strasse 3, 60327 Frankfurt am Main, Germany / Tropenhaus Frutigen, Tropenhausweg 1, 3714 Frutigen, Switzerland
paul@nexttuna.com
[1] Next Tuna GmbH, Londoner Str. 3, 60327 Frankfurt am Main, Germany / C-Feed AS Brattørkaia 17B 7010 Trondheim Norway

Introduction

In the framework of the European Green Deal, the EU commission has published its Aquaculture strategic guidelines. In these guidelines, the circular approaches, waste valorisation and recirculating aquaculture production are key elements to increase the needed EU aquaculture production.

Within the Horizon 2020 framework, the Commission financed three major research projects looking into novel approaches of aquaculture farming and circular economy in aquaculture (Gain, IMPAQT and iFishIENCi). These projects bring essential new impulses to the discussion on waste valorisation and circular concepts in aquaculture. However, the majority of presented circular solution take the approach from the perspective of the additional value creation, rather than from the need of the fish farmer. This presentation want's to bring back the focus of the discussion to the needs of the industry.

The Farmers Perspective

However, compared to the scientific approach to the topic, a fish farmer has a far more practical approach to waste management, waste valorisation and circularity.

At the moment all waste handling in aquaculture is a necessity due to legal/public requirements. Waste management is part of the production license of each aquaculture facility but the rules for waste management differ tremendously from country to country within the EU, from region to region within one country and even from site to site within one region.

For the fish farmer, waste management, in most cases, does not produce more fish, or makes the product more appreciated. Waste management only adds costs, in a very competitive business environment.

Thus, any new approach to waste valorisation to be accepted by the industry, it needs to have some key features:

1. Change the waste handling for the farmer from a cost factor, to a revenue stream, or at least to a lower cost factor.
2. Easy and simple solution, as the farmer wants to focus on fish production and not on waste valorisation.
3. Robust and reliable solution, the farmer never wants to come in a situation, where he has to stop the production, because the waste handling system is out of operation.

Potential solutions

In order to achieve the positive acceptance by the industry, solutions to waste valorisation need to have the following features:

1. Low mutual dependency and interconnection. None of the partners should be dependent of a well working process of the other partner. Thus, issues in the valorisation process do not affect the production capacity of the fish farm and vice versa.
2. No spatial dependency. The valorisation process should not absolutely need to happen next to the fish farm, as the required space, license, infrastructure might not be available. Ideally the valorisation of waste become just a question of smart logistics.
3. Mutual benefit. Both the aquaculture producer and the waste valorisation should profit from the valorisation process.

In conclusion new potential valorisation technologies need to go far beyond the actual applied industry standard of sludge thickening and subsequent biogas production or land application as fertilizer.

EFFECT OF FILAMENTOUS FUNGI *Neurospora intermedia* AND FEEDING PERIOD ON GUT MICROBIOTA OF RAINBOW TROUT (*Oncorhynchus mykiss*)

Aprajita Singh*, Sajjad Karimi, Aleksandar Vidakovic, Markus Langeland, Johan Dicksved, Jorge Ferreira, Mohammad J. Taherzadeh, Anders Kiessling and Torbjörn Lundh

Department of Animal Nutrition and Management, Faculty of Veterinary Medicine and Animal Sciences
Swedish University of Agricultural Sciences, 750 07 Uppsala, Sweden

Introduction

Microbial proteins including filamentous fungal biomass contain noticeable levels of protein, fatty acids and other nutritious components (Karimi *et al*., 2018). Also fungi cell wall contains chitin and chitosan and other polysaccharides as their bioactive components having immunomodulatory and antimicrobial properties (Mario *et al*., 2008, Esteban *et al*., 2001). Thus, fungi may play a role in improving the health of farmed fish. Several studies has been reported that environmental (abiotic) and host (biotic) factors play important role in shaping the gut communities (Ingerslev *et al*., 2014a; Ringø *et al*., 2016; Yan *et al*., 2016; Sun *et al*., 2020). Most of these studies investigated the short or long term dietary effect of diets on gut microbiota. However, a study targeting the gradual change in microbial communities over time with the type of diet that to our knowledge has not been described earlier. Diet can adversely modulate the gut microbial composition leading inflammation of distal intestine as in case of Atlantic salmon fed with higher levels of soy protein (Gajardo *et al*., 2017). It is necessary to understand the interaction between host, gut microbiota, diet and feeding strategy for the development of novel diets ensuring better fish health and welfare. Hence, this study was conducted to observe role of *N. intermedia* in modulating the intestinal microbiota of rainbow trout under provided feeding periods.

Materials and Methods

Three experimental diets were prepared, a reference diet (RD), a non-preconditioned diet (NPD) and a preconditioned diet (PD). Diet RD was prepared with fishmeal as a major protein source without fungal biomass. Formulation for diet NPD and PD were created by mixing 30 percent of *Neurospora intermedia* biomass and 70% of diet RD according to (Cho, 1979). Formulation for diets PD and NPD were same, however, diet PD was conditioned in a convection oven (Electrolux Professional, FCE061) at 105°C for 5 min in order to increase the degree of gelatinization of starch and emulate temperature treatment during extrusion conditions. Twenty fish were distributed randomly in each experimental tank (mean weight: 127± 4 g) and were acclimated for 9 days on commercial diet. Feeding was provided in excess at 1.5% of body weight in excess. Gut microbiota were analyzed on day 0, 10, 20 and 30. Similarity Percentage Analysis (SIMPER) and Analysis of Similarity (ANOSIM), Principal coordinate analysis (PCoA) and Principal component analysis (PCA) were performed using Paleontological Statistics Software version 4.03 (PAST).

Results

The bacterial OTUs abundance were dominated by two phyla Firmicutes (58%) and Proteobacteria (15%). From day 0 to day 30, Firmicutes ranged from 38 % to 79% followed by Proteobacteria which ranged from 8% to 24% for different diets. *Peptostreptococcus* (9%), *Lactococcus* (*L. lactis,* 7%), *Brevinema* (6%), *Streptococcus* (5%), *Deefgea* (5%) and *Anaerotruncus* (4%) were the most abundant over 30 days. Diet and day has significant effect on shaping the gut microbial composition. The pairwise comparison of the treatments groups were significantly dissimilar within and between day intervals for top 6 OTUs. PCA plot reveals the occurance of *Peptostreptococcus* and *Streptococcus* are correlated. Their abundance was correlated to initial days of feeding in all diets whereas abundance of *Lactococcus* was more correlated to final days of feeding. One way ANOSIM confirmed that the microbial composition was similar at day 0 and day 30 whereas dissimilar at day 10 and day 20. The overall microbial composition for diet RD is different from PD and NPD at day 10.

Discussion

The analysis reveals that the core gut microbiota was dominated by Firmicutes followed by Proteobacteria which is similar with other studies on salmonids (Nayak, 2010; Gajardo *et al*., 2017). Bacterial composition for plant protein based diets or fish meal free diets show increase in abundance of Lactobacillales in rainbow trout and salmon respectively (Schmidt *et al*., 2016; Michl *et al*., 2017). Earlier studies suggested that change in microbiota with change in diet was observed in salmon, rainbow trout and brown trout after first feeding (Ingerslev *et al*., 2014b; Michl *et al*., 2017; Michl *et al*., 2019). No change in the gut microbiota with the time was observed suggesting after certain days or longer feeding gut microbiota gains stability. Similarly, it was observed from the analysis that gut microbiota were significantly dissimilar at day 10 and day 20 and were similar at day 30 of feeding suggesting that the microbiota might be approaching stability.

(Continued on next page)

Conclusion

- It can be concluded that diets with *N. intermedia* and duration of feeding shapes the gut microbial composition of rainbow trout.
- N. intermedia can be fermented in the gut by lactic acid bacteria.
- There is a shift in gut microbial composition with days of feeding and microbiota attains stability at 30 days. Therefore, minimum 30 days feeding trial is suggested for functional gut microbiome studies.

A NEW TURBELLARIAN PARASITE INFLICTING SERIOUS MORTALITIES IN RED DRUM AQUACULTURE

Introduction

Turbellarian flatworms are controverted organisms with changing taxonomical adscription. Most of these platyhelminths are terrestrial and aquatic free-living organisms, but also include symbiotic species, and few cases of parasitic ones associated to fish, crustaceans and molluscs. Here, we report an epizootic due to a rhabdocoelan infection in cultured red drum (*Sciaenops ocellatum*) in a sea-cage farm in a tropical area. We describe the morphological, histological and molecular approaches for its identification.

Methods

Two subsequent outbreaks in 2018-2019 affected red drum in the first year after entering the farm (weight ranging from 12g to 180 g). Water temperature ranged from 23 to 29.5°C and salinity was 36 ‰. Different types of samples of fish presenting acute mortalities and clinical signs were taken. Fresh smears of gills were observed at light microscope on site. Necropsied gills were fixed in 10% neutral buffered formalin (NBF), processed routinely, embedded in Technovit7100-resin, sectioned at 1 µm and stained with Giemsa, PAS, and alcian blue-PAS. Some NBF-fixed specimens were dehydrated, cleared with dimethyl phthalate and stained with iron acetic carmine. Another sample set was stored in 70% ethanol for molecular identification. The ribosomal genes 18S and 28S were PCR-amplified (Giribet et al., 1996; Jovelin & Justine, 2001) and used concatenated to infer a phylogeny by Bayesian inference. Other representatives of Rhabdocoela present in GenBank were included in the analyses. Bacterial samples were taken for basic bacteriological analysis.

Results

Prevalence of infection was 100 % in some stocks, and mortality ranged from 5% to 60%. Clinical signs included anaemia, weight loss, pale and necrotic gills with mucous masses, desquamation and erosion of the skin, and asphyxiation. Bacteriological results were variable, from negative to opportunistic bacteria or septicaemia, often accompanied by splenomegaly. Microscopical observation of gill scrapings of affected fish revealed ciliated turbellarians with eyespots. When gravid adults were mounted in seawater under a glass coverslip, active swimming eyed juvenile emerged. Worms, with characteristic anterior eyes, were visible under low magnification (Fig. 1). The morphometric study of fixed worms showed that adults were elongated, piriform with pointed posterior end (854-1403 × 356-589 µm) and a short anterior distal projection. Eyespots were separated. Pharynx was subconical and anterior. Testes and ovary were small and follicular. Some large specimens exhibited numerous completely developed juveniles occupying most of the body. Based on the body shape, pharynx arrangement and the presence of juveniles, the worms were tentatively assigned to the family Graffillidae.

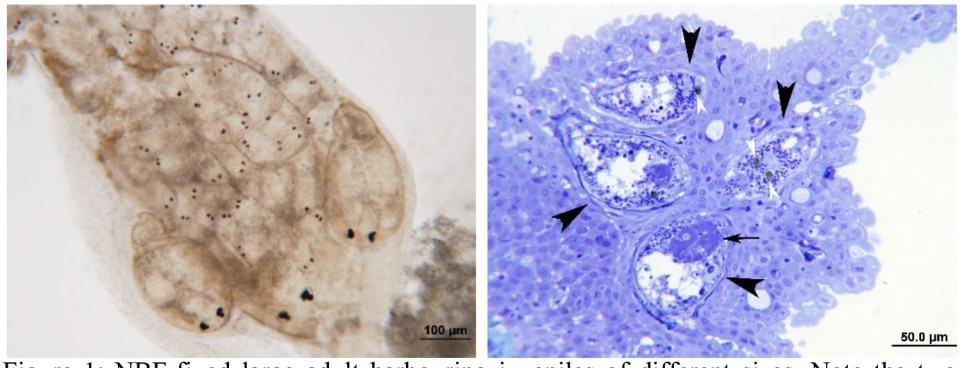

Figure 1: NBF-fixed large adult harbouring juveniles of different sizes. Note the two eyespots in all of them (left). Giemsa-stained gill section showing four worms (black arrowheads) buried in the tissue. Note the eyespots (white arrowheads) and the pharynx (arrow) (right).

(Continued on next page)

Histologically, worms were placed in shallow epithelial tunnels on secondary and primary lamella, and even on the cartilages of gill arches, and some small specimens were found free among gill filaments (Fig.1). The infection caused destruction of the normal gill architecture with minor histopathological reaction, lacking signs of necrosis or inflammation. Among the epithelial host cells forming the tunnel walls, little or no focal hyperplasia was observed. The primary direct effect of the turbellarian gill infection was the loss of respiratory function by impairment of gas exchange in parasitized lamella. In some sections, long filamentous bacteria covered the tissue and worm surface, suggesting secondary bacterial infections involved in the epizootic case. The worms enclosed within epithelial tunnels appeared to be covered by a sheath of cellular and mucous material.

The molecular study placed the parasite within the Order Rhabdocoela, Suborder Dalytyphloplanida and Infraorder Neodalyellida. However, it was highly divergent from all the deposited sequences of the group, indicating that it may belong to a new species not yet described. It did not match with the recent sequence of the old known *Pseudografillaria arenicola* (Meixner, 1938), and it could be similar to a turbellarian causing epitozootics (with mortalities > 60%) in the same fish species as well as in other cultured marine fish in China (Wang et al., 2002).

Attempts to treat the infections with formalin baths were unsuccessful.

Conclusions

The histological examination revealed the invasive nature of the worms infecting red drum, and the gill damage could easily explain the anaemia and the asphyxiation of the fish. According to the obtained molecular data, the available orphan sequences and morphological descriptions, the species could be new to science, but probably present in other far distant locations and hosts. Studies are ongoing for the full description of the species. The current study and the previous reports on turbellarians causing lesions on various marine fish from the Pacific, Caribbean, Chinese and Australian waters, suggest that these parasites may represent and emerging problem in aquaculture, as they are transmitted fish-to-fish, and topic treatments can be ineffective since they live within gill tissues. Future studies are needed to decipher if other reservoir hosts could be involved in its transmission to cultured fish, and which farming conditions favour its blooming.

Introduction

In the last years, the increase in aquaculture production has forced a change in fish feed composition, with increasing substitution of fish meal (FM) and fish oil (FO) by more available plant sources. Despite the fact that their inclusion rates in compound feeds for aquaculture have shown a clear downward trend in the twenty past years (FAO, 2018), their total replacement by plant feedstuff is still not optimal, leading to reduced growth and reproductive performance (Lazzarotto et al., 2015)no whole breeding cycles of fish fed diets free from marine resources has been reported to date. We therefore studied the reproductive performance of trout after a complete cycle of breeding while consuming a diet totally devoid of marine ingredients and thus of n-3 long chain polyunsaturated fatty acids (n-3 LC-PUFAs.

The broodstock diet, and in particular the lipid and fatty acid composition of the diet, is known to play a key role in reproductive efficiency and survival of the progeny (Izquierdo et al., 2001). And a major problem when replacing both FM and FO by plant sources is the lack of n-3 long chain polyunsaturated fatty acids (n-3 LC-PUFAs), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

Materials & methods

For that purpose, we studied the effect, in rainbow trout female broodstock, of the plant diet supplemented with microalgae (MA) compared to a conventional commercial diet rich in FM and FO (C) on a reproductive performance and egg quality. The microalgae *Schizochytrium sp.,* chosen to supplement plant-based diet in this study, is known to be a rich source of DHA. An 18 months trial involving two reproductive cycles was carried out. During two spawning seasons, we followed the performance of female reproduction measuring fecundity and egg quality. We also investigated the consequences of maternal nutritional history on offspring after the second spawning season. Experimental design is presented in figure 1.

Results & discussion

Despite a significantly lower growth rate in female fed MA diet, the reproductive performances were not affected (egg weight, absolute fecundity). Moreover, in terms of egg quality, during the second cycle of reproduction, the egg diameter was significantly lower with the MA diet, but the eggs presented a significant better egg integrity (less white eggs after 24 hours of hydration) than with a C diet, which is a sign of a better egg quality. Regarding embryonic development, eggs from females fed MA diet had significantly higher hatching survival rate than eggs from females fed C diet. No effect was observed on fry weight at resorption. We linked this better egg quality to a better-balanced fatty acid profile.

Moreover, feeding female with the MA diet had no effect on the growth and survival of the progeny compared to feeding with C diet. However, consequences of maternal nutritional history were observed in the lipid metabolism of progeny. Progeny from female fed MA diet had increased fatty acid biosynthesis and cholesterol synthesis metabolisms. Genes involved in these metabolisms were up-regulated in progeny from female fed MA diet compared to progeny from female fed C diet, whether challenged with an MA diet or fed a commercial diet (figure 2).

Conclusion

To conclude, in the present study, we demonstrated that DHA-rich microalgae supplementation in a plant-based diet allowed to maintain reproductive performance and egg quality comparable to a conventional commercial feed rich in FM and FO. Moreover, this study confirms a reprogramming of the lipid metabolism of progeny in relation to the origin of maternal nutritional.

Introduction

Atlantic salmon (*Salmo salar*) is an anadromous fish species, born in freshwater, spend most of the life in seawater and thereafter return to freshwater to spawn. For salmon aquaculture, female broodstock are kept in seawater for initial sexual maturation and transferred to freshwater few months prior to spawning. To keep the continuation during production cycle for aquaculture, it is important to have access to new generations of salmon throughout the year.

By adjusting the time for transferring sexually mature broodstock female from sea cages to land-based freshwater cages, the breeding companies have developed protocols to expand the spawning season. Water temperature, feeding and light regimes are abiotic environmental factors that can either accelerate or prolong the time until spawning. However, adjustments in production protocols might introduce both beneficial traits but also functional changes in tissues due to poor nutrition during organ development for the new generation according to the Barker hypothesis (Reviewed by Heindel and Vandenberg, 2015). This phenomenon is called intergenerational programming whereby the nutritional status of the parents influences the next generation (Reviewed by Heard and Martienssen, 2014).

The 1C metabolism, which includes choline, vitamin B6, vitamin B12, and folate, as well as the amino acid methionine, has previously shown to influence broodstock fecundity, but also liver lipid phenotype, metabolism and epigenetic gene regulation in mature zebrafish progeny (Skjærven et al., 2018). For salmon, a shift from normal spawning period by five months in RAS systems disturbs the nutritional status and gene expression in both the female broodstock and their offspring, which results in less allocated nutrients into RAS spawned eggs followed by a deprived growth by the time for first feeding (Skjaerven et al., 2020). Here, we continue by investigating the nutritional status in broodstock and offspring when transferring sexually mature female from sea cages to land-based freshwater cages but thereafter adjusting the abiotic factors to obtain two months earlier and later spawning than normal spawning in November. The aim of this project was to investigate if the offspring seasonal groups had differences in their epigenetic DNA methylation profile, gene expression regulation and nutritional status and also link these results with offspring growth.

Material and methods

Atlantic salmon broodstock normal spawning in November was compared with two months earlier or later spawning. We measured the nutritional status in broodstock liver and muscle, and the offspring nutritional profile during development. DNA and mRNA were extracted from offspring liver tissue to investigate the epigenetic DNA methylation profile (method: Reduced Representation Bisulfite Sequences (RRBS)) and gene expression regulation (method: RNA sequencing).

Results

The present study revealed that the seasonal changes significantly alter the nutritional level of the nutrients in both broodstock and offspring. Early spawning broodstock incorporated less nutrients into the eggs but the measures revealed a sufficient broodstock nutrient status. Late season spawners had similar nutritional status in offspring as normal spawners. Broodstock liver and muscle from late season broodstock indicate hunger. Enrichment analyses from mRNA sequencing revealed that genes controlling cell cycle and proliferation were significantly altered between spawning groups. Comparing early and normal spawning season revealed around 3500 differentially methylated cytosines. Especially interesting was the gene *ctl2b*, encoding the choline transporter, which had 9 significant hypermethylated CpG sites in promoter, 5 of which had 20% more methylation in the early spawning group.

(Continued on next page)

Discussion and conclusion

We believe our results provide an important understanding of the interplay between the abiotic environmental factors and nutritional status which together control the intermediary metabolism regulating growth and robustness from broodstock to next generation. Our in-depth study not just indicates a need for adjusting the broodstock feed to comply with the nutritional needs when changing abiotic factors, but also shows us how fragile and sensitive marine organisms are to a changing climate.

Introduction

Changing feed raw materials from marine to plant-based alters the requirement levels of certain micronutrients for Atlantic salmon (*Salmo salar*). Recommendations have been re-evaluated through the EU-funded ARRAINA project (Vera et al., 2020, Hemre et al., 2016) and feeding plant-based diets through smoltification of Atlantic salmon needs verification of optimal levels of one-carbon (1C) nutrients. Recent research points to those 1C nutrients, which are methionine as a key micronutrient along with folic acid, vitamin B6 (pyridoxine) and vitamin B12 (cobalamin), for improved and healthy growth through smoltification (Espe et al., 2020). NRC* funded projects explore the 1C nutrient-responsive mechanisms in muscle, which are of metabolic, molecular and epigenetic nature and that can help to explain the improved growth observed. The availability of certain nutrients can affect histone tail modifications and DNA methylation that together regulate mRNA expression and thereby control metabolism, which is one underlying explanation for nutritional programming. Epigenetic changes during early life stages such as early impact in pre-smolts can program life-long consequences on physiology, robustness and growth. Understanding how growth is controlled by those non-genetic mechanisms becomes important for a rapidly growing aquaculture industry whose concerns are to optimize production, sustainability and quality.

Material and methods

Two experimental diets provided by Skretting ARC were fed to Atlantic salmon 6 weeks prior to smoltification until 3 months after saltwater transfer in triplicate tanks at Skretting's research station. A Control and a moderate 1C+ diet contained varying levels of methionine (6.7 and 9.5 g/kg), folate (2.6 and 4.8 mg/kg), vitamin B12 (0.15 and 0.18 mg/kg) and vitamin B6 (6.75 and 9.31 mg/kg), respectively. The formulation of the Control diet included 1C nutrients on requirement and recommended levels (NRC, 2011, Espe et al., 2014, Hemre et al., 2016), whereas 1C+ diet contained a moderate 1C nutrient surplus package to support maximal performance. Both diets contained 240 g/kg soy protein and 150 g/kg pea concentrates as main protein source, and smaller amounts of fishmeal (120 g/kg) and krill meal (20 g/kg). Lipid source was a mixture of rapeseed oil (81 g/kg) and fish oil (127 g/kg). Muscle samples from both dietary groups were taken in the end of the freshwater and in the on-growing saltwater period. Global metabolic profiling was performed on pooled muscle samples (five individuals per tank, n=3). RNA and DNA were extracted from single muscle samples (n=9) for gene expression (RNA-seq, n=9), DNA methylation (RRBS, n=9) and analysis of a histone tail methylation (H3K4me3) and acetylation (H3K27ac) mark (CUT&RUN, n=6).

Results

Salmon fed the 1C+ diet throughout smoltification significantly increased body weight and decreased liver weight in the seawater period, which was reflected in a higher condition factor and specific growth rate compared to the Control group (Espe et al., 2020). There were no differences in growth performance during the freshwater period. Feed conversion ratio and protein utilization were not different during either the freshwater or the saltwater period. Pre-liminary results from both metabolic and gene expression signatures in muscle revealed significant 1C nutrient-dependent changes already at pre-smolt, but differences intensified when analyzing post-smolt muscle (Adam et al., under review). 1C+ fed salmon showed less free amino acid and putrescine levels, and higher methionine and glutathione amounts in post-smolt muscle. Transcriptional differences between both dietary treatments revealed lower expression of genes related to translation, growth, and amino acid metabolization in post-smolt muscle when fed additional 1C nutrients. DNA methylation and histone tail modification data are under analysis and key results will be presented.

(Continued on next page)

Discussion and conclusion

Increased 1C nutrient levels given in the feed over the challenging smoltification period resulted in best growth performance in the saltwater period. The overall metabolic profile in muscle of salmon fed the Control diet suggests a lower amino acid utilization for protein synthesis, and increased methionine metabolization in polyamine and redox homeostasis, whereas gene expression profiles are indicative of compensatory growth regulation at local muscle tissue level. Linking both metabolic and gene expression profiles, our findings point to fine-tuned nutrient-gene-interactions fundamental for improved growth capacity through better amino acid utilization for protein accretion when salmon was fed additional 1C nutrients throughout smoltification. Following a multi-omics approach, integration of metabolic and gene expression with DNA methylation and histone tail modification profiles will reveal possible epigenetic mechanisms involved in improved growth. These results also provide documentation for adjustment of dietary nutrient levels in aquaculture and highlight the employment of nutritional programming strategies on healthy and robust growth.

Introduction

In fish farming, feeding is one of the management operations that can most impact overall production performance. This means that, to achieve a good performance in economic and environmental terms, fish farming companies have to equip themselves with the right tools to support the definition of good feeding practices (e.g., ration size). One of the most used tools to determine the ration size are feeding tables, which have shown to be effective in providing guidance in a simple, accessible and practical way.

Usually, feeding tables are constructed based on empirical data, and what varies between the multiple approaches used are the extrapolation methods employed (e.g., statistical models, mechanistic models, hybrid models) and criteria/targets defined (e.g., maximize growth, minimize feed conversion, minimize economic conversion). Each extrapolation method has its own advantages and disadvantages, depending on the situation in which it is being applied. The most important is to ensure that the chosen method is adequate to produce a robust and accurate feeding table (e.g., feeding rates per size and temperatures).

The objective of this work is to present a public decision-support tool (FEEDEST; www.webtools.sparos.pt/feedest), developed in the context of the PerformFISH project (www.performfish.eu) to allow fish farmers to estimate the feeding rates, for European seabass or gilthead seabream, that allow reaching the maximum fish growth potential, while ensuring minimal feed conversion and feed waste.

Methodological approach

The FEEDEST tool (Figure 1) was built on the top of a nutrient-based fish growth model. This model was developed based on a "energy-protein flux" concept (Nobre et al., 2019) and was calibrated for European seabass (*Dicentrarchus labrax)* and gilthead seabream (*Sparus aurata*) using data from a wide range of growth trials (both published and not).

One important aspect of this model, which is also common to most fish growth models, is that it requires feeding rates to be set as an *input* when operating in normal mode, while we consider it to be an *output* of the tool. To solve this inverse problem, we use a divide-and-conquer approach, where we split the difficult (multidimensional) problem into a large set of simple (unidimensional) problems which can be efficiently solved: for each possible input diet (only 3 options), we bin the input space and solve the problem for "feed amount" while keeping other variables fixed. Because the diets are pre-determined, we can pre-calculate approximately-optimal feeding tables, leading to very fast (real-time) re-optimization of the feeding tables for the user's conditions when using this tool.

Tool overview

FEEDEST is implemented as a web-application (R/Shiny framework). It presents a reactive interface and requires a minimum set of inputs (i.e., species, diet, number of fish, initial fish weight, and temperature profile), thereby improving user-experience.

In terms of outputs, the tool provides not only time-dependent estimates of growth and feeding rates, but also estimates of environmental impact (in terms of nitrogen waste). Furthermore, the tool allows the user to export its results as a spreadsheet, which also contains the specific feeding table that the user should follow (see Figure 2).

Final remarks

In the context of the PerformFISH project (www.performfish.eu) the FEEDEST public decision-support tool was developed, aiming at support the implementation of better feeding management practices by the Mediterranean fish farming industry, and it is freely available at: https://webtools.sparos.pt/feedest/. This work illustrates how nutrient-based mathematical models can be used to build user-friendly practical decision-support tools to support efficient feeding management practices.

Introduction

Osteogenesis is a process which can be modulated by several factors including macro and micronutrients supplementation. Among the various proven and studied micronutrients, boron (B) has an important role in the maintenance and development of bone [1–3]"container-title":"FASEB Journal (Federation of American Societies for Experimental Biology. Bone related diseases are a common problem today and vitamin D deficiency is one of the main reasons for weak bones. Some earlier studies showed that the boron supplementation alleviates the problems associated with vitamin D3 deficiency such as disruptions in the mineral metabolism [4]supplementation of two levels (5 and 25 parts per million; ppm. Using zebrafish as a model, the effect of boron supplementation at two selected concentrations and its synergistic effects with vitamin D3 on skeletal development were analysed at a transcriptomic level defining the pathways modulated in the treated groups. The analysed data opens to greater understanding of the actions of these compounds to improve skeletal health which is either useful for aquaculture or biomedicine.

Materials and Methods

Zebrafish embryos were collected and divided into six groups each in triplicates- control group with ethanol (C), Vitamin D3 (VD), First concentration of boron (B10), Boron 10 with vitamin D3 (Sigma) (B10VD), Second concentration of boron (B100) and Boron100 vitamin D3 (B100VD). Boric acid (Sigma) was used to make the required concentrations of boron groups. At 7 DPH, larvae were sampled for RNA extraction and sequenced on Illumina platform to generate 150 x 2 paired end (PE) reads. ~30 million PE reads were generated across each experiment group in triplicates. Quality trimmed reads were then mapped to the reference genome assembly using STAR aligner. Read counts for the protein coding genes were retrieved using featureCounts. Differential gene expression analysis between different groups was performed using deseq2 package in R. Gene Ontology and KEGG pathway analysis was performed using clusterProfiler package in R. Plotting was done using ggplot package in R.

Results and Discussion

RNA-seq analysis identified several thousands of genes to be differentially expressed in at least one of the comparison groups (Fig1a). Clustering the data based on expression pattern revealed three different clusters (Fig1b) with one cluster clearly enriched for GO and KEGG pathways related to skeletal development. The outcomes revealed a clear evidence for boron and Vitamin D synergy contributing to enhanced bone physiology. Most affected pathway was the MAPK where many genes were seen to be highly expressed in the synergy groups than vitamin D. The calcineurin, denoted by the *ppp3cca* gene, which is a part multiple bone related pathways such as MAPK, WNT and Ca signalling, was seen upregulated in the B10VD synergy group and are known to be expressed in osteoblasts [5]. In the KEGG anlaysis of the TGF-β–BMP pathway, *Smad4* was significantly upregulated in the B10VD group and Smad family is associated with BMP activation of genes involved in mineralisation and osteoblast differentiation [9]. In brief, the synergistic effect of boron with vitamin D3 was clearly evidenced in the skeletal pathways by the transcriptome study using zebrafish larvae model. This information can be useful for aquaculture nutrition to enrich the vitamin D3 effect by the additional supplementation of boron to enhance the ossification and alleviate the vitamin D deficiency pathologies in the cultured fishes.

GENETIC PARAMETERS AND GWAS OF LIPID TRAITS IN MUSCLE AND LIVER OF EURPEAN SEABASS (*Dicentrarchus labrax*)

Background

Lipid deposition is an important factor of production efficiency, product quality and health in animal production. The liver is a major lipid storage site in European seabass (Dias et al., 2005). However, excess lipid accumulation in the liver can negatively affect production efficiency and liver function and health, with onset of fatty liver disorder. The lipid content of muscle tissue affects organoleptic and processing qualities of fish fillets, and the omega-3 fatty acid content is important for the nutritional quality. As a significant part of the Mediterranean diet, seabass is an important nutritional source of the health-promoting essential omega-3 fatty acids EPA and DHA.

Substantial genetic variation has been reported for muscle lipid content in seabass (Besson et al., 2019; Saillant et al., 2009). Studies in other fish species have revealed a genetic component to the omega-3 levels of fillets (Horn et al. 2018; Wang et al. 2019). The genetic parameters of fatty acid composition traits and liver fat have not yet been explored in seabass. The aim of this study was to estimate genetic parameters of lipid and omega-3 fatty acid content in muscle and liver of European seabass. For the first time in seabass, a GWAS on lipid and fatty acid traits was performed.

Materials and methods

European seabass originating from ABSA-Culmarex were used in this experiment. Fish were fed commercial feed and kept in commercial sea cages in Murcia, Spain. Samples of liver (n = 87) and muscle (n = 313) were homogenized and total lipids were extracted using the Folch extraction method. The fatty acid composition of the total lipids was determined using the Mason & Waller method by means of gas chromatography.

The fish were genotyped using the 60K MedFish array (Peñaloza et al. 2020). Genotypic data was filtered using the Plink software. Approximately 21K SNPs passed filters and quality control. A genomic relationship matrix between the animals was generated with the "-grm" function implemented in GCTA software, and used for the estimation of the genetic parameters. The genomic relationship matrix was computed according to VanRaden (2008) as $\frac{ZZ\prime}{2*\sum_{i=1}^{Nsnp} p_i(1-p_i)}$; where p_i is the allele frequency of the second allele and $Nsnp$ is the total number of SNP markers.

(Co)Variance components and the corresponding heritability were estimated from bivariate and univariate restricted maximum likelihood (GREML) analyses, including effect of sex and batch as fixed effects. GWAS was performed using a linear mixed animal model implemented in GCTA program with the "–mlma-loco" function. With fixed effects including (phenotypic) sex, batch, and 5 principal components as covariates (only sex and batch for liver traits due to the small dataset). The following traits were analysed for both muscle and liver tissue: Total fat (%), DHA (%), EPA (%), DHA/ALA ratio, omega-3/omega-6 ratio.

Results and discussion

On average, the fish weighed 346 g and had a muscle fat content of 9 %, ranging from 2 to 21 %. The phenotypic and genetic correlation between muscle fat and liver fat was weak, suggesting independent regulation of the two lipid deposits. This was supported by the high heritability of muscle fat (0.59), which was within the range of previous estimates (e.g. Besson et al. 2019; Saillant et al. 2009), and the lower heritability of liver fat (0.17).

(Continued on next page)

We found high heritability for omega-3 related traits in both tissues, but for different specific traits, one exception being DHA, which had high heritability in both liver (0.45) and muscle (0.51). In liver, EPA and DHA/ALA ratio had high heritability, while in muscle omega-3/omega-6 ratio had a high heritability (0.41). The high heritability of DHA and omega-3/omega-6 ratio in muscle indicates a substantial potential to improve the fatty acid profile of fish fillets through selective breeding, by increasing the ratio of anti-inflammatory omega-3 to pro-inflammatory omega-6 fatty acids.

The proportional content of DHA was 6.4 % and 7.3 % in muscle and liver, respectively, which was higher than the proportion supplied in the feed (3.9 %). There was a positive phenotypic correlation between muscle DHA and liver DHA/ALA ratio (0.6), and both of these traits had a high heritability (>0.4). As the DHA/ALA ratio can be seen as a marker of omega-3 bioconversion of ALA (18:3n-3) to DHA (22:6n-3), these results may imply that European seabass has omega-3 bioconversion activity in liver that has a strong genetic component to it, and that impacts the DHA content of muscle.

The GWAS showed a clear signal on LG X with chromosome-wide significant peaks for the four traits muscle and liver omega-3/omega-6 ratio, muscle DHA and liver EPA. Although these traits did not have the same top significant SNPs, some were in the same region; 5,6-5,8Mb and 7-8Mb. One very strong candidate gene was identified here: *Peroxisome proliferator-activated receptor alpha*, a nuclear transcription factor central in regulation of genes involved in lipid metabolism, including mitochondrial beta-oxidation. Another signal was found for the SNP AX-172297229 on LG 11 for the two traits DHA and DHA/ALA ratio in liver. Three candidate genes involved in lipid and/or omega-3 metabolism were found ± 300Kb region of this SNP: ALOX5, PLCB3 and SPTLC3. ALOX5 is especially interesting as it can mediate the lipoxygenation of DHA.

Conclusions

Differences in genetic parameters between liver and muscle tissues reflect differences in lipid metabolism. There is a substantial potential to increase DHA content of seabream fillets through selective breeding. The results also suggest that there is omega-3 bioconversion activity in liver of seabass that has a strong genetic component to it, and that impacts the DHA content of fillets. GWAS results showed signals on LG X for omega-3 traits across tissues, in a region where the candidate gene PPARα is located.

Introduction

In recent years, with the growth of aquaculture and the interest in improving the health of fish during the breeding process (Asimi and Sahu, 2013), the search for natural products with a source of bioactive compounds has increased. Macroalgae offer a novel and value-added dietary ingredient in diets formulated for fish. Like terrestrial plants, the nutritional content of macroalgae can vary greatly among species, seasons, and locations. Beside from its basic nutritional value, algae contain several pigments, immunostimulant compounds, and secondary metabolites that may have beneficial effects on farmed fish (Wan et al., 2018; Cruces et al., 2012; Oliveira et al.2013). Macroalgae such as *Codium* and *Osmundea* abound in the area of Galicia (NW Spain) and the north of Portugal, where the interest of exploitation is increasing due to the bioactive compounds they contain. Within the ALGALUP project, an experiment has been carried out to evaluate the effect of 4 diets with inclusions of macroalgae (*Codium* spp. and *Osmundea pinnatifida*) and extracts of these rich in polysaccharides on growth and digestive physiology in juvenile turbot (*Scophthalmus maxima*).

Materials and methods

750 juvenile turbot from Nueva Pescanova with an average weight of 10.3±2.38 g were used. Fish were distributed in 15 tanks of 200 L with 50 fish per tank. During the following 60 days turbot were kept in a recirculation system with a daily renewal of 10% and were fed 3 times a day. 3 tanks were assigned to each one of the 5 diets formulated and manufactured with the support of SPAROS, Portugal. Four diets contained macroalgae soluble fiber obtained by enzymatic hydrolysis using a combination of protease, cellulase, hemicellulase and pectinase. Diets DC5% and DO5% contained 5 % of soluble fiber from *Codium* spp. and from *O. pinnatifida* respectively, whereas diets DC15 and DO15 contained 1.5 g/kg of soluble fiber from *Codium* spp. and from *O. pinnatifida* respectively. A commercial feed was used as control diet (DC). Water conditions were maintained at 16 ± 0.5 ºC, 35 ‰ of salinity and 7.2 ± 0.9 mg / L of dissolved oxygen. RAS parameters were stable throughout the experiment. Ammonia, nitrate, and nitrite were measured daily. Every 4 weeks fish were weighed, and the length was measured. Before handling, the fish were anesthetized with 200 mg / L of 2-phenoxyethanol. At the end of the experiment, fish were euthanised with 600 mg / L of 2-phenoxyethanol. Condition factor, specific growth rate (SGR), conversion index (FCR), protein efficiency index (PER) and relative growth rate (RGR), were calculated. Also 10 fish from each tank were dissected by separating and weighing liver and viscera and the hepatosomatic index (HSI) and the viscerosomatic index (VSI) were calculated.

Table 1. Initial and final weight, growth (SGR and RGR percentages) and feed conversation (FCR and PER ratios), HIS and VSI index of turbot juveniles fed with the experimental diets. Different letters indicate significant differences (ANOVA P<0.05)

(Continued on next page)

Results

At the end of the experiment turbot juveniles had a mean weight of 26.29±0.65 g and a length of 11.8±0.61 cm. No significant difference was observed between diets neither in weight nor in length (P> 0.05). Although, in terms of growth, a difference was detected in the SGR and the RGR. The DC15 diet showed the lowest values in both rates with 1.7 and 1.35 respectively. These data were significantly different from those of the DO15 diet, which has driven the highest values in SGR (2.02) and RGR (1.76). The growth data of the diets including whole macroalgae and extracted polysaccharides did not show significant differences with the control. However, the trend has clearly shown that the DO5 and DO15 diets favor an increase in the SGR of 6 and 9.25%, respectively, compared to the control and 8 and 14%, respectively, in terms of the RGR.

During the experiment, fish fed the DC15 diet showed the lowest feed intake and biomass gain. Although no significant difference is observed, the FCR also follows the same trend with the worst data observed in the DC15 diet. It should be noted that the DO15 diet improved FCR by 8.2% and 13% respectively compared to the DC and DC15 diet.

The analysis of the hepatosomatic index data showed that the control diet had a significantly low value compared to the rest of the diets. In the case of the viscerosomatic index, the lowest values were observed in the DO15 diet and DC when the highest in the DC15 diet.

Introduction

Macroalgae cultivation is gaining interest in the EU, both as an alternative to imports from third countries and to the harvesting of wild biomass. Whereas cultivation in coastal waters may involve large areas and production volumes, land-based cultivation in tanks provides the opportunity of including seaweeds in IMTA schemes to remove inorganic nutrients from aquaculture effluents, thus reducing costs of water treatment and providing an additional value-added product. *Codium tomentosum* Stackhouse 1797 and *Chondrus crispus* Stackhouse 1797 are two autochthonous species of commercial interest in Europe, but information on their culture is scarce. In this work we provide some data regarding their acclimation to indoor culture, and their potential of biomass production and capacity of nutrient uptake.

Materials and methods

Experiment 1. *C. tomentosum* was cultured in aerated 5-l flasks. Light was provided by daylight white LED lamps (W) or a combination of daylight white plus red-enriched LED lamps (WR), yielding 330 µmol m^{-2} s^{-1} and 360 µmol m^{-2} s^{-1} respectively. Photoperiod was circadian, 14 h light: 10 dark. Culture medium consisted in filtered seawater supplemented with $NaNO_3$ and NaH_2PO_4. Three culture conditions combining light and nutrient conditions were tested: 19 W, 500 μM $NaNO_3$ + 50 μM NaH_2PO_4 (W50); 2) W, 500 μM $NaNO_3$ + 75 μM NaH_2PO_4 (W75) and 3), WR, 500 μM $NaNO_3$ + 50 μM NaH_2PO_4 (WR50). After 5 weeks of culture, part of the *C. tomentosum* biomass was removed from culture flasks to avoid self-shading, and experiment was continued for 3 more weeks. Cultures were run in triplicate.

Experiment 2. *C. crispus* was cultured in aerated 1-l flasks and lightened by daylight white LED lamps (81 µmol m^{-2} s^{-1}, photoperiod as in Experiment 1). Culture medium was filtered seawater supplemented with either 500 μM NH_4Cl (N cultures) or 250 μM NH_4Cl + 250 μM $NaNO_3$ (NN cultures) + 50 μM NaH_2PO_4. After 7 weeks of culture, part of the *C. crispus* biomass was removed from culture flasks and nutrient concentration was doubled. Experiment continued for 7 more weeks. Cultures were run in triplicate.

Results

Experiment 1. *C. tomentosum* grew continuously in both phases of the experiment and in all culture conditions tested (Figure 1A). WR50 cultures experienced the highest SGR, suggesting that the enrichment of light in red wavelengths is beneficial for this species (Figure 1B). *C. tomentosum* cultures fully consumed N and P supplied on a weekly basis. N uptake ranged between 0.030 and 0.045 g kg^{-1} fresh weight d^{-1}, with no statistical differences among culture conditions. P uptake ranged between 0.004 and 0.010 g kg^{-1} fresh weight d^{-1} in W50 and WR50 cultures. W75 cultures responded to the higher P concentration by a 20 % to 30 % increase of P uptake rate, but these differences were statistically significant in some cases only.

Experiment 2. No statistical differences were observed in the growth of *C. crispus* cultured either with NH_4^+ or a mix of NH_4^+ and NO_3^- as N source during the first phase of the experiment. Nevertheless, when nutrient concentrations were doubled in the second phase, growth was higher in N cultures (Figure 2A). This was also observed in the SGR (Figure 2B). Both N and P uptake significantly increased ($p<0.05$) with the doubling of nutrient concentration, from 0.070-0.106 to 0.127-0.280 g N kg^{-1} fresh weight d^{-1} and from 0.009-0.011 to 0.011-0.045 g P kg^{-1} fresh weight d^{-1}, but in general no differences were found between nutrient uptake among N and NN cultures.

Results suggest that both *C. tomentosum* and *C. crispus* can be adapted to indoor cultivation for long periods. Light quality was an important factor in *C. tomentosum* cultures, since the increase of the supply of red wavelenghts resulted on a higher growth rate. Self-shading must be avoided to ensure that light intensity is sufficient to promote growth. In the conditions tested, changes in nutrient concentrations were not relevant for the growth of *C. tomentosum*, but the growth of *C. crispus* decreased when a mixture of NH_4^+ and NO_3^- at high concentrations was used as N source, compared to NH_4^+.

Both light and nutrient quality and intensity are crucial factors for the cultivation of macroalgae and these results may provide useful indications for the establishment of larger-scale indoor cultures of *C. tomentosum* and *C. crispus*.

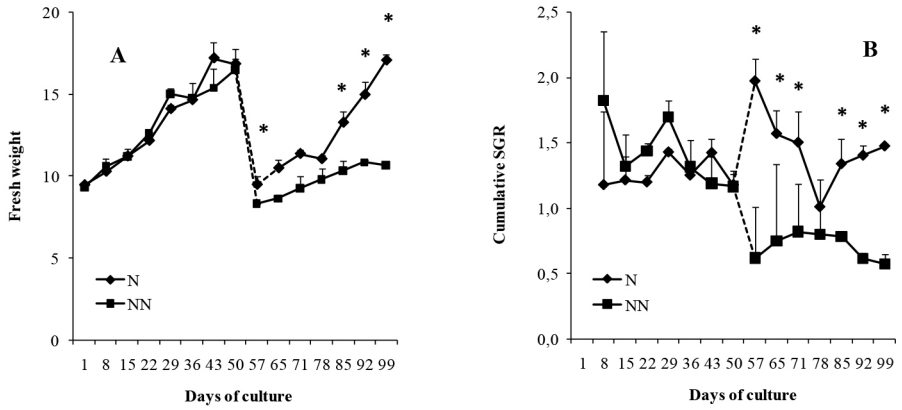

Figure 2. Increase of fresh biomass (A) and cumulative specific growth rate (B) in cultures of *C. crispus*. Asterisks mean statistically different values ($p<0.05$) among culture conditions on a given day. Dashed lines indicate when biomass was partially removed from culture flasks.

EATING ALGAE AS A REGULAR PART OF A EUROPEAN DIET? IMPROVING THE GENERAL PUBLIC'S LITERACY OF ALGAE TO ENCOURAGE A CHANGE IN CONSUMER EATING HABITS

Estelle Soulet[1]*, Iwona Gin[1], Lotte Bronswijk[2]

[1] Nausicaá, Centre National de la Mer, Boulevard Sainte Beuve, 62200 Boulogne sur Mer, France
[2] North Sea Farmers, Den Haag, The Netherlands
valgorize@nausicaa.fr

Introduction
Eating seaweed as a regular part of the diet? Not for most Europeans - not yet, anyway. The ValgOrize[1] research project co-funded by the Interreg 2 Seas European programme hopes to change that by stimulating seaweed production and consumption in Europe.

To feed the growing world population, 50 to 70% more food must be produced by 2050. The sustainable cultivation of marine organisms such as algae can play an important role in feeding the world.

Worldwide, approximately 90% of algae are used for food applications. The European Union only represents a really small part of the worldwide production (less than 1% of the global production volume) and market. A number of obstacles stand in the way of further introduction. One of them is a European consumer reluctance to eat algae because of the limited knowledge about their vitamin and mineral content, food applications, how to cook them, cultivation methods, prejudice about taste and smell and association with beach debris.

Our method
Before determining the communication campaign and educational tools to reach out to the general public, desk and market research[2,3] and expert interviews have been carried out to find out about public perception of algal consumption, consumer motivations and the food trends. The results have shown that the European consumers in the North Sea basin are motivated first of all by the practicality to find and cook algae, attractive pricing and adapted packaging. The study by the North Sea Farmers has further shown that adapting algae products to the western palate has an important role in the European product development and that the current European food landscape is subject to several trends and developments. The main trends that could help increase public awareness of seaweed and microalgae consumption have been identified: the globalised cuisine that seems to create awareness of algae as food, the overwhelming presence in the modern European diet of Asian seaweed products such as sushi or wakame salad, the consumer openness to try new types of food, the consumer awareness of the impact of food on their health and on the planet, the popularity of health-enhancing food with nutritional benefits, the search for alternative protein sources, the guarantee of high quality and sustainable cultivation methods[4,5].

Our tools to improve consumer algae literacy
Based on these research findings, the ValgOrize project has been developing communication and learning tools to improve the European consumers' perception of seaweed and algae and the market acceptance. They are circulated on social media, in partner organisations newsletters and other public outreach channels.

A comic strip was published to illustrate how algae arrives on a consumer' plate in stages: cultivation of micro and macro algae, harvesting, processing, consumption (culinary benefits and health benefits of seaweed), as well as the role of algae in the treatment of polluted water.

Moreover, as series of fact sheets about seaweed and microalgae is being developed to improve the consumer knowledge of their nutritional and health benefits, habitat, how to cook and eat them.

A sequence of tasting events for the general public have been scheduled on community major cultural events such as local festivals, The EU4Ocean Coalition festival – Celebrating the Atlantic Ocean and the North Sea at the European Maritime Day annual conference and the World Ocean Day.

Introduction

Consumption of fish and seafood has been increasing globally (FAO, 2020). A large part of the fish for consumption comes from aquaculture, with estimates ranging between a quarter and more than a half across the world (EUMOFA, 2020; FAO, 2020). Forecasts at the global level suggest that the market for aquaculture products will continue to grow (FAO, 2020). In order to be competitive in this evolving international market, new products can be developed to match consumers' preferences. Identifying consumer segments with international relevance for food-related products becomes increasingly important in this context. Consumers place value on certain value-added attributes of new aquaculture fish products (Banovic et al., 2019), however, they differ in terms of their food-related lifestyles and such differences can help explain which attributes are most sought after by different consumer segments. The present study aimed to identify how the importance of attributes valued by consumers when choosing new aquaculture fish products varies by their food-related lifestyle. Understanding the most relevant attributes for different consumer segments is the first step towards the successful development and marketing of new aquaculture fish products.

Materials and methods

An online survey that included a discreet choice experiment was used to collect data from consumers in three European countries (i.e. Spain, France and Germany) that vary in their fish consumption and household expenditure for fish and seafood products (EUMOFA, 2017). The survey included consumers' food-related lifestyle, their preferences in terms of attributes of new aquaculture fish products and several demographic and psychographic measures. Consumers' food-related lifestyle was measured using the modular food-related lifestyle instrument, which is a newly updated and cross-culturally valid scale (Brunsø et al., 2021). Consumer preferences for new aquaculture products (i.e. Sea & mountain meagre burger, Organic sea bream with couscous, Grilled sea bass with lemon) were assessed through a discreet choice experiment. People were asked to make 12 choices between three versions of the product varying in the following attributes derived from previous literature (Banovic et al., 2019, Cantillo et al., 2020): 1) ASC label, 2) NutriScore, 3) country of origin, 4) health claim, 5) price. Multilevel latent class cluster analysis that accounts for the fact that respondents are nested within countries was conducted in LatentGold using the three core dimensions of the modular food-related lifestyle (i.e. food involvement, food innovativeness and food responsibility) to segment the consumers. To identify the classes of consumers based on their choices, LatentGold choice analysis was performed. The food-related lifestyle segments were introduced as covariate in the choice analysis to assess their impact on choices.

Results

Based on their food-related lifestyles we identified four segments of consumers and one country group (i.e. all three countries belonged to a single group). The 'foodies' (11%) are those consumers who are highly involved in food, highly innovative and care about responsibility in food systems. The 'adventurous' (44%) consumers are also interested in all these dimensions, though to a lower degree than the 'foodies'. The 'moderate/conservative' (40%) segment represented those consumers that score about average on all these dimensions. The fourth segment consisted of those who are 'uninvolved' (6%) as they score very low on all food-related lifestyle dimensions.

(Continued on next page)

In terms of choice of new aquaculture fish products, we find that all attributes were significant and influenced people's preferences towards the chosen products. However, consumers differed in the importance placed on the different attributes and in this regard we identified five groups of consumers with similar preferences within the group but dissimilar between groups. There was a highly significant relationship between the consumer segments based on food-related lifestyle and the choice groups based on people's new aquaculture product choices. The 'foodies' are especially prevalent in the choice groups that value the ASC label and the NutriScore, but also domestic products with a health benefit and medium prices. The 'adventurous' prefer the ASC label as well as the NutriScore, but the former is of higher interest for them. They also prefer domestic products with a health benefit, but price is their top priority thereby products targeted towards them should be low to medium priced. The 'moderate/conservative' share some of their preferences with the 'adventurous' but in addition they are more prevalent in the group that does not value the ASC label but likes the NutriScore, EU products with a health benefit and especially products with low prices. Lastly, the 'uninvolved' consumers were more prevalent in the choice group that is mostly interested in domestic products that are medium priced, they dislike the NutriScore but place some value on the ASC label.

Conclusion

These results have important implications for new product development in the aquaculture market as they show the attributes that are most valued by different segments of consumers. As not all consumers seek the same value-added attributes from new products, our results are highly relevant for targeting new aquaculture products to the most promising segments of consumers in order to ensure their success on the market.

STABILISATION OF POLYCHAETE (*Nereis virens)* BIOMASS DURING FROZEN STORAGE

IB. Standal, R. Mozuraityte and R. Slizyte

Department of Fisheries and New Biomarine Industry, SINTEF Ocean, Trondheim 7010, Norway

Introduction

Cultivation of low trophic organisms, such as polychaetes, has been proposed as one mean for recycling nutrients from sidestreams, and at the same time producing omega-3 rich lipids and marine proteins, that are in high demand both for feed and human applications. Polychaete worms are presently cultivated in both Europe and Asia, but at relatively small scale and mainly sold in the premium feed market (e.g sold as live feed or freeze-dried). Live polychaete worms have particularly showed beneficial effects in shrimp broodstock diets, but the mechanisms responsible for the superior effect of live feed is not known. Marine raw materials are highly perishable, therefore proper handling and preservation methods are needed to maintain the valuable lipids, proteins and other components after harvesting. However, only few studies have investigated the effect of different storage/prosessing conditions on important quality parameters on polychaete biomass.

In order to up-scale and use polychaetes as an alternative aquafeed ingredient – the production and processing should be cost and energy efficient – while still maintaining the quality of the raw material. The goal of the present study was to evaluate the stability of the biomass during different frozen storage conditions, including effect of heat-treatment. Quality was evaluated based on both lipid and protein composition.

Materials and methods

Cultivated *Nereis virens* was procured from a commercial producer. Three different storage processes were tested namely 1) industrial frozen worms (vacuum packed and blast frozen (-38 °C) and further stored at – 27 °C, 2) frozen storage in plastic bags at – 18 °C and 3) pre-treated by blanching prior to frozen storage at – 18 °C. Quality was evaluated after 1, 6 and 12 months storage, and compared with control samples, i.e. worms sampled/analyzed directly after snap freezing by liquid nitrogen.

At each sampling point, lipid quality was evaluated based on, oxidative quality, amount of free fatty acids, fatty acid composition and lipid profile evaluated by Nuclear magnetic resonance spectroscopy. Changes in protein fraction were evaluated based on amount -and composition of amino acid composition, and changes in acid soluble metabolites, such as free amino acids and osmolytes.

Results

Frozen storage, both at – 18 °C and -27 °C, led to relative fast changes in lipid composition and quality. For example, the content of free fatty acid significantly increased after 6 months frozen storage compared to control samples. The results show that introducing heat-treatment prior to frozen storage was effective to prevent activity of endogenous enzymes leading to lower lipid hydrolysis during frozen storage (Figure 1).

Lipid oxidation took place during the storage, especially at a storage temperature of –18 °C, both in non-treated and blanched biomass (**Figure 2**). On the other hand, vacuum packed worms stored frozen at – 27°C, showed much lower lipid oxidation. Blanching led to reduction of minerals/salt, but also some leakage of lipids and low molecular weight metabolites. The leakage led to higher protein efficiency ratio (PER) of blanched worms – compared to biomass without this pre-treatment. There were only small changes in the profile of low molecular weight metabolites profile during frozen storage.

Discussion and conclusions

In order to use polychaetes as an alternative aquafeed ingredient - there is a need to find economically relevant handling and processing methods of large volumes of biomass, while maintaining acceptable quality. The results obtained in this study – shows that both high endogenous enzymatic activity and lipid oxidation is a challenge. Therefore effective measures to hinder such activity is important, e.g for preserving phospholipids. The results shows that prolonged frozen storage of un-treated biomass should be prevented. Processing or fractionation direct after harvesting – could be one solution to maintain valuable lipids and proteins. Blanching is one method for hindering enzymatic activity in biomass with high endogenous activity – and is also beneficial for salt reduction – however, some loss of lipids and free amino acids are anticipated.

UPDATING THE ORGANIC ACID STORY: NEW TECHNOLOGY FOR ADDED VALUE

B. T. Standen*, M. Spiegelhofer, N. Roth

*Benedict.Standen@dsm.com

Organic acids have been widely used in aquaculture, and their benefits have been well documented. However, there are certain misconceptions about their usage, one of the main being that are primarily used for an 'acidifying effect'. Whilst this can be true, in order to achieve this a large amount of organic (or inorganic) acids are needed to overcome the buffering capacity of high protein feeds or the gut. High dosage may come with higher costs and takes up valuable space in the diet, which is often limiting. Further, utilizing inorganic acids can damage equipment, adding unnecessary maintenance costs.

A better usage of organic acids, is for their direct antimicrobial effects which can be enhanced by other components, which act in synergy to boost said benefits. BIOMIN has developed a commercial acidifier product called Biotronic® Top3 which contains a unique Permeabilizing Complex™. This facilitates the transport of the organic acid blend (propionic, formic and acetic acid) and phytochemical (cinnamaldehyde) through the Gram-negative membrane of pathogens. Once inside the cell, the acids dissociate and disrupts cell metabolism and membrane functionality, slowing their growth and killing them.

Here we demonstrate the high efficacy and consistency of Biotronic® Top3, indicated by low MIC (minimum inhibition concentration) across a wide range of aquaculture pathogens. Benefits beyond conventional MIC testing was explored, demonstrating that the acid blend with Permeabilizing Complex™ negatively effects the pathogen physiology by disrupting membrane function, membrane potential and efflux pump activity. In the current study, the MIC value ranged from 0.1% for *Moritella viscosa* and *Tenacibaculum maritimum*, and 0.2% for *Yersinia ruckeri* and *Vibrio parahaemolyticus*. In a previous experiment, an MIC value <0.05% was also obtained for *Piscirickettsia salmonis*, the causative agent of Salmonid Rickettsial Septicemia (SRS).

In order to investigate pathogen physiology, representative pathogens from salmon and shrimp culture (*M. viscosa* and *V. parahaemolyticus*) were incubated with Biotronic® Top3, at high and low dose, for 30 minutes. Different dyes were used to indicate specific characteristic, which were validated using prokaryotic flow cytometry protocols. The stains used were propidium iodide, DiBAC4(3) and ethidium bromide to assess membrane integrity, membrane potential and efflux activity, respectively. In each case, low fluorescence was observed in control treatments (i.e. without Biotronic® Top3), indicating a healthy and viable population. However, when exposed to the enhanced acidifier, fluorescence was increased corresponding to increased membrane damage, depolarized membrane potential and decreased efflux pump activity. Interestingly, the latter might have important implications in reducing antimicrobial resistance. Importantly, there was a strong dose dependent effect, showing a clear product response.

Together, these results indicate that the Permeabilizing Complex™ adds value and complements organic acid blends, and can have strong antimicrobial effects at relatively low inclusion levels. *In vivo* studies (not described here) have also corroborated these effects in the field, reducing disease and contributing to sustainable aquaculture production.

BIOPROSPECTING FOR CYANOBACTERIA AND MICROALGAE IN PELOIDS – EXTREME ENVIRONMENT KNOWN FOR ITS HEALING PROPERTIES

Seawater is an environment in which numerous organisms evolve, some with great potential for biotechnology. In recent years, however, many scientists have moved away from the assumption that the origin of life was in pools of water, and instead propose life on Earth probably originated in accumulations of warm, nutrient-rich mud. This mud, also called a peloid, has formed over many years through various processes and is a rich source of living organisms that, due to their adaptation to this unique environment, produce a wide variety of primary and secondary metabolites with numerous and diverse activities, including anti-cancer, anti-inflammatory, antiviral, and immunomodulatory ones. In this research, two important questions were addressed using collected samples of a localized peloid with demonstrated healing properties. First, whether it is the mineral (abiotic) or the secondary metabolic (biotic) component that contributes most to the healing properties of the peloid. Secondly, the biodiversity in this ecological niche was explored in order to build an ecological model of the microbial communities present in it, to gain insight into their dynamics and to identify key species.

Importance:
The use of peloids in medical therapy dates back to ancient times. Abiotic components such as clay and mineral water are believed to be the main components of the healing properties of natural peloids. The places where peloids are usually found are characteristically shallow and enclosed lagoons. The constant UV exposure and increased salt concentration could classify peloids as an extreme environment. The spectrum of claims for which peloid therapy provides relief ranges from purely cosmetic, skin-related, musculoskeletal to immunological problems. These claims can hardly be supported by mineral content and heat-retaining properties alone. However, organic compounds from decaying microorganisms as well as secondary metabolites from microbial communities could explain the observed range of health benefits. The fact that the relationship between the therapeutic activity of peloids and their composition outside the range of mineral and physicochemical properties has not been adequately studied indicates a real biotechnological potential. Since one of the main microorganisms discovered in peloids with therapeutic properties is microalgae, which produce a range of organic compounds, they should be the focus of study of this complex and promising natural resource.

PRELIMINARY DYNAMIC ENERGY BUDGET MODELS FOR STUDYING THE THERMAL TOLERANCE OF E. SEABASS AND MEAGRE

Orestis Stavrakidis-Zachou[1,2]*, Nikos Papandroulakis[1], Pavlidis Michail[2], Konstadia Lika[2]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Center for Marine Research, AquaLabs, 71500, Gournes, Heraklion, Greece
[2]Department of Biology, University of Crete, 71003, Heraklion, Greece
e-mail: ostavrak@hcmr.gr

Introduction

Developing tools to describe temperature induced effects on fish becomes increasingly important for aquaculture in the context of climate change. Dynamic Energy Budget models can describe the bioenergetics of individual fish as a function of temperature and food availability and, thus, offer means of studying the effects of temperature on relevant fish parameters and traits. In particular, temperature effects in DEB models are quantified via the parametrization and use of the Arrhenius function (Kooijman, 2010). Simulations can then be performed under different temperature conditions to study the effects on fish traits, while the patterns in parameter values may be used to compare the bioenergetics and the thermal tolerance of different species (Freitas *et al*., 2010). Here, we have parametrized DEB models with particular focus on higher temperatures for two aquaculture species, the European sea bass and the meagre, and developed a preliminary module for describing changes in body composition.

Materials and methods

The DEB models were parametrized according to Marques *et al*. (2018) using experimental data and data from literature and are provided in Stavrakidis Zachou *et al*. (2019, 2021). In addition, growth performance and respiration data at temperatures close to the edges of the species thermal tolerance range were included to parametrize the Arrhenius function and thus calculate a correction factor to describe changes in the various physiological rates across the entire thermal tolerance range.

Moreover, a module is being developed to model changes in the proximate composition of the fish reared under different temperature conditions. This is done by simulating temperature driven changes in the model state variables such as reserve (E) and structure (V), which in DEB context comprise the fish biomass, and subsequently translating them to changes in proximate composition.

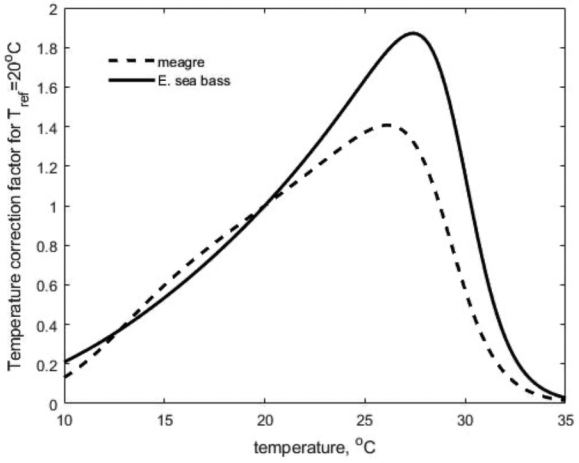

Figure 1 The temperature correction factor (for a reference temperature of 20 °C) across the thermal tolerance range for E. seabass and meagre

(Continued on next page)

Results and Discussion

The two models were parametrized and validated against datasets from farms as well as experimental data at high temperatures. The derivation of parameters for the Arrhenius function revealed differences in the thermal tolerance patterns of the two species in terms of the optimal temperature as well as the decline of performance towards the edges of the tolerance range. As depicted by the calculated correction factor, a factor that compares the various metabolic rates to a reference temperature (here 20 ^{o}C, where it equals 1) (figure 1), the width of the tolerance range was similar for E. seabass and meagre. However, the peak (which represents the highest metabolic activity) was higher for the former and also shifted to the right, occurring at a higher temperature compared to meagre. . Moreover, the reduction of performance at the upper end of the tolerance range was sharper for E. seabasss.

Compared to experimental data, the models could capture the decline in the voluntary feed intake and growth at temperature close to the upper end of the tolerance range, reasonably well. Provided that no shrinking occurs (reduction of structural mass) the energetic demands in DEB models are fueled only by the energy reserves. Consequently, preliminary simulations have shown that as temperature increases beyond the thermal optimum, the contribution of structure relative to that of reserve in the total biomass also increases. As a result, the model can depict some trends in body composition namely the increase in moisture content and the concomitant decrease in protein and lipid contents. Such trends are typically observed under low feeding or starvation conditions (Shirvan *et al.*, 2020), which is also the case for high temperature regimes due to the reduction in appetite. Therefore, application of such DEB models in aquaculture not only offers means of elucidating and comparing thermal tolerance patterns across species, but may also provide tools to quantify thermal effects on growth and body composition.

Introduction
Pikeperch (*Sander lucioperca*) currently drawing a great attention for aquaculture (Schulz et al., 2006) mainly in intensive recirculation aquaculture system. However, pikeperch have received little interests from feed manufacturers (Bochert, 2020). Though some commercial aquafeeds dedicated for percids have been available, salmonids-targeted feeds are widely used in practice. Insect meal produced from black soldier fly (BSFM) is rich in amino acids, lipids, vitamins and minerals. From these reason BSFM have been considered as potential alternatives to fish meal. The aim of this study was to investigate the effect of dietary defatted BSFM in diets for juvenile pikeperch on intestine microbiota.

Materials and methods
Four isonitrogenous and isolipidic experimental diets were formulated, comprising one fishmeal-based diet (CO), and three diets, where fishmeal was replaced at 25 (HI9), 50 (HI18) and 100% (HI36) by BSFM. Experimental extruded diets were prepared at a commercial feed producer (Exot Hobby s.r.o., Czech Republic). All groups were conducted in triplicate in 84 days trial. Pikeperch juveniles (68.7 ±7.1 g) were randomly allocated to twelve 250 L round conical tanks. Fish were fed to apparent satiation using combination of automatic feeders (EHEIM Twins) at 07.00, 09.00, 11.00, 13.00 and one hand feeding at 15.00.

At the end of main growing trial, three fish per each tank were randomly taken and euthanized with overdose anesthesia). Nucleic acid was extracted from the gut content (500 mg as starting materials). Total DNA from the samples was extracted using the RNeasy Power Microbiome KIT (Qiagen. Milan. Italy) following the manufacturer's instructions. One microliters of RNase (Illumina Inc. San Diego. CA) was added to digest RNA in the DNA samples with an incubation of 1 h at 37°C. DNA was quantified using the NanoDrop and standardized at 5 ng/µl. DNA directly extract from digesta samples was used to assess the microbiota by the amplification of the V3-V4 region of the 16S rRNA gene. The PCR products were purified according to the Illumina metagenomic standard procedure (Illumina Inc. San Diego. CA). Sequencing was performed with a MiSeq Illumina instrument with V3 chemistry and generated 250 bp paired-end reads according to the manufacturer's instructions.

Results and discussion
The result from OTUs analysis showed that significant increase was observed in HI18 compared to fishmeal diet, while two other insect-based diets did not differ in observed species from fishmeal diet. Feeding pike perch with dietary HI resulted in higher Chao 1 index than those with fishmeal diets, while no difference was observed for all HI-based diets (Fig. 1). Those difference were also observed by plotting the PCA at genus level. It was also possible to observed a degree of separation between the control samples CO quite near to the insect meal at 9% while the microbiota of fish feed with 18 and 36 % of HI well separated (Fig. 2). In agreement with previous studies on intestinal microbiota of percid fish and freshwater species, the present study reveals that *Firmicutes*, *Proteobacteria*, *Bacteroidetes* were the most dominant phyla in the intestine of pikeperch, regardless of the HI inclusion level. The inclusion of HI up to 18% or 50%

fishmeal replacement in pikeperch diets increased abundance of *Clostridium*, *Oceanobacillus*, *Bacteroides*, and *Faecalibacterium*, whereas the predominant bacterium, *Cetobacterium* was found in the control and HI36 groups.

Introduction

The increasing rates of fish consumption require aquaculture to achieve sustainable solutions to maintain a healthy and productive environment, also for the surrounding ecosystems (UN Environment Programme 2017, FAO 2020). Among other issues, the spreading of parasites can represent a considerable challenge for fish farmers. In the Mediterranean sea, gilthead bream (*Sparus aurata*) farms are mainly challenged by the presence of the parasite *Sparicotyle chrysophrii,* which can cause lethal epizootics in sea cages. *S. chrysophrii* is a hermaphrodite parasite that attaches to fish gills; it releases eggs that can either remain attached to the host or be released in the environment, potentially attaching to cage nets (Antonelli et al. 2010, Repullés-Albelda et al. 2012). Eggs mature into miracidia that can eventually attach to other fish hosts, thus closing the life and transmission cycles of the parasite.

Epidemiological modelling represents a valid tool to help fish farmers understand parasite transmission and evaluate control measures. To this purpose, in the following we propose and analyse a novel epidemiological model that investigates *S. chrysophrii* transmission within gilthead bream farms.

Methods

We developed a stratified compartmental model to reproduce parasite distribution within fish hosts. The model accounts for eco-epidemiological and evironmental dynamics driven by aquaculture practices. To account for the major pathogenicity of adult S. chrysophrii, we distinguished between juvenile and adult parasites. To do this, we model the number of infected fishes considering both juveniles and adults parasites attached. The model also includes the parasite life cycle, which is essential to realistically reproduce the epidemiological dynamics.

Results

We run our model over wide ranges of critical parameters (as shown, as an example, in Figure 1 with reference to the transmission rate, β) to study transmission dynamics under different eco-epidemiological conditions. For some parameter combinations, the conditions for parasite invasion are not met, as shown also on the top panels in Figure 1. For other combinations, the model allows to track the progression of the outbreak and, potentially, to evaluate the best timing for interventions aimed at reducing or breaking parasite transmission.

Discussion and conclusions

We proposed a model to reproduce the transmission dynamics of *S. chrysophrii* within gilthead bream farms. We studied transmission dynamics for different environmental and eco-epidemiological conditions. Our approach can be a useful tool to help aquaculture farmers develop intervention strategies. Further developments of the model could include fish growth dynamics (Ferreira et al. 2021), which in turn depends on the hosts' infection status, to investigate how management practices could synergistically improve both fish health and aquaculture production.

INDUSTRIAL TESTING OF A NEW NORWEGIAN OZONE REACTOR AND SKIMMER SYSTEM

Kevin T. Stiller*, Stig Johansen, Michael Vadseth, Per S. Brunsvik

Nofima AS, Sjølseng, 6600 Sunndalsøra, Norway
Kevin.Stiller@nofima.no

The Mowi close containment smolt facility in Steinsvik was built by Krüger Kaldnes without an RAZONE treatment system of their process water. Steinsvik is ideal location to test a newly develop two phase ozone reactor tank- followed by a skimmer- system. The product of the Ålesund based company Normex is called RAZONE WATER CLARIFIER. The innovative approach based on preliminary findings to prolong the ozone exposer time in the RAS water through an additional reactor tank for a later so-called micro flock production that can be removed by the sea-/fresh- water "skimmer system" which is different build to a common protein skimmer that been normally only used in seawater. The ozone system was installed to the Smolt unit of Mowi Steinvik to treat around 10% of the reuse water.

In this project water quality and fish welfare was evaluated monthly over 3 production cycles in in Mowi Steinsvik. The first cycle was without an installed RAZONE system. The second cycle was done with a relative conservative Oxidation-reduction potential (ORP) that is used as a proxy of ozone dosage of around 280 mv and the second with around 300 mV.

The water quality obviously become clearer using ozone in the production sending water as bypass through the RAZONE system. Turbidity, color, Total suspended solids (TSS) and Total organic carbon (TOC) are significantly reduced. The reduction is even viable with normal eyes comparing the 3 smolt production cycles. The production can be influenced by abrupt appetite loss in fish. Feed spill events and decreasing water quality when the fish stop eating where highly reduced using the RAZONE system. The automatic feedback loop regulated through 2 OPR probes works secure and stabile.

Nitrite, Germ count, Copper, zinc, and cadmium reductions could be measured just directly behind the RAZONE system. If the 10% treated water is diluted with the untreated process water it is more difficult to detect smaller changes in these variables. Gill histology and welfare score could not detect any negative effect through the RAZONE system to the fish under the given conditions. However, it could be recognized that the smolt quality increased, especially in the last test run. The subjective scoring system made it difficult to provide a solid answer if the welfare status increased but it could be seen that the fin quality increased significantly in the last test run.

In summary using the RAZONE system provided healthy smolts as well as bettering and stabilizing the water quality during the production cycle.

MEGA DEVELOPMENT PROJECTS IN NORWEGIAN FISH FARMING: HANDLING LOCAL AND GLOBAL RISKS FOR THE COMMON GOOD?

K.V. Størkersen*[1], T. Thorvaldsen[2], T. Osmundsen[1], P. Almklov[1], M.S. Olsen[1], S. Afewerki[2], V.S. Amundsen[1], A. Misund[2]

Email: kristine.storkersen@samforsk.no

Introduction
Managing and regulating aquaculture has been described as a complicated issue because of lack of firm knowledge regarding risks such as diseases and environmental impact, as well as the dynamic nature of new solutions emerging (Osmundsen et al. 2017).

Development licensing is a policy instrument launched by the Norwegian government for technological innovation to reduce risk – especially regarding escape of fish, prevalence of salmon lice, as well as access to sea-based production localities. The development licensing aims for technical innovation of new farm concepts, rather than social, organizational, or biological innovation or research. These projects can be seen as fish farming in extreme, and due to their clearly defined aims and major risks, they can be studied as showcases of norms and notions in Norwegian fish farming.

Research gap
Through earlier research in Norwegian fish farming, there is knowledge of risk dimensions, risk handling in the fish farm organizations, (Fenstad, Osmundsen, & Størkersen, 2009; Gismervik et al., 2020; Holen, Utne, & Yang, 2018; Stien et al., 2020; Thorvaldsen, Holmen, & Moe, 2015) and governmental measures to control these risks (Gismervik et al., 2020) (Osmundsen, Olsen, & Thorvaldsen, 2020).

We know that several risks are insufficiently reduced, and aims not met. This have led the Norwegian government and public, to require a stop in growth. The development licenses are supposed to solve some of these issues. However, there have not yet been any studies about how the development licences contribute to or solve the risks and what goals the actors plan to solve.

Research question and methodological approach
We have studied six developing concepts, and asked: *What goals do they have and what risks have they considered to be vital to handle?* We have interviewed about 10 persons involved in each developing concept (so far 40 semi-structured research interviews). The actors have been representatives for fish farming companies, technology providers, biology and fish health consultants, other service operators, authorities, associations, verification companies, research institutes, and knowledge providers.

Findings and implications for the future fish farming industry and research
Through the interviews and case studies, we have been seen that the actors involved in development projects handle the same risks that all Norwegian fish farmers need to handle to stay in business – and some more. The most common risks are Lice; Mortality and disease; Emission (fish escape, pollution); Personal injuries; Bankruptcy, and Incompliance with regulations. In addition, in this data material, we find that the actors involved in the development concepts also aim to reduce local and global societal risks: Unemployment, food scarcity, and value creation for Norwegian fish farming. They underline their role to develop lice free, emission free, safe and healthy operations, and and to increase aquaculture shares in global food production. They develop new networks with new actors, but employ local and known third party companies.

Possible effects of development licenses in aquaculture globally, may be new industry structures, more global networks, and perhaps increased competence and reduced risks. However, regulation needs changes if the industry should further develop.

The findings of this study may guide policy makers and the regulation of the industry, thus contributing to framework conditions for sustainable innovation long-term. Industry stakeholders will get knowledge that may be used to further evaluate development licenses as a strategy for innovation.

e-mail:oivinds@hi.no

The policy and legal frameworks that regulate expansion of mariculture differs worldwide, and specifically between some of the major players in mariculture development, China, the European Union (EU), Norway and Canada. In China, marine functional zoning (MFZ) is the legal framework regulating use of marine space, while in the other nations marine spatial planning (MSP) is applied. We detail how mariculture is implemented and compare the development experience for MFZ in China, and MSP in the EU, Norway and Canada. A comparison of the stepwise processes of MFZ and MSP implementation clarifies the differences in status of mariculture among the countries.

China, the EU, Norway, and Canada all have governmental visions and objectives to develop their mariculture industries. They have established institutional frameworks for managing aquaculture planning although these are highly diverse, where a general concern and condition for further development and growth of the aquaculture industry is the environmental interactions between mariculture and the environment. We suggest a stronger recognition of the relationship between food security, intensification of mariculture and environmental sustainability, to gain a better understanding how mariculture development can become an important contribution towards sustainable sea food production.

In the prospects of future increase in competition for space and resources in the oceans and consequently the need for efficient governance, the apparent weak or receding position of mariculture in MFZ and MSP processes should be of considerable concern if the endeavors of providing more ocean food using mariculture is promoted. As mariculture is regarded as the most promising route to achieve a substantial increase in provision of food from the oceans, we conclude that there is a need for strengthening the position of mariculture and its implementation in maritime spatial planning frameworks like MFZ and MSP.

A FRAMEWORK FOR SUSTAINABILITY ANALYSIS OF LOW TROPHIC SPECIES AQUACULTURE ACROSS THE ATLANTIC

Introduction

There is clear evidence that low trophic aquaculture is one of the most sustainable food production system available globally. However, in Europe the growth of low trophic aquaculture is stagnating. AquaVitae (AV) is a research and innovation project funded by the European Union's Horizon 2020 program. AV's overall objective is to introduce new, and expand existing, low trophic species (LTS) products and processes to marine aquaculture value chains across the Atlantic. This includes macroalgae, echinoderms, shellfish and low trophic finfish species as well as exploring the use of LTS in integrated multi-trophic aquaculture (IMTA) systems. In addition to research on specific value chains, a significant part of the research activities in AV aim to support a sustainable expansion of LTS aquaculture by addressing aspects in all sustainability domains, e.g. consumer attitudes and market potential as well as policy and governance in the social domain, profitability and socio-economic aspects in the economic domain, and environmental monitoring, risk assessment, and ecosystem services in the ecological domain. Much of this work is integrated into one of AV's four cross-cutting work packages i.e. WP6 (Environmental Monitoring, Risk Assessment and Sustainability).

The main objective of WP6 is to develop recommendations on how to increase LTS aquaculture production with a net positive impact on sustainability in and around the Atlantic Ocean under the principle of circular economy and to understand the possible impact of climate change on aquaculture in this area. To fulfil this objective, WP6 is organized into five different activities aimed at developing a framework for sustainability analysis, risk assessments, and environmental monitoring as well as performing the actual analysis in each of these topics. The results will be summarised as recommendations on how the sustainability of increasing LTS Aquaculture production can be optimized, including which positive sustainability aspects to exploit, which negative sustainability aspects to minimize, which risks to consider in relation to these aspects and how to monitor the system for early identification and mitigation of specific risks. In this poster, the structure, methods and expected impact of the work in WP6 will be presented more in detail together with the results from the first activity, a framework for sustainability analysis of low trophic aquaculture around the Atlantic.

Methods and results

The first task in WP6 aimed at providing a unified context for the following activities of WP6, enabling efficient co-operation and exchange of information within the WP. The developed framework, therefore, describes a desired state for LTS aquaculture in the Atlantic region and explains how this is linked to Agenda 2030 and the UN's Sustainable Development Goals (SDGs). Acknowledging that the SDGs are integrated and indivisible, the SDGs with the strongest and most direct links to the desired state and vice versa were prioritized. A set of indicators to evaluate sustainability was developed in relation to the desired state and the SDGs (Figure 1).

The description of the desired state and prioritization of SDGs was based on a combination of literature reviews and interactions with experts, industry and other aquaculture stakeholders (e.g. third sector, public policy makers, consumers) at workshops and meetings, using a combination of top-down and bottom-up methods. In addition to SDG 14, Life below water, which was identified as being the core SDG linking LTS aquaculture to sustainable development, the four SDGs with the strongest and most direct links to the AV objectives were found to be 2 (Zero hunger), 8 (Decent work and economic growth), 12 (Responsible consumption and production) and 13 (Climate action).

(Continued on next page)

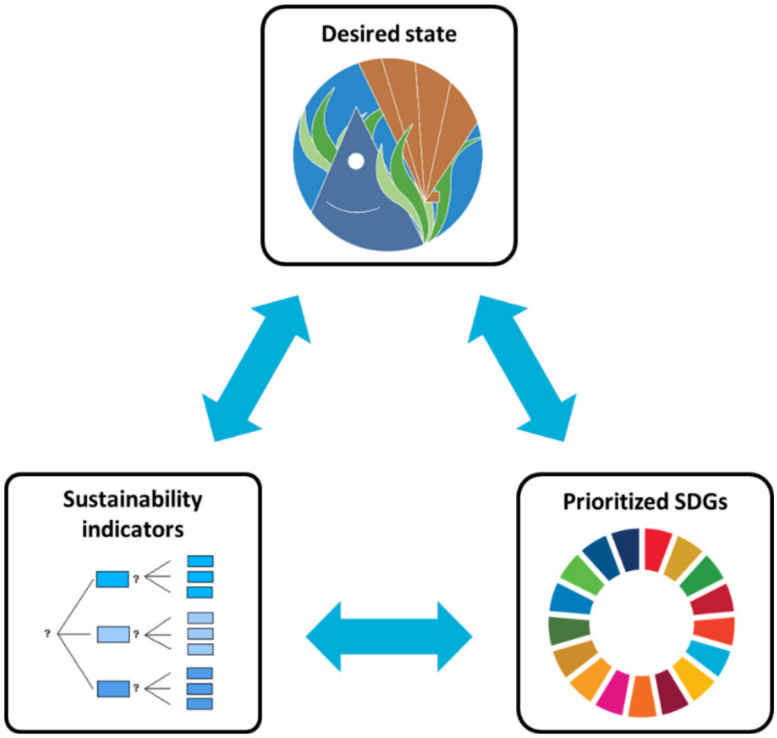

Figure 1. The interrelations of sustainability indicators, desired state and prioritized SDGs.

To compile the indicators, a broad screening of existing indicators was supplemented with the development of specific indicators. The screening covered, amongst other sources, the European Union Marine Strategic Framework Directive and Water Framework Directive, OSPAR, the SDGs, FAO and third-party certifications, and resulted in a database of 983 sustainability indicators. In addition to these 35 additional indicators were developed. Based on this, a set of 115 indicators was selected during a selection process, which included experts from within the AV consortium. The indicator set was developed to adequately describe, reflect and discern different types of LTS aquaculture, how they perform against a desired state and how they contribute to the SDGs most strongly linked to LTS aquaculture. The framework will be used to guide forthcoming sustainability analysis and risk assessments in WP6 with the aim to achieve the objective of the AV project and support the sustainable development of LTS aquaculture expansion around the Atlantic.

LESSONS LEARNED FROM STARTING AN INTEGRATED OFFSHORE AQUACULTURE-WINDFARM PROJECT IN TIMES OF A PANDEMIC (THE GERMAN NORTH SEA PILOT)

Introduction

The ocean multi-use concept envisages to bundle natural, human and financial resources in the face of scarcity of space in order to enhance the viability of offshore operations (e.g. combining aquaculture with other offshore industries). Offshore projects, especially when implemented with a multi-use approach, are facing manifold challenges due to their different needs in logistics and operational intensity, particularly when extreme events offshore require different responses for each of them. To achieve an optimum of combined resource use, highly detailed, well thought-out planning of the work is needed. The organisation of complex logistics, preparation of infrastructure and pre-testing of materials and technologies are serious challenges while also assuring appropriate training of operational, multi-disciplinary personnel. Furthermore, the application of health and safety standards for people involved in operations are essential for a successful functioning of the multi-use system.

The UNITED (Multi-**U**se offshore platforms demo**N**strators for boost**I**ng cost-effec**T**ive and **E**co-friendly pro**D**uction in sustainable marine activities) project addresses the integration of a relatively new form of an old economic branch, namely aquaculture, into an already existing but relatively new set of offshore activities, to increase the potential for synergistic effects, enhancing the idea of multi-use co-locations (MUCL) at sea.

Within the UNITED project, five demonstration trials ("pilots"), were set up in different contexts (North- Baltic Seas, Mediterranean). The German pilot combines offshore wind energy research and aquaculture at a very exposed location (45 nautical miles from the shore), and thus reflects a situation where remote operational logistics have to be more prominent than in all other pilots, although in principle needed by all.

The planning of this project was done at least a year before the unexpected outbreak of COVID19. Within weeks after project approval these plans and some objectives were at risk and became redundant due to the outbreak. This paper takes a special look at potential ways of solving unforeseen problems arising from the COVID19 outbreak with the focus on ad-hoc adjustments in the face of high uncertainty of their realisation. The described solutions demonstrate how intensified and rapid interactions and highly flexible and timely responses by all stakeholders can help to identify feasible alternatives to guarantee continued planning and subsequent operations

Materials and Methods

One of the major challenges due to COVID19 arose because of restrictions affecting the supply and service industries so that pre-test, and new design set-ups were seriously hampered. The pressure grew to focus on automation, alternative logistics, additional training and capacity building of personnel as well as health and safety issues.

The operational offshore phase of the project builds upon these developed strategies, which have only partly been tested so far. The pre-testing and adjustment phase of the project is ongoing and provided most valuable information on adaptations to COVID19 in an innovative field, as there are no practical examples from which experience can be gained. Limited examples of successful MUCLs under these new conditions requires research inputs to find new solutions to arising questions in support of the development:

- What requirements are needed in terms of social, environmental, economic, legal and technological approaches when realizing a MU project in times of a pandemic of unknown duration and potential resurgence?
- What innovative approaches are needed to integrate offshore infrastructures and additional maritime activities with regard to adjusted health/safety standards?
- How can adaptations/ alternatives be made during the pre-operational phase to foster the development of MU activities in case a Pandemic re-appears?

(Continued on next page)

Results

One lesson learned from the pre-risk assessment was the need to always develop alternatives (e.g. plans B and C) at the onset of the project. This even for the most unlikely impairment. Several properly planned activities ready for timely implementation, had to be interrupted /postponed and subsequently to be cut short due to governmental ad-hoc decisions ("lock downs", restricting response options). Another major negative effect of the COVID19 situation has been the extremely prolonged and even uncertain delivery times for equipment and parts as well as services, including the purchase of aquaculture species. Alternatives had to be found to serve the original plans for data acquisition, particularly for monitoring instrument and their capabilities. Fortunately, comprehensive knowledge on the offshore engineering business contributed to timely find alternatives to specific suppliers. This partly allowed to keep schedules with limited delays. Forming a broad stakeholder register turned out to be most valuable. The pandemic led to an extensively expanded range of stakeholders which needed almost daily contacts to cope with newly arising risks. Stakeholders helped in reducing frustrations, fostering consensus building and gaining improvement-oriented inputs. Thus, new adapted pilot solutions in one place mandatorily required a close communication not only within the pilot, but also between affected parties and this for the remainder of the project.

The pandemic demanded a new way of training and capacity building of personnel, creating teams with broad skills rather than single specialists. The pre-operational phase (first project year) has been used to determine the future-oriented skills for a safe operation of the pilots. The training objectives so far were not only to educate internal personnel but also to facilitate a trans-disciplinary knowledge exchange of best practices from different fields, and to combine skills in order to be operational at all times.

Conclusion/Outlook

The pandemic caused delays with a terrible "domino-effect" downstream from the source to the end-user (the Pilot). The need for a time buffer to cope with unforeseen obstacles should be considered in manpower planning of future projects so that sufficient flexibility is available to cope with the problems adequately. The pandemic situation demanded an even broader and more flexible approach than ever anticipated. In the future, every possible flexible/alternative operational modus (including financial consequences) should already be in the drawer before being confronted with unforeseen events, even if no opportunity for testing occurred. This situation is likely to continue in all pilots as there is little hope that a return to the former "normal" will be restored within the duration of the UNITED project. Documenting these lessons is strongly recommended as additional benefits to multiple sectors may be generated, and infrastructural synergies may be created in the face of uncertainty. Translating the COVID19 pandemic conceptually to the aquatic environment, early response strategies might avoid damage to the aquaculture business by requesting regulations that prevent the transfer of exotic species and diseases via globalized trade and increased recreational boating. This while aquaculture locations near shipping routes are rapidly growing, this way increasing contact and risks entailed.

IN VITRO AND *IN VIVO* BIOLOGICAL ACTIVITY OF GREEN MICROALGAE *Desmodesmus spinosus*

I. Strunjak-Perović[a,b,*], L. Perković[a], A. Martić[a], E. Djedović[a], S. Babić[a,b], L. Čižmek[a,b], T. Paradžik[a,b] and R. Čož-Rakovac[a,b]

Introduction

In recent years, studies of cellular extracts or isolation of intracellular and extracellular metabolites from different microalgae have been a high priority due to their diverse biological activity and possible discovery of novel nutraceuticals (Morais et al., 2015). A freshwater green microalgae *Desmodesmus spinosus* belongs to the family of Scenedesmaceae (Guiry, 2021). According to previous studies, genus of Desmodesmus showed relatively high antimicrobial and antioxidant activities due to the high content of pigments, phenolic compounds and tocopherols (Safafar et al., 2015). In this study, evaluation of biological activity of different polarity extracts from *D. spinosus* was conducted. Antioxidant activity was performed using both *in vitro* assays and *in vivo* zebrafish model, while an embryotoxicity test was performed in order to determine safety for non-target organisms.

Materials and methods

Cultivation of *D. spinosus* was carried out in an enclosed 2 L glass stirred tank bioreactor as a semi-continuous batch process. Temperature and pH values were kept constant at 25 °C and 9.2, respectively. The culture was stirred with an agitator at the rotation speed of 220 rpm. Air was provided from the bottom of the agitator at a flow rate of 120 L/h. The culture was illuminated with 2700 K warm white LED lamps. Microalgae cells were harvested in the exponential growth phase. The freeze-dried sample of microalgae *D. spinosus* was extracted by ultrasound-assisted extraction in four different solutions: water, water:methanol (1:1), methanol and methanol:dimethyl sulfoxide (1:1). Antioxidant activity was evaluated by implementing three *in vitro* assays: reduction of radical cation assay (ABTS) and ferric reducing antioxidant power assay (FRAP), while total phenolic content (TPC) was determined by Folin-Ciocalteu method. The toxicity of samples was determined using the zebrafish embryotoxicity test (OECD 236, 2013) up to 96 h of embryonal development. Upon establishing the concentration range of interest, zebrafish embryos were further employed to determine the protective effect of tested samples on H_2O_2-induced ROS generation *in vivo* (Jerković et al., 2021).

Results

Based on BLASTN results, microalgae used for this research was identified as *Desmodesmus sp.*, with the highest similarity to *Desmodesmus spinosus* (90% coverage, 96% identity). The highest *in vitro* antioxidant activity was obtained for methanol:DMSO cell extract solution using FRAP and Folin-Ciocalteu methods (Figure 1A). The lowest inhibitory concentration (IC_{50} = 0.876 mg/mL) obtained using ABTS assay was detected in methanol:DMSO solution extract which indicates the highest antioxidant activity, followed by MetOH>H_2O:MetOH>H_2O. The TPC showed a high positive correlation for both FRAP and ABTS assays with Pearson's correlation coefficients of 0.959 ($p < 0.05$) and 0.912 ($p = 0.09$), respectively. Additionally, a high positive correlation between FRAP and ABTS was found with Pearson's correlation coefficient of 0.967 ($p < 0.05$). Prepared extracts showed no embryotoxic potential at concentration of 0.5 mg/mL. Embryos pretreated with methanol and methanol:DMSO extracts of *D. spinosus* biomass showed a statistically significant decrease of fluorescence intensities for 52.75% and 50.06%, respectively, comparing to the group on H_2O_2 (Figure 1B).

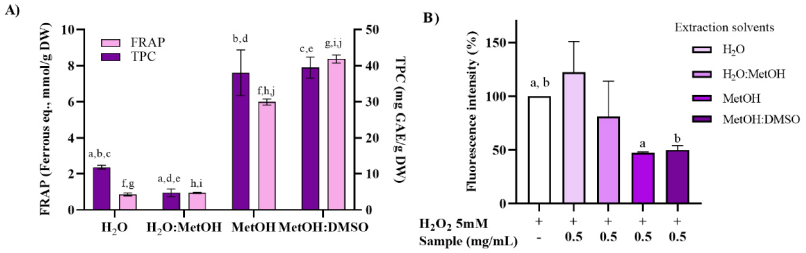

Fig. 1. Determination of antioxidant activity of *D. spinosus* cell extracts using: A) *in vitro* assays and B) *in vivo* zebrafish model. Columns sharing common letters indicate significant difference within each method. Results were presented as mean ± SD.

(Continued on next page)

Discussion

Conducted *in vitro* assays showed relatively high total phenolic content of *D. spinosus* MetOH and MetOH:DMSO extracts (38.05±6.33 and 39.47±2.93 mg GAE/g DW, respectively). Similar results were recorded by Patil and Kaliwal (2019) for *Scenedesmus bajacalifornicus* methanol extract (32.12 mg GAE/g DW). Although high antioxidant activity using *in vitro* assays was observed for two less-polar extracts (methanol and methanol:DMSO), all used methods showed significant correlations. Not statistically significant coefficient between TPC and ABTS suggest that the antioxidant activity of these extracts is, besides phenolic content, dependent on the presence of other compounds that exhibit different antioxidant modes of action. Results obtained on zebrafish embryos/larvae showed a protective effect of *D. spinosus* extracts against H_2O_2-induced oxidative stress, thus further confirming the high antioxidant potential of methanol and methanol:DMSO extracts. Overall, these findings indicate the potential of *D. spinosus* as a source of beneficial antioxidant agents in the functional food industry.

INCREASING IRRADIANCES INCREASE ANTIOXIDANT ACTIVITY, TOTAL PHENOLIC CONTENT AND AFFECT PHOTOSYNTHESIS OF ECONOMICALLY IMPORTANT MACROALGA SEA GRAPES *Caulerpa lentillifera*

L. E. Stuthmann[1*], R. Achuthan[1,2], K. Springer[2], A. Kunzmann[1]

Introduction

Caulerpa lentillifera is a green, macroalga of increasing economic interest, harvested as an aquaculture crop in several Asian countries (Chen et al. 2019). The alga is low-light adapted and its out-door culture takes place in shaded ponds (~ 50 μmol photons m^{-2} s^{-1}). In Europe, sea grapes are known as `green caviar´, due to the special texture of their edible fronds. Sea grapes contain significant amounts of polyphenols and vitamin C, resulting in high antioxidant activities (AOA, e.g. Matanjun et al. 2009; Nguyen et al. 2011)vitamin C, α-tocopherol, dietary fibers, minerals, fatty acid and amino acid profiles of three tropical edible seaweeds, Eucheuma cottonii (Rhodophyta. Antioxidants can avoid cell damage by functioning as scavengers of reactive oxygen species (ROS) and are therefore recognized as essential parts in human diets to counteract the metabolic syndrome (John et al. 2020). In plants ROS form as a byproduct of photosynthesis, especially under excessive light introducing photooxidative stress (Pospíšil 2016). In this study controlled light-stress is applied as a tool to trigger the antioxidant potential of sea grapes, while sustaining the healthy green color of the fresh sea grape fronds.

Material and Methods

Sea grapes were held in 2 L beakers (artificial seawater) in a water bath under irradiances of 50, 100, 200, 400 and 600 μmol photons m^{-2} s^{-1} for 21 days. Samples for measurements of AOA (ABTS assay, following Re et al. 1999), total phenolic content (TPC, Folin–Ciocalteu assay, following Ainsworth and Gillespie 2007), chlorophyll a and b content, maximum quantum yield of PSII (F_v/F_m) and pictures for color analysis were taken regularly over the run of the experiment. Data processing of chlorophyll content and color measurements (for a later processing using the image analysis software ImageJ) is still underway.

Results

Sea grape fronds were significantly enriched in AOA and TPC when exposed to excessive irradiances (≥ 200 μmol photons m^{-2} s^{-1}), compared to usual culture irradiances. However, AOA and TPC content of sea grapes were negatively correlated with F_v/F_m (Fig. 1 C), implying an overall decrease of the algae's physiological state with increasing antioxidant potential. Additionally, a partial de-coloration of sea grape fronds under irradiances ≥ 200 μmol photons m^{-2} s^{-1} has been observed over the experimental run.

Discussion

The results confirm, that antioxidative compounds accumulate in sea grape fronds under light-stress. Light irradiances ≤ 100 μmol photons m^{-2} s^{-1} seem to be too low to increase AOA and TPC significantly (Kang et al. 2020), however irradiances of ≥ 200 μmol photons m^{-2} s^{-1} more than doubled AOA and TPC, respectively. Decreasing F_v/F_m values and de-coloration, possibly induced by chloroplast relocation movement (Horstmann 1983) or chlorophyll degradation (Guo et al. 2015), might have a negative impact on the product quality. Therefore, carefully controlled higher irradiances could be applied as a post-harvest treatment in order to keep a balance between triggering AOA and sustaining healthy appearance of sea grape fronds.

Introduction

Because of their outstanding physicochemical properties, metal and metal oxide nanoparticles (NPs) have been widely used. These particles will be released into the environment as a result of large-scale manufacture and consumption. The transfer and magnification of NPs in the trophic chain is one of the most serious risks associated with their use.

As a result, data are required to assess the environmental risk of these emerging pollutants, particularly in terms of uptake and biological impacts. In vitro experiments can reveal how these NPs are capable of being internalised in cells, which is a necessary step before determining bioaccumulation in fish and molluscs, as well as bioavailability in humans.

Single-cell inductively coupled plasma – mass spectrometry (SC-ICP-MS) has opened a new area of research, allowing for the sensitive detection of metals in single biological cells at ultra-low levels (attograms per cell) not possible with existing instrumental techniques. As a result, the aim of this study was to observe if SC-ICP-MS could be used to analyse TiO_2 NPs inside kidney cells from sea-bass (Dicentrarchus labrax) and clams (Ruditapes philippinarum) as a prelude to bioaccumulation investigations of TiO_2 NPs in these cultured species.

Methods and results

The internalization of TiO_2 NPs in kidney sea-bass and clam cells was assessed by SC-ICP-MS after they were exposed to TiO_2 NPs (5, 25 and 45 nm) at different NPs concentrations and exposure times.

Several SC-ICP-MS parameters were investigated in order to establish a unique, high-sensitivity, and accurate approach for determining TiO_2 NPs in single cells from aquaculture products. Multi-cell coincidence was avoided by optimizing cell concentration and dwell time.

The effect of washing stages (1% PBS) on removing non-internalised TiO_2 NPs and/or TiO_2 NPs deposited onto the cell surface was also studied. This approach helps to avoid high dissolved backgrounds, potential interferences, and excess particles that could hide the signal emitted by single cells. The rate of internalization of TiO_2 NPs of various size distributions was assessed using optimized SC-ICP-MS conditions based on concentration and exposure periods tested. The findings are now being used to develop TiO_2 NP bioaccumulation assays in cultured sea bass and clams.

Introduction

Northern pike (*Esox lucius*) is a piscivorous fish with a broad geographical and environmental range. It plays an important ecological role as a predator, and is highly regarded as a sport fish. To satisfy the needs of anglers, pike fry are stocked in natural waters. The number of fry required can only be produced in controlled hatchery conditions.

Since pike do not spawn in confinement (Huet 1986), ovulation and spermiation is induced by hormonal treatment (Szabó 2001). Eggs can easily be stripped after ovulation, however, only a small amount of milt can be stripped from the male fish. To enhance sperm yield, the testes are surgically removed and sperm is obtained by squeezing the organs through cheesecloth. This method requires sacrificing the males, so it is important to determine the amount of milt that is necessary for successful fertilization. For the above reasons, we aimed to determine the amount of sperm required to fertilize northern pike eggs under hatchery conditions.

Materials and methods

Experiments and routine hatchery work were conducted concurrently during the northern pike breeding season in the hatcheries of the Dinnyés Fish Farm and the Danube Anglers Association of Ráckeve in Hungary. Basic data of northern pike breeding at the two hatcheries are summarized in Table 1.

Both females and males received an injection of a crude preparation of dried carp pituitary at a dose of 3.5 mg kg^{-1} body weight (BW). Pituitaries were administered in a 2.5 % aqueous dispersion of Carbopol resin (Szabó 2006). Injections were applied intraperitoneally at a volume of 0.5 ml kg^{-1} BW. Stripping of females was conducted on the fourth day after injection. From the male fish, the testes were surgically removed and the sperm was obtained by squeezing the organs through cheesecloth. The number of males used for fertilization procedures was approximately 20 percent of the number of the ovulated females. The testes from different males were collected in one beaker. Milt extracted from this mixture of testes was used to fertilize the eggs from each female.

We aimed to determine the optimal amount of sperm needed to fertilize northern pike eggs. Our goal was to fertilize large batches of eggs in the tests so that the results would be informative for hatchery practices. In both farms, three egg batches from three females were used for the experiments (Figure 1). The sperm : egg ratios tested were as follows: 10 ml, 5 ml, and 2.5 ml sperm for 1,000 grams of eggs, respectively. Treatments were performed in duplicate.

For the experiments, we tried to select relatively large females from which at least 1,000 g of eggs could be gained. Egg batches of 300 g were weighed from each female into three bowls. For each batch, 3.0 ml, 1.5 ml, and 0.75 ml of sperm were used, respectively. The dry gametes were then mixed gently and activated by adding 100 ml of water. After fertilization, eggs were placed into Zuger jars for incubation at 11±1.0°C. Fertilization percentages were established 18 hours after fertilization, when eggs were in morula stage.

Results and conclusion

It was found that fertilization of 1,000 g of northern pike eggs with 5 ml and 10 ml sperm gave similar results (Figure 1). If the eggs were fertilized with 2.5 ml milt, the fertilization rate was somewhat reduced. However, if the number of males available for breeding is limited, a quantity of 2.5 ml of semen may be sufficient to fertilize 1000 g of eggs without a significant reduction in the fertilization rate.

(Continued on next page)

Place of propagation:	Time of treatment / WT	Time of stripping / WT	Amount of stripped eggs	Average FR
Dinnyés	3.24.2019 / 12 ºC	3.28.2019 / 10 ºC	18 kg	71 %
Ráckeve	3.21.2019 / 8 ºC	3.25.2019 / 12.4 ºC	30 kg	75 %

Table 1: Basic data of northern pike breeding at the Dinnyés and Ráckeve hatcheries. WT: water temperature, FR: fertilization rate

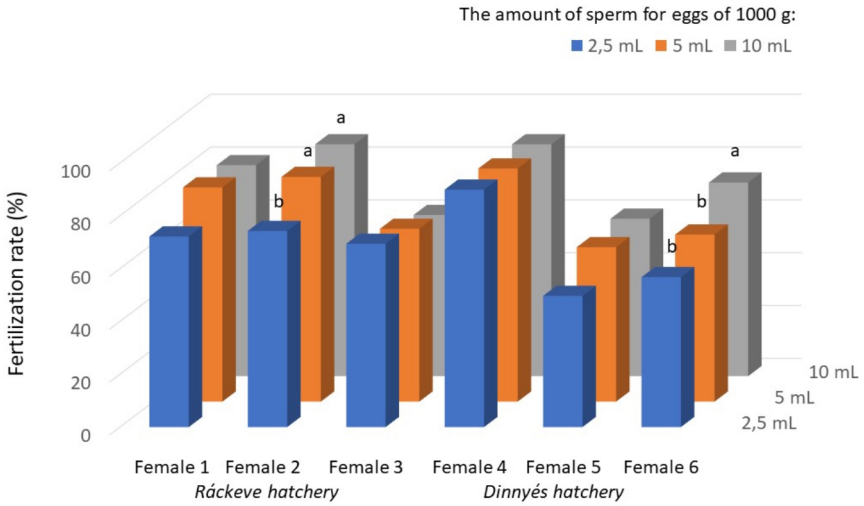

Figure 1: Fertilization rate data from three different "sperm : egg" ratios. Fertilization rates between egg batches fertilized with different amount of sperm were similar for females 1, 3, 4 and 5. In case of female 2 and 6, means that do not share a letter are significantly different (Kruskal-Wallis test, $p < 0.05$).

B CELLS FROM THE RAINBOW TROUT ADIPOSE TISSUE SPECIFICALLY RESPOND TO PERITONEAL ANTIGENS

Rocio Simón[1], Alba Martín-Martín[1], Esther Morel, Patricia Díaz-Rosales, Carolina Tafalla*

Animal Health Research Center (CISA-INIA-CSIC), Valdeolmos 28130, Madrid, Spain
Email: tafalla@inia.es
[1] These authors equally contributed to this work

The immune response of the adipose tissue (AT) has been neglected in most animal models until recently, after investigations in human and mice linked obesity to chronic inflammation, highlighting the immune nature of this tissue. Thus, in mammals, the AT is increasingly seen as an active immune site, playing important roles in systemic and peritoneal responses. Despite this, in teleost fish, only a few studies have addressed the immune role of the AT. These studies revealed significant changes in the levels of transcription of a wide range of immune factors produced by the AT in response to diverse intraperitoneally delivered stimuli, and demonstrated the presence of B cells within the tissue. In the current study, we have continued the characterization of the immune role of rainbow trout (*Oncorhynchus mykiss*) AT, focusing on how the different B cell populations, that are present in the AT, react to an intraperitoneal stimulation. Initially, the B cell populations present in this immune tissue were characterized in comparison to B cells from other sources. As occurs in other rainbow trout tissues, IgM^+IgD^+, IgM^+IgD^- and IgD^+IgM^- B cell subsets were identified in the AT. Interestingly, AT IgM^+IgD^- B cells showed a transcriptional profile that seems to correspond to cells that have already committed to plasmablasts/ plasma cells, being this profile much more pronounced than that of blood IgM^+IgD^- B cells. Consequently, the IgM-secreting capacity of AT cells is significantly higher than that of blood B cells. Additionally, we established how these B cell subsets responded when rainbow trout were intraperitoneally injected with a model thymus independent antigen, TNP-LPS. Our results demonstrate that AT B cell differentiate to plasmablasts/ plasma cells that secrete specific IgMs against the antigen, as happens in the peritoneal cavity, the spleen, the head kidney and in peripheral blood. Although the presence of these antigen-specific IgM secreting cells was more abundant in the peritoneal cavity, these differentiated B cells were detected in the AT for long time periods at levels similar to those of spleen and head kidney. Our results provide new evidence regarding the immune role of the teleost AT, demonstrating that it functions as a secondary lymphoid organ that promotes immunity to peritoneal antigens.

CHARACTERIZATION OF B CELL RESPONSES IN THE RAINBOW TROUT (*Oncorhynchus mykiss)* GILL

J. German Herranz-Jusdado, E. Morel, P. Díaz-Rosales and C. Tafalla*

Animal Health Research Center (CISA-INIA-CSIC), Madrid, Spain
E-mail: tafalla@inia.es

Introduction

Most teleost B cells co-express surface IgM and IgD (IgM^+IgD^+ cells) and down-regulate IgD after encountering an antigen as mammalian B cells do (becoming IgM^+IgD^- cells). In addition to these populations, IgD^+IgM^- B cells have been detected in catfish (*Ictalurus punctatus*) peripheral blood and in different rainbow trout (*Oncorhynchus mykiss*) mucosal surfaces such as gills or gut. Thus, in both rainbow trout gills and gut, IgM^+IgD^+ cells are rare, with most B cells expressing just one surface Ig. In this context, in the current study, we wanted to further characterize these B cell populations found in the rainbow trout gill by determining their response to immune stimulation. Effects on B cell viability, Ig secretion and expression of CCR7 and CD38 were studied. CCR7 has been shown to condition the response of lymphocytes in peripheral immune tissues, whereas CD38 is known to be associated with an increased Ig secreting capacity.

Materials and methods

Gill leukocytes were isolated from adult rainbow trout by Percoll gradients. Leukocytes were then exposed *in vitro* to heat-inactivated viral hemorrhagic septicemia virus (iVHSV), to bacterial lipopolysaccharide (LPS) or were left untreated. After 48 h of incubation, the percentage of B cells from each subset was established through flow cytometry, also studying the surface expression of CCR7 or CD38 in each group through the use of specific rainbow trout antibodies. Finally, the number of IgM-secreting cells in these cultures was also determined by ELISPOT.

Results

The percentage of IgM^+IgD^- B cells decreased in gill leukocyte cultures exposed to iVHSV but significantly increased in response to LPS. Consequently, the number of cells secreting IgM also increased in LPS-treated cultures. In contrast, the percentage of IgD^+IgM^- cells was not significantly affected by stimulation. Nevertheless, the percentage of IgD^+IgM^- cells expressing CCR7 or CD38 significantly increased in response to both stimulations, whereas CCR7 expression decreased in IgM^+IgD^- B cells upon LPS stimulation.

Discussion and conclusions

Rainbow trout IgM^+IgD^- and IgD^+IgM^- B cells from the gill respond differently to immune stimulation. Our findings contribute to a deeper understanding of how fish B cells are regulated at mucosal surfaces. From a practical point of view, this information will be helpful for the future optimization of vaccines that are delivered through mucosal routes.

Introduction

Organic aquaculture seems to be a very well promising sector in the global ecology and economy (FiBL & IFOAM, 2020). Organic aquaculture reflects a specific production approach driven by the growing public interest in sustainable utilization of resources (Mente et al., 2011, 2012, 2019; Lembo & Mente, 2019). In the context of sustainability, the search for ingredients that are characterized by low FIFO ratios is of much interest. The aim of this study is to examine the growth performance of sea bream (*Sparus aurata*) fed diets with a low FIFO mix of ingredients for organic aquaculture.

Materials & Methods

The experimental trial was conducted at the Department of Ichthyology and Aquatic Environment, University of Thessaly. Sea bream individuals with initial mean weight 6.87±0.07g, were acclimated to the laboratory conditions for 15 days before they were randomly distributed into 250l tanks. Each diet was allocated to triplicate groups. The fish were fed three times per day *ad libitum* and the rearing water quality (21° C, DO>6.5 mg/l) remained stable during the experiment. Four experimental diets were formulated to be isonitrogenous (48.3%), isolipidic (16.2%) and isoenergetic (21.3 KJ/g). The control diet was designed to simulate the composition of a commercial diet incorporating organic fishmeal trimmings, organic fish oil and soybean meal (organic and concentrate). A low FIFO mixture replaced fishmeal at three different inclusion levels, 20, 25 and 30% and three experimental diets were formulated (LFiFo20, LFiFo25 and LFiFo30, respectively). The low FIFO mixture consisted of organic processing fish trimmings, bacterial protein and yeast protein. The duration of the experiment was 60 days. Fish were weighted individually at the beginning and end of the experimental trial under anaesthesia. Feed consumption was recorded daily to evaluate accurately values for feed utilization.

Results

Fish fed the replacement diets (LFiFo20, LFiFo25, LFiFo30) had similar ($p>0.05$) weight gain and SGR values that were significantly increased ($p<0.05$) compared to control group of fish. Fish fed the LFiFo20, LFiFo25 and LFiFo30 had also similar ($p>0.05$) FCR values that were significantly decreased compared to the control group. Voluntary feed intake and survival were statistically unaffected among the diets ($p>0.05$).

Table 1. Growth performance of gilthead sea bream (*S. aurata*) fed organic low fishmeal diets.

	Control	LFiFo20	LFiFo25	LFiFo30
Final weight (g)	14.65±0.46^a	19.44±0.48^b	19.86±0.49^b	19.37±0.45^b
Weight gain (g)	7.58±0.11^a	12.37±0.57^b	12.75±0.35^b	12.14±0.97^b

Discussion

Since 2000, there has been an increasing demand for seafood farmed according to certified organic standards, notably in European countries (FGM, 2020). It follows, therefore, that like the terrestrial organic livestock production sector, the onus is on the aquatic nutritionist to formulate an organic feed close to the feed that each fish species is consuming in their natural environment. In the present study, a low FIFO mix with innovative ingredients and organic fishmeal trimmings improved the FCR and enhanced the growth performance of *S. aurata*. Microbial protein is an alternative source of high-quality protein able to replace animal protein like fishmeal in livestock nutrition and aquaculture (Matassa et al., 2016; Olmos et al. 2020). Furthermore, yeast meal contain appreciable crude protein (about 40–55%), and other bioactive components beneficiary to fish growth and development (Agboola et al., 2020)extensive studies exist on the role of yeast cell wall components in modulating health responses of fish. However, research on its use as a major protein source in fish diets is still in its infancy. The current review collates, synthesises and discusses the prospects of five major yeast species as future protein ingredients with respect to their nutritional adequacy in fish. Nutritional quality of Saccharomyces cerevisiae, Cyberlindnera jadinii, Kluyveromyces marxianus, Blastobotrys adeninivorans and Wickerhamomyces anomalus and their use as replacement for fishmeal and soy protein in the diets of Atlantic salmon and rainbow trout are discussed based on three protein quality indices: chemical score, essential amino acid index and ideal protein concept based on the first limiting amino acids, methionine. The crude protein contents of yeast (40–55%. The results suggest that wild sourced organic fishmeal trimmings can be successfully replaced by innovative ingredients of low FIFO that are based on microbial protein and yeast meal.

Future research using novel feed ingredients to replace fish meal in organic aquaculture should also take into account the quality of the raw ingredients, their process conditions and the fillet nutritional quality.

saraya.tavornpanichetinst.no

The objective of this study was to use risk assessment to determine the biosecurity risk associated with Viral encephalopathy and retinopathy (VNN) introduction and spread in Mediterranean seabass production, and to identify the control measures to manage the risks.

Biosecurity plans for prevention of introduction and further spread of disease pathogens involve knowledge on risk assessment of disease hazards in the region, likelihood of introducing the infectious agent into the production system, epidemiology and transmission routes, critical points for introduction and control. VNN was identified as the most important disease of seabass in the western, central, eastern and southern Mediterranean areas in terms of production and economic impact due to factors such as the high mortality and morbidity by literature, survey, and expert opinion.

A group of 10 experts consisting of fish health specialists, veterinarians, biologists, and epidemiologists were asked to provide their opinion regarding disease hazards, likelihoods of disease introduction and spread in the Mediterranean seabass. Expert knowledge elicitation (EKA) approach was used to elicit expert opinion and perform the risk assessment. Risk matrix was used to present the overall risk estimates by integrating the numerical scores for the likelihood of disease introduction and the economic consequences. The experts to identify the points at which VNN introduction and spread could occur and be prevented. At each action point, experts gave a weight for potential biosecurity measures concerning its feasibility and effectiveness for controlling VNN

The main risk pathways differ by type of production for which the likelihoods of introduction are similar for hatchery and pre-growing, but different from the likelihoods for on-growing. Intake of water, live fish and eggs, vehicle transporting live fish, human, equipment, and high-risk purchasing were identified by the experts as the risk pathway for all types of production. This illustrates a clear recommendation to encourage focusing on introductory risk.

The economic consequences of VNN depend on the type of production of the facility. The consequences of VNN introduction were regarded most devastating in economic terms for hatcheries and pre-growing units and the risk estimate was in general high or very high for these productions. For on-growing the risk estimates were regarded medium to high. Measures to comply with introduction entail requirements of reliable health certificates and quarantining newly acquired fish upon arrival. The measures for disease management entail removing dead fish daily, preventing direct contact between quarantined fish and the other fish on the facility, separate water flow between quarantined fish and the other fish on the facility, and follow-up investigation of disease outbreaks.

TOWARDS PRECISION AQUACULTURE: A HIGH PERFORMANCE, COST-EFFECTIVE IOT APPROACH

Introduction

Activities in aquaculture have seen a global annual growth rate of 7%, highlighting their increased relevance to animal protein production worldwide. As a result, the North and South Atlantic production has received considerable government and policymakers attention from the '90s onwards. For instance, Brazil's government stimulus and private investments helped increase the *per capita* fish consumption in this country, thus leading to a net production of 707 thousand tons in 2015. Such tailored interventions have taken Brazil to 12th place in the world's aquaculture league. On a global scale, aquaculture fish production reached 82.1 million tons worldwide in 2018 according to an FAO report. The substantial social and economic impacts of aquaculture farming cannot be underestimated as a catalyst for new employment posts throughout the whole value chain. Such benefits reach the small producers located on both sides of the Atlantic, including impoverished areas in low-to-middle income countries (e.g. communities in South America and Africa). Given the demand rise for high-quality animal protein to feed the world population, marine aquaculture is under tremendous pressure to accelerate production in a responsible, eco-friendly manner. A crucial enabler is the technology for real-time monitoring of aquatic organisms in an operational setting. Rigorous control of the environment's physical-chemical parameters is the first step towards an economically viable production. Unbalanced parameters can directly affect species' growth, generate pathogens and environmental conditions that may hinder animal reproduction and healthy growth. Aquaculture is an unpredictable biological system in which adverse outcomes cannot be ignored in the management of a production system. The European Commission adopted the term *Aquaculture 4.0* to contemplate the transfer of new technologies investigated in other industries, including Internet of Things (IoT), distributed computing, data analytics and artificial intelligence. The Internet of Things (IoT) is a rapidly growing technological field, providing social and economic benefits for all geographical areas but particularly low-cost technology delivered to low-to-middle income countries. For example, traditional water monitoring in aquaculture follows a very laborious and time-consuming procedure whereby essential variables are measured. The high cost of the needed human resources severely limits the monitoring and control of the aquaculture facilities.

IoT-driven monitoring and control in aquaculture is a challenging scenario in itself because of a number of constraints:

1. Site area: anything 5 and 30 hectares;
2. Difficult access (boats or off-road vehicles);
3. Power supply: none in open-water, none to limited in land-based facilities
4. Communication coverage: limited to none;
5. Climate and adverse weather conditions;
6. Lack of reliable and suitable monitoring technology;

Aquaculture 4.0 offers tools that can be leveraged and applied to level up production systems' quality and effectiveness. Previous limitations can be overcome when reliable technologies monitor and identify any undesired condition or event of interest learnt from data. A key question to ask is the following one: *how feasible is the design and deployment of a water quality sensor network that communicates data to an online platform for real-time visualisation and user decision making?*

AquaGreen Design

In order to answer that question we propose the *AquaGreen* system, an end-to-end IoT solution comprising a functional set of sensor nodes, an embedded network gateway, a cloud server software and a mobile app for real-time data visualization.

Our solution is based on a network architecture divided in a local and an external layer. The local layer addresses the communication from sensor nodes to the gateway over a Low Power Wide Area Network (LPWAN). On this layer, nodes sample specialised water quality sensors. Collected sensor data are encoded in a LoRa packet and transmitted to an in-range gateway node. Received sensor data (encoded in a JSON template), are forwarded via HTTP to an external

(Continued on next page)

cloud server. In the external layer Gateway nodes receive external connectivity either through an internet-connected WiFi router or cellular network, whichever is present at the aquaculture facility. In a few remote sites where there is limited to no internet access,it is anticipated that the gateway node enters into a delay tolerant network mode. This particular DTN setup requires end-user intervention to decide how to forward the stored data through some type of device-to-device transfer data off-loading via a smartphone cellular interface. In this work, gateway nodes communicate sensor data to external domain servers located in a commercial cloud infrastructure(e.g. AWS EC2 instances). A commercial ISP provides internet connectivity to the gateway node. The external cloud server offers a customised sensor data API that receives JSONformatted data and stores them into a NoSQL database for improved scalability in volume handling. The server API also provides endpoints for clients to consume the stored sensordata using a customised scheme with a regular expression scheme for data searching.

Implementation and results

LoRaWAN is a widely adopted solution in IoT networks due to its capability to connect to a wide area with many devices and still offer a low power communication. In this setup, LoRa is used as the physical layer protocol of a LPWAN network. A pair of TTGO LoRa32 v1.0 development boards were used to implement the sensor nodes. Each board includes an ESP32 MCU, an SX1276 LoRa Transceiver, a 3dBi antenna and a 0.96inch OLED display. The system has a JST battery plug and a battery charging unit. A Li-ion 3.7V battery powers up the sensor nodes. The sensor nodes also have a DS18b20 temperature sensor connected to monitor water temperature. The gateway node uses the same development board, but the temperature sensor is not attached and it is powered by a wall power outlet.

Initially, the implementation would be tested at FURG's Marine Aquaculture Facility (FURG-EMA) but due to local access restrictions to the aquaculture facility imposed in February 2021 by the worsening of the COVID-19 pandemic in Brazil the planned experiment scope was limited. The *AquaGreen* system had no other option but to be tested in an outside swimming pool. This lab setup still offered rigorous conditions to validate technical design assumptions.

To obtain the maximum battery life, the sensor node is kept in deep sleep mode most of the time. During this period, the temperature sensor is also powered down. On deep sleep mode, the overall system power consumption is reduced to around 10μA. The chosen system duty cycle contemplates that every 10 minutes, the sensor node wakes up from deep sleep to sample the sensors. The sample data is encoded in a LoRa packet and sent to the gateway node. The LoRa packet holds four key-value pairs of data samples (i.e. real-clock timestamp, sensor node id, instantaneous water temperature sensor sample and battery voltage level). Due to local regulations, only a maximum of 1\% duty cycle is permitted in LoRa communication. The system can send a packet (30 bytes payload plus 15 bytes header) every 10 seconds. To comply with the local rules, the actual packet rate is one every 10 minutes. As the final setup step, the sensor node was placed above the water in the swimming pool but having the temperature sensor probe under the water in a 1.2 water depth approximately.

The *AquaGreen* system ran for a non-stop period of 66 hours up to the point of fully discharging batteries in the sensor nodes. A total of 392 successful sensor readings were stored on the database during this time interval. Unfortunately, a packet loss of 2.3\% has been observed. Although this has not impacted the application, it calls for further investigation into whether a reliable communication protocol should be used. Our experimental results shed some light on the feasibility of a water quality sensor network that communicates data to an online platform for real-time visualisation and user decision making. This work presented preliminary results of a real-world pilot in a challenging environment for sensor and actuator networks. In addition, design principles and best practices for IoT aquaculture application development were presented. However, there are still many improvements to be made to the overall system.

HEALTH-PROMOTING EFFECTS OF DIETARY B-GLUCANS AND CURCUMIN ON GILTHEAD SEABREAM (*Sparus aurata*) JUVENILES FOLLOWING INTESTINAL INFLAMMATION

Introduction

The gilthead seabream (*Sparus aurata*) production has scaled up in the last few years due to its high demand and commercial value (Ashry et al., 2021). The intensification of aquaculture can translate into high stocking densities for farmed fish, which usually results in stressful conditions leading to reduced growth, immunosuppression, higher fish mortality, and huge economic losses (Ashry et al., 2021). Therefore, improving fish health and disease resistance of cultured fish is crucial (Župan et al., 2018). Numerous feed additives have proved to be beneficial in eliciting fish health. For instance, β-glucans are polysaccharide immunostimulants known to stimulate growth performance, improve general health and enhance disease resistance in fish (Župan et al., 2018). Curcumin is a feed additive with growth-promoting and immunostimulant potential known to enhance growth, stimulate immunity, improve the antioxidative status, and increase disease resistance in fish (Ashry et al., 2021). The present study mainly aimed to evaluate the effects of dietary β-glucans and curcumin on gilthead seabream health condition following an intestinal inflammatory stimulus.

Materials and methods

Gilthead seabream juveniles (55.5 ± 0.5 g) were randomly distributed in 12 tanks (250 L) and maintained in a seawater recirculating system (temperature: 20.6 ± 0.5 ºC; dissolved oxygen: 6.3 ± 0.5 mg L^{-1}; salinity: 35.3 ± 0.5 g L^{-1};). Fish were fed three dietary treatments in triplicates: a practical commercial-type diet was regarded as control (CTRL), whereas the CTRL diet supplemented with β-glucans extracted from algae (GLU) or supplemented with curcumin (CUR). The feeding trial lasted for 30 days. At the end of the trial, four fish per tank (n=12) were randomly collected and samples were taken to evaluate growth and health condition. After the 30 days of feeding, a dextran sodium sulphate (DSS) induced inflammation in the intestine was performed. Thereafter, four dietary treatments were used in triplicates. A group of fish continued to be fed on the CTRL diet (CTRL), whereas the remaining groups where exposed to DSS: CTRLDSS (CTRL + DSS), GLUDSS (GLU + DSS), and CURDSS (CUR + DSS) for 6 days. At the end of the trial, four fish per tank were randomly collected and samples were taken to evaluate health and inflammatory conditions at both systemic and local (i.e. gut) levels.

Results

No changes were observed regarding growth performance at the end of both trials. After the feeding trial, no major alterations were observed in the haematological profile. While plasma anti-protease activity decreased in the GLU group compared to the CUR and CTRL groups, plasma peroxidase activity increased in GLU group compared to the CUR group. Catalase activity in the liver was improved in the CUR group compared to the GLU group. After the DSS induced inflammation, CTRL group fed with DSS increased RBC (Figure 1) and white blood cells (WBC) (Figure 2) counts compared to unstimulated fish. The GLUDSS group presented a strong response to the elevated RBC numbers induced by the DSS treatment, while CURDSS group presented a better response to the increased WBC counts induced by the DSS treatment compared to the other DSS groups.

Discussion and conclusion

The present study suggests that dietary algae β-glucans or curcumin at the levels tested did not induce major effects in the parameters evaluated at the end of the feeding trial. However, these feed additives seem to improve the fish responses to the DSS inflammatory challenge. While β-glucans helped to adjust the effects of DSS in the RBC profile, curcumin, presented a strong response against the DSS effects in the WBC profile.

Introduction

Microplastics (MPs) and nanoplastics (NPs) pollution presents a threat to marine organisms and ecosystems (Guerrera et al., 2021). Several studies have focused on the effects of NPs on different aquatic species but most of them consist of short-term exposures, while studies concerning long-term exposures (>28 days) are scarce. In fish, health and welfare can be assessed with the analysis of relevant hematological parameters, such as hematocrit (HCT), red blood cell count (RBC) and white blood cell count (WBC). Automated analyzers are not yet routinely used to assess fish hematology parameters (Rebl *et al.,* 2021), but they represent several advantages when compared to the manual methods, such as an increased precision and exactitude of the results. The objective of the present study is to evaluate the hematological effect of a chronic exposure to polystyrene NPs (PS-NPs) in *Carassius auratus* (goldfish), using an automatic blood cell analyzer.

Material and methods

Goldfish (N=18) were exposed to 100 µg/L PS-NPs during 30 days. Blood was collected using a heparinized syringe and placed in tubes containing heparin. Some samples were discarded due to the formation of blood clots. All samples were analyzed within 1 - 2 hours from sampling. An automated laser flow blood cell analyzer (Sysmex XN1000V) with veterinary software version 3.04 and a betta version for bird blood analysis was used. HCT, RBC, WBC, hemoglobin concentration (HGB), mean corpuscular cell volume (MCV) and thrombocyte count (PLT) were counted automatically. Differential leukocyte count (lymphocyte, monocytes neutrophils and eosinophils) per 100 leukocytes were evaluated manually in blood smears stained with panoptic fast staining. All parameters followed a normal distribution, thus the Student's t-test was used to compare control with treated group.

Results and Discussion

In the present study we do not observe statistical differences between control and PS-NPs exposed group as it can be seen in Table 1.

To the best of our knowledge there are no previous available studies concerning the effects of NPs on fish hematology. However, in a previous study with MPs a significant decrease in RBC, HGB, HCT, PLT and WBC was found in juveniles of *Oreochromis niloticus* exposed to MPs during 15 days (Hamed *et al.,* 2019). Considering these previous findings, we could expect changes in blood parameters of goldfish in our study, since NPs are smaller than MPs and thus their probability to cross biological barriers and interact with cells is higher (Mattsson *et al.,* 2017). However, under the present studied conditions this was not the case, and our preliminary results show that NPs did not induce changes in any of the studied parameters. This absence of effects may be due to several differences between the studies, such as the type-size of the particle fragments, time of exposure, dynamic of the particles inside the organism, or animal age (adults *vs.* juveniles). Another limitation of the present study may be the low number of animals in each group. Further studies are needed to better understand the interaction between NPs and blood parameters in fish.

Introduction

The economic viability and the environmental sustainability of the aquaculture sector is closely entangled with the optimal use of dietary protein content and the utilisation of more sustainable ingredients to produce aquafeeds. Protein is the most expensive nutrient in the diets, therefore, reducing excess dietary protein inclusion while following the ideal protein concept, has a direct positive economic and environmental impact. Supplemental amino acids help to partially reduce the dependency on intact protein sources in meeting the requirements for the most limiting amino acids. It is essential that the dietary amino acid profile is balanced so that fish growth is maximised while lowering nitrogen excretion into the environment.

Commercial diets for Nile tilapia juveniles contain high levels of plant protein sources. Soybean meal has been utilised due to its high protein content and relatively well-balanced amino acid profile. However, soy-based diets are limited in methionine and require its supplementation to fulfil fish requirements. DL-methionine (DL-Met) and calcium bis-methionine hydroxyl analogue (MHA-Ca) are synthetic sources of methionine that are commonly supplemented in fish diets. However, differences in biological efficiency as a source of methionine may arise due to structural dissimilarities.

In this context, two nutritional studies were performed to optimise growth and diet utilisation in Nile tilapia juveniles. The first study aimed to reduce dietary protein levels in diets for juvenile tilapia and to minimise diet environmental impact while maximising biological efficiency. The second study evaluated the effect of different methionine sources (DL-Met and MHA-Ca) on the metabolism and growth of tilapia.

Generating data on growth, diet utilisation and metabolism in a commercial relevant species such as the Nile tilapia is of paramount importance for the Aquaculture industry.

Materials and Methods

Nile tilapia juveniles (initial body weight ± 5.9 g) were allocated into 15 tanks and were randomly assigned one of the five diets varying in crude protein (CP) levels: 36, 34, 32, 30 and 28% (D36, D34, D32, D30 and D28, respectively). Diets were formulated to be isoenergetic and meet the minimum amino acid requirements for tilapia. Fish were fed to apparent satiety, three times a day, for 8 weeks. At the end of the growth trial, nutritional indicators were determined. Moreover, metabolic trials were performed to obtain an *in vivo* snapshot of dietary protein utilisation in fish from the higher, intermediate, and lower protein dietary treatments (D36, D32 and D28). Random fish from each dietary treatment were tube-fed with the respective experimental diet labelled with ^{14}C-amino acid mixture (AA mix). Amino acid utilisation was determined as a function of the dietary protein content.

For the second trial, tilapia (initial body weight of ± 2.3 g) were distributed into nine tanks and were randomly assigned one of the three experimental diets (REF, DLM and MHA). The REF was a basal diet with no methionine supplementation, while DLM and MHA diets were supplemented with 0.11% of DL-Met and 0.13% MHA-Ca (equal on molar basis to DL-Met), respectively. Diets were formulated to be isonitrogenous (32% CP) and isoenergetic, using only plant ingredients as protein sources. Fish were fed to apparent satiety, three times a day, for 8 weeks. At the end of the trial, nutritional indicators as well as the content of hepatic free methionine and one-carbon metabolites were determined in fish fed control and supplemented diets. After the growth trial, a time-course metabolic trial was performed to understand how the different methionine sources were absorbed and metabolised in tilapia juveniles. The DLM and MHA diets were labelled with ^{14}C-DL-Met and ^{14}C-MHA, respectively, and tube-fed to fish from the correspondent dietary treatment. The metabolic fate of the ^{14}C-DL-Met and ^{14}C-MHA was analysed at 1, 2, 3, 4 and 6 h after diet ingestion.

(Continued on next page)

Results and Discussion

In the first study, tilapia from all treatments showed similar growth performance, while feed conversion ratio (FCR) was only significantly lower in fish fed D28 than in those fed the D36 diet. Fish fed the D30 diet presented higher protein retention and lower nitrogen (N) losses than those fed the D36 diet, suggesting an improved protein utilisation. Fish from the D36 treatment presented an increased protein utilisation for energy purposes, while protein retention in the muscle was maintained at the same level as in fish fed the low-protein diets. Considering all these results, this study demonstrates that it is possible to reduce protein levels in juvenile Nile tilapia diets to 30% CP without hindering fish growth and FCR, while reducing N losses to the environment.

In the second study, DL-Met supplementation significantly increased final body weight and improved FCR and protein efficiency ratio compared with the REF diet. DLM fed fish presented the highest N gain and the lowest N losses, indicating that these fish were more efficient in retaining N than REF or MHA fed fish. Methionine from the different dietary sources appeared to follow distinct metabolic pathways; while methionine from DLM diet seems to be transsulfurated, methionine from MHA and REF diets is probably remethylated to maintain the free methionine pool. Moreover, the metabolic trial revealed that ^{14}C-DL-Met was absorbed faster and more retained than ^{14}C-MHA, resulting in a greater availability of free methionine in the tissues when fish are fed the DLM diet. In the long term, dietary DL-Met supplementation improved growth performance and N retention in Nile tilapia, reducing the environmental impact.

The optimisation of diets that promote fish growth while reducing nutrient outputs to the environment is essential to achieve high sustainability standards in the Aquaculture industry.

Introduction

Microplastics are ingested by many marine organisms, including bivalves. Laboratory evidence, especially from the blue mussel *Mytilus edulis*, suggests that not all microplastics pass quickly through the digestive system and are egested but may become stuck on gills or pass into the circulatory system (Browne et al., 2008; von Moos et al., 2012)the potential for ingestion by animals increases. The consequences of macroplastic debris for wildlife are well documented, however the impacts of microplastic (< 1 mm. Human exposure to microplastics through bivalve consumption is likely since microplastics have been found in the soft tissue of shop-purchased bivalves (Li et al., 2018). Commercial bivalves are generally depurated prior to being marketed to reduce microbiological contamination. Depuration in a laboratory setting has shown to reduce microplastic concentrations in mussels *Perna perna* (Birnstiel et al., 2019). The present field study aims to assess the removal efficiency of microplastics in commercial depuration facilities.

Materials and methods

Ostrea edulis were obtained from two UK shellfish merchants in November 2017 (n = 20; five untreated and five depurated specimens per merchant). Samples were stored at -20°C and subsequent microplastic extractions performed based on Thiele et al. (2019). Briefly, soft tissue was digested in 10% potassium hydroxide for 48 hours at 40°C and digestates filtered over 1.2 μm after neutralisation with citric acid. Contamination mitigation included working in a clean air cabinet (Bassaire 03VB, BS EN ISO14644, class 5, with additional cover), use of glass and metalware whenever possible, furnacing of filter papers at 500°C for two hours prior to use and wearing of 100% cotton clothing including a previously lint-rolled laboratory coat. Laboratory microplastic contamination was assessed using procedural blanks and dampened filter papers as airborne controls. Counts of potential microplastics in blanks were used to estimate the limit of detection (LOD) by using 3x standard deviation per particle type and colour (Macdougall et al., 1980). Results were adjusted using the LOD. Light microscopy (magnification ≤ 160x) was used to enumerate and characterise potential microplastics and Raman spectroscopy (Renishaw inVia, 785 nm) to ascertain plastic composition. Microplastics were reported as median concentrations ± 1 standard deviation. A two-sample two-tailed t-test for unequal variances was performed.

Results

Frequency of occurrence of specimens with microplastics was 20% in untreated and 40% in depurated samples. Median concentrations in specimens with microplastics were 1.0 ± 0.0 microplastics in undepurated oysters and 1.5 ± 0.96 microplastics in depurated oysters (maximum 3 microplastics). Microplastic concentrations were not statistically different between untreated and depurated specimens (t-test, p = 0.19). By category, 55.6% of microplastics were fibres and the remainder fragments/film. All but two microplastics were 12 - 18 µm in size (fibre diameter or largest fragment dimension). One fragment measured 52 and other approximately 400 µm. Microplastics were identified as polyester/PET, polypropylene, polyethylene and acrylic.

(Continued on next page)

Discussion

Little information about microplastic concentrations in *O. edulis* exist, but values are similar to concentrations in the Pacific oyster *Crassostrea (Magallana) gigas* at other locations (Martinelli et al., 2020; Phuong et al., 2018)we quantified the presence of microparticles in wild populations of Pacific oysters (Crassostrea gigas. Human exposure to microplastics through bivalve consumption is a concern. It has been suggested that bivalve depuration decreases microplastic contamination based on depuration experiments in controlled laboratory settings with mussels *P. perna*, *M. edulis* as well as *C. gigas* (Birnstiel et al., 2019; Van Cauwenberghe and Janssen, 2014). However, our work shows that depuration in commercial facilities does not reduce microplastic contamination in *O. edulis*. While concentrations are low, most microplastics are of a size that raises concern about human health. Microplastics ≤ 150 μm have the potential to cross the human gut tissue barrier and therefore absorb into the body (Wright and Kelly, 2017). Further work is needed to evaluate microplastic removal potential at other facilities and to assess how processes could be improved to aid microplastic reduction in bivalves prior to human consumption.

Conclusion

Our trial — performed at two commercial depuration facilities — shows that depuration aimed to reduce microbiological contamination prior to human consumption does not reduce microplastic concentrations in *O. edulis*. While frequency of occurrence and concentrations are low, the size of microplastics found warrants further investigations aimed at reducing human microplastic exposure through bivalve consumption.

Introduction

The production of lumpfish (*Cyclopterus lumpus*) juveniles which largely relies on wild broodstock collection has continued to increase and there is very little knowledge on its reproductive biology (Powell et al., 2018). To close the life cycle of lumpfish in captivity, successful control of sexual maturation is necessary. Photoperiod and temperature are manipulated to control sexual maturation and ensure a year-round availability of other temperate fish juveniles (Wang et al., 2010)that is, induction (initiation of oogenesis. Although photoperiod can alter spawning in lumpfish females (Imsland et al., 2019, 2018)control of the sexual maturation cycle is critical for a sustainable production of the species. For year-round reliable production of juvenile lumpfish of the appropriate size for stocking salmon cages, there is a need for basic and applied knowledge on the control of sexual maturation in cultured lumpfish broodstock. Lumpfish (initial size 219g and 16.9cm, the speculated confounding effect of temperature (Imsland et al., 2018)control of the sexual maturation cycle is critical for a sustainable production of the species. For year-round reliable production of juvenile lumpfish of the appropriate size for stocking salmon cages, there is a need for basic and applied knowledge on the control of sexual maturation in cultured lumpfish broodstock. Lumpfish (initial size 219g and 16.9cm is still unknown, further, there is no information on the long term gonadal development in relation to environmental manipulations. The monitoring of sexual maturation in many cultured fish species involves invasive methods, crowding and extensive handling, which negatively affect the fish health and reproductive performance (Næve et al., 2019)sex hormone analysis, and histological analysis of spermatogenesis. There were significant correlations ($R2 = 0.68$, $P < 0.01$. The use of ultrasound is noninvasive, and it has been applied successfully in monitoring sexual maturation in for example Atlantic salmon (*Salmo salar*) (Næve et al., 2019)sex hormone analysis, and histological analysis of spermatogenesis. There were significant correlations ($R2 = 0.68$, $P < 0.01$. Therefore, this study was aimed at determining the effects of different photothermal regimes on gonadal development and plasma sex steroid levels and evaluating the efficiency of ultrasound in monitoring sexual maturation in lumpfish.

Materials and methods

Two experiments were conducted:

Experiment 1: two groups of lumpfish ($n = 300$, body weight = 697 ± 364.1 g) in four tanks, were exposed to either a continuous or a short autumn-spring signal photoperiod (two tanks each).

Experiment 2: two groups of lumpfish ($n = 4000$, body weight = 157 ± 32.2 g) also in four tanks, were exposed to either a natural annual photoperiod or a nine-month compressed annual photoperiod. Using external appearances, gonadosomatic index and histomorphology, in both experiments, temperature in one tank from each photoperiod was elevated by 3 °C during final gonadal maturation in females. There were four and sixteen sampling points in the first and second experiments, respectively, during which body weight and length were registered. Ultrasound was tested in sexing and assigning the fish to different maturation categories. Blood for radioimmunoassay of sex steroids was collected. Gonads were excised, their weights registered, and tissues were collected for histological analyses of gametogenesis.

Results

Experiment 1: gonadal development in females was more synchronized and advanced in the short-autumn signal photoperiod. Temperature elevation resulted in accelerated final maturation and ovulation in both photoperiod regimes. In males, gonadal development appeared to be less affected than it was in females.

Experiment 2: fully matured males were observed seven months before matured females were recruited. Gonadal development in females exposed to the compressed annual photoperiod was advanced. Spawning in the compressed annual photoperiod was advanced, and more so with elevated temperature. In males however, gonadal development was not different between the photoperiod and temperature regimes. The ultrasound categorization of sexual maturation in both females and males successfully followed the progression of gonadal development, and blood plasma levels of sex steroids.

(Continued on next page)

Discussion and conclusion

Our findings showed that compressing the natural photoperiods caused temporal shifts in levels of sex steroids that are responsible for advanced gonadal development and leading to earlier spawning. Similar findings were reported for wolffish populations; temporal shifts in sex steroid profiles were observed and, sexual maturation and spawning were advanced under exposure to an eight-month compressed annual photoperiod (Dupont Cyr et al., 2018). In lumpfish, a more predictable spawning and peaks in spawning were observed under a compressed annual photoperiod and a short autumn-spring signal, respectively (Imsland et al., 2019, 2018)control of the sexual maturation cycle is critical for a sustainable production of the species. For year-round reliable production of juvenile lumpfish of the appropriate size for stocking salmon cages, there is a need for basic and applied knowledge on the control of sexual maturation in cultured lumpfish broodstock. Lumpfish (initial size 219g and 16.9cm. The results obtained from accelerated sexual maturation and spawning under elevated temperatures in the present study, is similar to a study on rainbow trout where elevation of winter-spring temperatures caused an increased maturation rate (Wilkinson et al., 2010). Although ultrasound was successful in maturation monitoring, an ultrasound-based quantification of maturity in place of the conventional gonadosomatic index is still unavailable (Næve et al., 2019)sex hormone analysis, and histological analysis of spermatogenesis. There were significant correlations ($R2 = 0.68$, $P < 0.01$. Our findings demonstrated that the photoperiod and temperature combination was better than photoperiod alone in controlling sexual maturation in lumpfish. We also showed that ultrasound is a simple and non-invasive technique that could be used to assess sexual maturation in lumpfish.

Introduction

With the global population growing, the need for high-quality sustainably produced protein sources for human consumption is bound to increase. It is therefore important to develop novel, innovative and sustainable solutions to produce food and promote growth. Aquaculture will play a prominent role in that aspect. While probiotics for use in aquaculture have emerged as one possible solution for modulating the microbiota to promote growth, their effects remain inconclusive and uncertain. This may lie in the fact that microbiota research has largely been focused on the effects of microbiota on its host, rather than the potential effects host genetics have on its microbiota.

Elucidating potential host genetic effects on its microbiota has obvious biotechnological applications in the aquaculture industry. For example, designed feed to suit and promote growth of a particular genotype or genetic engineering of the host to promote a healthy microbiome. The field of applied hologenomics using zebrafish (*Danio rerio*) as a model organism provides a promising framework to study such effects.

Here, we applied a 16S metabarcoding approach in combination with a CRISPR/Cas mediated knockout of the gene coding for tyrosinase (tyr), the rate-limiting enzyme in melanogenesis, to provide a proof-of-principle that zebrafish can be used to study the effects of host genetics on its microbiota.

Methods

We generated a F0 generation of zebrafish by using CRISPR/Cas-9 to knock-out the *tyr* gene in the zebrafish genome. Phenotypes were classified into two groups based on pigmentation levels: albino and mosaic. The phenotypic groups were housed in separate tanks. The microbial community of faeces samples collected from the tanks containing the different pigmentation phenotypes was assessed with the bacterial 16S rRNA gene. The microbial communities of the two mutant pigmentation phenotype groups were compared to the microbial community of a third group with a wild type pigmentation pattern (figure 1).

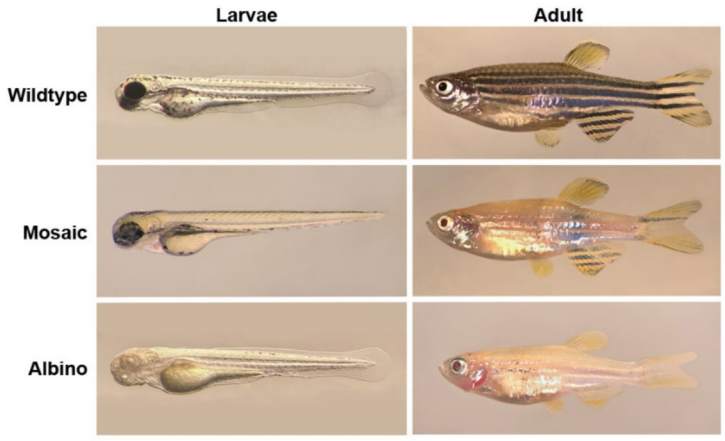

Figure 1. The three zebrafish pigmentation phenotypes generated, compared in their larval and adult stages. Photo by: Louise von Gersdorff Jørgensen and Moonika Haahr Marana

(Continued on next page)

Results
The knock-out of a single gene, *tyr*, using CRISPR/Cas-9, resulted in changes in pigmentation and in the zebrafish intestinal microbiota. Both alpha-diversity and beta-diversity differed significantly among the pigmentation phenotypes. The differences were mainly driven by the relative abundance of two genera: *Cetobacterium* and *Aeromonas*. Along with these genera, *Pseduomonas* and *Vibrio* were detected as differentially abundant among the pigmentation phenotypes. These genera may be implicated in immune- and metabolic-related mechanisms.

Conclusions
The results suggest an effect of tyrosinase function on the intestinal microbiota community of zebrafish. Overall, the study shows that the zebrafish presents a satisfactory model to study host-genomic effects on the microbiota and that further studies can shed even more light on such effects. Future studies should include a more multi-omic approach to gain more functional insights from the interactions between the host genetics and its microbiota. Moreover, such studies could prove highly valuable to the aquaculture industry. This could be in the form of probiotics tailored to the genotypes of broodstock fish, or perhaps the selection of genotypes that code for a healthy microbiota community.

SPERMATOZOA MORPHOLOGY AND REPRODUCTIVE POTENTICAL IN F1 HYBRIDS OF COMMON CARP AND GIBEL CARP

Tomáš Tichopád, Lukáš Vetešník, Andrea Šimková, Marek Rodina, Roman Franek, Martin Pšenicka

Sterility and semi-sterility often occur as a result of interspecific hybridization; however, the exact cause of sterility varies across the all animal kingdom; therefore, it is in the interest of scientists to examine every hybrid species separately. In the present study, the morphology of the spermatozoa of diploid F1 hybrids of *Cyprinus carpio* and *Carassius gibelio* was examined and compared with their parents. Hybrid spermatozoa showed great variability in head and flagellum lengths. These spermatozoa were diploid and triploid often with morphological abnormalities such as multiple flagella and nuclei. They were motile within two minutes after water activation which was almost two times longer than their parental species. We also analysed the reproductive output of F1 hybrids together with parental species in both parent positions via artificial spawning. Overall, the reproductive output of the hybrid × hybrid combination was the lowest; however, the hybrids were able to produce a small number of offspring documenting the viability of the F2 generation.

OCEAN LITEARCY AND HOW SERIOUS GAMES CAN PLAY A PART: THE CASE OF THE JELLYFISH AND MICROPLASTICS GOVERNANCE GAME MOREGOJELLY!

Tiller R*[1], Almås H, Ahlquist IH, Dankel D, Hakvåg M, Liu Y, Tiller W, Javidpour J

[1]SINTEF Ocean, 7465 Trondheim, Norway
*E-mail: rachel.tiller@sintef.no

***Introduction**:*

*The term Ocean Literacy, defined as "…*the understanding of the ocean's influence on humans and of our influence on the ocean*…" – was first discussed in 2004 after a group of scientists brough to the surface a concern that the general public had a lack of understanding about the importance of the Ocean which could hinder the uptake of knowledge around its importance* [1]*. We have now entered the UN decade of Ocean Science, where we will work global mobilization of the ocean community towards "The ocean we need for the future we want" – directly contributing to the implementation of the Sustainable Development Goals (SDGs) – even beyond Nr 14 – Life Below Water.* The term "Serious Games" dates back only half a *decade* [2], but the logic behind comes from military strategic applications called *wargaming* [3], which has a long and rich past. Although non-military games used for learning generally, and ocean literacy specifically, has developed gradually since the 70s, it was not until the popularization of digital games, around the turn of the millennium, that serious games rose to prominence in *academia* [4, 5]. Since then, vast amounts of serious games-research have been published each *year* [6] – chiefly on digital games, but also increasingly for hybrid and analog *games* [7]. In this article, the potential benefits of serious games for learning and motivation *within the context of ocean literacy, the UN decade of ocean science and the sustainable development goals* will be presented alongside an approach to using serious games as a tool for unintrusive data collection.

Material & Methods:
In 2020-2021, high school students from three different cities in Norway participated in a total of six Serious Game sets (two in each city) called MoreGoJelly! The game was developed through a collaboration with game developer House of Knowledge and the research institute SINTEF Ocean in Norway. The game was played live, with game boards for the participants in Trondheim and Tromsø, Norway, and it was played digitally with participants from Bergen, Norway. The latter was a pandemic need, because of demands for social distancing. The digital version was developed to simulate the board, game pieces and game setting as close as possible. The logic of the game centred on an assessment of a Serious Game as a communication tool for ocean literacy, with an emphasis on assessing similarities and differences between groups of future generation representatives from three different geographical regions in Norway (western-, mid- and northern- Norway) and diverse backgrounds. The game was to be played as a multi-player game with no more than four players, to ensure that all players were given ample time to discuss and participate in the game. They first had to fill in a personal questionnaire, and then as a group, they were presented with four sustainable development goals (SDGs 3 – good health and well-being, 8 – decent work and economic growth, 12 – responsible consumption and production and 14 – life below water) that they had to rank the top three in terms of importance within the game context of assessing microplastic pollution and jellyfish blooms in terms of how either and both affect coastal communities in Norway.

Because of this contextual setting, the game was set up around a map of Norway, and with game cards that first gave background information, preparing the students to play. The game board also had three fields for where they had to place the SDG goals they chose to prioritize – and in which order. This first step was followed by game cards that first gave the players a scenario where they had to assess how this event would affect social, economic and environmental sustainability of the region. They were then presented with three governance options, where they also had to rank how their governance choice would affect the three sustainability pillars. All in all, they were presented with nine events and nine governance cards (total of 27 governance options). They were given three opportunities throughout the game to change the order of their SDG cards.

(Continued on next page)

Results:
In the first ranking, all groups in all cities placed SDG 3 as either number one or number two. Further, all but one of the groups from Bergen had positioned SDG 12 as either number one or two. The group from Bergen chose SDG 14 instead. In the second round of ranking, only one of the groups from Trondheim changed their order of the SDGs. On the last card, when they for the third time were given the choice to re-rank - one of the two groups from each city (3 out of 6 groups) changed their positioning of the SDGs. Two of the three groups changed the position of two goals, while the last group moved all of the goals. All groups ended with SDG 12 on either first or second place, except for one group from Bergen who instead chose SDG 14. All but one of the groups from Tromso ended with SDG 3 in either first or second place. The group from Tromso had chosen SDG 14 instead of SDG 3 as the others. SDG 8 was positioned last in four out of six groups, and in third by the two remaining groups.

Discussion & Conclusion:
Consciously designing for each of these concepts around SDGs for ocean literacy can help leverage the potential benefits of serious games. However, it is the interaction between them that creates a lasting experience for players. For instance, social interaction is a crucial aspect of situated learning [8] especially for tacit knowledge [9], connected to the base need of relatedness [10], and as a potential strength when employing experiential learning – drawing on sharing of and learning from varied experiences [11]. Experiential learning can also be further strengthened when mapped to the antecedents of flow [12] – both of which can be seen as related to the self-determination theory need for competence [10]. Furthermore, despite the perceived importance of these concepts, there are of course several other potential benefits a game can have over traditional learning, such as multimodality, self-explanation [13], personalization, and adaptivity [14] to name a few. Ensuring the ocean science community can also contribute towards the implmenetation of the SDGs will take moving beyond traditional methods and including future geneartions in the discussions. Part of that move includes ocean literacy – ensuring "…the understanding of the ocean's influence on humans and of our influence on the ocean…" – and that this understanding is reached at a younger age so that the future decision makers already have a thorough understanding of the importance of the Ocean.

Introduction

Wastewater treatment plants (WWTP) perform primary and secondary biological treatment of municipal and related waters, and sometimes tertiary treatment for agricultural irrigation and wetlands restoration. The complex microbial community found in the treated effluent of WWTPs, although significantly reduced, might still contain pathogenic bacteria which present a threat to fish living downstream. If used for human consumption, such fish may pose a potential public health risk (Topić Popović et al, 2019). *Shewanella baltica* is a relatively rare finding amongst the bacteria withdrawn from native Prussian carp (*Carassius gibelio*). It is less known as a fish disease agent, although it was associated with outbreaks in farmed and ornamental fish (Kozińska and Pękala, 2004; Sicuro et al, 2020). In order to investigate the sensibility and accuracy of MALDI-TOF MS identification of *S. baltica* strains from Prussian carp, the isolates were grown on two culture media enriched by various NaCl concentrations, incubated at different temperatures and incubation times.

Materials and methods

Shewanella baltica strains were cultured on Tryptone Soy agar (TSA) and on TSA additionally supplemented with 0.5, 1.0, 1.5, and 2.0 % NaCl. They were also cultured on MacConkey agar (MCA), and on MCA additionally supplemented with 0.5, 1.0, 1.5, and 2.0 % NaCl (Oxoid Ltd, England UK). All plates were incubated at 22 °C and at 37 °C for 24 and 48 hours before further analyses.

The taxonomic position of the isolates was determined by the MALDI Biotyper using MALDI-TOF (Matrix Assisted Laser Desorption Ionization-Time of Flight) Mass Spectrometry (Bruker Daltonik GmbH, Bremen, Germany). The on-target extraction method was applied for MALDI TOF MS sample preparation as described in Topić Popović et al. (2015a, b). Recorded mass spectra were processed with the MALDI Biotyper 3.0 software package (Bruker Daltonik), using standard settings.

Results and discussion

Although all MALDI-TOF MS measurements identified the tested strains as *S. baltica*, the type of the culture medium affected identification results. The TSA medium enabled a correct identification against the database in 84.53% of all measurements, if observing irrespective of NaCl supplementation, time of incubation, and incubation temperature, while the MCA medium allowed a correct identification in 56.59% of cases. The best identification scores were for strains cultivated on TSA for 24h at 22 °C for 75% of tested *S. baltica*. Contrarily, if assessing the impact of supplemented NaCl on these strains, the 1.5% NaCl was the optimum concentration for 91.67% of strains under these conditions.The strains cultured on MCA had lower identification results, and when incubated for 48h at 37 °C, they had unreliable identification scores. The number of unreliables was high also for *S. baltica* isolates cultured for 24h at 37 °C (1.381 ± 0.193). Best identification scores on MCA were after 48h at 22 °C for 43.33% of tested strains. The optimum concentration of supplemented NaCl under these conditions was 2% NaCl where 66.66% of strains had probable species identification. To summarize, the reliability of MALDI-TOF MS identification of bacteria from TSA significantly outperformed identification from MCA. The impact of media type on MALDI-TOF MS identification accuracy was also established for *Photobacterium damselae* (Kazazić et al, 2019b) and *Staphylococcus aureus* (Walker et al, 2002). The impact of temperature on identification sensibility and accuracy was even more adverse, particularly for MCA. The growth of *S. baltica* requires sodium chloride (Austin and Austin, 2016), thus the 1.5% and 2% NaCl supplemented TSA and MCA enhanced MALDI-TOF MS identification accuracy, respectively.

REPLACEMENT OF FISH MEAL BY ANTARCTIC KRILL MEAL IN DIETS FOR EUROPEAN SEA BASS (*Dicentrarchus labrax*): GROWTH PERFORMANCE, FEED UTILIZATION AND LIVER LIPID METABOLISM

S. Torrecillas[1*], D. Montero[1], M. Carvalho[1], T. Benitez-Santana[2], M. Izquierdo[1]

Email: silvia.torrecillas@giaqua.org

Introduction

Fish meal (FM) can be partially replaced in the diets of many fish species, but in most cases, high or complete replacements have detrimental effects on fish performance and health. This side effects are mainly due to imbalanced amino acids and micronutrients, the presence of antinutritional factors or to a direct reduction of feed intake because of decreased diet palatability as the level of alternative protein sources increases. To the date, there is no information on the effect of dietary krill meal (KM) on European sea bass performance and liver lipid metabolism, being the main objective of the present study.

Materials and methods

Three isoproteic and isolipidic experimental diets were formulated containing different KM levels: 0% (control group), 5% and 7.5% KM (Qrill^{TM} Aqua; Aker BioMarine Antarctic AS, Norway). European sea bass juveniles were randomly distributed in 12 indoor 500 L fiberglass tanks (3 tanks/diet) at an initial stocking density of 1.5 kg·m^{-3}. Fish average initial weight and length were 22.54±0.30 g and 11.4±0.1 cm (mean ± SD) and were manually fed until apparent satiation for 90 days (3 times a day, 6 days a week). At the end of the feeding trial, growth performance parameters and food conversion ratio were calculated. Livers, dorsal muscle and whole-body samples from 5 fish per tank were sampled for chemical composition, fatty acid and lipid classes analyses. Livers of 3 fish per tank were collected for morphological and gene expression analyses.

Results

After 90 days of feeding, fish fed KM5 and KM7.5 diets presented higher final weight and improved SGR than fish fed control diet ($p<0.05$) (Fig. 1). FCR was improved from 60 days of feeding onwards when diets were supplemented with KM (Fig. 1). Whole-body, muscle and liver proximate composition were not affected by the experimental diets. Regarding tissue fatty acid composition, whole-body and muscle seemed to be more affected by diet composition than liver, which only presented an effect of KM on Σn-6 HUFA, being the highest in those fish fed KM5. Fish fed KM showed a tendency to present lower liver cholesterol levels than fish fed control diet. KM dietary content was positively correlated with the pigmented material content (*r= 0.84, p=0.01*). Fish fed KM diets (Fig. 2B, 2C) presented smaller hepatocytes area with a more regular-shaped morphology around sinusoidal spaces compared to fish fed the control diet (Fig. 2A). This effect was particularly noticeable in fish fed KM7.5, pointing to a dose-dependent effect of KM on these parameters. Sea bass fed KM5 and KM7.5 diets showed decreased *mRNA* levels of *fads2* ($p<0.1$) and *hmgr* ($p<0.05$). Despite that no significance differences in *fabp7* relative expression were detected among sea bass fed the different dietary KM contents, fish fed KM5 and KM7.5 diets expressed slight lower *mRNA* levels, which were significantly correlated with liver cholesterol. (Pearson (Pearson correlation= 0.99, p=0.04). *lpl* mRNA levels were linearly correlated with liver lipids (Pearson correlation= 0.99, p=0.03).

Conclusions

The results of the present study showed that dietary KM at 5% and 7.5% as partial replacer for FM promotes European sea bass juvenile's growth performance, feed and nutrient utilization. Besides, KM modulates liver lipid metabolism and reduces liver hepatocytes vacuolization. Therefore, presenting KM not only as an alternative protein source in practical diets for European sea bass with low FM/FO content, but also as a potential functional ingredient capable of promoting liver health status.

EXPLORING EUTHANASIA METHODS FOR DEVELEPOMENT STAGES OF *Danio rerio*

J. Ramos; L. Tort

Department Cell Biology, Physiology and Immunology, Universitat Autonoma de Barcelona, Bellaterra, Spain
Email: juanramoblas@gmail.com

Introduction:

Zebrafish, *Danio rerio* is a small fish from the Hindukush valley and is one of the most used fish in research, special for biomedicine. During the early development stages, zebrafish are very sensitive to environmental conditions and also, they have to properly develop different organs like the gills, as they can breathe through the skin till day 14. These factors are really important for euthanasia; as euthanasic agents usually block muscular contraction. So, as relevant physiological features are different between adults and fries, the environmental conditions and protocols should be specially designed for the different development stages. Welfare supervision is mandatory in animal research including fish, but not for not larval feeding stages. So, protocols for husbandry, anesthesia or euthanasia have not been properly developed for these stages. As a consequence, this lack of standard protocols and no regulation for welfare supervision could end up with unreliable research and could negatively impact on fish welfare. In this work, we assessed euthanasic methods for developmental stages of zebrafish.

Material and methods:

Three different euthanasic agents, lidocaine, clove oil and tricaine(MS-222), were tested in three different stages of development, in order to see their efficacy and other implications. Lidocaine and clove oil were dissolved in ethanol, but tricaine was not. These anesthetics were used at high concentration in wild type *Danio rerio* gastrula stage, pharyngula and early larva. After exposing zebrafish to the anesthetics, efficacy, aversion, and specific gene expression was tested in order to verify their effects at different stages.

Efficacy was tested exposing the embryos for 1h to the euthanasic solution, removing them for the solution and watching heartbeat and embryo integrity after 24 hours of exposure. Aversion is the reaction of the embryos in order to escape from a noxious stimulus, anesthetics or euthanasic agents. In order to know how the different anesthetics, affect genetic expression, zebrafish samples were taken at 1, 3, 6, 10, 15 and 25 minutes for the 3 different development stages and for each anesthetic. In addition, embryos were recorded for 30 minutes in order to assess how anesthetic affects heart beat blocking, interference of cellular division or other processes related with the euthanasic procedure.

Results:

At the different development stages, zebrafish react in different ways and intensity when they are exposed to anesthetics. Their reaction depends not only on the product also the concentration and the water quality (specially the pH) affects to the aversion reaction. MS-222 and clove oil seems to be aversive products as zebrafish reacts the two last stages meanwhile no reaction was detected when exposed to Lidocaine. The reaction to the two aversive products tested was also different in time and intensity.

The embryos exposed to different anesthetics showed different functional processes in the different development stages. as observed under the microscope. For example, in the gastrula stage and earlier, an alteration in the cellular division or an embryo lysis can be detected, meanwhile in the last stage, raquis contraction, mucus hypersecretion and lysis can be observed. Heartbeat, that can be detected from the pharyngula stage, can be blocked, but after removing the embryos from anesthetics, recovered again.

Ten different genes (…….) were tested at different time points. Preliminary results showed differences in most of them.

Lidocaine	**Clove oil**	**Tricaine**
1g lidocaine	1ml clove oil	1g MS-222
2g bicarbonate		2g bicarbonate
50 ml ethanol	9 ml ethanol	
450 ml water	490 ml water	500ml water

(Continued on next page)

Conclusions:

Euthanasia is a regulated procedure by welfare law for adult fish. These procedures should be effective and reproducible, with no welfare implications for the animals and the technician.

Early development stages of zebrafish have different physiological traits than the adults, so especial protocols and studies should be developed. Euthanasia is commonly applied by an overdose of anesthetics, so fish lose consciousness and die by asphyxia, because muscular contraction is blocked. As during development stages, they are able to breathe through the skin, common anesthetics are not capable to euthanize, even when heart is not beating.

We find two different euthanasic protocols that are capable two kill at early development stages: Lidocaine and clove oil. But they affect zebrafish fry in a different way before and after losing the consciousness, as they express aversion to the anesthetic and different genetic pathways are expressed.

COMPARISON OF THE PREDATORY ACTIVITY OF DIFFERENT SPECIES ON THE SEA URCHIN *Paracentrotus lividus* (LAMARCK,1816)

N.Tourón*[1], E. Paredes[2], S. Campos[2], D. Costas[1] and J.M. García-Estévez[1]

Abstract
In the existing bibliography to date, different species of crustaceans, fish and other invertebrates are mentioned as predators of the sea urchin *Paracentrotus lividus*, although no detailed information is found in this regard nor is it mentioned which is its main predator, due to which a Predation experiment of this species have been performed, introducing 3 different species as potential predators and observing both the capacity and the speed of predation of each one of them on individuals of the species *P.lividus* of different size ranges.

Within the framework of the OCIMER project (Optimization of the integral cultivation of the sea urchin *Paracentrotus lividus*) that is being developed in the facilities of the ECIMAT (Station of Marine Sciences of Toralla), two repopulations of coastal áreas of the Vigo Bay (Galicia,Spain) were carried out with juvenile specimens of the sea urchin species *P.lividus*); This information will be very useful for the subsequent monitoring of the individuals released to the natural environment, as well as to take into account the abundance of their largest predators in future repopulations with juvenile individuals of this species.

Material and Methods
Sea urchins (*P. lividus*) were introduced in 6 boxes of 150 l capacity with two size ranges: 10 mm in diameter (15 urchins) and approximately 20 mm in diameter (15 urchins) in each box; In 3 of them 5 adults were also introduced (boxes 1, 2 and 3), and a control box was placed where only sea urchins were kept without the predatory species; the urchins were fed with algae of the genus Laminaria sp. The 3 species that were tested as predators of *P. lividus* were the next: 3 starfish (*Marthasterias glacialis*), 3 velvet crab (*Necora puber*) and 2 spider crab (*Maja squinado*) were previously left without food for 5 days, and then were placed in the boxes containing urchins in 3 batches, leaving the experiment long enough for each predatory species to consume all the urchins at its disposal, with a maximum duration of the experiment of 28 days.

Highlights
- Only spider crabs were able to prey on adult urchins, while starfish and crabs only preyed on juvenile urchins of both size ranges, without a significative difference in predation rate between the two sizes.

- No significant protective effect of adults on juvenile individuals was observed against predators, probably due to the lack of interstices in the boxes that they do have in the rocks of the natural environment.

- All the urchins in the control box remained alive throughout the experiment.

Conclusion
Among the 3 predator species chosen, by far the largest predator of *P. lividus* is the spider crab, followed by the crab and lastly the starfish; Furthermore, the spider crab is the only one capable of predating adult specimens. It would be interesting to continue the experiment soon by introducing different species of fish. The starfish is not an active sea urchin predator.

Introduction

Sea urchins, have been used as model systems in biology and ecotoxicology for more than a century now. The sea urchin is a gamete 'production powerhouse'. Given the transparency of the egg, the synchronicity of divisions, the ease of manipulation and the abundance of gametes, Sea urchins provide an excellent system to address general cell biological questions, including cryopreservation. Here we studied the cryopreservation of gametes, embryos and larvae of four species of sea urchins that could be located at the National Park "Illas Atlanticas de Galicia" in the North west coast of Spain. Three regular sea urchins, *Parancentrotus lividus, Echinus esculentus, Sphaerechinus granularis* and one irregular sea urchin *Echinocardium cordatum* were used for development of cryopreservation protocols.

Results

Results showed us that despite these species are close genetically, to the point that some can hybridize, and that their geographical distribution is overlapped, their response to cryopreservation is unique and individualized, and therefore it will require the development of individual protocols for their cryopreservation. In the case of sea urchins the main difference is the selection of the suitable cryoprotectant agent for each specific species and cell type. This might be due to the extraordinary sensitivity to chemicals present in the water that has made sea urchins perfect models for the study of ecotoxicology, as their early development stages could be used to identify negative effects of pollutants in the water in concentrations of parts per billion (ppb).

Conclusion

We have successfully cryopreserved sperm from two of the species with a 30-50% relative fertilization to fresh controls, egg cryopreservation was unsuccessful, in the case of embryos successful protocols could be developed for blastula embryos and no older larvae cryopreservation was achieved. This is the first time that three of this species were studied.

EUROPEAN PERCH (*Perca fluviatilis*) FED DIETARY INSECT MEAL (*Tenebrio molitor*): FROM A STABLE ISOTOPE PERSPECTIVE

H.Q. Tran[1]*, M. Kiljunen[2], V. Stejskal[1]

[1] University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Institute of Aquaculture and Protection of Waters, Na Sádkách, **České** Budějovice, Czech Republic
[2] University of Jyväskylä, Department of Biological and Environmental Science, Jyväskylä, Finland
Email: htranquang@frov.jcu.cz

Stable isotope analysis was conducted to investigate stable isotope ratios of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$), diet-tissue discrimination factors of carbon ($\Delta^{13}C$) and nitrogen ($\Delta^{15}N$). Bayesian mixing models were performed to assess relative contribution of insect meal and other ingredients to the development of tissues of European perch (*Perca fluviatilis*). Accordingly, four experimental formulations, characterized by the increasing inclusion levels of yellow mealworm (*Tenebrio molitor*) larvae meal (TM) at 0, 6.8, 13.5 and 20.3% as replacement for fishmeal at 0 (TM0), 25 (TM25), 50 (TM50) and 75% (TM75), respectively, were fed to juvenile perch (initial bodyweight, 20.81 ± 3.36 g) in a recirculated aquaculture system for 105 days.

$\delta^{13}C$ and $\delta^{15}N$ of TM were -16.75 and 3.53‰ and significantly distinguished from other terrestrial and marine feed components ($P < 0.05$). Inclusion of dietary TM did not affect $\Delta^{13}C$ value in blood and liver ($P > 0.05$) but did reduce in muscle ($P < 0.05$), whereas $\Delta^{15}N$ was significantly increased with the increasing inclusion level of TM in all tissues ($P < 0.05$). The growth of perch had a significant negative relationship with diet-muscle $\Delta^{15}N$. The contribution of TM to muscle (7.7 ± 3.8%) was comparable to its dietary inclusion (6.8%) in TM25 but double in the blood (13 ± 6%). TM appeared to be an essential ingredient incorporated into liver, as its contribution was consistent or higher than dietary inclusion (TM25: 25.4 ± 12.1 vs. 6.8%; TM50: 31.1 ± 14.9 vs. 13.5%; and TM75: 29.4 ± 14.4 vs. 20.3%). The higher inclusion levels of TM (more than 6.8%) did not elevate its contribution to muscle, blood, and liver (probability, $P_{BIC} < 0.95$) but significantly decreased that of fishmeal in all tissues ($P_{BIC} > 0.95$). Soy-derived ingredients, soybean meal and soy protein, were an important ingredient in the development of all tissues regardless of dietary TM.

The present study provided insightful information on the role of various diet components in perch tissues, which could underlie further development of aquafeed formulations for emerging perch farming in Europe.

Introduction

Genomic selection uses genome-wide SNP genotypes to predict breeding values, and this methodology has been widely applied in terrestrial livestock and several aquaculture species, conferring cumulative improvements in a wide range of economically important production, health and welfare traits. The development of a medium-density SNP array for Pacific and European Oysters (Gutierrez *et al*., 2017), and the publication of a chromosome-level reference genome assembly (Peñaloza *et al*., 2021), have opened new promising avenues for the design of effective genomic selection strategies in these species. However, the capacity to routinely genotype at high density (HD) large numbers of individuals, as is required for genomic selection, remains prohibitively expensive for much of the sector. In previous studies in Atlantic salmon, genotype imputation has been proposed as a cost-effective method to implement genomic selection in breeding programmes (Tsairidou *et al*., 2020, Tsai *et al*., 2017). Imputation allows prediction of HD genotypes from low density (LD) SNP panels, by using information from haplotypes shared between related individuals (Li *et al*., 2009). Hence it requires dense genotyping only for a subset of the population, thereby substantially reducing the genotyping costs. The aim of this study was to test and assess genotype imputation for genomic prediction in Pacific oyster, using two different imputation software, and data for survival to the ostreid herpesvirus OsHV-1, a trait known to have a polygenic genetic architecture and hence being suitable for genomic selection (Gutierrez *et al*., 2020, Gutierrez *et al*., 2018).

Materials and Methods

Our study focused on a commercial breeding programme population challenged with the ostreid herpesvirus OsHV-1 (Cawthron Institute, New Zealand) (Gutierrez *et al*., 2020). Binary survival data recorded at the end of the trial and continuous time-to-death data were available for 718 individuals. All individuals, including their parents, were genotyped using the Affymetrix SNP array for oysters (Gutierrez *et al*., 2017) (25,600 SNPs). After mapping to the latest reference genome (Peñaloza *et al*., 2021) and performing quality control, 13,763 SNPs and 743 individuals (699 offspring and 44 parents) were retained for subsequent analyses. The analysis comprised three main parts: (a) heritability and genomic prediction analyses for the HD directly genotyped data; (b) generating a range of LD SNP panels from the HD data, and testing their genomic prediction accuracy; and, (c) imputing the LD SNP panels to HD to assess their imputation accuracy, and estimate genomic prediction accuracy using HD imputed data.

Genomic prediction was assessed via 20 repeats of 5-fold cross-validation, to estimate the mean prediction accuracy from the correlation between predicted breeding values (BVs) and phenotypes, corrected for the trait heritability. The BVs were estimated in ASReml/3.0 (Gilmour *et al*., 2009) using the following generalized linear mixed animal model which implements the logit link function for the binary survival data:

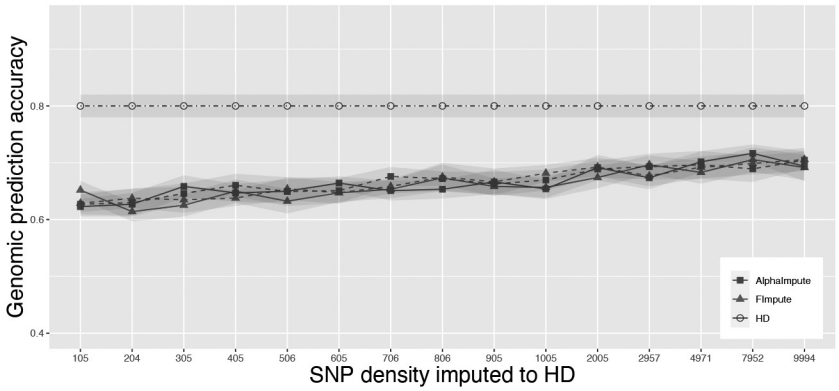

Figure 1. Genomic prediction accuracy calculated as means over 20 * 5-fold cross-validations, with LD genotypes imputed to HD using (a) FImpute (pink) and AlphaImpute (green)

(Continued on next page)

Tank was fitted as a fixed effect in $\boldsymbol{b}$, and genetic relationships between individuals were fitted as random effects through the genomic relationship matrix $\boldsymbol{G}$ calculated from SNP data with ~ N(0,). Heritability estimates were adjusted to the underlying liability scale. Time-to-death was analysed using a linear model. Low density *in silico* SNP panels were constructed via random sampling of SNPs within each chromosome but proportionally to chromosome length. Genotype imputation was performed using (a) AlphaImpute v2 (Whalen and Hickey, 2020, Hickey *et al*., 2011), and (b) FImpute v3.0 software (Sargolzaei et al., 2014). A range of imputation scenarios were tested where the majority of offspring were genotyped at LD for densities ranging between 100 and 10,000 SNPs, and parents were genotyped at HD.

Results and Discussion

The heritability estimated using the genomic relationship matrix calculated from HD SNP genotypes was 0.39 (s.e. 0.05) for survival and 0.64 (s.e. 0.05) for time-to-death. The mean genomic prediction accuracy over 20 replications of 5-fold cross validation was 0.80 (s.d. 0.02) for survival and 0.73 (s.d. 0.02) for time-to-death. Reducing the SNP panel density from HD to 100 SNPs resulted in ~ 31 % decrease of the genomic prediction accuracy for both survival and time-to-death. Imputation accuracy increased with increasing density of LD SNP panels imputed to HD, and overall, FImpute provided higher imputation accuracies than AlphaImpute in this data, although this difference was not statistically significant. Genomic prediction accuracies using imputed genotypes increased for higher densities imputed to HD, likely reflecting the better imputation accuracy for higher densities. Prediction accuracy was not found to differ significantly between genotypes obtained through using different imputation software (Figure 1). When using imputed genotypes, the prediction accuracies were found to be inferior to those obtained from directly genotyped HD data, regardless the software used for imputation.

While pedigree data can be used to predict breeding values only at the between-family level, in this study, genomic prediction was performed using the genomic relationship matrix calculated from imputed and directly genotyped data, which captures both between- and within-family variation. Further analyses are underway to test alternative scenarios of constructing the LD and HD groups, and to assess their impact on imputation and genomic prediction accuracy.

DYNAMICS OF MOORED CLOSED CONTAINMENT SYSTEMS WITH COUPLED WAVE LOADS, SLOSHING AND ELASTIC DEFORMATIONS

A. Tsarau*, B. Su, Y. Shen, R. Firoozkoohi and P. C. Endresen

SINTEF Ocean, P.O. Box 4762 Torgarden, 7465 Trondheim (Norway)
E-mail: andrei.tsarau@sintef.no

Introduction

Net pens for sea-based fish farming are prone to parasite infestations and can be hard on the environment. To control the production environment, closed cages with impermeable walls have been designed in various shapes, commonly with a vertical symmetry axis and a circular shape in the waterplane measuring 10-35 m in radius (). A hydraulic system is used to exchange water and to create an internal current. Scaled models of closed and semi-closed (i.e., with a permeable bottom) cages are shown in Fig.1.

Being designed to withstand waves with significant height (*Hs*) up to 2 m and peak period (*Tp*) up to 4-5 s (as along the Norwegian coast), closed cages can experience significant wave-induced loads and may suffer from sloshing (i.e., liquid movement in a tank with a free surface) [1]. Both effects are challenging to predict due to the coupling between the mooring system, cage motions, its elastic deformations, sloshing and internal currents. We analysed these coupling mechanisms and their effects separately in [2-5] and present some findings here.

The effect of an internal current on sloshing in an axisymmetric cage with a rotating liquid is mainly due to the Coriolis effect. Experiments (Fig.1c) show that this effect is significant when where is the current angular velocity (rad/s) [2]. Neglecting this effect implies either large cages (>25 m) or small current velocities The latter is assumed in our further analyses due to the lack of appropriate models handling rotating flows.

The effect of mooring system and cage motion is seen in Fig.2 showing the surge, pitch and sloshing responses from model tests of the two cages in Figs. 1a,b (with = 20.25 m and draft in full scale) in waves with *Hs* =1 m and a white-noise spectrum truncated at T = 3-25 s. Commonly for both the closed and semi-closed cages and in all tested irregular wave conditions, the surge motions (and thus the mooring forces) were found to be dominated by the slowly-varying wave drift loads near T_{moring}= 116 s, corresponding to the natural period of the cage-mooring system [3]. Thus, slowly-varying and mean wave forces have great importance in the design of mooring system for closed and semi-closed cages. Further, the pitch motions were also significant at high periods, including events of parametric instabilities due to in-and-out-of-water motions of the floater [4].

The coupling of sloshing and cage motion caused the local minima and maxima of the cage responses at the wave frequencies, as seen in Fig. 2 near the vertical lines at T_{11} and T_{12}, which are the natural periods of sloshing in a rigid circular cylinder with modal shapes shown in Fig. 3. According to linear potential theory, the sum of the cage mass (M) and the added mass due to sloshing (A) can be infinitely great near T_{11} and T_{12}, and therefore the surge motion is minimal at these periods. At somewhat lower periods, when $A < 0$ and $M + A \approx 0$, the cage motions increase dramatically, and the sloshing waves heights exceed the exterior wave components at the same periods (Fig. 2). Coincidentally, this occurred near T_{21} – another natural period of sloshing that cannot be linearly excited in rigid cages but can be coupled to deformations in elastic cages.

The coupled sloshing and elastic deformations of the closed cage in Fig. 1a were observed mainly for the radial deformation modes shown in Fig.3, causing resonant amplification of interior waves near T_{21}. A numerical analysis of this effect was attempted by combining the structural analysis program LS-DYNA with WAMIT. The model correctly predicted the resonant frequencies, interior waves and cage deformations elsewhere (Fig. 4), but not in the resonant zone where the free-surface nonlinearities might matter [4]. Further studies of hydroelasticity, as in [5], may provide useful insights, but certainly more research is needed on this problem.

Welfare in animal husbandry includes considerations of biology, ethics, ecology, law and economics. These diverse aspects must be translated into common quantifiable parameters and applicable methods to objectively assess welfare in animals. To assist this process in the field of aquaculture, where such methods are largely missing, we developed a model to assess fish welfare. A network of information was created to link needs, i.e. fundamental requirements for welfare, with parameters, i.e. quantifiable aspects of welfare. From this ontology 80 parameters that are relevant for welfare, have practicable assessment methods and deliver reliable results were selected and incorporated into a model. The model, named MyFishCheck, allows the evaluation of welfare in five distinct modules: farm management, water quality, fish group behaviour, fish external and fish internal appearance, thereby yielding five individual grades categorising welfare from critical, poor, acceptable to good. To facilitate the use of the model, a software application was written. With its adaptability to different fish species, farming systems, regulations and purposes as well as its user-friendly digital version, MyFishCheck is a next step towards improved fish welfare assessment and provides a basis for ongoing positive developments for the industry, the farmers and the fish.

Introduction

The aquaculture industry is in need of adequate methods for animal welfare assessment and the work presented is a next step towards this goal. The model described incorporates the specific advantages of existing welfare assessment attempts (Stien et al. 2013; Pettersen et al. 2014; Noble et al. 2018; Saraiva et al. 2019; Studer et al. 2020) in a single application. We focus on three key requirements:

Comprehensiveness: (I) We incorporate parameters from function-, nature- and feelings-based welfare concepts. This ensures an inclusive assessment that is unaffected by the potentially incomplete knowledge about welfare or bias of the assessor. (II) We assess the overall welfare in five modules (farm management, water quality, fish group behaviour, fish external and fish internal appearance). By not abstracting a high-resolution assessment into one overall index, the five distinct module grades facilitate the identification of potential causes of welfare problems. (III) With at least ten parameters per module we ensure sufficient coverage of signs of and prerequisites for welfare to allow an interpretation of the welfare state of the fish.

Applicability: (I) We ensure the applicability of the model by selecting the parameters based on three characteristics: science-based relevance for welfare, practicability of existing measuring methods and reliability of the results delivered. (II) The model can be used with only a subset of the modules or the parameters, enabling a flexible and purpose-oriented use. Scientists can benefit from a comprehensive model that allows a detailed assessment of fish welfare, while a simplified version of the same model has an increased practicability that assists fish farmers in their daily routines. (III) We provide a user-friendly version of the model by means of a software application. The users can profit from an efficient parameter evaluation and standardised documentation, which is important and should be as easy and intuitive as possible.

Developability: (I) Parameters that need to be adapted to specific fish species, production systems or local regulations in order to deliver meaningful results are highlighted. This facilitates future adaptation of the model to other species, systems or countries. (II) We provide access to the digital ontology the model is based on. This enables the inclusion of new knowledge by making it easy to adjust existing needs, parameters or relationships and to add new ones when pertinent.

Model development

The model development consisted of five phases (Fig. 1) where first a digital information network, an ontology, for fish welfare was created. On this basis welfare parameters were selected and grouped into five modules. In a third phase, a literature review and an expert survey were conducted to define the parameter intervals, scores and weights. These were incorporated into a mathematical equation delivering one grade per module. As a last step, two different applications were developed.

(Continued on next page)

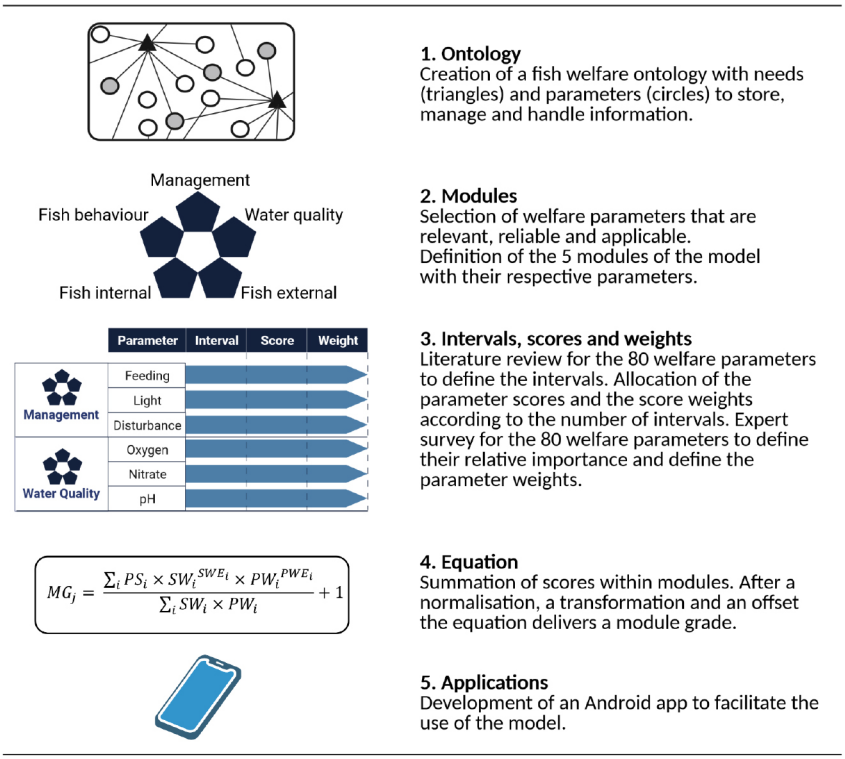

Figure 1: Graphical abstract of the model development of MyFishCheck

Conclusion

The MyFishCheck model developed here allows researchers to assess fish welfare based on the full model in a standardised and efficient way. This enables representative surveys of the whole industry, evaluations of measures across farms and validation of theoretical ideas or lab trials in practice. Initial tests on six different farms showed that the model is applicable on different fish species, different aquaculture systems and different locations. In addition, the available Microsoft Excel version of the model facilitates its use in science. Further, the model allows fish farmers to perform regular controls based on a customised version of the model as part of their quality control management. This enables the documentation of on-farm welfare standards, the tracking of improvements and the tracing of problems. During the testing, the model reliably produced lower module grades where parameters showed negative effects on welfare. Additionally, the app enables the user to perform these single-point evaluations more conveniently and to store, evaluate and compare past assessments. The model represents a next step towards a standardised evaluation of welfare, a digital documentation of assessments and a widespread application of welfare assessments. MyFishCheck will both in its current form as well as in future adaptations serve the field of aquaculture by assisting advancements for the common goal of better fish welfare.

Introduction

Generally, rotifers (*Brachionus* sp.) and brine shrimp (*Artemia* sp.) are commonly used as live prey for marine fish larvae in comparison with copepods due to the existence of standardized cost-effective protocols for their mass production (Conceição et al., 2010). However, their nutrient profile is deficient, particularly in many essential minerals (such as copper, zinc and selenium) in both rotifer and artemia in commercial hatcheries compared to copepods. The mineral profile of these live prey is not sufficient to cover the requirements of marine fish including gilthead seabream (*Sparus aurata*) (NRC, 2011; Hamre et al., 2008). Moreover, the nutrient composition of live prey is difficult to maintain and control during the long period in the larval rearing tanks. Therefore, it is necessary to establish balanced microdiets for early stage marine fish larvae.

Copper (Cu) is an essential trace element for survival, development, and normal growth in fish (NRC, 2011; Domínguez et al., 2019). Additionally, a Cu-dependent enzyme, lysyl oxidase (LOX) mediates the final step in the biosynthesis of collagen and normalizes the deposition of calcium and phosphorus in bones which impact the bone integrity (Tomaszewska et al., 2017). Cu deficiency caused low torsional strength of bone in chick tibia with the low lysyl oxidase activity (Opsahl et al., 1982). In fish, the copper deficiency resulted in reduced growth, high mortality and induced oxidative stress (Domínguez et al., 2019; NRC, 2011). Additionally, the negative results of copper excess caused reduced fish growth, increased oxidative risk, hepatic damage and cholestasis (Domínguez et al., 2019). Moreover, a high exposure of copper to larvae impact skeletal deformities (Barjhoux et al., 2012). Therefore, supplementation of optimal copper level in diet is necessary to fulfill the nutritional requirement of fish and to avoid the risk of toxicity. However, the information about mineral nutrition in marine fish larvae, and particularly gilthead seabream is still scarce. Hence the aim of this study was to investigate the effect of the dietary supplementation of Cu on growth, survival, antioxidant status and bone development in gilthead seabream larvae.

Materials and Methods

Diets. Copper sulfate pentahydrate ($CuSO_4.5H_2O$) was used as the copper source, supplemented in the basal diet composed of squid meal and casein at the levels of 0, 1.3, 2.3, 3.3 mg/kg in the isoenergetic and isonitrogenous diets. To contain a total analyzed levels of 17, 18, 19, 25 mg Cu/kg, respectively. ***Fish and experimental conditions.*** Larvae (initial dry weight 0.46 ± 0.09 mg, total length 7.9 ± 1.61 mm, 26 dph) were randomly distributed into twelve tanks (2100 individuals/ 200 L FRP tank) and hand fed every 45 minutes from 8:00 am to 8:00 pm until 46 dph. ***Sampling.*** Growth was monitored by measuring the weight and length of larvae at three different points: initial (26 dph), intermediate (33, 40 dph) and final (46 dph). At the final sampling, larvae were collected for histology, whole mount stain, gene expression, TBARS and remaining larvae for mineral analysis. Daily mortality was calculated for survival rate. ***Statistics.*** All data were tested for normality and homogeneity of variances and means compared by Ducan test and one-way ANOVA ($P < 0.05$). Quadratic regressions were used to establish a relation between dietary Cu level and their effect on the different indicators.

Results

Larvae fed the non-supplemented diet (Cu 17) showed the highest malondialdehyde (MDA) among the treatments (fig 1.a.). The antioxidant gene expression - cat was lowest in larvae fed the non- supplemented diet (Cu 17) (fig 1.b.). Severe skeletal anomalies and growth did not have significant differences when larvae were fed different dietary Cu levels ($p > 0.05$).

(Continued on next page)

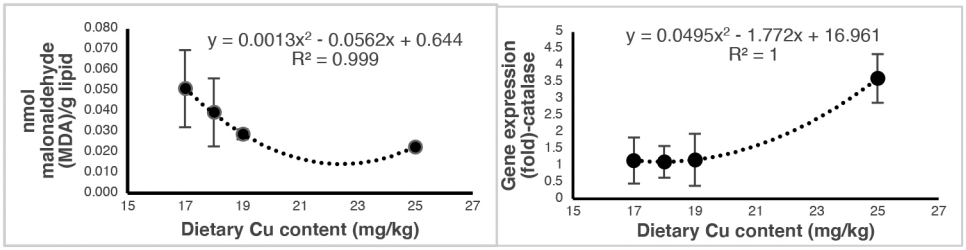

Figure 1 Thiobarbituric acid reactive substances (TBARS) - MDA (a) and antioxidant gene expression - *cat* (b) of gilthead seabream larvae (46 dph) fed different diets ($p < 0.05$)

Discussion and conclusion

Larvae fed diets with different levels of Cu (17-25 mg/kg) showed no significant differences in growth. However, in gilthead seabream fingerlings 5.5 mg Cu/kg were enough to cover their requirements for growth when fed a diet with only 10% fish meal and 75% terrestrial meals (Domínguez et al., 2019). This points out that small fish need higher nutrient requirements than larger fish. Despite dietary Cu did not have a significant effect on growth, there was a tendency to increase survival rate with increasing dietary Cu levels ($y = 0.0143x^2 + 0.1361x + 60.224$, $R^2 = 0.9975$). Additionally, a significant correlation between the DHA content in larvae and survival rate was found in the present study ($y=0.117x^2-4.3085+106.05$, $R^2=0{\cdot}9469$). Copper deficiency caused low torsional strength of bone in chick tibia with the low lysyl oxidase activity (Opsahl et al., 1982). However, no significant differences of severe skeletal anomalies were observed in the present study. Moreover, growth performance and skeletal anomalies are not the only indicator to quantify mineral requirements in fish. TBARS analysis is one of the most popular and commonly used methods to study tissue peroxidation. In contrast, to prevent oxidative damage, antioxidant enzymes such as *cat* (catalase) intercept reactive intermediates in the oxidant reactions. It has been demonstrated that either deficient or excess dietary Cu induced oxidative stress (Domínguez et al., 2019). In the present study, larvae fed the lowest Cu diet (17 mg/kg) showed the highest degree of the TBARS value and lowest *cat* gene expression. Overall, based on these results it is suggested that it is necessary to supplement Cu in the diet and the adequate dietary Cu concentration (25 mg/Cu kg) increased the antioxidant defense in gilthead seabream larvae (46 dph), while supplementing up to 25 mg/ Cu kg diet caused no negative effects on the growth.

Introduction

High-quality genome information is nowadays considered as a prerequisite of major significance in any animal and plant selection and breeding objectives. The meagre *Argyrosomus regius* is a fish species of elevated economic interest for the Mediterranean aquaculture in recent years, and there is ongoing effort to increase the efficiency of breeding performance. For this purpose, access to the full genomic sequence of the species would provide an important resource for exploring loci associated with quantitative traits and the genetic diversity of different wild populations and broodstocks. Here, we present the first complete nuclear genome for *A. regius*, which has been produced through a combination of long and short read technologies. This sequencing strategy, coupled with an efficient pipeline for assembling and polishing the genome, led to a contiguous, high-quality genome that provides an excellent base for future genomic studies in meagre.

Materials and Methods

Genome sequencing was carried out via a combination of third generation long read (Oxford Nanopore MinION) technology that provides contiguous long reads and a second generation (Illumina HiSeq4000) platform that produces short reads with high fidelity, which can be exploited to correct the former. Thus, a base assembly was first built using the Flye Assembler[1] and polished from the long-read data, followed by polishing and error correction using the low error short read data (Racon[2], Medaka (https://nanoporetech.github.io/medaka/), Pilon[3]), while all intermediate and final assemblies were assessed for the quality in terms of contiguity and completeness (Quast[4], Busco[5], Merqury[6]). This pipeline has been containerised in house, and is freely available (https://nellieangelova.github.io/De-Novo_Genome_Assembly_Pipelines/). Transcriptome sequencing was performed using total RNA extracted from 8 different tissues (listed in fig.1) on the Illumina HiSeq4000 platform. From these data, a final consensus transcriptome was constructed using Mikado[7], incorporating intron junction, ORF prediction and homology information. Augustus[8] and PASA[9] were then used to carry out gene prediction based on the genome and transcriptome assemblies.

Results and Discussion

The MinION platform produced a total of 38,119,965,327 bp, with more than 99.5% passing quality control, giving a final 54.5× genome coverage and 3,003,301 sequences with a mean length of 12,640 bp. Illumina sequencing produced a total of 166,912,732 sequences of 150 bp, with more than 85.8% passing quality control, giving a 30.9× genome coverage. Transcriptome sequencing produced more than 100,000,000 sequences of 150 bp per tissue sample, with more than 90% of them passing quality control. The genome assembly produced from the long and short read data consists of 1,012 contigs, totalling 696,249,749 bp in size, with an N50 of 2,798,312 bp and an L50 of 23. This high level of contiguity is coupled with high completeness scores from both Merqury (96.9%, based on Illumina data kmer counting) and BUSCO (98.7%, based on conserved gene presence/absence), while the final consensus transcriptome also shows comparably high completeness (BUSCO 96.3%). Based on these data, the gene prediction pipeline annotated a total of 24,589 genes with a mean size of 16,437bp and a final BUSCO score of 95.6%. The constructed reference genome will set the basis for gaining deeper understanding of meagre biology and will boost the efforts for selective breeding through genomic selection.

Introduction

Sea bream (*Sparus aurata*) is one of the most commercially important aquaculture species. The increased incorporation of plant raw materials in the diets contributes to the increase of their phytoestrogen content. Major phytoestrogens found in fish feeds include genistein, daidzein, biochanin A and coumestrol (Matsumoto et al. 2004). These compounds have been associated with estrogenic potencies in fish (Pelissero and Sumpter 1992). Their metabolites may also possess estrogenic activity, with equol to be superior to all other isoflavones in its antioxidant activity (Rowland et al. 2000). The estrogenic effects are found to include alterations in lipid metabolism, plasma triglyceride and cholesterol levels, as well as overall growth rates (Kaushik et al. 1995; Chakraborty et al. 2014). The aim of this study was to estimate the effects of two diets with different phytoestrogen content on blood parameters and somatic indices of sea bream.

Materials and Methods

Two diets, A (protein 44.2%, fat 15.1%, ash 7.3% and moisture 6.4%) and B (protein 44.9%, fat 16.6%, ash 6,9% and moisture 6.5%), were provided by Biomar Hellenic. The phytoestrogen content of feeds and fish fillets was determined by LC/MS-MS. The compounds identified were daidzein (10.4±0.2μg/g for diet A and 2.64±0.06 μg/g for diet B), genistein (3.9±0.2μg/g for diet A and 1.4±0,1 μg/g for diet B), biochanin A (1.14±0.03μg/g for diet A), coumestrol (1.98±0.07 μg/g for diet A and 0.72±0.05μg/g for diet B) and glycitein (0.42±0.05μg/g for diet B). Specimen initial size was 101.4±0.8g. A 12-week experimental rearing was carried out in a Recirculating Aquaculture System, consisting of six 147-L tanks (three replicates/treatment, 12 fish/tank). Fish were fed at satiation twice a day. At the end of the experiment, the following parameters were estimated: body weight (BW), specific growth rate (SGR), feed conversion ratio (FCR), viscerosomatic index (VSI), hepatosomatic index (HSI) and Fulton's condition factor (K). Blood samples were also collected from the caudal vein and stored in heparinized tubes. Blood samples were centrifuged and plasma was collected, for the assessment of cholesterol (CHOL), glucose (GLU), albumin (ALB), alkaline phosphatase (ALP), glutamate oxaloacetate transaminase (GOT), glutamic pyruvic transaminase (GPT), lactate dehydrogenase (LDH) and triglycerides (TG) using commercial kits (Biosis).

Results

VSI and HSI were significantly higher in the low- (diet B) than in the high- (diet A) phytoestrogen treatment. In addition, daily feed consumption per fish was significantly higher in treatment B compared to A during the 3rd month of rearing, while FCR was lower during the 1st month. Condition factor, body weight and SGR were similar in both treatments. Plasma ALB, TG, CHOL, ALP and GPT levels were higher in fish fed the diet B compared to A, whereas no significant differences for GLU, LDH and GOT levels were observed. Equol was detected in certain fish of high-phytoestrogen treatment.

(Continued on next page)

Discussion

Fish fed the low-phytoestrogen diet demonstrated a trend for decreased FCR, indicating a better utilization of feed. It has been shown that the use of diets with high concentrations of phytoestrogens resulted in relatively low growth rates of fish (Chakraborty et al. 2014). According to previous studies, high inclusion of plant-derived raw materials, reduces liver lipids (Dias et al. 2005; Torno et al. 2019), leading to reduced VSI and HSI, similar to the present results. The low levels that were observed for ALB in treatment A, may be attributed to its role in the regulation of plant-deriving exogenous compounds to estrogen receptors (Baker 2002). Plasma CHOL and TG levels were decreased in high phytoestrogen dietary treatment, as has also been found in trout (Kaushik et al. 1995) and sea bass (Dias et al. 2005). The low ALP concentrations are in accordance with previous study on sturgeon, where decreased levels were observed in treatments with elevated isoflavonic phytoestrogens (Yousefi Jourdehi et al. 2014). The increased GPT and ALP levels in the low-phytoestrogen treatment may be related to the liver lipid accumulation (Michael et al. 1987). In conclusion, the differences in dietary phytoestrogen content, affect significantly blood parameters and somatic indices. However, these results could also be attributed to differences in dietary fat content and feed consumption. It has been suggested (Rowland et al. 2000) that the dietary fat intake decreases the capacity of gut microbiota to synthesize equol in humans, contributing to an interindividual variation in isoflavone metabolism, as in the present study. Further experimentation is required in order to clarify if the observed results were due to differences in dietary phytoestrogen concentrations, macronutrient content, gut microbiota, metabolites or interactions thereof.

GROUP REGULATION AND ENVIRONMENTAL OUTCOME: EVIDENCE FROM ZONAL OUTPUT RESTRICTION IN NORWEGIAN AQUACULTURE

Ragnar Tveterås*, Tenaw G. Abate, Dagim G. Belay

University of Stavanger Business School, 4036 Stavanger, Norway
Email: ragnar.tveteras@uis.no

Introduction

Sea lice parasite has become a main environmental challenge for salmon farming. Sea lice creates concerns both for the welfare of farmed fish and the stocks of wild salmonids, as it can lead to increased mortality both for farmed salmon and wild salmon. In Norway sea lice are regulated both at the farm level and production area level, the latter through the so-called "traffic light system". A sea lice regulation at the farm site level was introduced in 2013. In 2017, the government of Norway in addition introduced the traffic light system (TLS), that divides the Norwegian coast into 13 aquaculture production zones and labels them 'Green', 'Yellow', or 'Red' based on the estimated sea-lice-induced mortality rates on the wild stock. If a production zone is labeled 'Green'/'Red', production capacity should increase/decrease by 6% whereas 'Yellow' means the current level of output should be maintained.

The research questions we ask are as follows: (1) Does output restriction improve environmental outcomes? Even though it seems that output restriction would automatically improve environmental outcomes, Helfand (1991) analytically outlined that the effect is not straightforward. (2) If output restriction improves environmental outcomes, does the improvement come at the cost of economic outcomes such as firms' efficiency loss and/or reduction in profits?

Empirical analysis

We use two data sources to empirically analyze the above research questions: (1) Publicly available weekly data on lice counts at farm level and other variables by The Norwegian Food Safety Authority (NFSA), the Norwegian Veterinary Institute and the Directorate of Fisheries. (2) Firm-level annual economic data (production data) from the Norwegian Directorate of Fisheries

For the first research question we have two complementary empirical strategies to establish a clear causal relationship between the TLS and environmental and economic outcomes, and obtain unbiased estimates. First, we have a regression discontinuity design in time (RDiT), where we explore the temporal aspect using 'week' as a running variable and the treatment date (week) as a threshold. When we estimate econometric RDiT models on the lice count

$$y_{it} = \gamma_0 + \gamma_1 1(TLS) + \gamma_2 x_{it} + \varepsilon_{it}$$

we find that TLS leads to a significant reduction in adult female sea lice count.

Second, we use a Difference in difference (DiD) estimation approach to explore the spatial aspect by exploiting variations in the intensity of output restriction. When we estimate econometric DID models on the lice count

$$y_{it} = \beta_0 + \beta_1 TLS + \boldsymbol{\beta_2} post_t \cdot TLS_{it} + \beta_3 x_{it} + \eta_t + \alpha_i + \vartheta_z + \varepsilon_{it}$$

we find that the introduction of TLS leads to a significant reduction in adult female sea lice count.

To address the second research question on the economic effect of sea lice restriction we undertake an econometric analysis of production costs and profits. We estimate cost functions and profit functions which enable us to separate the effects of input prices, scale economies, technical change and external effects on production costs in salmon farming. The results are mixed. Overall, an increase in sea lice prevalence is associated with an increase in production costs. However, the effect is only statistically significant when full production costs is the dependent variable. For profits the effect of an increase in sea lice prevalence is significantly negative when we estimate a pooled model, i.e. lower sea lice prevalence is associated with higher profits, but not significantly different from zero when we include firm-specific effects in the profit function.

(Continued on next page)

Table. Estimated mean elasticity with respect to average adult female sea lice per salmon from translog cost and profit functions

Model	Estimate	Std.error	t-value	p-value
Pooled cost	0.019	0.013	1.53	0.127
Firm effects cost	0.015	0.012	1.20	0.229
Pooled full cost	0.044	0.016	2.72	0.006
Firm effect full cost	0.030	0.017	1.73	0.084
Pooled profit	-0.152	0.072	-2.12	0.034
Firm effect profit	0.027	0.030	0.92	0.358

Conclusions

Using unique data from this policy experiment, we investigate whether sea lice regulation improves environmental outcomes and/or affects firms' cost efficiency and profit. We take advantage of spatial and temporal variation in the regulation's implementation to show that a threat of zonal output restriction did reduce the prevalence of sea lice in all production zones across different specifications. Difference-in-difference estimations show that a greater reduction in the prevalence of sea lice is observed in 'Red' labeled zones compared to 'Green' and 'Yellow' zones. Evidence from estimation of cost functions and profit functions indicate that the introduction of the TLS resulted in cost increases and a reduction in profit.

POTENTIAL INTERACTION BETWEEN VITAMIN D AND VITAMIN K IN RELATION TO GROWTH, CALCIUM METABOLISM AND BONE MAINTENANCE IN GILTHEAD SEABREAM JUVENILE (*Sparus aurata*)

Introduction

Studies on plant-based ingredients have been increasing for aquafeed production due to the diminished availability and increasing price of high-quality fish meal and fish oils (FAO, 2020). This alternative source of plant-based ingredients may alter the nutritional profile of the produced aquafeed, which directly affects the nutritional requirement of the fish (Francis et al, 2001) including vitamins, which play a major role in growth, health, and reproduction in fish. Vitamin requirements for various fish species have been established in NRC, 2011, but the requirement level for gilthead seabream (*Sparus aurata*) was still unknown.

Gilthead seabream is one of the most cultured fish species in the European Union (EU) aquaculture system and contributes around 6.77% of all European aquaculture production (APROMAR, 2020). Even though the production rate is high, the gilthead seabream is often detected with skeletal anomalies during the culture period which affects the production cost, growth, and fish survival rate (Andrades *et al*., 1996). There are several studies on skeletal anomalies in gilthead seabream based on developmental stage, temperature, genetic background and nutrition (Boglione and Costa, 2011, Izquierdo *et al*., 2016). Therefore, the present study focused on the micronutrients, especially vitamin D and vitamin K, due to the lack of information about these vitamins on gilthead seabream juveniles.

Vitamin D (VD) and Vitamin K (VK) are fat soluble vitamins, which deliver synergistic effects on calcium (Ca) metabolism, skeletal development, and mineralization of bones. In fish, the source of vitamin D depends on the dietary intake, and it helps in calcium deposition and skeletal development (Lock *et al*., 2010), while vitamin K helps in posttranslational modification and activation of the vitamin K-dependent proteins, that eventually help in skeletal development of fishes (Krossøy *et al*., 2011). This suggests a pleiotropic effect in vitamin D and K, that helps in understanding the interaction of these vitamins in growth and skeletal development of fish. Thus, the aim of the study was to evaluate the potential interaction between vitamin D and K in skeletal development and to identify the optimum requirement of these vitamins in gilthead seabream juveniles.

Materials and methods

Seven different isoenergetic and isonitrogenous plant-based diets (FM – 10%, FO – 6%) were formulated with increasing levels of VD_3 and VK_3 (Table 1,2). Gilthead seabream juveniles with initial weight of 72.63 ± 0.33 g were randomly distributed into 21 tanks in triplicate groups and manually fed 2% body weight until apparent satiation for 105 days. Every two weeks, fish were sampled for growth parameters such as length and weight. Water quality and feed intake were monitored throughout the experiment. At the end of the trial, fish were analysed for growth performance, protein utilization and body indices. Samples were taken for X-ray, histology, gene expression and vitamin analyses.

Results

After a period of 105 days feeding, fish doubled the weight, in which the final body weight (FBW) showed no significant difference (P – 0.19) among the groups by one-way ANOVA. But with respect to two-way ANOVA the VD*VK interaction showed a significant difference (P – 0.002) between treatments. Other parameters such as Feed conversion ratio (FCR), Specific growth rate (SGR), Feed intake (FI), showed no significant difference in one-way ANOVA as well as no interaction effect ($P \leq 0.05$) by two-way ANOVA among the groups, except for Protein efficiency ratio (PER) which showed significant differences among the groups in both statistical tests (Table 2).

FE	0.47 ± 0.02	0.47 ± 0.02	0.48 ± 0.02	0.47 ± 0.02	0.43 ± 0.03	0.44 ± 0.05	0.49 ± 0.03	0.23	0.05
FI	159.97 ± 5.29	161.48 ± 2.21	163.55 ± 3.72	159.04 ± 6.51	156.61 ± 7.80	154.86 ± 6.14	161.92 ± 4.55	0.49	0.349

*Values represent means ± standard deviation of triplicates.

Discussion and Conclusion

The results from the present study suggest no significant difference in growth performance by one-way ANOVA. However, two-way ANOVA suggests an interaction effect among the groups with respect to FBW. Moreover, there were no significant differences observed in FI by both statistical tests, indicating there might be a combination effect of dietary VD and VK in FBW of the gilthead seabream juveniles. Abawi and Sullivan (1987) also suggest that higher supplemental levels of vitamins D and K would improve growth performance of poultry. On the other hand, in Atlantic salmon (*Salmo salar*) VD, VK, Ca, and dissolved CO2 exposure did not cause any deleterious effects on bone mineralization or fish health (Graff *et al*.,2002). Therefore, further analyses are being conducted to understand the interaction effects of these vitamins in skeletal development and calcium metabolism in gilthead seabream juveniles.

Introduction

Using methods of obtaining information by a non-invasive method in the aquatic environment is in demand and is constantly used in all sectors of aquaculture. In biology, we often estimate the state of the object by its color. The classical spectrophotometric methods have a disadvantage of the point measurement, where only small area of the fish skin could be evaluated. Such method is invasive, since there is a direct contact. The correctly set camera could give a valuable color characteristic across the whole fish body, if image processing methods are applied. Proper light and camera calibration are two related, but separated tasks. To improve the measurement acquisition, we developed a simple device, a box or chamber, with standardized light conditions, automatic camera calibration, environmental sensors, weighting scale, and software applications for color analysis and evaluation.

Materials and Methods

The existing methods for the white balance were mostly developed for the corrections of the image taken with the incorrect settings. However, they are general enough to work directly on camera setting. Since the amount of light from the LEDs illumination is suffcient, two simplest methods of white balance algorithms could be used, the Retinex method, and GrayWorld method.

The captured images could be easily analysed with the software application for the segmentation (fish to background), color transformations and characteristics (sRGB, cRGB, LAB, HSV), image and set characteristics. The segmentation and color analysis is tuning automatically the parameters and thresholds.

Results and Discusion

The camera is calibrated automatically, using described methods. The standard color checker chart was used for the comparison of white balance calibration.

The device is standardizing the condition for the color measurements, automatically setup the camera parameters as white balance, brightness, and contrast to allows accurate color analysis from the captured images. The devise is easy to use, without advance user operation. It is connected with the analysing software for the segmentation, color transformation, and statistic. The device should help with the data aquisition as well as the analysis, comparison, and color evaluation.

ENVIRONMENTAL PREFERENCE OF NILE TILAPIA ACCORDING TO BEHAVIOURAL TRAITS

A. V. Montalt*, P. Arechavala-Lopez, C.M. Maia, M. Cabrera-Alvarez, J.L. Saraiva

Fish Ethology and Welfare Group, Centro de Ciências do Mar (CCMAR), Faro, Portugal
*Corresponding author: avmontalt@gmail.com

Introduction

Along their life-history, animals develop behavioural strategies to ensure their survival. Nonetheless, inside fish schools, completely opposite conducts among individuals are revealed. Some display a bolder role while others are shyer; in between both extremes, a continuum of behavioural profiles takes place. When those behaviours are stable across a wide range of social and environmental contexts, individual personality is defined. This proactive-reactive pattern has been identified in nature but also in aquaculture, where the interest on animal welfare is growing exponentially and, alongside it, the will to improve rearing methods. Yet, little is known about how to adapt artificial habitats to fish behavioural patterns. Arechavala-Lopez et al. (2021) suggested environmental enrichment (EE) as a potential way of reducing stress and enhance fish welfare; while Maia et al. (2017) presented preference tests as a tool to accurately determine fish preferred choices. Merging both, EE and preference concepts, this project aims to assess whether proactive and reactive individuals of Nile tilapia *Oreochromis niloticus* have different preference responses for any of two types of EE.

Material and Methods

We studied 50 Nile tilapia (Silver Natural Male Tilapia™ , Til-Aqua International B.V., Netherlands) weighing 44.2 ±9.7g. Every week we anaesthetised and tagged 10 individuals with t-Tag100 (BTS-ID ™), transferred them to a 300L holding tank (100x55x55cm; density: 1.5kg/m^3) and left them undisturbed for a 64h recovery period.

We first ran a risk-taking test (RT), placing one subject fish in a testing tank (100x55x55cm) divided into a $^1/_5$ and a $^4/_5$ areas by a vertical acrylic wall (Fig.1A). The wall had a bottom opening (10x9cm), initially covered by a lid. After 5min in the $^1/_5$ area, we opened the hole and recorded subject's activity for 20min. Subsequently, we returned the fish to its holding tank. We tested each fish of the 10-fish group once a day in 3 consecutive days before 64h of recovery. We calculated the average latency to cross the opening, rating the individuals as high or low risk-takers. After the recovery, we ran a preference test (PT). The testing tank (100x55x55cm) had 3 vertical areas of the same size. The central area was empty while the right and left areas displayed one of two kinds of EE: a shelter structure (pot), and a framework of hanging ropes and sticks (Fig.1); their position was counterbalanced after each trial. We released one fish into the central area and recorded its behaviour for 20min. After 3 repetitions in consecutive days, we euthanised them. We used The Observer XT ™ (Noldus, the Netherlands) to analyse the videos, tracking subjects' position and quantifying behavioural traits. We calculated a preference index (Maia et al., 2017) for each subject based on its EE choices (duration and intensity). We are currently studying links between choice patterns and RT profiles.

Results

Risk-taking test: We identified three main categories of latency (Low, Medium and High) by ordering individuals by their average latency among trials (Fig.1B). We also evaluated the Coefficient of variation of the latency (CV), discriminating a similar 3-category pattern. The average latency to cross the hole decreased over the trials while the average number of crosses through the hole increased (Fig.1C).

Preference test: We calculated the preference index for each individual, categorizing them into three groups: Pref-Shelter (44%), Pref-Complex (30%) and Undecided (26%). Intensity of response for EE heavily fluctuated among individuals (Fig.1D).

(Continued on next page)

	Shelter	Complex
Mean	1107	465
SD	1767,25	1445,89
CV	0,63	0,32
Min value	-2282	-2185
Max value	4921	4371

Fig. 1. A: Experimental tanks schemes for RT and PT tests on Nile Tilapia; B: Distribution of individual average latency to cross the hole on RT test; C: Average latency and number of crosses in RT test; D) Preference index stats for both EE, (+)values mean preference while (-)values mean non-preference.

Discussion

Until now, we have evaluated risk-taking behaviour and preference tendencies, which provide an overview of the main types of responses. Decreasing latency and increasing crossing events over trials suggest a habituation process to the RT arena. We are pondering different proxies of fish personality to develop a compound RT index. First analyses of the CV of latency already gave us an insight on the consistency of fish performance in consecutive RT trials, showing that some fish continuously behave in the same way while others vary their behaviour on each trial. Also, the addition of variables linked to activity levels (e.g. zone changes per minute, total number of zone changes) and exploratory behaviour (e.g. max. distance from hole, surface/bottom ratio) will supplement the mentioned index providing a complete fish behavioural profile. Regarding the PT, further than our qualitative categorization, an exploration of the quantity, intensity, and nature of interactions with the two EE types will give us a deep perspective on fish preferences. Further development of behaviour-preference profiles will yield the need to design environments adapted to fish requirements, favouring their welfare and thus, increasing their added value as product.

Introduction

Peloids are naturally formed mud suspensions with variable content of clay, inorganic and organic compounds, water, and gases throughout the seasons. Consequently, their microbiological composition is in a continuous change and little is known about their prokaryotic distribution and community structures (Carretero et al., 2020).

Since Roman times, a peloid micro-location on the Croatian Adriatic coast near the small-town Nin is used for pelotherapy (use of peloids for medicinal purposes) (Gomes et al., 2013). Nowadays, the health resort is under constant supervision of the Zadar Health Institute and part of the tourist attraction and health tourism of Croatia. Healing of arthritis, spinal deformities, muscular and skeletal system problems, skin diseases, and rheumatic disorders are just some of the applications of Nin peloid mud. However, insufficient knowledge and limited scientific reports concerning the abiotic and biotic content of peloid mud is still a barrier for understanding its contribution to the healing effects. To that end, investigation of the microbiological diversity and compound composition of Nin peloid mud is highly warranted. Therefore, the main objective of this work was to identify the most common bacterial strains in the Nin peloid mud, their biochemical profile, and their fatty acid composition.

Materials and methods

Sample collection was conducted in August 2020 from several locations across the Nin peloid mud micro-location (44°14'59.2'' N, 15°10'24.5'' E). Peloid mud samples were collected into sterile Falcon tubes, stored at 4° C, and analysed the next day for chemical composition and presence of yeasts and bacteria. Samples were inoculated onto Marine agar plates and incubated for 48 h at 20 °C. A total of 39 primary isolates were analysed using matrix-assisted laser-induced desorption/ionization (MALDI) connected to the time of flight (TOF) mass spectrometry (MS) channel (MALDI-TOF MS) (Bruker Daltonics, Bremen, Germany) (Topić Popović et al., 2017). A total of 33 bacterial isolates were cryo-preserved and selected for further testing. DNA extraction (Qiagen, Hilden, Germany) and 16S sequencing (Macrogen, Amsterdam, Netherlands) were utilized to identify bacterial strains unidentifiable by MALDI-TOF MS. The API 20E tests (BioMerieux, Marcy l'Etoile, France) (Topić Popović et al., 2014) and fatty acid (FA) analyses (Varian Inc., Palo Alto, USA) (Bujak et al., 2018) were conducted on overnight bacterial cultures to provide insights into their biochemical profile and cellular fatty acid composition.

Results

Analytical and microbiological methods were conducted on seawater and sediment samples of peloid mud. Consumption of $KMnO_4$ was between 32.6 and 56.3 mg O_2 L^{-1} seawater. Ammonia concentration was under 0.01 mg N L^{-1}. Obtained nitrate concentration was between 0.2 and 0.7 mg N L^{-1}. Microbiological analysis showed that 100 g of sediment contained 108 colonies of coliform bacteria, 41 colonies of *E. coli* (limit 500), 71 colonies of faecal enterococci (limit 200), 7349 colonies of sulphite-reducing clostridia, zero colonies of *P. aeruginosa* and yeasts per 100 g of sediment.

The API 20E results revealed that none of the isolated bacterial strains synthesized arginine dihydrolase and urease. Half of the strains were positive for β-galactosidase, tryptophane deaminase, gelatinase, and indole production. A fifth of the isolated bacterial strains fermented sucrose, mannose, glucose, produced indole and acetoin, and decarboxylate lysine and ornithine. A quarter of the isolated bacterial strains fermented amygdalin, while almost all strains produced oxidase. 16S sequencing and MALDI-TOF MS analysis showed that peloid harbours a richness of bacterial species, with at least three distinct community types. The predominant fatty acids in Gram-positive bacteria were i-C15:0 and ai-C15:0, whereas in Gram-negative bacteria the main fatty acids were C16:0, C16:1, C18:0 and C18:1.

(Continued on next page)

Discussion and conclusion

Analytical and microbiological results revealed no anthropological impact on the microbiological composition of peloid mud. Overall results have proven remarkable quality of water and sediment for pelotherapy purposes.

The primary screening of bacterial isolates was conducted using MALDI-TOF MS. It is a powerful diagnostic method for the fast screening of isolated bacteria that helped us in the isolation process. However, we could not identify most of the bacteria isolates because the reference database spectra lack the spectra of environmental bacteria. Results obtained using the API 20E method provided additional information on the biochemical profile and metabolic pathways of isolated bacterial strains. The results differ depending on the bacterial strains and are in correspondence with literature data. The FA composition of bacterial cells varies depending on the species and has thus been used as a biomarker in taxonomy. It was an excellent tool to overcome the shortcomings of the MALDI-TOF MS regarding its lower level of taxonomic resolution for environmental samples. Despite their drawbacks, together with the 16S sequencing, which is the golden standard for the identification of bacteria, we identified all isolated bacterial strains from the peloid.

The acquired data can provide a better understanding of peloid muds, their microbiological and chemical properties. It is of great importance to identify metabolic pathways and compounds produced by the microorganisms, which could benefit human health and healing processes. Further studies will involve detailed tests on isolated bacterial strains and their properties, including several parameters, such as antimicrobial and antibiotic testing and bioinformatics models of the relationship between microbiological communities in the peloid mud.

Introduction

The zootechnics in aquaculture is in constant evolution, in order to reach the maximum production rates, making the initial economical investment the more profitable as possible in the shortest time. Biomass control and precise feed estimation for finest fish growth are key and routinary activities in culture facilities. These periodical protocols usually imply animal persecution, tank withdrawn, and human handling, which may lead to stress induction on the individuals.

Over recent years, different mechanisms based on image analysis for quantifying the tank biomass have been studied in some commercial species, showing different levels of accuracy in their estimations (Saberioon et al., 2017). In addition, in the particular case of *Solea senegalensis* some specific constraints, such as overlapping of flatfish individuals in the bottom of the tank, should be considered in the development of these artificial recognition systems.

The initial hypothesis of this work was that the implementation of a precise image recognition system via artificial neural networks for biomass prediction in *Solea senegalensis* might provide an accurate biomass estimation, reducing human handling, potential stress induction and, eventually, an improvement on animal growth.

Material and methods

In order to validate this hypothesis, 30 adult F1 Senegalese soles born and reared in our facilities were divided into two homogeneous cohorts in terms of weight. One of them was established as control group (CTRL), which was standard manually sampled and the other one, the experimental group (EXP), was maintained under a lower human-animal interaction culture relying on a new image analysis predictor for biomass calculation with a lowest estimation of 0.8 centimetres, and around 95% of accuracy detection (Marco et al., 2021). Thus, animals belonging to CTRL group were exposed to a monthly manual sampling which included tactile, visual, olfactory, gustatory and auditory stimuli contrary to EXP counterparts. This sampling was performed following standard protocols in animal production centers for biometrical measurements. Each group was split into three replicates (n =5; biomass density: 1.6700 ± 0.009 kg/m^2 per tank). All animals included in the experiment were fed daily with a commercial diet of Europa 5® pellets from Skretting Spain S.A (Burgos, Spain) to an adjusted quantity of the 0.5% biomass of each tank.

Visible implant elastomers (VIE) tagging was used to monitor individual growth. Before the beginning of the experiment, each fish was tagged with a unique code based on the number and position of marks on the dorsal area. This approach allowed fish recognition using a UV lamp, avoiding withdrawing them from the tank in the EXP group. Top view photographs from each EXP tank were taken to calculate the precise biomass within them using the developed algorithm. Biomass data provided by the image analysis system were used to adjust food ration in the experimental tanks.

The experiment lasted 10 months. Two key points were established at: 5 months (halfway of the experiment) and 10 months (end of experimentation).

Specific Growth Rate (SGR) at 5 and 10 months were represented as the mean ± standard error of mean (S.E.M.). The comparison of biometrical data between groups was analyzed using a Mann Whitney test. Statistical analyses were performed with Prism8 (GraphPad Software, San Diego, CA, USA). p-values < 0.0500 were considered statistically significant.

The experimental design and all procedures including animals in the present study were approved by the institutional Animal Care and Use Committee (authorization number PI-10-16) at the Marine Culture Plant El Bocal of the Spanish Institute of Oceanography in Santander, Spain. All animals were standard manipulated according to the Guidelines of the European Union Council (2010/63/EU), following Spanish regulations (RD/2013) for the use of laboratory animals.

(Continued on next page)

Results and discussion

Animals included in the EXP group (lower human-animal interaction) reported a statistically significant higher SGR at both evaluation points: 5 months ($p=0.0038$) and 10 months ($p=0.0040$) when compared to CTRL animals. The reduction of the human-animal interaction by the application of this artificial neural network system based on image analysis would benefit flatfish aquaculture, reducing the cost associated with manual labour. Furthermore, the validation of this system opens up new opportunities for the development of easy-to-use tools for flatfish aquaculture industry since the algorithm can be implemented by any device such as a mobile phone. Our results indicate that a lower human-animal interaction, implying potentially lower stress induction, improves biomass gain in Senegalese sole individuals in a short period of time of its life cycle. Further studies will be focus on the study of stress related mechanisms that could trigger this handling response in order to provide specific treatments to counteract this effect.

Introduction

Lactic acid bacteria (LAB) are one of the most studied probiotic bacteria in terms of their beneficial effects on aquatic species health. *Pediococcus acidilactici* CNCM MA18/5M, is a LAB strain which is registered in the European Union for use in feed for aquaculture. Previous studies have focused on the positive effects of this probiotic on a variety of species with commercial interest such rainbow trout (Ramos et al., 2013), tilapia (Standen et al., 2013) or blue shrimp (Castex et al., 2010) among others.

The current experiment aims to explore the potential beneficial effects of a prolonged probiotic supplementation (up to 150 days post hatching (dph)) with this strain on growth performance in *Solea senegalensis* culture.

Material and methods

This experiment was conducted in accordance with the Spanish and European law on animal experimentation and was specifically approved by the Bioethics Committee of the University of Cantabria (authorization number 2021-02).

Embryos were obtained by *in vitro* fertilization (IVF) (Rasines et al., 2013) using F1 *Solea senegalensis* gametes from only one couple. General culture protocol and feeding regime were based on Cañavate and Fernández-Díaz (1999) with slight modifications. One dph, the batch of siblings was homogenously split into 6 tanks (Volume: 200 L; density: 50 larvae L^{-1}). Two experimental groups (3 tanks/group) were created differing in the feeding program: 1) the control group (CTRL) in which live food (rotifer and artemia metanauplii) was enriched with a commercial product (Easy Dry SELCO®, Inve Aquaculture) and 2) the experimental group (PROBIO) in which live food was enriched (10^{11} CFU mL^{-1}) with *Pediococcus acidilactici* MA 15/5M (Bactocell®, Lallemand). Once weaning was over (90 dph), the PROBIO group maintained the probiotic supplementation in the pellets. The probiotic was included in the inert food of this experimental group using the oil coating technique (20 % w/w vegetal oil).

Growth was evaluated taking into account three temporal frames: 1) Live-inert cofeeding (3 dph; beginning of feeding-90 dph; end of weaning), 2) Inert feeding (90 dph-150 dph), and 3) Complete trial (3 dph -150 dph). Specific Growth Rate, SGR $((\ln W_f - \ln W_0)*100/T_f-T_o)$ was used as variable to evaluate fish growth. Statistical analysis was performed using SPSS 21.0. Normally distributed variables were analyzed using the student's t-test. Values with $p < 0.05$ were considered to be statistically significant. Data are expressed as mean ± SEM.

Results and Discussion

The prolonged dietary supplementation with *P. acidilactici* CNCM MA18/5M from the beginning of larval feeding (PROBIO) equaled CTRL group in terms of growth ($p = 0.372$) after the first temporal frame (live-inert cofeeding) (Table 1). These results report evidence on the capacity of the bioencapsulated probiotics in live food to provide similar growth rates upon the end of weaning when compared to tanks in which live feeding was enriched using a commercial enrichment product (SELCO®) in *S. senegalensis* specimens. In the second temporal frame involving inert feeding exclusively (90 dph-150 dph) the statistical analysis did not report significant differences ($p = 0.0720$) between CTRL and PROBIO (maintaining probiotic supplementation with probiotic-coated pellets) although a higher mean SGR value was registered in this experimental group (Table 1). Overall, taking into account the complete trial, up to the last evaluated sampling (150 dph), a significant increase ($p = 0.037$) was reported in the growth values in the PROBIO tanks (Table 1). It is our purpose to maintain constant probiotic supplementation during more months to monitor the evolution of growth, as well as other indicators such as gonad development. So far, our data provide clues indicating the potential positive effect of constant probiotic supplementation in the culture of Senegalese sole, which may be the starting point for the development of new specific feeding programs based on this approach.

(Continued on next page)

Table 1. Growth performance of *S. senegalensis* cultured with the two experimental feeding programs: control (CTRL) and long-term supplemented with *P. acidilactici* CNCM MA18/5M (PROBIO) during the three studied temporal frames in the culture. Data are expressed as mean ± SEM. Mean values with different superscript letters in the same column were significantly different among treatments ($p< 0.05$)

	SGR (%)		
Experimental Group	**Live-inert cofeeding (up to 90 dph)**	**Inert feeding (90-150 dph)**	**Complete trial (up to 150 dph)**
CTRL	10,839 ±0,057[a]	2,925 ±0,147[a]	7,495 ±0,089[a]
PROBIO	10,929 ±0,068[a]	3,541 ±0,207[a]	7,807 ±0,048[b]

MARINE FINFISH AQUACULTURE, ANTIBIOTICS AND ESCAPED FISH: THE ELEPHANT IN THE ROOM

J.M. Valero-Rodriguez*; P. Sanchez-Jerez; K. Toledo-Guedes.

Department of Marine Sciences and Applied Biology, University of Alicante. Alicante, Spain
* Email: Juanma.valero@ua.es

Introduction:
Climate change is profoundly affecting worldwide aquaculture. For example, heat waves could increase the incidence of diseases that could be typical of warmer environments. The use of antibiotics to treat individuals in the culture may be associated with a risk (Dang *et al*. 2021). Extreme meteorological events can also occur as a result of this global change, leading to damage in facilities, breakage of networks and, consequently, escapes of individuals from aquaculture farms (Callaway *et al*. 2012). These escapees can be caught and misclassified as wild product by local and recreational fishermen and depending on the timing of the event, considerable amounts of antibiotics could reach consumers as a result (Figure 1). This study focuses on identifying critical points and suggesting management measures than may be used to face possible harmful consequences derived from these events. We try to convey the need of a modern prevention and mitigation approaches to ensure safety for all consumers.

Materials and methods:
An initial set of searches using ISI Web of Science and Google Scholar catalogues were done between March & June 2021 using search strings aimed at different objectives. The first search string was aimed at identifying the current state of influence that climate change has on the aquaculture industry, as well as the relation between warmer temperatures, illnesses emergence and escape events. The second and third search strings were aimed at pre- and post-escape management measures and their current trends. Some publications missed by the initial search were provided by experts in the field or discovered by reading the full reference lists of all articles that provided relevant data, as well as review articles on related topics.

Results:
A total of 500 papers and reports were thoroughly examined. More than 50% of the selected papers were based on experiments located in Asia, 25% from Europe, 6% from Oceania, 9% from South America and 10% from North America. More than 40% of the papers delved on the detection of antibiotics resulting from aquaculture activities and 40% of them looked for methodologies for the bioremediation and/or reduction of the amount of said substances. While 40% of the papers collected explored the methodologies involved in good practices to avoid aquaculture escapes, only 20% of the papers mentioned the effect of climate change on antibiotic presence in the environment.

On the one hand, we compiled information and suggested improvement measures regarding current trends aimed at the decision-making process for the aquaculture facilities location. We also delved on the rationale of antibiotics use in cultured species and suggested alternatives with less associated risk, such as vaccination.

On the other hand, we identified knowledge gaps within: the development of management plans focused on the contingency of escaped specimens; the refinement of good practice manuals on culture management; early detection measures; preparation of recapture plans; communication networks that notify local authorities about the escapees and traceability of the amounts of antibiotics that reach local markets in the form of poorly labelled fish.

Guidelines and conclusions:
This work showed the need for improvement in different areas aimed at avoiding unwanted quantities of antibiotics from reaching consumers. Regarding prevention work, a series of measures were suggested based on the data found. E.G.: while countries such as Norway are very experienced in implementing preventive vaccines, others are still using large amounts of antibiotics with their cultures, showing a time lag relevant in our globalized world. Likewise, the fact of restructuring the data used in the site selection systems is necessary to incorporate useful information related to climate change that could lead to a full prediction model. Data conveying frequency of thermal anomalies could be an applicable example. Likewise, post-escape measures such as mitigation and management plans or the traceability of escaped fish likely to contain significant amounts of antibiotic must be improved to ensure the sale of a safe consumable product. Ultimately, only the combination of improved pre- and post- escape measures can minimally ensure a risk- free quality product.

Introduction
The increased global demand for food and feed combined with a changing climate confronts societies with the challenge to develop Climate Smart Food Systems. Increased food production has to be achieved in the context of a growing set of climate change-related risks, competition for space, scarcity of resources and the need to preserve the world's ecosystems. In recent years, there has been significant interest in the potential contribution of marine lower trophic species, including seaweeds, in such Climate Smart Food systems, for multiple reasons.

The growth of the global seaweed sector, already a source of income to farmers in moderate and tropical regions and now expanding to other regions, is fuelled by the development of (new) applications of seaweeds in food, feed, cosmetics and pharmaceuticals (Buschmann et al. 2017). Seaweeds not only can help meet future food demand – locally and abroad – they can also play an important role in stimulating food production on land and at sea, and contribute to the provision of ecosystem services, including climate mitigation. On land, marine resources can assist with improving soil quality and terrestrial production system efficiency, for both crops and livestock (Abbott et al. 2020; Seghetta et al. 2017). At sea, marine resources can increase nursery habitats and provide valuable ecosystem services such as CO2 and mineral fixation, nutrient recycling, and long term carbon storage (Froehlich et al. 2019; Duarte et al. 2017).

The valuation of such ecosystem services can support the seaweed farmers in setting up their business case for seaweed cultivation and can also be an additional source of income in low-income countries (van den Burg, Dagevos, and Helmes 2019; Hasselström et al. 2020). In this line of reasoning, various initiatives such as Seaforester and Oceans2050 emphasise the value of restoring global kelp ecosystems.

Objective
This study provides a realistic perspective on the role of seaweeds in a future Climate Smart Food system. It identifies different pathways for climate mitigation, opened up by seaweed cultivation and use. For each of the identified pathways, we review the evidence base and identify challenges and risks. Furthermore, the pathways are discussed in the light of the organisation of current seaweed value chains and economic feasibility, currently and in the foreseen future. The study concludes with recommendations for business and government to advance the role seaweeds.

Methodology
The study pulls together information from two multidisciplinary research programmes: "Towards a circular and climate positive society: Marine Resources" and "Safe Seaweed by Design". The first phase involves a review of literature on the role of seaweed in climate mitigation, including Life-Cycle Analysis and Blue Carbon literature. In the second phase, identified pathways are evaluated, using economic models and literature.

Intended output
The results from the study will support development of seaweed application possibilities in future Climate Smart Food systems. It will also be used to inform policy decisions in meeting goals set out under EU strategy to Sustainable development for climate smart food systems and circular economy.

Atlantic salmon (*Salmo salar)* is an anadromous salmonid of high economical value globally. Since it is a nutritious food product, Atlantic salmon contributes significantly to economic and employment security in many countries worldwide. With aquaculture being one of the most rapidly expanding food production sectors, the global salmon production in 2019 reached approximately ~2.6 million tons. For salmons, entry into seawater is a crucial part of their life cycle and a critical step in production. A high pathogen pressure in the marine environment combined with a suppressed immune system of the fish results in a higher susceptibility to infections and diseases. Fish welfare is recognized to be essential for high product quality and a good health status. Stressed fish commonly have poor health and performance. Monitoring fish health status by measuring gene expression of biomarkers could be a useful tool to take measures for stress reduction. Microalgae are considered to be promising functional feed ingredients, as they have beneficial effects on immune status. Knowledge on the immune-promoting and stress-compensatory effects of microalgae diets in Atlantic salmon remains however limited.

This study aims to investigate the transfer into marine farming systems and the influence of microalgae diets as probiotic feed on the expression of genes functioning as biomarkers for fish health status. The Biomark HD/Fluidigm test system is used for multigene expression analysis. The results from this study will identify the most promising microalgae candidates and help the development of a BioChip indicating fish health status. Since NF-kB inhibitors emerged to be important immune regulators, these molecules will be analyzed in more detail.

Introduction

Using breeding programs to reduce feed conversion ratio (FCR), namely the ratio between feed intake (FI) and body weight gain (BWG), could highly strengthen aquaculture sustainability. However, selective breeding programs require phenotyping individual FCR, and thus FI, on a large number of fish, which is particularly challenging. A solution is to rear fish in individual aquaria and collect uneaten pellets (Besson et al., 2019). In literature, this method is exclusively used on juvenile fish for practical reasons. Estimating individual FCR beyond juvenile stage is, however, critical since much more feed is consumed during the later stages of growth than during the younger stages. Determining whether FCR estimated at a young age accurately predicts FCR at commercial size has major implications for the design of selective breeding program. In particular, when individual rearing is used, labour costs and space needed would be much lower to individually phenotype juvenile fish rather than fish at commercial size. Selecting male Nile tilapia on their FCR estimated over only two weeks might permit to improve the whole production cycle FCR by about 1% per generation with a 50% selection intensity (Rodde et al, 2020). However, these results were established on only 30 male tilapia and needed to be confirmed on more individuals, including females. In the present study, 60 fish (30 females and 30 males) were reared over 30 weeks and we assessed whether phenotyping individual FCR over only two weeks could accurately predict individual FCR over the 30 weeks.

Material and methods

Animals were originating from the 18th generation of GIFT (Genetically Improved Farmed Tilapia) produced from the 4th March to the 4th April 2019 at the WorldFish Research Station in Jitra (Kedah State, Malaysia). On the 22nd of July 2019, fish were isolated in 10 L aquaria part of a same water recirulating system. Over the whole experiment, fish were fed a commercial diet (Cargill®) to 90% of the optimal feeding rate to reduce feed wastage, as explained in Rodde et al (2020). After two weeks of acclimation, the experiment started on the 5th of August 2019 (35.3 g and 35.5 g for females and males BW, respectively). On the 14th of October (around 90 g), fish were transferred to individual 60 L aquaria to provide them extra space to grow. The experiment ended after 30 weeks, on the 2nd of March 2020, once fish at commercial size (342.7 g and 288.4 g for females and males BW, respectively). Each fish was anaesthetized with clove oil once a week and weighed to adjust feed ration. Every day, uneaten pellets were removed from the aquaria at least two hours after the last meal and counted to estimate the total amount of feed wasted by each fish. Body weight gain, FI and FCR were calculated over 15 two-week periods. The FCR was also estimated over the 30 weeks of the experiment (global FCR named "FCRg"). Individual FCR measured over the two-week time steps and FCRg were normalized using log-transformation (lnFCR and lnFCRg) and Pearson's correlation between each two-week period lnFCR and lnFCRg was estimated. Then, the potential genetic gain on FCRg was compared when fish were selected for i) FCRg directly and ii) FCR estimated over a two-week period as an indirect selection criterion. To perform this simulation, selection intensity was set to 50% (the 15 best females and males were selected) and heritability was set to 0.32 as estimated for juvenile FCR in GIFT Nile tilapia by de Verdal et al. (2018).

(Continued on next page)

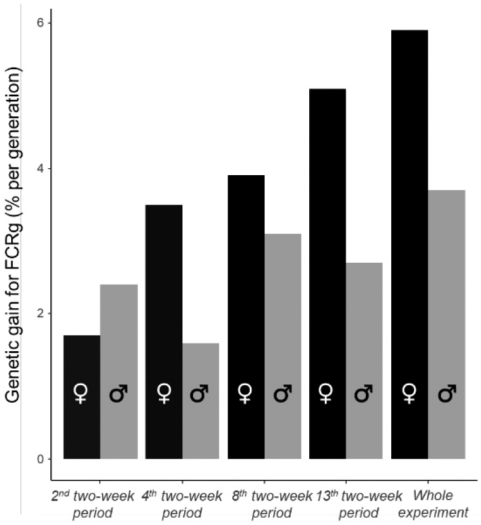

Figure 1 Genetic gain for FCRg depending on various selection periods

Results

In total, 30 females and 29 males were successfully phenotyped. FCRg was 1.87 ± 0.44 (CV = 23.4%) and 1.94 ± 0.33 (CV = 16.7%) for females and males, respectively. When including both females and males in the analyses (n = 59), lnFCR appeared to be significantly correlated with lnFCRg over 14 two-week periods out of 15 (r = 0.26-0.75 for significant correlations). For females and males separately, lnFCR and lnFCRg were significantly correlated over 11 and seven periods, respectively (r = 0.48-0.88 and r = 0.39-0.82, respectively). Projections revealed that direct selection on FCRg would improve FCRg by 5.9 and 3.7% per generation for females and males, respectively (Fig. 1). In comparison, selection on FCR on the 4th two-week period (worst correlation, r = 0.26) would improve FCRg by 3.5 and 1.6% for females and males, respectively, whereas selection on FCR on the 13th period (best correlation, r = 0.75) would improve FCRg by 5.1 and 2.7% for females and males, respectively (Fig. 1). Two other simulations were made selecting on the 2nd and the 8th periods to balance correlations of respectively r = 0.40 and 0.65 with time to wait before performing selection. An improvement of FCRg by 1.7 and 2.4% was projected for females and males, respectively, for the 2nd period, and by 3.9 and 3.1% for females and males, respectively, for the 8th period (Fig. 1).

Discussion and conclusions

These results suggest that estimating the FCR of juvenile tilapia over two-week periods could be relevant to perform a selective breeding program for FCRg at lower costs in both female and male tilapia. Genetic gains projected here were higher than the 1% per generation estimated in Rodde et al. (2020), this being explained by both stronger correlations between lnFCR and lnFCRg and higher variability of FCRg (the CV of FCRg was only 10.8% in Rodde et al., 2020). The impact of individual rearing on fish performance remains, however, debatable. Moreover, the heritability of 0.32 used here and published by de Verdal et al. (2018) was estimated over only one week at juvenile stage with fish reared in small groups, which differs greatly from experimental conditions presented here.

Introduction

Greater amberjack (*Seriola dumerili*) is considered an excellent candidate for the diversification of Mediterranean aquaculture species due to its fast growth rate, adaptability to intensive culture conditions, its excellent flesh quality, its global market recognizability and high market price. Aquaculture of greater amberjack was established in Japan and later adopted in European countries (Sicuro & Luzzana 2016). Although significant scientific progress has been made globally concerning the rearing and reproduction of greater amberjack, important steps of the production process, such as nutrition, need further development. Innovative semi-moist feeds are very promising showing improved KPIs in commercial scale (moisture 20-30% compared to conventional extruded feeds with <10%). Semi-moist feeds result in enhanced digestion process and better utilization of feed nutrients due to the reduced time required for intestinal hydration compared to the standard dry pellets (Ruohonen et al,1997). This type of feed is also used in Japan for Japanese amberjack (*S.quinqueradiata*) (Sicuro & Luzzana 2016).

Materials and methods

Two experimental trials were conducted with the first one carried out in the facilities of the Hellenic Centre for Marine Research, Institute of Marine Biology, Biotechnology and Aquaculture in Athens. Greater amberjack of an initial body weight of 83.9±11.6g were obtained from Argosaronikos Fishfarms S.A. and distributed in groups of 20 fish in 9 cages (three replicates of each treatment) of $1m^3$ capacity. Conventional feed, specially designed for greater amberjack, was modified to three different levels of moisture content (Table 1). Fish were fed the experimental diets *at libitum* three times per day. Temperature ranged between 24-26 °C.

The second trial took place in Argosaronikos Fishfarms S.A., in Salamina. Eight thousand fish with an initial body weight of 125±10g were used for the validation of the selected lab scale diet. Four cages (two replicates) were used with approximately two thousand fish per cage. Both experimental diets were produced with extrusion, a commercial feed with 8% moisture content and a semi-moist feed with 20% moisture (Table 1).

Results and Discussion

The results of the first trial showed a positive effect of moisture content in growth performance and feed utilization (Table 2). Specifically, feed consumption had a positive correlation with the increase of moisture content, this was observed for other species too (Ruohonen et al.1997). Correlation was equal to R=0.912. Higher feed consumption (in dry matter) had as result the increase of final body weight for fish fed semi-moist diets (13.9 & 23.8%). Specific growth rate (SGR) showed significant differences between the groups fed the experimental diets compared to those fed the conventional moisture feed. A trend was observed for better feed conversion ratio (FCR) for fish fed the experimental diets with P=0.055. The field trial validated the aforementioned results (Table 2). Fish fed the semi-moist feed gained more weight compared to those fed the conventional moisture feed. Showing significant higher SGR for experimental population fed the semi-moist diet compared to those fed the conventional feed. No significant differences were observed in FCR between the experimental groups. Although feed consumption was lower for groups fed the semimoist feed, those populations performed higher final weight. Similar results with both trials were also observed by Papadakis et al. 2008 for the same species.

Introduction

Several scholars have deepened the analysis of consumer behaviour towards fish products and many determinants of choice have emerged (Carlucci et al., 2015). Many studies have focused on the role of demographic variables (Tomic et al., 2016), highlighting in particular the relevance of age and household dimension (Birch & Lawley, 2012). Among the most considered aspects in empirical surveys, the perception of health benefits is considered as one of the promoting factors that could explain fish consumption patterns (Neale et al., 2012). As well, the issue of perceived convenience or discomfort of fish has often emerged as influential in consumer choice (Cosmina et al., 2012). Although there is a high propensity for the purchase of fresh products by most consumers (Neale et al., 2012), numerous empirical evidences have observed among the barriers also the perceived difficulty in preparing fresh fish has an influence negative on purchasing behavior (Altintzoglou et al., 2010). Origin and production methods are considered among the most important attributes in food preferences, also in the case of fish products (Mauracher et al., 2013), and as well, great attention is given to nutrition claims and sustainability labels (Menozzi et al., 2020). The agroecological context exert at the same time an influence on consumer habits, showing for example how consumers who traditionally live in areas fish-oriented people prefer to eat unprocessed seafood products (Tomic et al., 2016). The role played by the main factors contributing to consumer awareness complete the general framework, which include trust in information sources (Pieniak et al., 2007), self-efficacy in quality assessment (Sveinsdóttir et al., 2009) and the ability of quality signals to provide accurate information (Adinolfi et al., 2011). Price is still little explored in the study of fish consumption behaviour, since the quantity of different species and the wide range of their prices make it difficult to perform any assessment (Neale et al., 2012). However, empirical evidences show that fish is widely perceived as more expensive than other sources of protein and particularly meat (McManus et al., 2012) although there is little certainty about how this perception affects purchasing behaviour towards fish and fish products (Khan et al., 2018).

Aim

The analysis of this consumer survey collected the main factors influencing the consumption of fish products from the literature. The empirical review is aimed to determine how these factors impact on the consumption of seabass and seabream (BB) determining homogeneous groups of consumers.

Method

Cluster analysis techniques have been commonly used by economists to investigate the characteristics and motivations of food consumers and it's one of the most widely used methods in marketing research. The segmentation of consumers into different homogeneous groups allows consumers' behaviour to be summarized in a limited number of distinct consumption profiles. Vanhonacker et al. (2013) investigated consumer behaviour towards fish products using this method. A survey was conducted as part of the Horizon PerformFISH project, which gathered relevant information on consumer decision making, in order to explore the behaviour of Italian consumers towards BB products. The application of the MCA-CA (multiple correspondence analysis-cluster analysis) algorithm allows to define typological groups based on previously selected dimensions corresponding to the survey section.

Results

The analysis showed 9 different consumer groups shown in the following image.

Introduction

The success of aquaculture not only depends on the use of sustainable protein sources, but also on the ability to produce high quality products. From a commercial viewpoint, flesh firmness is one of the most appreciated characteristics, and it is strongly influenced by a set of intrinsic traits such as the number and size distribution of muscle fibres [1]. In addition, both growth performance and muscle protein synthesis are regulated by extrinsic factors including diet characteristics, environmental conditions or stressors [2]. Several studies have demonstrated that plant and animal protein hydrolysates provide bioactive peptides able to confer physiological benefits, through the regulation of gene expression and signalling pathways, making them suitable ingredients for inclusion in aquafeeds with potential advantages on economically important traits such as growth performance, body composition and flesh quality. Although some pathways related to muscle fibre proliferation and hypertrophic growth have been studied in fish and associated to their nutritional status, there is no knowledge on the effects of swine blood hydrolysates (BH) in the regulation of these genes in aquaculture fish species, which were investigated in this work.

Methods

Three fractions of swine BH obtained by autohydrolysis (AH) or enzymatically were selected. The enzymatically obtained BH were further submitted to a micro- (MF) and nanofiltration (NF). Dried hydrolysates were then included in five isolipidic and isoproteic diets for European seabass: a fishmeal (FM) based diet (positive control, PC), a commercial-based diet where 50% of FM was replaced by vegetable proteins (negative control, NC) and three diets where 3% of each BH was added to the NC. Diets were assigned to triplicate groups of 71 European seabass juveniles (initial weight 12.3 ± 1.4 g), and fed to apparent satiation in a recirculating saltwater system (RAS). After 12 weeks, 9 fish per treatment were sampled: fish were softly scaled before taking a cross-sectional slab, that was photographed for determination of the cross-sectional area (CSA). A white muscle sample was collected for RNA extraction, and a small portion of the fillet was frozen in isopentane cooled by dry ice, for histological analysis.

Results

Fish fed NF had similar final weight and length as NC but differed significantly from the PC that had the best performance. Fish fed MF diet had the lowest values for both parameters (MF<AH≤NF≤NC<PC). Regarding muscle cellularity results, MF diet showed significantly smaller white muscle CSA compared to all other diets, and the lowest number of fibres. However, fibre density did not vary significantly among experimental diets. Fibre's diameter mostly varied between 60 and 65 μm, with only 5-7% of them being lower than 20 μm and 3-4% higher than 120 μm. The MF group had the highest percentage of intermediate size fibres (40-60 μm) and lowest percentage of small-sized fibres (< 20 μm) and highest percentage of large sized ones (>120 μm).

MF diet down-regulated gene expression of *myod1*, *fgf4* and *capn1* compared with the PC, and up-regulated *mafbx* and *mymk*; NF diet down-regulated *fgf4, fgf6 and capn1*; while fish fed the AH diet showed no significant differences in the expression of these muscle growth markers compared to the PC group.

(Continued on next page)

Conclusions

Both *myod1* and *fgf4* play a pivotal role in myoblast proliferation and differentiation, and its downregulated expression in fish fed MF suggests an impairment of muscle hyperplastic growth that was further reflected in the lowest number of muscle fibres. This was further supported by the upregulation of *mafbx,* responsible for protein breakdown. However, a possible compensatory growth mechanism was observed through the concomitant downregulation of *capn1* and upregulation of *mymk* suggesting a reduction in muscle proteolysis but increased myoblast fusion. Nevertheless, these compensatory mechanisms were not sufficient as the MF group presented the worst growth performance. Fish fed the AH diet, despite showing a reduced growth compared to both controls, did not show any change in the expression of growth markers in muscle. But fish fed NF showed a significant downregulation of *capn1* compared to both the PC and the NC diets, which seems to have a pivotal role in supporting muscle accretion and final muscle cross sectional area.

In conclusion, different swine blood hydrolysates (BH) regulate muscle growth through the expression of genes either involved in myoblast proliferation, differentiation and fusion or muscle atrophy.

Introduction
Sea urchin gonads have been increasingly demanded, for their unique organoleptic properties. Therefore, urgent action is needed to protect this species and its natural habitat, being echinoculture a potential solution to this problem. In fact, in the past years, feasible ways of producing sea urchins with marketable gonads, namely *Paracentrotus lividus*, have been studied. The market price and consumers' acceptability of cultured sea urchins' gonads are influenced by sensory traits. Colour is a highly important feature, since it is the first stimuli presented to the consumer, therefore, a major influencing factor in marketability. Echinenone is the most abundant carotenoid in the gonads and its deposition depends on availability, uptake and bioconversion of β-carotene from dietary sources (Symonds et al. 2007). In this study, the effectiveness of an extruded diet supplemented with a natural source of β-carotene was evaluated after 4 and 8 weeks of feeding.

Materials and methods
A control diet (CTRL) was formulated and compared to an isonitrogeneous and isoenergetic diet (DUN), containing *Dunaliella salina* (1.5% inclusion) as a natural rich source of β-carotene. The diets were cold extruded (<30 °C) and softly dried (<45 ºC). The diets were distributed every 48h, during 8 weeks, to triplicate groups of sea urchins, placed in plastic mesh cages in a saltwater recirculation aquaculture system (RAS) with a stocking density of 3.0 $kg.m^{-2}$; temperature 15.4 ± 0.7 ºC, salinity 33‰, and a 10h L/14h D photoperiod. After 4 and 8 weeks of feeding, 4-5 sea urchins per tank were individually weighted, measured, and gonads sampled for texture and colour evaluation (lightness, redness, yellowness, chroma and hue angle, *i.e*. L*, a*, b*, C* and h* respectively) using CIElab colour space.

Results and Discussion
The tested diets were well accepted by the sea urchins. Feeding the sea urchins for 4 weeks did not produce a significant increment in GSI. However, GSI increased significantly from 8.1 to 16.1 in females and from 9.4 to 16.9 in males, after 8-week of feeding the experimental diets. No differences could be observed among diets for GSI values. After 8 weeks of feeding, female from DUN group showed significantly higher a*, but lower L*, b* and h*values than those from the CTRL. In males, a significantly higher b* value could be observed in gonads from DUN group compared to those from the CTRL. Gonads resilience and firmness did not vary among dietary treatments. To ascertain whether the gonads from DUN group would be accepted by consumers, the results were compared with previous studies performed with *P. lividus* (Baião et al. (2021) which gonads were scored 8 (from 1-9) in acceptability by the consumer (ACC8)). The C* value of females fed DUN diet was similar to that of ACC8, showing a high similarity. Moreover, L* value was lower whilst the a* value was higher than those observed in ACC8 gonads, which are reported as favourable features. Resilience was also improved in DUN fed urchins. In males, gonads were very similar to those highly scored by consumers (similar CIElab values).

Conclusion
The tested diets were able to successfully enhance gonadal growth in both sexes during the 8-week growth trial under a recirculation pilot-scale system. When considering consumers' demands reported by Baião et al. (2021), lower L*, but higher a*, b* and resilience values were related to more appealing gonads. The present results clearly showed that DUN diet is effective in producing gonads corresponding to such quality traits that will be highly accepted by consumers.

Introduction

Algae have become almost 30% of the 120 million tons of global aquaculture production in 2019. The microalgae stand out in the use as functional foods or dietary supplements and extraction of bioactive compounds (Barkia *et al*., 2019). In fish feed, these theoretically provide the necessary amino acids, beneficial polysaccharides, fatty acids, antioxidants, vitamins, and minerals, becoming promising candidates for the reduction or replacement of fish meals and also fish oils. However, their incorporation either as direct feed ingredient or in its defatting forms as a co-product for the human industries has not met the expectations. Nowadays, their incorporation seems limited as additives with moderate levels of inclusion (2.5 to 10 mg/kg) (Milad *et al*., 2016; Abdulrahman *et al*., 2018). Different microalgae factors (cultivation conditions, processing, physiological state, bioavailability, digestibility, etc) have been directly associated with poorer and different results in fish trials, part of which stems from fish species and culture conditions. In addition, their high cost of production together with the above mentioned has slowed down their incorporation in aquaculture with respect to what was initially expected and desired. Therefore, research into new processing techniques to improve the use of microalgae in fish nutrition is mandatory and can also help the necessary sustainability of this industry. Nowadays, *Isochrysis* sp. (ISO) is one of the most experienced and important microalgae due to its physiological characteristics and nutritional value that confers antioxidant, antibacterial, and immunomodulatory effects. ISO fat is widely used in cosmetics and as a feed supplement, being the remaining by-product usually discarded as residue. In aquaculture, some investigations for the substitution of fish oil and fish meal as additives with non-moderate amounts of ISO reported adverse effects that compromise fish health and welfare. Due to the observed effect of the microalgae as is in fish nutrition, and the globally increased amount of its defatted by-products derived from other industries, it is becoming interesting to consider them as novel aquafeed materials. The aim of present study is to theoretically compare and discuss biochemical properties and benefits for the ISO by-products against the raw ISO, and biotechnological needs to improve their use in the near future.

Material and Methods

Processed: ISO and CO-ISO were obtained from the Biotechnology Department (ITC, Canary Islands), the latter obtained after fatty acid extraction process by supercritical CO_2 extraction from the raw correspondent ISO.

Biochemical analysis: The proximate composition of the ISO and CO-ISO (moisture, ash and crude protein) was determined according to AOAC protocol (2000). Lipids were determined according to Folch *et al*. (1957). Amino acid profile was analysed by HPLC according to the EU rules (ISO 13903:2005; EU 152/2009).

Results

CO-ISO has a lower percentage of lipids, proteins (8.22 and 36.71% respectively) and amino acids (table 1) but an increase in ash (14.02% table 1) compared to ISO. A priori this may be a disadvantage, however, it has been seen that percentages of 5 and 10% of ISO inclusion in feed for *Seriola dumerili* can cause negative effects on animal growth and health (Ventura-Castellano *et al*., 2019) and its substitution by CO-ISO can allow good growth performance and animal welfare (Ventura-Castellano *et al*., 2021). Due to the negative effect on the parameters analysed in the diets with ISO, which could be associated with an excess of fucoxanthin and the fatty part of it, an optimized approach would be the use of CO-ISO. Even so, the accessibility, bioavailability, digestibility, and utilization of aa, lipids, carbohydrates, and other bioactive of this by-product and microalgae could be improved by means of pretreatments based on the combination of different biotechnological techniques for their degradation, once again without losing sight of the use of waste from other industries to mitigate climate change and achieve a circular economy.

Introduction

The multi-use concept for the North Sea, encouraged by the European Union, have brought up new commercial opportunities for the offshore and aquaculture sectors. The European Horizon 2020 UNITED (Multi-**U**se offshore platforms demo**N**strators for boost**I**ng cost-effec**T**ive and **E**co-friendly pro**D**uction in sustainable marine activities) project (UNITED 2021) appears as a joint effort between research and industrial partners to enhance aquaculture in the vicinity of offshore wind turbine parks. One of the activities within the UNITED project was the design of a seaweed cultivation net system for *Laminaria saccharina* (the design is owned by Offshore Seaweed Systems; Offshore Seaweed Systems 2021). The system will be installed at the FINO3 research platform (FuE-Zentrum FH Kiel GmbH 2021), located 45 nautical miles offshore in the German part of the North Sea. As part of the design process, a numerical study of a simplified seaweed cultivation net system was performed using a lumped-mass approach numerical model to evaluate the dynamic behaviour of the system subjected to waves and currents induced loads.

Theoretical Background

The two key parameters when modelling seaweed net systems is to correctly capture the hydrodynamic interactions of the net and the seaweed with the incident flow, respectively. The former has been studied mainly for fish nets by means of experimental testing (DeCew et al. 2010) and numerical models based on dynamic 3D models (Lader and Enerhaug 2005) and the lumped-mass approach (Cifuentes and Kim 2017). Cifuentes and Kim (Cifuentes and Kim 2017), adapted the experimental drag coefficient formula estimated by DeCew and Tsukrov (DeCew et al. 2010) validating it with experimental results improving the dynamic 3D models by addressing the influence of net solidity, , and Reynolds number, .

The latter has focused on experimentally obtaining the drag coefficients of a single blade of seaweed subjected to an unidirectional flow on a wave flume (Vettori and Nikora 2019). However, these experimental studies do not represent the behaviour of a net full of seaweed. To solve this limitation, the authors of this research propose to consider the growth of the seaweed in the net as biofouling on the net structure. Therefore, the drag coefficients of the net and seaweed combination will be adjusted based on the thickness of the seaweed following the recommendations of the DNV OS 301 (DNV GL 2018) for marine growth.

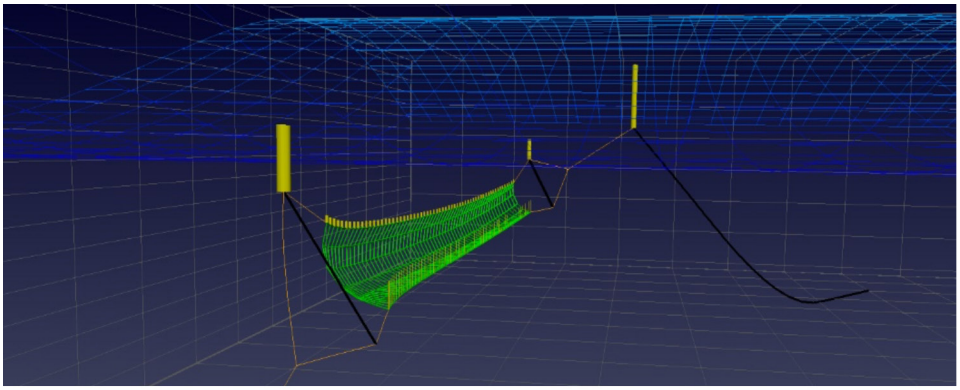

Figure 1 Snapshot of hydrodynamic calculation for $H = 14.5\ m$ and $T = 12.1\ s$.

(Continued on next page)

Numerical model

The numerical calculations have been performed using the in-house developed mooring dynamic solver MoorDyn-UGent, based upon the open source code MoorDyn (Hall 2017) and adapted by Pribadi et. al (Pribadi, Donatini, and Lataire 2019). A numerical net of 30 m length and 3 m width (for the cultivation of *Laminaria saccharina*) installed vertically supported by different buoys and clump weights has been modelled and subjected to different wave and current combinations. The net has been discretized as a combination of cylindrical elements with two mesh sizes: i) equivalent to the real net (0.5 m x 0.5 m) and ii) coarser than the real net (1.0 m x 1.0 m). The drag coefficient of the net and seaweed combination has been obtained using the adapted formula of Cifuentes and Kim (Cifuentes and Kim 2017), corrected with the DNV OS 301 (DNV GL 2018) standards.

Results

Figure 1 shows a snapshot of the hydrodynamic simulation for a wave height, , and a wave period, , with a net discretization of 0.5 m x 0.5 m. In the numerical study performed it was observed that the numerical net discretization does not affect the tensions calculated on the anchor lines of the simplified seaweed cultivation net system. Furthermore, it was noticed that at the test site location, the major part of the load suffered by the system origins from the wave-induced hydrodynamic loads with a small contribution of the current-induced load.

Discussion and conclusion

A new numerical approach for calculating the mooring line tensions of a seaweed cultivation net system has been presented. This numerical approach is based on considering the growth of seaweed as fouling over a net following the DNV-OS 301 recommendations for cylindrical elements. The numerical results presented in this abstract will be validated against experimental data gathered during the UNITED project to assess the applicability of the numerical approach.

OYSTER PRODUCTION IN A MAN-MADE SALTWATER CREEK SYSTEM IN THE NETHERLANDS

G.P. Verbeeke*, E.P.A. Merks, L. Sanders, A.C. Lataes, J. van Houcke

HZ University of Applied Sciences, P.O. Box 364, 4380 AJ Vlissingen (The Netherlands)
Email:gabrielle.verbeeke@hz.nl

Introduction

In the Netherlands traditionally two main sites are used for oyster production: Lake Grevelingen and the Eastern Scheldt. Production in these systems have their challenges as food availability is low and competition high in the Eastern Scheldt, while in Lake Grevelingen water quality issues arise occasionally. The sector is therefore looking for additional cultivation sites. Recently a man-made saltwater creek system was constructed as a new nature reservation area in the Southwestern part of the Netherlands. Within the 300 ha area approx. 30 ha is designated for aquaculture activities. In 2020 first experiments focusing on the oyster production potential within the area started. As growth of oyster is dependent on the environmental circumstances (Barillé et al., 1997; Bernard et al., 2011; Cognie et al., 2003; Palmer et al., 2021) the system characteristics were also investigated.

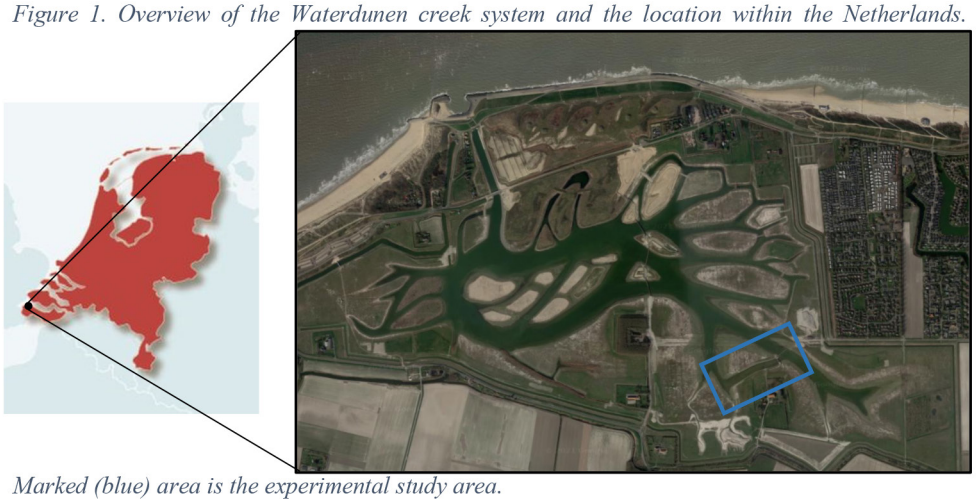
Methodology

The Waterdunen area, a man made saltwater creek, is located near Groede, The Netherlands. The creek system is fed by North sea water through culverts that dampen the tide. The system is exposed to a tidal curve of approx. 1.2 m. At the end of the 3.2 km creek system a 7.500 m^2 experimental location has been developed. At the inlet of this area three paddlewheels are able to increase the flow through of oxygen rich water.

System characteristics were investigated using continuous data loggers (water temperature, dissolved oxygen, chlorophyll, turbidity and flow velocity). Furthermore every three weeks water samples were analyzed for microalgae abundancy during the period December 2020-August 2021.

Growth of the Pacific cupped oyster (*Crassostrea gigas*) at different live stages (oyster spat of 14mm, half-grown oysters of 32.5g and commercial size oysters of 60.3g) was assessed using three oyster cultivation methodologies (off bottom and bags with an inundation time of 16 h. and bags with an inundation time of 12 h.). The growth of oyster spat was assessed every three weeks using measurements of the length of 300 individuals per treatment. Growth of the half-grown and commercial size oyster was assessed using total weight, tissue weight and condition index (AFNOR) every six weeks for 90 individuals per treatment. In addition the growth of on bottom European flat oysters (*Ostrea edulis,* 52.5g) were also assessed using the same measurements and sample size. Mortality of all oyster groups was evaluated over time by counting dead individuals.

Figure 1. Overview of the Waterdunen creek system and the location within the Netherlands.



Marked (blue) area is the experimental study area.

(Continued on next page)

Results

Preliminary results show relatively high chlorophyll content within the water system (3.3 – 16.7 μg L^{-1} December – March) as compared with the main cultivation sites in the Netherlands (0.51 – 4.1 μg L^{-1} and 0.48 – 11.6 μg L^{-1} December – March for Lake Grevelingen and Eastern Scheldt respectively (Rijkswaterstaat, 2021)). Due to the low water column and tidal curve temperature fluctuations can be fast (water temperature of 6.5˚C at 6 February 2021 and 0.5˚C at 12 February 2021).

A clear effect of inundation time on the growth and mortality of all oyster groups was found. Highest growth occurred in the oysters that had the longest inundation time (while these groups showed lowest mortality. Pacific cupped oyster spat started growing within the winter months while half-grown and commercial size Pacific cupped oysters started showing growth in spring. In all cases growth was mainly related to the chlorophyll content in the water. The European flat oysters did not shown any growth and high mortality was found in this group, most likely due to high turbidity in the water column.

Introduction

The European sea bass is one of the most important species of Mediterranean aquaculture with 191,000 tons produced in 2016 (FAO). With a repartition area ranging from the Atlantic Ocean (southern Norway to Senegal) to the Mediterranean Sea, the European sea bass is genetically structured in three populations: Atlantic, West Mediterranean and East Mediterranean (Bahri-Sfar et al. 2000)with the noticeable exception of one Egyptian sample which grouped within the western clade, a fact attributable to the introduction of aquaculture broodstock. No heterogeneity was observed within the western basin ($\theta = 0.0014$ and n.s.. Characterizing these three populations can enable hatcheries to select the breeders with the best genetic background for specific breeding goals and rearing conditions, and thus to speed up genetic improvement. A previous study has investigated phenotypic differences between these populations using a partial diallel design with five natural populations and sub-populations (Vandeputte et al. 2014). In this study we focused on the main three natural populations in a "pure strain" design, to characterize their growth and quality traits with repeated measurements along two years.

Material and Methods

Three groups were produced by artificial fertilization in February 2018. Atlantic (AT) and West Mediterranean (WM) groups were produced by mating wild sires and wild dams from each of the populations in a full-factorial mating design, thus producing pure AT and WM offspring. Equal numbers of eggs from 22 WM dams, fertilized with sperm from 40 WM sires, and eggs from 9 AT dams, fertilized by 26 AT sires, were used. The East Mediterranean (EM) group was produced by mating 39 wild EM sires with 13 F1 EM x WM dams, thus producing 75% EM-25% WM backcross progenies. Each group was reared in triplicate tanks until 244 dph (30g), where 2106 fish were PIT-tagged, mixed and split into three replicate common garden groups. The fish stayed in 1.5 m^3 tanks until 432 dph at an average temperature of 20.9°C, and were then transferred to three 5 m^3 tanks. They were fed *ad libitum* with commercial feed (Le Gouessant Neo Grower) using self-feeders. The temperature was kept at an average of 20.5°C until 704 dph, and then lowered to 15.6°C until 858 dph where all fish were measured for the last time. Body length was measured at 0, 11, 40, 53, 80, 108, 136, 157, 188, 213, 244, 300, 341, 390, 432, 472, 522, 579, 634, 704 and 858 dph, as well as body weight starting at 108 dph, to calculate DGC (Daily Growth Coefficient) following this formula:

$$DGC_i = \frac{\omega_f^{\frac{1}{3}} - \omega_i^{\frac{1}{3}}}{t} \times 100,$$

where ω_f is the final body weight and ω_i is the initial body weight of the fish during a period of t days. Muscle fat content was estimated using a Distell FishFatmeter in the last 8 biometrics. At 864 dph, fish were sacrificed and dissected, their sex was identified and liver, digestive tract and gonads parts were weighed to the nearest 0.1 g. Then, the fish were de-headed, and manually filleted on the left side. Head, left fillet and half-carcass were weighed to the nearest 0.1 g. Liver, viscera, gonads, head, fillet, vertebral axis, carcass and gills yields were calculated. Different types of Anova models were built in order to test the effect of the strains and larval tanks for each biometry. Individual growth and yields were modeled as follows:

$$Y_{ijklm} = \mu + S_i + P_j + t_{k(j)} + T_l + \varepsilon_{ijklm}$$

With the phenotype of fish m, μ the intercept, S_i the fixed effect of sex i with three levels (male, female, unknown), P_j the fixed effect of population j; $t_{k(j)}$ the random effect of initial tank k, nested within population j, with three levels per population, the fixed effect of common garden tank l, with three levels, and ε_{ijklm} the random residual.

(Continued on next page)

Results and Discussion

During the first period of growth after tagging (244-463 dph), there was a highly significant effect of populations on DGC ($P<0.001$) with the highest DGC (1.28± 0.01) recorded in the EM population and the lowest DGC (1.07± 0.01) obtained in the WM population. During the second period of growth (463-704 dph), generally characterized by low growth performance, a significant effect of the populations on DGC was also detected ($P<0.05$) with the same ranking, although differences between populations were much smaller. During the third period (704-858 dph), characterized by a low temperature, the AT population has the highest DGC ($P<0.001$).

On quality traits, Table 1 shows significantly ($P<0.001$) higher head and vertebral axis for the Mediterranean populations compared to the Atlantic population, with the EM population having the highest values. There was a significantly ($P<0.001$) higher viscera yield for Atlantic population compared to Mediterranean populations. Filet yield showed significant differences ($P<0.001$) with means ranging from 55.6 ± 0.7 % (AT) to 57.0 ± 0.7 % (WM).

Conclusion

Most of the traits studied were significantly affected by the origin of the fish (AT, WM or EM). The EM population was found very promising for hatchery production, with fast growth, high carcass and fillet yield, and low fat in the fillet. The AT population was less efficient (poor processing yields and high fillet fat), however this may be due to the high rearing temperatures conditions (>20°C) potentially favouring the Mediterranean populations. Consequently, it would be extremely interesting to test these populations using different temperature profiles, along with robustness in those conditions, as it seems more and more clear that AT fish have a specific adaptation to low temperatures (and maybe a maladaptation to high temperatures).

Introduction

Many aquaculture species, for example penaeid shrimp and several fish species, require microalgae as feed during certain life stages. For bivalves it even constitutes the main feed during their entire life. Growing microalgae can be a burden for individual hatcheries and farms as it requires considerable investment and space, is relatively labour-intensive and not always reliable, resulting in variable quality and sometimes even crashes.

To date several companies worldwide have specialized in producing a variety of microalgae species in systems ranging from open (raceway) ponds to highly advanced photobioreactors. Together with advances in processing techniques they offer (increasingly cost-effective) alternatives to the use of live microalgae.

Despite these advances, the use of processed algae-products in aquaculture to date still seems limited and mostly directed towards production of live feed (*e.g.* rotifers) or inclusion as ingredient in formulated feeds. Only a limited number of publications exist on the use of these processed algae, especially for shrimp. Moreover, algae concentrates and pastes seem to be preferred over dried forms. The latter however have the advantage of being more stable, resulting in easier transportation and longer shelf life making them a convenient product.

In the current presentation we report on trials conducted with different species of commercially available freeze-dried microalgae (Proviron, Belgium), as feed for penaeid shrimp (*Litopennaeus vannamei*) larvae and cupped oyster (*Crassostrea gigas*) spat as compared to live algae. In addition, we adopted RAS technology and an automated feeding unit. We believe these introductions can improve the currently used culture technology, making it more (cost-)effective and reliable, especially in a European context.

Materials & Methods

L. vannamei nauplii were obtained from Imaqua BVBA (Lochristi, Belgium) and stocked in 100-L cylindroconical poly-ethylene tanks at a density of 100-150 larvae. L^{-1} in a temperature- and light-controlled room. The larval tanks were connected to a filter unit consisting of a biological filter and a protein skimmer, allowing to operate the tanks in batch or in RAS. A standard feeding protocol was applied using microalgae at around 100 cells μL^{-1} for zoea stages and introducing Artemia instar I nauplii from the late zoea 3 stage onwards. Suspensions of freeze-dried algae were cooled and automatically fed to the larval tanks at regular intervals using a newly developed dosing device.

Factors tested for shrimp larvae were algae species (*Chaetoceros muelleri* and *Thalassiosira pseudonana*), algae processing (fresh or freeze-dried), water management (batch or RAS) and algae feeding system (manual or automated). Trials were terminated when all treatments reached postlarval stage (10-12 DPH). Evaluation criteria were water quality, larval development, survival to postlarval stage and visual observation (fouling, fecal strings).

For the oyster experiments, *C. gigas* spat (size T2) were obtained from De Oesterput bvba (Ostend, Belgium), and stocked at a density equal to 3 kg per m² in sieves which were hanging in100L cylindroconical poly-ethylene tanks. Temperature was set at 20°C, and a light-dark cycle at 12:12 hours. Three independent recirculating systems (each with drum filter, protein skimmer and automated feeding system) and one batch system (control) operated each with three rearing tanks. Three feeding regimes were tested in the recirculating systems, all consisting of the same three algae species (*Tetraselmis chuii*, *Chaetoceros muelleri* and *Isochrysis galbana*): 100% live algae, 100% freeze-dried algae and a 50:50 mixture. The batch system received live algae only. All oysters were fed 1.5% of the spat wet weight in dry weight microalgae, in a 1:1:1 ratio in algae dry weight. The trial ran for 5 weeks. Oyster growth (shell and meat weight, and shell length), water quality and water mineral levels were monitored and evaluated.

(Continued on next page)

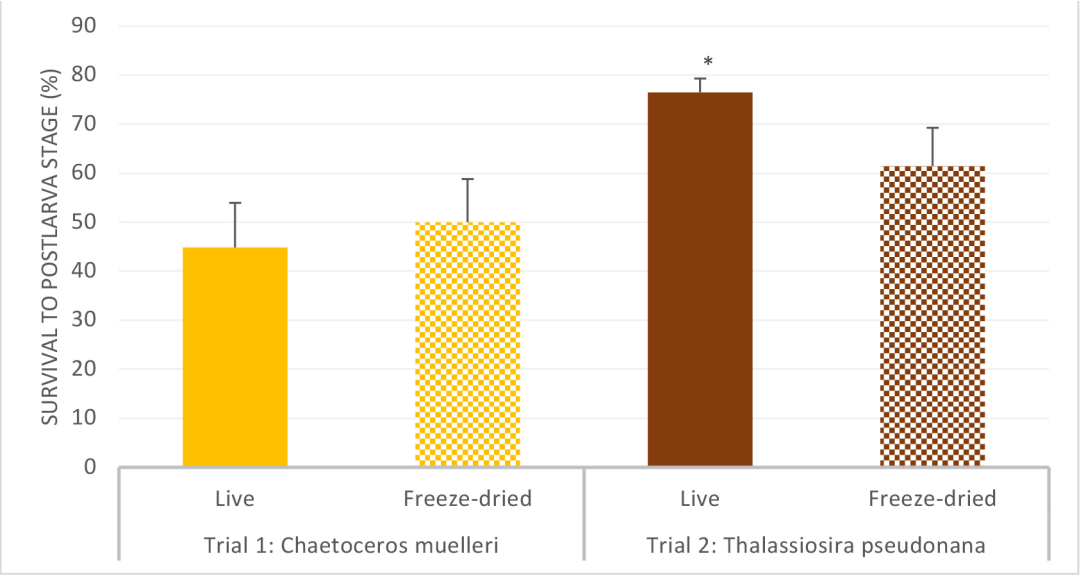

Fig. 1. Survival of shrimp larvae to the postlarval stage, fed either live or freeze-dried *Chaetoceros* or *Thalassiosira* algae as part of their diet. * denotes statistically significant differences between treatments with the same alga species.

In all trials, all microalgae were supplied by Proviron (Belgium), including live *C. muelleri*, *T. pseudonana*, *Isochrysis* sp. Tahitian strain and *T. chuii* and their freeze-dried form, known under the product names ChaetoPrime, ThalaPrime P, IsoPrime and TetraPrime C, respectively. The fatty acid profiles of the different algae were also determined.

Results

High survival (50-61%) to the postlarval stage was obtained for shrimp larvae fed freeze-dried *C. muelleri* and *T. pseudonana* , similar or only slightly lower compared to larvae fed the live form (figure 1). Effects on water quality, larval development rate and external appearance will be discussed as well.

Similarly, results of the trials on (partial) replacement of live algae with freeze-dried algae for *C. gigas* oyster spat will be presented.

Lastly, results on automated dosing of freeze-dried algae in combination with adopting RAS technology, instead of batch systems with manual water exchange (common for shrimp) or flow through systems (common for oysters), will be discussed.

Conclusions

Our study demonstrates that freeze-dried algae can be a good alternative for live algae resulting in almost similar growth and survival for some species. Adopting RAS and automated feeding systems could improve water quality, reduce inputs and overall make aquaculture systems function more autonomously, which is considered especially advantageous for application in Europe.

Introduction

In intensive aquaculture, practical procedures as weighing, measuring, spawning or transport are frequent, which can induce stress in fish and influence their welfare. To minimize these negative effects which can have significant economic impacts, the use of anaesthetics is increasingly recommended. Tricaine methanesulphonate (MS-222) is a synthetic anaesthetic often used in aquaculture and research, however some studies support that this compound may induces further changes on different parameters of the fish welfare. In this sense, it is necessary to find compounds that have anaesthetic properties and are harmless to fish, the environment and the consumer with the purpose of enable safe and sustainable use. Thymol and menthol are natural antioxidant compounds with proven anaesthetic properties in different species. The zebrafish is a teleost fish which has been used as a model fish for aquaculture research. Its larval stages are highly suitable for addressing welfare mechanisms by anaesthetics as most receptors are found after 72 hours post-fertilization (hpf). Therefore, the objective of this work was to evaluate the anaesthetic profile of menthol and thymol and biochemical changes in anaesthetized and recovered animals.

Material and methods

Zebrafish larvae (72 hpf) were anaesthetized with different concentrations of thymol (12.5 – 400 mg L^{-1}) and menthol (25 – 600 mg L^{-1}) prepared in E3 medium (negative control). MS-222 at 200 mg L^{-1} was used as a positive control group. The time it took to lose the ability to swim and the response to a touch stimulus on the tail was registered. Then, the animals were placed to recover in E3 medium and the time until the animals returned to swimming normally noted. After finding the concentrations best suited for aquaculture procedures (induction time be less than 180s and of recovery less than 300s), a new set of animals was anesthetized and collected while others were allowed to recover to evaluate biochemical changes. After 24 and 48h of recovery, the animal's heartbeat was evaluated.

Results

The induction and recovery time of MS-222 was 35.60 (17.00 – 60.45), 86.40 (60.90 – 159.60) seconds, respectively. The natural compounds tested had an induction time very similar with that of MS-222: for thymol 200 mg L^{-1} it was 33.92 (30.00 – 48.83) seconds and for menthol 400 mg L^{-1} it was 21.00 (17.00 – 60.45) seconds. However, the recovery time was higher in all concentrations tested in comparison to MS-222. In the heartbeat evaluation, all animals had a normal heartbeat after 48 hours of recovery. At the biochemical level, larvae under the effect of thymol showed an increase in SOD activity and a decrease in LDH and ATPase activity. After the recovery, there was an increase in SOD activity and a decrease in GSH and GSSG levels and ATPase activity. In the case of menthol, there was an increase in SOD, GST and GPx activities and a decrease in GSH, GSSG, LPO and LDH after induction. After the recovery, a decrease in LPO level and ATPase activity and an increase in ROS, AChE, CarE and GST activities were observed.

(Continued on next page)

Discussion and conclusion

Natural compounds tested showed a good anaesthetic profile similar to MS-222 with a low induction while increased recovery times. No mortality rates were obtained, and no alterations in heartbeat rate were observed. Regarding the biochemical changes observed, the induction of SOD and other antioxidant defences activity by thymol or menthol during and after anaesthesia could be an adaptive response to the stress which neutralizes the impact of ROS generated induced, as described in other studies. LPO reduction with menthol anaesthesia may indicate that the compound used prevents the oxidation process of the lipids present in cell membranes. The decrease in LDH activity in relation to control might represent a reduction of cellular anaerobic processes and a possible reduction of oxidative damage. In general, the antioxidant improvement of defenses seems to be happening for both thymol and menthol.

Though further studies are needed to understand the concentration-time relationship and the physiological changes at these development stages of *Danio rerio* as the literature is scarse, the use of these natural compounds to avoid stress in teleost fish seems to be a very interesting way and with great benefit for both animals and the environment.

Introduction

Marine invertebrates in general and polychaetes in particular, are attracting a great deal of attention as promising candidates for their use as alternative ingredients for aquaculture. Polychaetes are good sources of long-chain (C20-24) polyunsaturated fatty acids (LC-PUFA), especially the so-called "omega-3" (ω3 or n-3) eicosapentaenoic acid (EPA, 20:5n-3) and, to a lesser extent, docosahexaenoic acid (DHA, 22:6n-3). Their nutritional value, along with their detritivorous feeding habits enabling their culture on sidestreams from agri-food industries, has prompted interest to explore circular economy strategies for production of polychaete meals as alternative ingredients to fishmeal for aquafeed formulation [1]. Fatty acid (FA) composition of animals is accounted for by diet and endogenous production (biosynthesis). Interestingly, LC-PUFA biosynthesis can be modulated by diet (nutritional regulation) and environmental factors such as temperature [2]. This offers a great opportunity to establish culture protocols that enhance ω3 LC-PUFA biosynthesis and therefore result in production of highly nutritious polychaete biomasses. The present study aimed to assess the combined effects of diets varying in LC-PUFA composition and temperature on the FA profiles of the nereid polychaete *Hediste diversicolor*.

Materials and methods

To evaluate the combined effects of diet and temperature, an experiment with a multifactorial design testing five diets (see below) and five temperatures (5.8, 9.5, 12.5, 14.7 and 17.1 °C) (25 treatments) was carried out with three worms (biological replicates) each. Five worms from the stock were analysed as a reference at the beginning of the trial (START). Four diets were made up of a mix of two sidestreams. Sludge from salmon farming was used as a base and progressively substituted at 0, 33, 66 and 100 % (AS100, AS66, AS33 and AS0, respectively) by solid phase digestate from biogas production (SBD). Fish feed (FF) was used as control treatment. The worms were placed in individual 800 ml beakers with 8 cm thick sediment layer and were fed for two weeks. Survival and growth data (specific growth rate, SGR) were recorded. At the end of the experiment, the guts were emptied for 4 h before the worms were weighed individually and freeze dried for further lipid and FA analyses. Total lipids were extracted and quantified gravimetrically, and an aliquot was transmethylated to fatty acid methyl esters (FAME), which were analysed using gas chromatography. The results were chemometrically processed using principal component analysis (PCA) (SPSS® Statistics version 27).

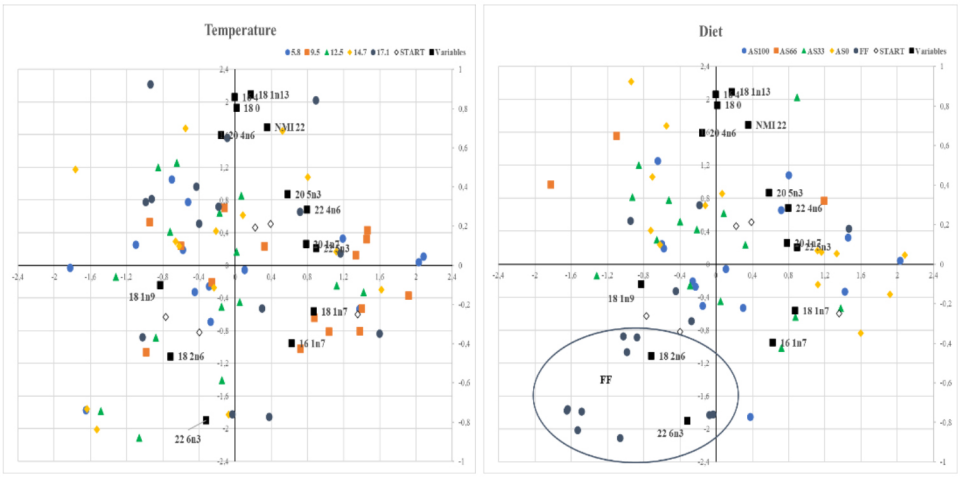

Figure 1. Biplots of the PCA analysis of the fatty acid profiles of *H. diversicolor*. Identification of the scores is based on temperature (left) and diet (right). Temperatures: 5.8, 9.5, 12.5, 14.7 and 17.1 ºC. Diets are named according to the % substitution of biogas sidestream on salmon farming sludge (AS100, AS66, AS33, AS0), FF: fish feed; START: worms at the beginning of the trial.

(Continued on next page)

Results

At the end of the trial no significant differences in SGR were found, with an average value of 1.61 being recorded. Survival was high (88 %) throughout the experiment. Our results did not show any clear effect of temperature on the FA composition of *H. diversicolor*, whereas a clear segregation between the FF group and the other dietary treatments was found. This segregation is mostly associated to the levels of 18:2n-6 (linoleic acid, LA) and 22:6n-3 (DHA) (Figure 1).

Discussion and conclusions

No temperature-driven segregation patterns could be identified in the FA profiles of *H. diversicolor*, which is in agreement with former reports [3]. The present work thus confirms that diet is the major factor influencing lipid composition in this species as reported by [4]. The segregation of the FA patterns of the control (FF) group was associated to LA and DHA, major constituents of fish aquafeeds [1,4]. In fact, the lack of a clear effect of sidestream diets on the FA composition of *H. diversicolor* could be due to the similar profile of the sludge and SBD components, along with their low lipid and FA contents (4-7% and 6-37%, respectively). Worms fed with sludge and SBD contained a high amount of monounsaturated (26%) and unsaturated FA (59%), close to those of the START treatment (27% and 62%), and to values reported by [5] in *H. diversicolor* fed with sludge (25% and 45%, respectively). These results suggested a lipid homeostatic capacity of *H. diversicolor*, based on its biosynthetic capacity, leading to a certain level of trophic upgrading. Dietary effects would be then more evident when the homeostatic threshold is surpassed, for example with lipid and PUFA-rich diets such as FF. The cultivation of *H. diversicolor* using sidestreams is thus promising, and further studies on gene expression underway in our laboratories will contribute to clarify these preliminary results.

Introduction

Aquaculture of carnivorous species is greatly dependent on the supply of marine ingredients, which provide adequate levels of essential nutrients including long-chain (C_{20-24}) polyunsaturated fatty acids (LC-PUFAs), particularly the "omega-3" (ω3) including eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) [1]. Primary production of these compounds was thought to take place exclusively by the action of photosynthetic microalgae, heterotrophic protists and bacteria [2]. However, a study has revealed that multiple aquatic invertebrates including polychaetes possess enzymes that enable them to produce ω3 LC-PUFAs *de novo* and, consequently, their culture with an adequate supply of biosynthetic fatty acid (FA) precursors and enhancing such pathways emerges as a highly innovative strategy to produce nutritious and sustainably sourced ingredients for aquaculture [3]. The capacity by which an animal species can biosynthesise LC-PUFAs depends upon the complement and function of two types of enzymes, namely fatty acyl elongases and desaturases. The aim of the present study was to characterise molecularly and functionally two elongases (Elo) and one front-end desaturase (Fed) involved in the LC-PUFA biosynthesis of the common ragworm *Hediste diversicolor*.

Materials and methods

To obtain the full-length sequences of the *H. diversicolor* Elo and Fed open reading frames (ORFs), BLAST searches were carried out on a raw transcriptome prepared from one single individual. The ORF sequences were identified and then isolated by PCR using *H. diversicolor* complementary DNA (cDNA) as template, with primers containing specific restriction sites for further cloning into the yeast expression vector pYES2. The *H. diversicolor* Elo and Fed were functionally characterised by heterologous expression in yeast. Transgenic yeast containing the different *H. diversicolor* Elo and Fed ORFs were grown in the presence of a series of exogenously supplemented polyunsaturated fatty acid (PUFA) substrates to test their elongation and desaturation capacity, respectively. After 2 d of incubation, yeast were harvested and washed prior extraction of total lipids. Total lipids were used to prepare fatty acid methyl esters for analysis by gas chromatography with mass spectrometry detection (GC–MS). Conversions of PUFA substrates to the corresponding elongation or desaturation products were calculated by the proportion of substrate PUFA converted to PUFA product(s) as [areas of all products /(areas of all products + substrate area)] × 100.

Results

Our results show that *H. diversicolor* has at least two Elo and one Fed with putative roles in the LC-PUFA biosynthetic pathways. We termed them as Elovl2/5 and Elovl4 based on their phylogenetic relationship with well characterised elongases from other animals. Functional characterisation results showed that the *H. diversicolor* Elovl2/5 is indeed a PUFA elongase since elongated PUFA substrates with C_{18} and C_{20}. Similarly, the *H. diversicolor* Elovl4 showed elongation capacity towards C_{18} and C_{20} PUFA substrates but, additionally, C_{22} PUFA substrates (Table 1). Functional characterisation of the *H. diversicolor* Fed1 confirmed its role in the LC-PUFA biosynthesis as it showed this enzyme has Δ5 activity converting 20:3n-6 and 20:4n-3 into 20:4n-6 (arachidonic acid) and 20:5n-3 (EPA), respectively (Table 1). No activities as Δ4, Δ6 or Δ8 were detected (Table 1). Along PUFA substrates, the *H. diversicolor* Fed1 also had Δ5 activity towards saturated substrates such as 18:0, which was converted to 18:1n-13.

Discussion and conclusions

The present work demonstrates that *H. diversicolor* possess at least two distinct elongase genes, namely Elovl2/5 and Elovl4, with putative roles in the biosynthesis of LC-PUFAs. Molecular and functional characterisation of the Elovl sequences from *H. diversicolor* revealed that Elovl2/5 have C_{18} and C_{20} PUFA as preferred substrates for elongation, that is very common in invertebrates [4]. The Elovl4 is able to elongate C_{22} substrates to C_{24} products, and thus compensates for the lack of C_{22} activity within Elovl2/5, as occurs in molluscs [4]. Functional characterisation of the *H. diversicolor* Fed1 Δ5 confirm its role in LC-PUFA biosynthesis. Δ5 desaturases have been previously demonstrated in some molluscs as well as echinoderms [4]. The herein reported results on the functions of the Elovl2/5, Elovl4 and Δ5 desaturase, along with those of the previously characterised methyl-end desaturases [5], clearly show that *H. diversicolor* has a highly diverse repertoire of LC-PUFA biosynthesising genes with complementary activities enabling an active production of these essential compounds.

Introduction

Energy transfer in aquaculture systems depends on the interactions between the biota contributing to the food web, e.g. the culture species, algae, bacteria, and fungi. The interacting biota are part of an ecological trophic cascade exchanging energy and nutrients. The efficiency of energy transfer through the food web can be influenced by the diet and the resulting fecal composition. In Pacific white shrimp culture, when starch dominates the dietary carbon input, the majority will leave the system as CO_2, limiting access for further carbon utilization in the system. Supplementing non-starch polysaccharide (NSP) in the diet results in more carbon retained in the shrimp feces due to its low digestibility in shrimp. However, the heterotrophic bacteria in the rearing tank can utilize this carbon and transfer part of its energy to the food web. Together with algae, heterotrophic bacteria are at the base of the food web. In a biofloc system both biotas are present. This research compared the effect of a high and a low NSP diets on biofloc performance and shrimp production. Furthermore, the study also estimated the contribution of biofloc to shrimp growth reared in biofloc systems by estimating the growth in a zero biofloc system - recirculating aquaculture system (RAS).

Materials and methods

This experiment compared two diets differing in the NSP level: high (NSP) and low (CON). The first mentioned diet contains wheat bran as the NSP source. Two experiments, a growth and a digestibility experiment, were carried out. In the growth experiment, two culture systems were compared (Table 1): biofloc and RAS (with clear water rearing tanks) system, for 6 weeks. The digestibility experiment lasted for 5 weeks and was done only in RAS only. The biofloc treatments were performed in circular 1000-L fiber mesocosm tank in triplicates. The clear water rearing tanks were 120-L aquaria all part of the same RAS, with 4 replicates per treatment. The stocking densities were 100 ind/tank in biofloc tanks, 30-25 ind/aquaria in RAS, both for the growth and digestibility experiment. The shrimp were fed iso proteinic, once daily.

Results

The results showed that NSP diet increased the carbon to nitrogen (CN) ratio of the shrimp feces from 11.8 in CON treatment to 20.5, which later stimulated more biofloc formation ($P<0.05$). The algae concentration in the biofloc at week-6 was higher when shrimp was fed with NSP diet ($P<0.05$). The NSP diet had a lower apparent digestibility coefficient (ADC) of dry matter, protein, energy, carbohydrate, and minerals ($P<0.05$). The experimental diet did not show any effect on the shrimp production ($P>0.05$), but the system did ($P<0.05$), due to the higher stocking density in tanks (Table 2). Feed conversion ratio was higher with NSP diet ($P<0.05$). Biofloc presence as an additional natural food that contributed to an increase of the shrimp biomass by 32% in NSP and 46% in CON diet in BF tanks. The fraction of egested energy stored in shrimp biomass based on biofloc consumption was higher BF tanks fed the CON diet than in BF tanks fed the NSP diet ($P<0.05$). The NSP diet resulted in a 24% higher carbohydrate content in shrimp biomass at harvest ($P<0.05$).Future research should focus on the effect of NSP type in the diet on shrimp performance in biofloc tanks.

Conclusions

- Increasing the NSP content in the diet increases the C:N ratio in the feces.
- Although the NSP diet is less digestible than the CON diet, when fed isoproteinic, the final weight reached was similar, in either RAS or BF system.
- In BF tanks fed the NSP diet, more biofloc was present than in BF tanks fed the CON diet, but shrimp did not realize more growth based on biofloc in NSP fed BF tanks than in CON fed BF tanks.

Introduction

Aquaculture is a process of controlled cultivation of freshwater and marine organisms, mainly for human consumption and the renewal of fish stock [1]. It is highly dependent on the water quality which should be continuously monitored to undertake preventive actions in case of anomalies. Also, special attention should be paid to the environmental effect of aquaculture systems with an aim to reduce it as much as possible [2]. The water quality analysis includes control of several parameters, such as oxygen level, pH, chemical substances and others. Marine pollution is caused by various sources, from ships (e.g. oil spills) to onshore industries (e.g. toxic waste, chemical dissolutions). In case of aquaculture production, the decomposition of fish feed has the greatest impact but the infrastructures themselves also contribute. Materials immersed in saltwater can cause chemical anomalies by their decomposition. This is emphasized in case of ships where various antifouling coatings dissolve and release harmful substances, such as copper [3]. These substances enter the biosystem of marine organisms and can, by consumption of fish and mussels, affect human health. The deposition of uneaten feed on the seabed slows down the growth of marine flora and their degradation creates a chemical imbalance. The level of harmful substances, e.g. nitrogen and phosphorous, increases and leads to eutrophication of the marine area [4]. To reduce the negative impact of aquaculture production on the environment, greater funds are invested in monitoring systems and sensor networks to control the water quality and ensure a healthier environment.

Methodology and equipment

This study contributes to the preservation of the ecosystem, by installing a stationary multiparameter probe in an aquaculture farm, that collects real-time data about seawater quality and enables issuing alerts if a sort of anomaly appears. The aquaculture farm is located in the lower part of the Krka River estuary, characterised by a frequent inflow of freshwater that alters the salinity and a higher level of copper concentration harmful for marine organisms [3]. The specific characteristics make the location a valuable source of data for an environmental study. The multiparameter probe (EXO2, YSI, Xylem) has 7 ports, one port reserved for a central wiper and 6 ports for holding the sensors for temperature, conductivity, pH/ORP (Oxidation-Reduction Potential), dissolved oxygen, turbidity and depth. Other parameters that cannot be directly measured (such as total dissolved solids) are calculated through built-in correlations. The central wiper automatically cleans the surface of the sensors to prevent the growth of fouling and marine organisms, e.g. algae and mussels. The probe ensures a sampling rate of at least 1 Hz and data export in various formats (MIS, CSV, ASCII,…). The probe is located in an aquaculture farm at depth around 2 m (within the halocline) near an onshore workstation, which facilitates data transfer due to easy access to energy and an Internet connection. In-house program was developed to collect the data from the probe every 10 minutes.

Results

The first measurements were conducted during July and August 2021. The data were analysed following the FAO guidelines for aquaculture production [5]. The temperature ranges from 24°C to 28°C, as expected for the summer months. The majority of fish species has the optimum performance at temperatures of about 15°C, while at temperatures above 20°C they consume less food [5]. The optimal pH range for fish is from 6.5 to 8.5 [5] and the results show good values in a range from 7.74 to 7.97. Oxygen requirements depend on the cultivated species and increase at a higher temperature [5]. The results show a range from 5.6 mg O_2/L to 9.1 mg O_2/L. Salinity results show a greater range due to the inflow of freshwater and its position at the halocline, which harms marine organisms and needs to be further analysed. Turbidity shows low, controlled values and occasional peaks.

(Continued on next page)

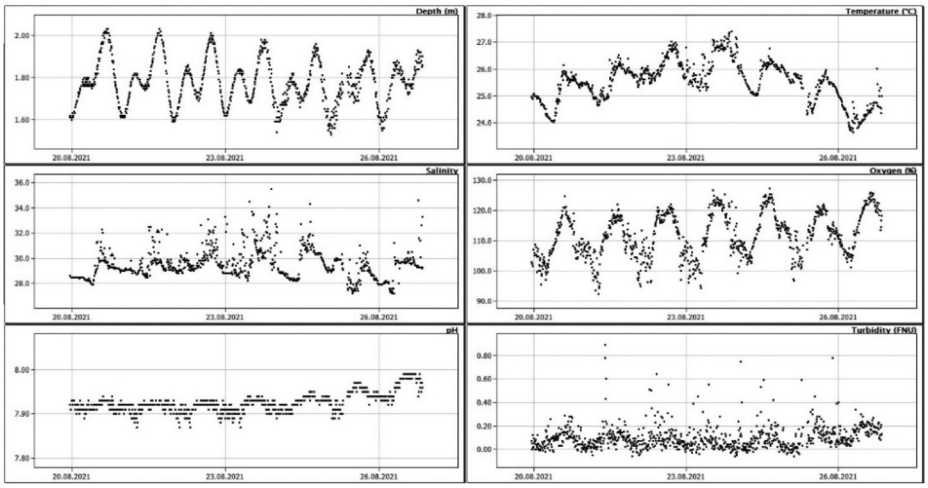

Figure 1. Water quality parameters – weekly results

Concluding remarks

Early results obtained by the described real-time monitoring system indicate that it is fully operable and appropriate for application in any type of aquaculture farm. Further measurements will give a better overview of the water quality during different seasons when greater precipitation and colder weather could have an effect on the water parameters. A larger database will enable more accurate analysis and preparation of guidelines for improving the work of aquaculture farms to reduce the environmental impact and establishing a balanced marine ecosystem.

Introduction

Rapid advances in NGS technology have resulted in remarkable accumulation of marine metagenomics data which is essential for better understanding marine biodiversity, anthropogenic influence and bioprospecting. Deep sequencing reveals exceptional biodiversity of marine microbes from various niches (including sediments, microbiomes of marine macroorganisms or hydrothermal vents) and their capacity to produce robust enzymes with novel properties (Birolli et al, 2019). In addition, microalgae are becoming very promising source of novel enzymes (Vingiani et al, 2019). Thus, accurate protein annotation is extremely important since HTP experimental assays to validate protein annotations poses a serious challenge. Our results showed that current profile sequence similarity search methods like HMMER and PSI-BLAST are inadequate to distinguish proteins that share profile similarity but lack catalytically active sites (Vujaklija et al, 2016). Functional variations between family subtypes often depend on specificity determining residues (Goldstein et al., 2009). Therefore, the ability to distinguish different residues at such positions is very important. Motif scanning (motif-HMM) possesses unique advantages over classical profile-sequence search methods to discriminate proteins with conserved overall profile but lacking essential residues or sequence variations within motifs (Biđin et al, 2020).

Methods

In this study we developed and used Leitmotif, a motif scanning web application. It provides many parameterization options and the possibility to define up to five different motifs. Leitmotif is briefly described below and in more detail on the web application's help pages https://leitmotif.irb.hr. It offers (1) setting immutable residues in selected motif by clicking the corresponding sequence logo letter; (2) setting motif distances and motif distance penalties; (3) setting transition probabilities within motifs; (4) choosing one of the four offered algorithms (Simple pseudocounts, Dirichlet mixture, Henikoff and Modified ancestral) for computation of match state emission probabilities and choosing sequence weighting and BLOSUM/PAM matrices.

Results and discussion

To illustrate the benefits of Leitmotif's novel parametrizations (IR –immutable residues, DP – distance penalties) we used a manually curated dataset of GDSL liypolytic family. Since GDSL lipases are characterized by three most conserved motifs we have tested new parametrizations using three, two and one motif(s) as input. To model the situation where limited information is available, only two essential residues were set as IR (Table1). Ser and His and motif distances were chosen based on expert knowledge (Vujaklija et al 2016). Note that for any other family, information about conserved residues and motif distances is readily available from the seed sequence alignments, even when the total number of sequences is low (Biđin et al, 2020). All transition probabilities were set to 0.99 to enable motif-HMM to make insertion(s) or deletion(s) within the motif(s). This was applied since in our previous study we found a certain number of GDSL sequences with deletions in motifs. (Vujaklija et al 2016). Table 1 shows how novel parameterizations significantly improves protein annotation.

In summary, here we show how conserved residues and motif distances that characterize some protein families can be used as an additional information to improve protein annotation. Our results pointed out that the best results can be achieved when implementing both, immutable residues and selected motif distances combined with penalties. Leitmotif is freely available web application at https://leitmotif.irb.hr

VIRGIN SALMON- BROODSTOCK CARRYING STERILTY TO NEXT GENERATION

Genetic introgression of escaped farmed Atlantic salmon (*Salmo salar*) into wild populations is a major environmental concern for the salmon aquaculture industry. Using sterile fish in commercial aquaculture operations is, therefore, a sustainable strategy for bio-containment. So far only the methodology used commercially for producing sterile salmon is triploidization; however, triploid fish are less robust. A novel approach to achieve sterility is to produce germ cell-free salmon. One way to accomplished this is to knock out the *dnd* (*dead end*) gene using CRISPR-Cas9. The lack of germ cells in the resulting *dnd* crispants, thus, prevents reproduction and subsequent large-scale production of the sterile fish. We have therefore sought to develop an approach suitable to obtain sterility, but combined with a method to inherit sterility in *dnd* knockout broodstock (Patent WO2020/070105): Inheriting sterility in broodstock salmon can be achieved by rescueing *dnd* gene function (by *dnd* mRNA co-injection) of *dnd* crispant salmon embryos. In one-year old rescued *dnd* crispant salmon we found germ cells, type A spermatogonia in males and previtellogenic primary oocytes in females. We have further followed rescued *dnd* crispants through oogenesis and spermatogenesis and obtained an F1 generation from incrosses. This method allows the large-scale production of Atlantic salmon broodstock that can inherit the sterility trait, but are able to produce 100% germ-cell free offspring. There may be partial, but not critical, limitations of the method due to potential functions of *dnd* during gametogenesis, something we are currently exploring in rescued F1 fish showing complete or partial *dnd* loss-of function, and in gametes obtained from rescued F0 crispants. This approach may solve the problems of both, genetic introgression and precocious maturation in farmed salmon, while ensuring a stable production of 100% sterile fish, and thus represents a significant commercial potential. Use of this sterility technology may also pave the way for safe genome editing of other traits, such as disease resistance, which would be contained in sterile individuals and hence presented a negligible risk of passing edited alleles on to wild stocks.

LOSS OF *FSHR* INHIBITS MATURATION IN MALE ATLANTIC SALMON

Introduction

Early puberty is a major problem in farmed Atlantic salmon males as it stunts growth and entails welfare problems due to the maturation-associated loss of osmoregulation capacity in seawater. A better understanding of the regulation of puberty is the basis for developing improved rearing protocols to avoid these problems. As puberty onset is controlled by activation of the brain-pituitary-gonad (BPG) axis, our aim here was to study if puberty is initiated when the gene encoding the follicle-stimulating hormone receptor (*fshr*) is rendered non functional. It is known that lack of *fshr* in male mice is associated with smaller testis and a reduced Sertoli cell number, but the mutants are still fertile. On the contrary, both medaka and zebrafish *fshr* KO males show no clear phenotype regarding testis size and fertility. Apparently normal spermatogenesis and fertility in these model fish may be related to Lh receptor-activation and the ensuing androgen production stimulating testis maturation. In salmon, this may be different since in other salmonids Fsh, like in mammals, cannot activate the Lh receptor and since Lh is usually not secreted until the spawning period. We therefore expected a phenotype different from *fshr* KO zebrafish and medaka males.

Material and methods

We made *fshr* mutants using CRISPR-Cas9 technology. In view of the long generation time, we first studied highly mutated F0 generation *fshr* crispants. *fshr* crispants and control males were reared in a common garden, and precocious maturation was induced by exposing the one-year old postsmolts to continuous light and 16º C water temperature for a period of three months. Samplings (testis, pituitary and plasma) took place 1, 2, 5 and 9 months post induction. For the F1 generation, the sampling times were 2, 7 and 11 months post induction.

Results

At the first sampling (1 month), all males displayed low GSI values and no effect of the *fshr* KO could be detected on plasma androgen levels or stage of spermatogenesis. However, in the samples collected during the last two samplings, we observed slightly (5 months) and clearly (9 months) lower GSI values in *fshr* KO mutants compared to control. The results in F0 crispants were variable, but we observed initially a delay in the start of maturation. The males then went through maturation but displayed a shorter cycle compared to control males. Later analysis suggested that the weak and variable phenotype in F0 crispants may be related to presence of in-frame mutations, which may leave some of the mutated protein at least partially functional. Most mutants reached maturity and we crossed four highly mutated fish (2 of each sex), to create an F1 generation. At one-year of age, we pit-tagged and genotyped 200 F1 fish for sex and *fshr* genotyping and were able to identify sibling fish having either wild-type, $fshr^{-/-}$ or $fshr^{+/-}$ genotypes with known mutations. When stimulating pubertal maturation in F1 fish, clear effects were observed. None of the $fshr^{-/-}$ (N=10) males entered puberty while 22% of the $fshr^{+/-}$ males (N=72) and 85% of the wild-type males (N=24) entered maturation.

Conclusion

We show that Atlantic salmon males do not enter puberty when lacking *fshr*, which is dissimilar to findings in zebrafish and medaka, but similar to findings in mouse.

EFFECT OF MACKEREL IN TOMATO SAUCE, MARINATED HERRING AND ANCHOVY TRIMMINGS ON GROWTH PHYSIOLOGY AND INTESTINAL HEALTH OF RAINBOW TROUT *(Oncorhynchus mykiss)*

Introduction

The world's fish production reached 179 million tons in 2018 (FAO, 2020). About 70% of this fish undergoes further processing before reaching the consumer market (Ghaly et al., 2013). The processing steps create significant amounts of side streams ranging between 20 and 80% (Stevens et al., 2018). In addition to fish side streams, about 35% of the output from fisheries and aquaculture becomes food waste. Both food waste and processing side streams may be of high nutritional value. Today, 25–35% of the fishmeal and fish oil is produced using aquaculture side streams (FAO, 2020) but many high value side streams and food wastes, at different stages of the refining process, remain unused. Therefore, our aim is to screen three waste products, from different stages of the refining chain for their nutrient composition and suitability as feed ingredient in diets for rainbow trout *(Oncorhynchus mykiss)*.

Material and Methods

The side streams tested included anchovy trimmings (A), marinated herring (H) and mackerel in tomato sauce (M). Three experimental diets were formulated to contain 50% of each test ingredient as the sole source of fish meal which resulted in 43% (A), 44% (H) and 44% (M) protein. The control diet (C) consisted of conventional ingredients including commercial fishmeal and 43% protein. All diets were produced via cold pelleting. Before the, experiment 180 rainbow trout were acclimatized to a land-based freshwater recirculating aquaculture system at 10°C. During the experiment, fish were fed one of the experimental diets in excess twice per day for 12 weeks. Measurements of weight and length were taken monthly. Tissue samples including blood, liver and intestine were taken at the end of the experimental period to assess the health and welfare of the animals. Additionally, samples of both proximal and distal intestine were used to assess intestinal nutrient uptake and barrier functions *in vitro*.

Results

During the 12-week feeding trial, most fish more than doubled their weight. However, fish fed diet C and diet A had significantly higher growth rates than fish fed diets M and H (Fig 1.A). Feed intake was reduced for the H treatment group compared to the diet A (Fig 1.B). In the proximal intestine, lysine transport and transepithelial potential (assessing barrier function) were significantly reduced in fish fed diet H. Lysine transport was also reduced for fish fed diet A. Additionally, a higher epithelial resistance was observed in the distal intestine of fish fed diet H. Plasma cortisol levels were higher in fish fed diets C and M compared to diets A and H. This coincided with an increase in plasma glucose in the fish fed diet M compared to the fish fed the diets C and A.

Discussion

The side streams included in the M and H diets were refined and contained tomato sauce and marinade respectively, which may be one reason for the reduced growth in these groups. For diet H, a reduction in feed intake was also observed indicating a lower palatability, which can contribute to the reduced growth. Reduced epithelial transport in the proximal intestine in fish fed diet H indicates a reduced capability for active nutrient uptake, potentially contributing to the reduced growth observed in this group (Vidakovic et al., 2016). The highest growth rates were observed in fish fed diet A even though it contained the lowest amount of protein and fat as well as high amounts of ash. However, the anchovy trimmings had not undergone any processing or refining which could have altered the natural taste, and were freshest, which may have resulted in the higher feed intake observed. Interestingly, diet A also led to a reduction in lysine uptake without compromising growth, indicating the presence of a compensatory mechanism such as increased feed intake (as observed) and longer residence time of chyme in the intestine.

(Continued on next page)

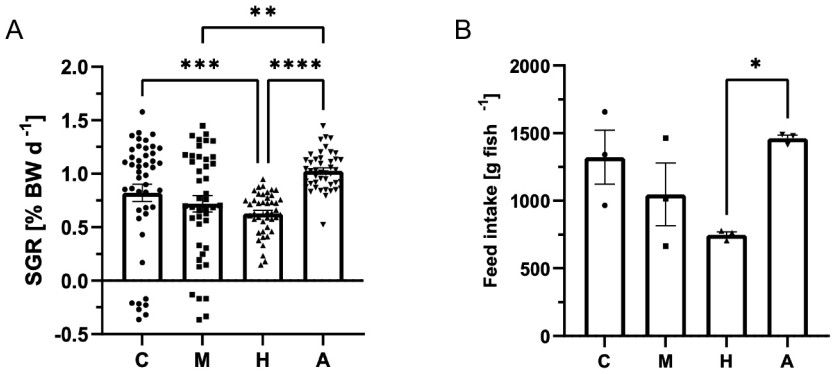

Fig 1. Growth and feed intake of rainbow trout fed 4 different diets, control (C), mackerel (M), herring (H) and anchovy (A). Left; specific growth rate (SGR), right; feed intake (FI), Bars indicate standard error of mean. Individual data point are individual fish for SGR and replicate tanks for FI. Symbols, ****, ***, **, * refer to p-values <0.0001, <0.001, <0.01, <0.05

Conclusion

The highest growth rates were observed in the treatment group fed with unprocessed anchovy trimmings (A). Thus, the refining processes of the herring and mackerel may introduce non-palatable and/or anti-nutritional factors leading to reduced growth and impaired barrier function of the proximal intestine. In this study the anchovy trimmings were the most promising side stream for the use as a feed ingredient in its raw form while the mackerel in tomato sauce (M) and marinated herring (H) may require additional treatment before they can be included in diets at high levels.

EVALUATION OF THE EFFECT OF TEMPERATURE AND FOOD RESTRICTION ON COMPENSATORY GROWTH OF PACIFIC WHITE SHRIMP *Litopenaeus vannamei* IN BIOFLOC SYSTEM

W. Wasielesky*, E. Prates, M. Holanda, Luis Poersch and J.M. Monserrat

Marine Station of Aquaculture, Federal University of Rio Grande, Rio Grande City, Rio Grande do Sul State, Brazil
manow@mikrus.com.br

Introduction
Compensatory growth is defined as a phase of accelerated growth when favorable conditions are restored after a period of growth depression caused by a stressing factor. It is a strategy developed in some species due to frequent stress situations in the environment, assuming trade-offs in resource allocation among growth, reproduction and self-maintenance. In aquaculture, the use of feed restriction and low temperatures as a trigger for compensatory growth can be considered strategies to reduce feed supply, costs and to increase the period of production of tropical species in regions that growing seasons is limited by low water temperature. In addition, Biofloc Technology System (BFT), can also bring several production advantages compared to the traditional systems in ponds, as increase the stock density, and improvement in water quality and biosafety. Furthermore, microorganisms community besides removing nitrogen compounds, also acts as a food supplement for shrimps, providing a constant feed supply 24 h a day.

Thus, the present study aimed to evaluate the occurrence of compensatory growth in *Litopenaeus vannamei*, in three different temperatures (20, 24 and 28º C) under feed restriction reared in a biofloc system, and its effect energy reserves and immunological condition of shrimps.

Materials and Methods
The experiment lasted 64 days and was divided in two phases: (1) Restriction and (2) Recovery. *L. vannamei* were stocked with 1.78 g (±0.38) in a stocking density of 300 shrimps/m³. In the first phase (36 days), the experiment was performed using a 3 x 2 (three temperatures and two feed regimes) experimental design, totaling six treatments (in triplicate). Three temperatures were chosen as optimum (28 ºC), intermediate (24 ºC) and low (20 ºC) and two feeding regimes were established for each temperature: the control that received 100% of the calculated feed rate and feed restriction, where the feed rate was 40% of the control. In the second phase (28 days), all the experimental units (n=18) were exposed to favorable conditions (100% of feeding rate and 28 ºC). Three shrimps per tank (nine per treatment) was collected at days 0, 36 and 64 to determine energy reserves content (total protein, glycogen and triglycerides) in hepatopancreas and assess differential hemocyte count (DHC) in hemolymph.

Results
In the end of the experiment, previously restricted shrimps held at 24 and 28 ºC displayed complete body weight catch-up through compensatory growth following the restriction period with depressed growth ($P > 0.05$). Shrimps maintained at 20 and 24 ºC with no feed restriction did not reach 28ºC treatment body mass when favorable temperature (28 ºC) was established ($P < 0.05$). Protein levels in hepatopancreas were not affected in any treatment over the experiment ($P > 0.05$) and glycogen was used as a metabolic fuel in all restricted groups during phase 1 ($P < 0.05$), but fully recovered when total feed supply was offered ($P > 0.05$). Triglycerides were also used in restricted shrimps held at 24 and 28 ºC in phase 1 ($P < 0.05$), and after recovery period, only treatment previously maintained at 24º C presented total recovery ($P > 0.05$). DHC presented differences among treatments ($P<0.05$) but was maintained in the safe range for healthy shrimps reared in BFT system over the experimental period. Also, survival was not affected by feed restriction or low and intermediary temperatures ($P > 0.05$).

Conclusion
Therefore, it is possible to submit *L. vannamei* to partial feed deprivation with a later recovery period as a trigger for total compensatory growth, in order to improve feed efficiency and decrease of feed supply. Also, in regions that low temperatures are a limiting to shrimp growing seasons, it is viable to explore partial compensatory growth to increase annual production.

Introduction

Although inclusion rates of fishmeal and fish oil have already been strongly reduced in aquadiets, they remain staple ingredients, and a main environmental and economic concern of aquaculture today (Schmidt et al. 2016). Terrestrial plant protein sources have been key to alternative feed protein but the main interest to date has been in soy products, which have come under public criticism due to the widespread use of transgenic seeds and deforestation for soy cultivation. Recent studies focus on additional terrestrial protein sources, mainly grain legumes like field pea, lupin and faba bean (Carter & Hauler, 2000; De Santis et al. 2015; Øverland et al. 2009), which are regionally and organically produced. Legumes provide nitrogen for themselves and subsequent plants (Blume, 2010; Sulieman, 2015) and thus reduce the overall fertilization needs during crop rotation. Here we present validated diets for 3 species relevant for European Aquaculture (*Litopanaeus vannamei*, *Salmo salar*, *Dicentrarchus labrax*) containing locally grown lupin and faba bean. The diets are formulated tightly aligned to the requirements of each species, which is necessary not only from the economic but also from the ecological point of view. These formulations and diets are valuable for producers aiming to make fed aquaculture of salmon, shrimp of seabass more sustainable in the future.

Material and Methods

Controlled feeding experiments have been conducted in a RAS device (8-12 weeks) with three species of high relevance for European aquaculture (*L. vannamei*, *S. salar*, *D. labrax*). Aquafeeds containing meal or protein concentrate of Blue lupin (*Lupinus angustifolius* Boregine) and Faba bean (*Vicia faba*) as fish meal and soy product replacement were formulated to accurately meet the species and stage nutritional requirements, i.e. equal energy content, protein and amino acid profile, lipid and fatty acid composition, vitamins and minerals. After an appropriate trial period, samples were taken for metabolic, histologic and immunological analyses.

Results and Discussion

Untreated lupine meal can be used as an alternative protein source at rates of up to 10% (-20%) of the total feed (= 30-40% of animal protein) without growth or metabolic impairment compared to a commercial shrimp feed (Fig. 1a, b). A moderate lupin inclusion obviously operated as bioactive compound stimulating the shrimp's immune system (Fig. 1b, d).

Faba bean protein concentrate as well as Lupin protein concentrate can be used at rates of 35% of the total feed as a regional alternative to soy and as a partial fish meal replacement in feed for postsmolt Atlantic salmon without any impairments of health and growth (Fig. 2a).

Lupine kernel meal can be used in high inclusion rates (-50%) as a replacement for fishmeal in diets for the carnivorous European Seabass, with appropriate pre-treatment effectively mitigating negative effects on growth in smaller individuals (<30g) (Fig. 2b).

In conclusion, grain legumes and their products have great potential as a main protein source in diets for carnivorous aquaculture species in Europe.

Introduction
Black soldier fly larvae (BSFL) (*Hermetia illucens*) have a great potential as a sustainable novel feed ingredient in fish feed. Numerous studies reported the effects of dietary inclusion of BSFL on fish species including Atlantic salmon (*Salmo salar*) (Belghit et al., 2018; Weththasinghe et al., 2021). These studies have proposed that the fractions of BSFL might differently affect the fish. However, to the best of our knowledge, the effects of different fractions of BSFL have still not been evaluated in a single study. Therefore, the present study investigated the effects of full-fat meal and fractions of BSFL in diets on nutrient digestibility, growth performance and gut health in Atlantic salmon pre-smolts.

Materials and methods
Six experimental diets were produced: a control diet based on fishmeal, plant protein sources and fish oil (CD); full-fat BSFL meal diet (IM), defatted BSFL meal diet (DFIM); de-chitinized BSFL meal diet (DCIM); BSFL oil diet (IO) and BSFL exoskeleton diet (EX). The full-fat, defatted and de-chitinized meals replaced 15% of the protein content of the control diet. A total of 900 Atlantic salmon pre-smolts with 28 g of mean initial weight were distributed into 18 fiberglass tanks (50 fish per tank), and fed with one of the six experimental diets. The growth performance parameters and nutrient digestibility in fish were estimated. The histological evaluations of pyloric caeca and distal intestine of fish were done. In addition, immunological parameters (IL-1 β and IgM) in distal intestine were evaluated by indirect ELISA. The RNA sequencing of distal intestine and 16S rRNA sequencing of gut microbiota of fish are ongoing.

Results and discussion
The full-fat and de-chitinized meals improved the growth rate of salmon, while defatted meal, oil and exoskeleton fraction supported similar growth performance in fish as the control. Furthermore, the improvement in the growth rate of fish fed the full-fat meal diet was accompanied by higher feed intake, whilst defatted meal gave a better feed conversion ratio than the full-fat meal. Replacement of dietary protein with defatted meal, de-chitinized insect meal or exoskeleton fraction reduced protein digestibility, whereas neither full-fat meal nor fractions affected lipid digestibility (Table 1).

In the pyloric caeca, fish fed de-chitinized insect meal diet showed low occurrence and severity of enterocyte steatosis compared to control and full-fat meal diets (Figure 1A). Evaluation of the distal intestine revealed normal and healthy morphology for most of the fish. The fish fed de-chitinized meal showed a higher level of pro-inflammatory cytokine IL-1β in the distal intestine compared to the fish fed the control diet (Figure 1B), whereas distal intestine IgM level showed no difference between the fish fed insect diets and the control diet.

Conclusions
In conclusion, the full-fat BSFL meal improved feed intake and growth rate in salmon when replacing 15% of dietary protein, however, defatted meal gave a better feed utilization than full-fat meal. Dietary inclusion of de-chitinized BSFL meal improved the histology of pyloric caeca of fish by reducing enterocyte steatosis and increased pro-inflammatory IL-1 β level in the distal intestine. These results contribute to establish a baseline for the study of insect-based diets that are capable of modulating the immune system of fish.

SUSTAINABLE WATER SOLUTIONS TO INCREASE YIELDS AND IMPROVE QUALITY

Diane White

diane.white@evoqua.com

Objectives
Discover the challenges and opportunities faced by global aquaculture including climate change, population growth, more mindful consumerism, and environmental regulations.

Learn why sustainable water solutions are essential for the protection and growth of this market.

Discover the new technologies that are supporting land-based hatcheries and the enterprising ways farmers can enhance their water treatment process, improve fish welfare and boost stock yields.

Method
New regulations and changes to sea-based aquaculture are driving the growth of land-based hatcheries. As our population grows, and together with climate change and more mindful consumerism, the demand for fish continues to evolve rapidly.

Evoqua uses sustainable water disinfection and filtration treatment technologies to help fish farmers address microbial management, produce larger fish, increase stock density and yields, improve water quality, and vastly improve fish welfare.

Results
Improved water quality in land-based hatcheries and sustainable treatment technologies that keep water clean and free from disease increases stock yields in existing infrastructures. Thanks to sustainable and non-chemical solutions for Recirculating Aquaculture Systems (RAS), the world now produces more seafood from fish farms than wild catch.

Conclusion
Evoqua provides sustainable solutions for productive fish growth and improved water quality that vastly reduces the risk of prevalent fish diseases like Infectious Salmon Anaemia and Gill disease. Our experts assist with regulatory compliance, and provide solutions that are simple to operate and easy to maintain, delivering optimal performance from a smaller footprint.

The speaker
The speaker is Diane White - Industrial Disinfection Sales Manager for the Aquaculture Industry at Evoqua Water Technologies. With over 25 years of experience within the water treatment industry & 12 years as a UV specialist, Diane is an expert in advanced treatment solutions to support the challenges facing the Aquaculture industry.

ECO-FORMULATION OF FISH FEEDS: A PROMISING EFFICIENT SOLUTION TO LIMIT AQUACULTURE IMPACTS ON THE ENVIRONNEMENT

aurelie.wilfart@inrae.fr

Introduction

To meet the growing demand for seafood and the need for protein sources, aquaculture is expanding. It now provides more than 50% of fish for human consumption and this proportion is expected to continue to increase over the long term to meet the food needs of more than nine billion people by 2050. All animal production systems, including aquaculture, are widely criticized for their environmental impact and animal feed is responsible for the majority of these. Currently, feeds are formulated to fulfill fish nutritional requirements while minimizing feed cost and taking into account incorporation constraints of particular feed ingredients such as fishmeal and fish oil. To reduce environmental footprint of feed, feed formulation should take simultaneously into account the cost and the environmental impacts of raw materials. Recently, Garcia-Launay et al. (2018) developed a multiobjective formulation algorithm which uses the constraints of least-cost formulation and calculates a multi-objective function that includes both feed cost and environmental impact indicators obtained by life cycle assessment (climate change, non-renewable energy use, phosphorus demand, land occupation). The objective of the present study was to adapt and apply this algorithm to design eco-friendly diet (eco-diet) and assess their nutritional value in rainbow trout.

Material & Methods

In this study, two isoprotein, isolipid and isoenergetic diets were formulated: a control diet (C-diet), close to commercial feeds currently used in rainbow trout aquaculture and an ECO-diet, formulated using a multiobjective function to minimize both the environmental footprint (including climate change, phosphorus demand, acidification, NPPU and water demand) and price of feed . The digestibility of the diet was measured and a 12 weeks-growth trial was conducted (3 tanks per diet) on juvenile rainbow to assess the consequences of these diets on growth performance, body composition and nutrient utilization. Finally, the results were used in a life cycle approach to estimate the environmental impact of 1 kg of body-weight gain.

Results

Diets are presented in Table 1. Multiobjective formulation reduced the level of fishmeal and fish oil of 55 % but introduced animal proteins and fat as well as yeast proteins (Table 1). Environmental impacts estimated by life cycle assessment were all subjected to a reduction from 23 to 46%. Whereas diets exhibited similar protein digestibility, the eco-diet showed a significant lower apparent digestibility coefficient (ADC) of lipids, energy and ash but enhanced ADC of starch, even ADC values could be all considered as high. At the end of the growth trial, no significant differences difference in body weight was observed but analysis of the growth curves using a mixed linear models revealed a significant difference between the two diets in favor of the control diet (Figure 1). Feed efficiencies were similar but daily feed intake was significantly enhanced in fish fed the C-diet. Fish fed the Eco-diet showed a lower protein gain resulting from higher protein intake. Body composition was similar between the two diets. Producing 1 kg of weight gain induces less environmental impacts with the Eco-diet than with the commercial diet, whatever the impact considered. The reduction is more important for NPPU, water demand and phosphorus demand (Figure 2).

Discussion

The present study demonstrates that lowering environmental footprint of the feed reduces the use of fishmeal and fish oil with little even no consequence of growth performance, but it can significantly reduce the environmental impact of producing one kg of trout, depending of the impact considered. Development of eco-friendly aquafeed through multi-objective formulation appears as a promising solution to reduce the reliance of aquaculture on marine ingredient and thus promote the sustainable development of aquaculture.

SCREENING OF POTENTIAL PROBIOTICS ISOLATED FROM NORMAL BACTERIAL FLORA OF *Litopenaeus vannamei* AGAINST VIBRIOSIS

F. Wulandari*, I. Herliana, T. Y. Prajitno A. Nurina and V. Anggara

Research & Diagnostic Departement of PT Vaksindo Satwa Nusantara, Indonesia
E-mail: febriana.wulandari@japfa.com

Introduction

Vibriosis is considered one of the most important bacterial diseases in shrimp farms of Indonesia. This disease is responsible for high mortality in aquaculture worldwide. Advancing the immune response through probiotics application is expected to be an environmentally friendly alternative to prevent the disease. The purpose of this study was to identify candidates for normal bacteria flora of the shrimp gut that has potency as probiotics to inhibit *Vibrio harveyi* infection.

Materials and methods

Sampling was conducted in Probolinggo and Banyuwangi, Indonesia. Gut samples from vannamei shrimp (*Litopenaeus vannamei*) that survived a vibriosis outbreak were diluted with serial dilution technique then cultured in SWC-agar at 30 ºC for 24 hours. The bacteria that grow are then coated with *Vibrio harveyi* strain MR5339 and incubated at 30 ºC for 24 hours. Bacterial colonies that appear clear inhibition zones for *V. harveyi* are then cultured and purified using SWC-agar only. These bacterial colonies were designated as probiotic candidates. This study used PCR and Sanger sequencing of the 16s gene to identify probiotic candidates. In vitro challenge tests using SWC agar were carried out on four identified probiotic candidates against *V. harveyi* isolate obtained from the field.

All of these probiotic candidates were challenged in vitro by culturing with *V. harveyi* on SWC agar. After that, the number of *V. harveyi* colonies that can still grow was counted. The challenges test were carried out with two doses ratio between probiotic candidates and V. harveyi,of 1:1 and 2:1. The inhibition percentage of *V. harveyi* bacteria was calculated by the formula:

$$x = \frac{V.\ harveyi \text{ without challenge (CFU)} - V.\ harveyi \text{ after challenge (CFU)}}{V.\ harveyi \text{ without challenge (CFU)}} \text{ x } 100\%$$

Results

Four probiotic candidates obtained and identified as *Bacillus cereus* (B1-02 & B1-04), *Bacillus albus* (B2-05) and *Enterococcus faecium* (E1-12). Our study showed that a dose of B1-02, B1-04 and B2-05 bacteria could inhibit V. harveyi above 99% while E1-12 was 43.85%. Furthermore, the challenge test with double dose of probiotic candidates showed that there was an increase in the percentage of inhibition by bacteria B1-02, B1-04 and B2-05 although not significant otherwise inhibition by E1-12 increased significantly more than 2 times. Details of inhibition data can be seen in Table 1 and Figure 1.

Conclusions

Our study showed that *B. cereus*, *B. albus* and *E. faecium* were found to be able to inhibit *V. harveyi* growth. All of that bacteria could inhibit V. harveyi more effectivelly at two-fold dosage. Presumably, *B. cereus*, *B. albus* and *E. faecium* could be used in the shrimp culture as the probiotic. Indeed, more research into the in vivo challenge test is required in the future.

Curcumin (diferuloymethane) is a polyphenol extract from the rhizome of the plant *Curcuma longa* and it is known to possesses a strong antioxidant capacity, and anti-inflammatory, antimicrobial and immunostimulatory proprieties. The use of this natural plant extract as a feed additive for juvenile fishes have showed good results as an enhancer of growth, oxidative status, stress resistance and promoter of digestion capacity (e.g., Alagawany *et al*., 2021). However, knowledge on the impact that dietary curcumin may have in early larvae stages is still scare. Marine fish larvae are a transitory stage very vulnerable and highly prone to stress that exhibit a drastic metamorphosis involving several morphologic and metabolic changes to achieve the juvenile stage (Hamre *et al*., 2013). Therefore, the aim of this work was to assess if curcumin supplementation could promote gilthead seabream larvae robustness and digestive maturation to ultimately improve fish growth performance.

Two experimental trials were conducted to test the effects of different doses of curcumin (LOW and HIGH) in gilthead seabream larvae and postlarvae. In Experiment 1, 42 days after hatching (DAH) gilthead postlarvae were fed exclusively control or the supplemented diets for 20 days. At the end of the growth trial fish were sampled to analysed oxidative status, gut maturation, and morphology. In Experiment 2, 4 DAH larvae were fed the experimental diets for 27 days, in an early co-feeding regime until 24 DAH. Diet impact was assessed at several sampling points, to determine the oxidative status, digestive capacity, and feeding incidence of the larvae throughout ontogeny.

The first trial showed that fish from HIGH and LOW significantly improved the oxidative status compared to CTRL treatment, through a decrease in the content of protein oxidative damage and an increase in the total antioxidant capacity. Moreover, postlarvae fed curcumin supplemented diets also presented an upregulation of *nfr2* and *gr* in HIGH and *hsp70* in LOW treatments, when compared to non supplemented fish (CTRL). On the other hand, no differences were observed in the growth performance, intestine morphometry and digestive enzymes activities.

In the second trial, no differences were observed in growth performance at larvae from 4 to 24 DAH. However, at the end of the experiment (31 DAH) larvae fed LOW diet had a better condition factor than CTRL fish. Moreover, 31 DAH larvae fed HIGH diet showed higher trypsin and chymotrypsin activity levels when compared to CTRL fish. LOW and HIGH larvae were able to prevent an increase in the mtROS production during development, in contrast to non supplemented larvae (CTRL).

In conclusion, dietary curcumin supplementation seems to promote larvae digestive capacity and modulate the oxidative status during early ontogeny of gilthead seabream. In fact, in postlarvae this supplement was able to enhance fish oxidative status through an increase in the total antioxidant capacity and reduction in the content of protein oxidative damage. Both studies provide new evidence that dietary supplementation of natural compounds, could be a nutritional strategy to enhance marine fish larvae robustness at early life stages of development. Therefore, this study contributes to improve larvae quality production in marine hatcheries and promote a more sustainable industry.

The use of *Chlorella vulgaris* and *Trachidiscus minitus* as live feed enrichments for rotifer and artemia fed to Pikeperch (*Sander lucioperca*) larvae was tested during this trial. Larvae were fed a combination of rotifers (until day 15 post hatchting) and artemia (from day 12 post hatchting) under seven different enrichments: a) *Nannochloropsis occulata (Nanno 3600 reed Mariculture), b) Chlorella vulgaris cultured at 20 degrees Celsius in BG117 media*, c) *Chlorella vulgaris cultured at 30 degrees Celsius in BG117 media, d) Chlorella vulgaris cultured at 20 degrees Celsius in Urea media, e) Chlorella vulgaris cultured at 30 degrees Celsius in Urea media, f) Trachidiscus cultured at 15 degrees Celsius and g) Trachidiscus cultured at 25 degrees Celsius*. After 21 days from the trial initiation significant differences were found between treatments on total length (TL), myomere height (MH), and fatty acid composition. In terms of growth parameters, larvae from treatment c had significantly higher values in total length (11.48 mm) and myomere height (2.04 mm). Furthermore, larvae from treatment c) showed significant higher concentration of Docosahexaenoic acid (DHA) (%), and Linoleic acid (LA) (%) and larvae from treatment g) had significant higher concentration of Eicosapentaenoic acid (EPA) (%) and Arachidonic acid (ARA) (%).

Overall, larvae from treatments c and g, performed better than the other treatments, likely due to the difference in Essential Fatty Acids (EFA) concentration. The results from this trial, will help to optimize the pikeperch larvae nutritional requirements and diversify the live feed enrichments used during first feeding.

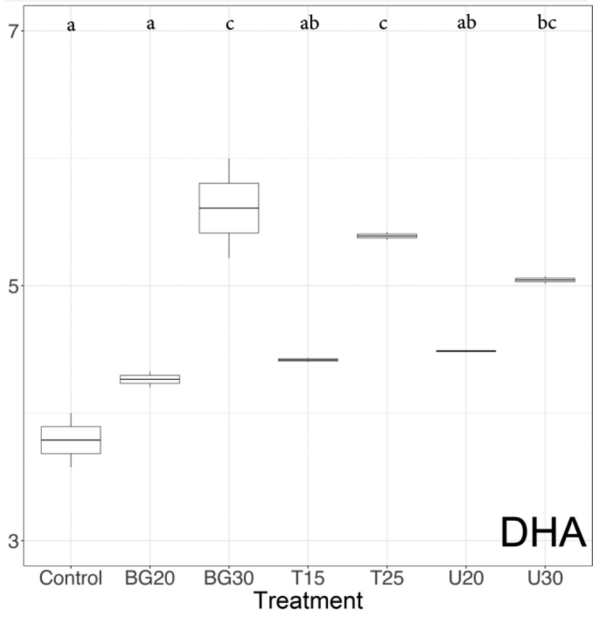

Figure 1. Pikeperch larvae DHA concentration after 21 days from 7 different enrichment diets

Introduction and objective

Reactive oxygen species (ROS) are becoming increasingly appreciated as signaling molecules, regulating varying cellular processes, such as proliferation and differentiation, beyond the role as damage signal [1, 2]. The key mechanism of redox signaling and control involves is impacting the structures, functions, activities or trafficking of associated proteins via the reversible or irreversible redox modifications of redox-sensitive amino acids [3, 4]. Accumulating evidence indicates a strong relationship between increased oxidative stress and periods of high growth rates in fish [5-7]. However, whether and how the redox system changes during the growth stimulation seen in Atlantic salmon, and do the growth hormone (GH) signals interact with redox signaling directly to increase metabolism or is the oxidative stress a secondary function of a higher metabolic rate and oxidative phosphorylation in the mitochondria caused by growth hormone stimulation remain unclear.

The objective in this study is to elucidate the relationship between growth stimulation and redox environment of Atlantic salmon and the potential role of ROS in contribution to the effects on GH.

Material and methods

This study had two sequential experimental phases (EP) termed EP1 and EP2, both lasting for 6 weeks. Atlantic salmon (initial weight: 38.7 ± 0.6 g) were divided into two groups and reared in 6 replicate tanks at stable temperature (around 12°C) and continuous light. We provided salmon with a diet low vitamins (L) with 230mg/kg ascorbic acid as stay C and 120mg/kg α-tocopherol using the acetate form, while diet high vitamins (H) had 380mg/kg ascorbic acid and 210mg/kg α-tocopherol, respectively. At the beginning of EP2, half of the fish from each group was implanted with formulation of recombinant bovine GH (Posilac®), while the other half was sham-implanted with same volume of the sesame-seed oil vehicle. We evaluated the liver and muscle redox environment and health condition of Atlantic salmon via accessing the total glutathione (tGSH) levels, the redox potential (Eh), ascorbic acid (AA), α-tocopherol (α-TOH), malondialdehyde (MDA) concentrations, the activities of antioxidant enzymes including superoxide dismutase (SOD), glutathione peroxidase (GPX), glutathione reductase (GR), glutathione S-transferase (GST) and catalase (CAT) and cataract score compared between treatments in EP1 and EP2.

Results

Here we show that redox-related parameters measured in the EP2 were influenced by growth hormone and diet to varying degrees. Notably, GH-treated salmon had lower levels of reduced glutathione, a more oxidized redox potential of muscle, and higher MDA concentrations of liver. We found that fish fed diet H had higher ascorbic acid and α-tocopherol of liver and muscle than those fed diet L, whereas implantation GH significantly decreased their concentrations. The activities of antioxidant enzymes of liver and muscle were differently regulated by GH implantation, which may be associated with the difference in tissue antioxidant capacity and regulation. There were interactive effects between GH and diet on GPX of liver, and SOD and GR of muscle. Furthermore, we found GH-treated salmon had higher cataract score in the EP2, which suggested cataract is more severe in fish implanted with GH.

Conclusion

Our results demonstrated GH has an oxidative effect on liver and muscle of Atlantic salmon and that there is an interaction between the effects of antioxidant and GH on redox signaling. The present study is intended as a starting point to further understand the potential interactions between growth and redox signaling of fish.

Introduction

The red flesh color is an important quality trait for farmed Atlantic salmon. The color is due to the salmon's ability to deposit the carotenoid astaxanthin in the muscle. The retention of astaxanthin in the muscle is not very efficient, normally less than 10% of the ingested astaxanthin is retained in the muscle. There are indications that the fillet color has decreased in recent years. Reduced inclusion of marine ingredients in the modern salmon diet (Ytrestøyl et al., 2015, Aas et al., 2019) has led to reduced levels of several nutrients (phospholipids, vitamin A and cholesterol) that may affect flesh pigmentation in Atlantic salmon, both during absorption in the gut and through interference with metabolic conversion of astaxanthin to vitamin A. In addition to its provitamin A function (Schiedt et al., 1985), astaxanthin is a powerful antioxidant that reacts with free radicals and singlet oxygen (Naguib et al., 2000, Dose et al., 2016). Increased oxidative stress has been suggested as a possible cause of decreased flesh pigmentation in salmon, but experimental evidence supporting this hypothesis is limited. In this project, the effect of dietary retinol and astaxanthin concentrations in combination with stress on astaxanthin deposition and metabolism were tested in Atlantic salmon.

Materials and methods

Diets with two concentrations of astaxanthin (30 and 60 mg/kg) combined with three levels of vitamin A (6500, 35 000, 100 000 IU/kg), six diets in total, were fed to A. salmon for 16 weeks (start weight 190g: final weight:1000g). The trial was done in tanks with flow through seawater and feed intake were measured for calculation of astaxanthin retention in the muscle. After the 16-week feeding trial, four of the diets (high/low astaxanthin and retinol) were fed for a period of 5 weeks and split in a group that were stressed and a control group without stress. The stress was induced by lowering the water level and oxygen concentration in the tanks three times/week. Samples of muscle, liver and intestine were sampled for analysis of astaxanthin and breakdown products by HPLC and NMR. Visual color was assessed by a Minolta Chroma Meter and SalmoFan™. Hepatocytes and enterocytes were isolated and incubated with ^{14}C-labelled astaxanthin to study the metabolism of astaxanthin to retinol *in vitro*. Samples of liver, muscle and intestine were taken for analysis of gene expression by microarray.

Results

Growth rate was not significantly affected by dietary astaxanthin or retinol concentration. The flesh color measured by Minolta redness (a*-value) and Salmofan scores was lower at the highest dietary vitamin A concentration. This was confirmed by analysis of astaxanthin concentration in NQC by NIR and HPLC. A decreasing astaxanthin concentration with increasing vitamin A in the diet was also found in liver and plasma, but not in intestine. The retention of astaxanthin in the muscle was highest in the salmon fed the diet with 30 ppm astaxanthin and medium vitamin A concentration. Analysis of samples from the stress trial and *in vitro* trial as well as gene expression are currently on-going and will be presented.

GENOMIC SELECTION AND INTROGRESSION SIGNATURES RESULTING FROM ADAPTATION TO HIGH SALINITY: A CASE STUDY ON AN INDONESIAN FARMED TILAPIA (SUKAMANDI) STRAIN

Xiaofei Yu[1*], Hendrik-Jan Megens[1], John W.M. Bastiaansen[1], Langqing Liu[1], Martien A.M. Groenen[1] and Hans Komen[1].

1. Animal Breeding and Genomics, Wageningen University & Research, The Netherlands.

Background
Tilapia is currently the most important fish in aquaculture in the tropics and subtropics. Originally a freshwater species, it is cultured in a wide range of conditions. Among the most challenging is when high salinity is involved, e.g. culturing in estuaries or high salinity ponds in polyculture with shrimp. Optimized tilapia strains generally do not tolerate high salinity well. Although the physiological characteristics for osmoregulation are reasonably well understood, it is less clear how selection results in salinity tolerance. Here we investigate one such strain that was bred to perform well in brackish water. Specifically, we infer signatures of selections in the genome. In addition, since the salinity tolerance in the strain was hypothesized to be derived from another species, we also inferred signatures of introgression between species.

Materials and methods
Indonesian farmed tilapia (Sukamandi) strain was derived from the BRPI research institute (Sukamandi, Java), and has been selected for growth for four generations under salinity levels varying from 15 to 58 ppt. Fin clips from a total of 20 fish were sampled from the nucleus population in 2019. In order to understand the genomic architecture of Sukamandi strain, whole genome sequencing data of blue tilapia were downloaded from the Sequence Read Archive (NCBI bio-project number PRJNA358089 and PRJEB23203). Nile tilapia, originating from the Genetically Improved Farmed Tilapia (GIFT) population, were collected by the Genomar company. We performed a joint-calling strategy for genetic variants, genetic differentiation and diversity analysis, selection signatures and Identity by descent detection.

Results
We compared the genome of this Sukamandi strain to that of Nile tilapia (*Orechromis niloticus*) and blue tilapia (*Orechromis aureus*), the latter a putative donor of the salinity tolerance. Our results indicate that the Sukamandi strain is genetically much more similar to Nile tilapia (*Orechromis niloticus*) (Fst=0.042) than to blue tilapia (*Orechromis aureus*) (Fst=0.386). By two pairwise comparisons (as shown in Figure 1), 33 salinity adaptive genes involved in MAPK3 activity, potassium ion homeostasis, ATPase activity (coupled to transmembrane movement of ions), calcium ion binding pathway were identified. Combining genome-scale scanning for selection and introgression, revealed that salinity tolerance related genes, such as *slc25a24* and *cdh1* were under selection (as shown in Figure 2).

Conclusion
Salinity adaptive genes disclosed by genetic differentiation comparison with blue and Nile tilapia strain were partially under selection. The genome of Sukamandi strain appears to be overwhelmingly of Nile tilapia origin but introgression from blue tilapia may have conferred some of the observed salinity tolerance. We provide the genetic basis for breeding resilient tilapia -Sukamandi strain.

EVALUATION OF THE NUCLEAR ESTROGEN RECEPTORS OF SEA BASS (DICENTRARCHUS LABRAX) AS TARGET SITES FOR ENDOCRINE DISRUPTING COMPOUNDS: POTENTIAL EFFECTS ON REPRODUCTION AND THEIR USE FOR RISK ASSESSMENT

Introduction

Estrogens are involved in the regulation of a wide range of processes in teleost reproduction (Lubzens et al, 2010; Schulz et al, 2010), and exert their functions mainly through ligand-activation of their specific cognate receptors. Nuclear estrogen receptors are transcription factors that bind to estrogen response elements (EREs) on gene promoters to regulate their expression (Tsai et al, 1994), and three subtypes of these receptors have been identified in teleosts. Differences in binding affinity and seasonal expression patterns in reproductive tissues among estrogen receptor subtypes suggest different roles during oogenesis, vitellogenesis and testicular development along the brain-pituitary-gonad axis. It is known that endocrine-disrupting compounds (EDCs) may act as agonists or antagonists of regulatory actions of steroid receptors or of the production of the receptors themselves. Thus many different points in the endocrine control of fish reproduction can be potential targets for the actions of EDCs. In aquaculture, the presence of estrogenic compounds in water is as worrying as its presence in new formulation of commercial fish diets (Arpin-Pont et al, 2016; Nacher-Mestre et al, 2013; Quesada-García et al, 2012). Nevertheless, the lack of information available on the role of each nuclear estrogen receptor in teleosts, including European sea bass, makes it difficult to have an accurate knowledge on the impacts of EDCs on reproduction. This study focused on investigating the role of the three nuclear estrogen receptor subtypes in European sea bass, on evaluating the impacts of endocrine-disrupting compounds on nuclear estrogen receptors functions and on their use as tools for risk assessment.

Material and methods

To investigate the role of the three nuclear estrogen receptors subtypes in European sea bass, analysis of the expression of their coding genes during a whole reproductive cycle was investigated by qPCR in testis, ovary and pituitary. Localization of the nuclear estrogen receptors along the brain-pituitary-gonad axis was performed by immunohistochemistry using specific antibodies for each subtype.
Using the human embryonic kidney cell line HEK293, we have performed transient transfections (1) to characterize nuclear estrogen receptors (Esr1, Esr2a and Esr2b) by using transactivation of an ERE- luciferase reporter gene assay; (2) to study the effect of two possible EDCs, genistein – a phytoestrogen also present in fish meals – and fluoxetine – an antidepressant, mainly constituent of Prozac - on all nuclear estrogen receptors from sea bass.

Results

The coding genes of the three nuclear estrogen receptor subtypes of sea bass are highly expressed in reproductive-related tissues such as pituitary and gonad. Quantification of *esr1*, *esr2a* and *esr2b* expression in the gonad and pituitary during a whole reproductive cycle showed different expression patterns depending on stage and subtype. Localization of the three nuclear estrogen receptors along the pituitary-gonad axis showed differences among subtypes depending on the gonadal stage.

The functional characterization of the nuclear estrogen receptors showed that there are different ligand affinities among the nuclear estrogen receptor subtypes, which also translate into differential receptor responses when we evaluate the effect of potential EDCs, such as genistein and fluoxetine.

(Continued on next page)

Conclusion

The results suggest that the three nuclear estrogen receptors of European sea bass are not redundant and have differential roles in the regulation of gametogenesis, as proposed also in other teleosts, which means that the effects produced by EDCs can induce potential adverse effects at reproductive level.

The results also show that *in vitro* bioassays using nuclear estrogen receptors are a good tool for risk assessment of potential endocrine-disrupting compounds.

Introduction

Herbal derivatives and extracts have been used in fish diets as natural growth promoters and immune stimulants (Abdelwahab et al., 2020). The aim of present study was to investigate the effects of garlic powder in feed on growth performance, body proximate composition, apparent nutrient digestibility, selected blood and immune parameters, and resistance to overcrowding stress in Eurasian perch juveniles.

Materials and Methods

After 14-day acclimation, 110 fish per tank were distributed randomly into twelve 185 L tanks in recirculation aquaculture system (RAS). Feed formulation was extruded at Exot Hobby s.r.o. (Černá v Pošumaví, Czech Republic). European perch (*Perca fluviatilis*) (initial weight 25.0±0.4 g) were fed a diet including 0 (Control), 10 (G10), 20 (G20), and 30 (G30) g kg^{-1} garlic powder. Fish were fed manually based on apparent satiation at 08.00, 12.00, and 16.00 for 87 days.

Results and Discussion

No significant differences in growth performance, viscerosomatic and hepatosomatic index were observed among groups ($p > 0.05$). Condition factor was significantly lower in the G30 diet compared to other groups ($p < 0.05$). This agrees with Sahu et al. (2007) who reported that garlic powder in rohu diet did not significantly improve SGR or FCR. Moreover, no significant differences were observed among groups in whole body dry matter, fat, or ash ($p > 0.05$). But the level of protein in the G30 diet was significantly higher than G10 ($p < 0.05$). Significantly higher dry matter digestibility was observed in all garlic groups compared to control ($p < 0.05$). Significantly higher fat digestibility was found in G10 and G30 compared to control and G20 ($p < 0.05$). No differences in protein digestibility were observed among groups ($p > 0.05$). The number of RBC and WBC in G10 was observed significantly higher than other groups ($p < 0.05$). Lymphocyte and myeloid cell percent did not differ among groups ($p > 0.05$).

No significant differences in blood serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity, triglycerides, or total protein were observed among groups ($p > 0.05$). Garlic powder at all levels was associated with significantly lower levels of cholesterol ($p < 0.05$). Significantly higher levels of albumin were detected in G10 and G20 compared to other groups ($p < 0.05$). In agreement with our result garlic powder did not show significant effect on ALT and AST activity in Asian sea bass (*Lates calcarifer*) (Abdelwahab et al., 2020). Garlic powder reduced cholesterol in rainbow trout (Mohebbi et al., 2012), and increased blood serum albumin in rainbow trout (Nya and Austin 2009). We did not find blood serum total protein to differ among groups the same as (Nya and Austin 2011) who observed in rainbow trout. Garlic powder inclusion did not affect respiratory burst and phagocytic activity ($p > 0.05$). Immediately after stress, all garlic diet groups showed significantly higher levels of cortisol compared to the control ($p < 0.05$). At 24 h, significantly higher and lower cortisol levels were detected in control and G30 groups, respectively ($p < 0.05$) while glucose was significantly higher in controls than in garlic-fed groups ($p < 0.05$).

Introduction
Aquaculture faces a major issue to reach its full potential, due to biofouling, which is affecting products quality, quantity and environment- labour- equipment integrity. According to market experts, current treatment measures represents from 10 to 20% of farm exploitation costs (costs of chemicals, nets cleaning and repair, and fish escapees). Therefore, this study aims to prevent micro-fouling layers apparition on offshore aquaculture fish farm cage nets with ultrasonic (US) waves to increase not only the aquaculture productivity and operational efficiency but also to verify the implementation and performance in the field. However, there is a lack of knowledge about the effects of applying US on fish growth, feeding behavior and health. Therefore, in order to facilitate the adoption of the system, the innocuity of the technology on fish's welfare and health has to be evaluated. In this study, we determined and defined the maximum level of power and frequency after an adequate trial period with US to get the most effective anti-fouling system without harming the commercially important European sea bass (*Dicentrarchus labrax*).

Material and Methods
Field trial (1) was conducted in an offshore mini-cage system (one test and one control cage; diameter: 3 m, depth: 5 m) without fish and the effectivity of US treatment was measured by video recording of the cages to evaluate biofilm formation for 1-month. Full (continuous ultrasound signaling) and pulse/intermittent fire were tested in order to observe the power consumption and its effectivity on the algal accumulation on cage nets. Both cages were installed nearby the Barge at the offshore fish farm.

Field trial (2) was conducted in an offshore cage system (one test and one control cage; diameter: 20 m, depth: 8 m, stocking density: 30.000 to 50.000 fish) with various (full-fire/intermittent fire) configurations. The effectivity of US treatment was measured by video recording of the cages to evaluate and compare biofilm formation after 1-month. In addition, fish mortality and behaviour (feed intake, swimming behaviour) as stress marker were observed in order to select the best frequencies and power.

Field trial (3) will be conducted in operational cages (two test and two control cages; diameter: 30 m, depth: 20 m, stocking density: >50.000) with US treatment (fixed frequency and operational mode full or pulsed fire will selected after analysing the Field trial (2) assay). In order to evaluate the effect of a specific power/treatment configuration on full or pulse fire on feed intake, growth and health of European sea bass, five sampling will be performed at the offshore fish farm. These are initial sampling (d0; before US application, d2: two days after US application, d32, d62, d92: one-month interval between sampling). For the impact on feed intake and growth: weight, length, FCR, feeding behavior; for the impact on health and stress response: histological studies on skin, liver and gills, Cortisol level, LDH, Glucose, Na+, K+, Cl- ions in blood, and additionally skin mucus, blood smears, haematocrit levels and gene expression in skin, liver and gills will be analysed.

Results and Discussion
Results from the preliminary Field trial (1) offer an initial glance on the impact of different levels of frequencies on the accumulation of algae on mini-cage nets. Hereby, enhancing the wave density with close proximity positioning of the transducers exhibits clearly the highest impact area thus confirming that the placement and combination of transducers induced the most effective during 1-month of trial. Field trial (2) showed that algae do not grow near the transducers and high frequency transducers have more impact for preventing the anti-fouling on the cages compare to low frequency transducers. However, the system set up needs to improve power and performance to reduce algae growth on the whole area of the cages. Nevertheless, no stress response was observed on fish feeding and behavior during the US application.

(Continued on next page)

Final results are pending! However, we expect that the US application being tested for preventing of anti-fouling will be new to the aquaculture industry, and can be implemented as a standardized application in offshore fish farms. However, as stress response can be observed in different levels in different fish species, the end product should be tested in other commercially important species as well in order to proof the safeness of system and tune fine it for each species and condition.

This study is part of the project “Smart System for the Prevention of Biofouling on Aquaculture NETs by Ultrasonic Wave Technology” (NetWave), and it has received funding from the European Union’s H2020-EIC-FTI-2018-2020 programme under grant agreement no. 958776.

PRELIMINARY RESULTS OF EXPERIMENTS TESTING THE FEASIBILITY OF CO-CULTURE OF SHRIMP AND ALGAE IN RAS SYSTEM

Introduction

In Europe, the majority of animals considered alien species are farmed in closed systems and a great deal of emphasis is placed on their sustainability. One of the requirements for such farms is to minimise their impact on the environment, which in the context of aquaculture means that farm water discharged into the environment must meet very stringent standards for various types of pollution, including nutrients. Thanks to the high levels of nutrient uptake, high photosynthesis level, and high growth rate algae have recently come into focus for their application potential in RAS systems.

Therefore, 2 experiments were conducted to demonstrate that native algae can be used in RAS cultures as biofilters to purify the culture water of *Paneus vannamei* (whiteleg shrimp). In the first experiment the idea of "algae scrubber" on a trickling filter was tested. In the second experiment, native filamentous green algae of the genus *Chaetomorpha* were tested.

Materials and methods

Experiments testing the simultaneous culture of algae and whiteleg shrimp were carried out between May 2021 and September 2021 in two RAS-500 systems designed by AquaMedic Poland located at the Institute of Oceanography, University of Gdansk. Both RAS are identical and have 500 dm^{-3} cultivation pools and system operation is controlled and monitored by a dedicated computer. For algae cultivation, additional flow-through tanks with a maximum volume of 125 dm^{-3} equipped with Aqua Illumination Prime HD lamps were connected to the original systems. In both algae tanks the same light exposure time was set (10h light and 14h dark cycle), and the same default light parameters were used: 60% blue light, 60% green light, red light, 60% warm white light, 60% cold white light. The values of the main water parameters (temperature, pH, salinity, redox potential) were continuously monitored during the experiments. Additionally, the concentration of nitrogen (NH_4^+, NO_3^- and NO_2^-) and phosphorus compounds (PO_4^{3-}) as well as Fe ions were measured every 2 days with a Hach Lange DR5000 spectrophotometer using sachet tests during the first 2 weeks and then once a week.

For the first experiment testing the development of algae biofilm on a trickling filter, in the algae culture tank, three 50 x 35 cm nets were mounted on the water supply pipes in such a way that water flowed down them continuously along their entire length.

In the second experiment, filaments of green algae *Chaetomorpha linum* collected locally from the coastal waters of the Baltic Sea were used in variants with nitrogen gas and distilled water pre-treatment, with and without acclimatization.

In both cases, intensive observations of biofilm and *Ch. linum* filaments were carried out. Additionally, *Ch. linum* biomass was measured on a SBS-LW Balance Scale with a measurement accuracy of 0.001 g. As in the case of water parameters, during the first 2 weeks analyses were performed every 2 days and then once a week.

Results and discussion

In both experiments, the basic properties of the culture water in RAS (i.e. temperature, pH, salinity, redox potential) and concentration of NH_4^+ crucial for shrimp growth were kept stable at desirable levels. However, the concentration values of nitrate (NO_3^-) and nitrite (NO_2^-) and orthophosphate (PO_4^{3-}) increased with shrimp culture age to values that significantly exceeded the environmental values. For example, after 21 weeks, NO_3^- concentrations reached 25 $mg \times dm^{-3}$, and PO_4^{3-} – 9.8 $mg \times dm^{-3}$. In both experiments, culture waters were supplemented with Fe ions because they initially lacked this key element for photosynthesis.

Initially, in the first experiment, no biofilm was formed to act as a biofilter, confirming the initial assumption that in the case of a RAS system meeting the high purity requirements no algal colonization of the system would occur. Only after the introduction of *Ch. linum* filaments into the algae tank a biofilm formed, consisting mainly of diatoms and cyanobacteria.

(Continued on next page)

In the experiment with *Ch. linum* it was shown that native algae without and after acclimatization process show intensive growth only for a period of several weeks (6-9 depending on the variant of the experiment). It was also observed that irrespective of the method used to purify *Ch. linum* filaments obtained from the environment, microalgae were always introduced into the system along the host algae. Hence, only the culture of specially prepared and purified strains e.g. from unialgal cultures can ensure the purity of the RAS system. Furthermore, the decline of the growth of *Ch. linum* after a couple of weeks indicates suboptimal conditions for its development. This is probably due to inadequate light conditions or lack of key micronutrients, which were not measured.

Based on the experiments, no significant effect of algal co-culture on the reduction of nutrients in RAS systems was recorded.

Conclusions

Both microalgae and macroalgae can be cultured in RAS with shrimps. However, in order to achieve satisfactory levels of water purification and algal biomass growth, the introduction of selected and pre-adapted algal species is required along with the provision of suitable growth conditions.

Introduction

Viral Nervous Necrosis (VNN) is identified as an emerging agent in wide variety of wild and farmed fish. Rising temperatures on the shores of the Persian Gulf, imported fish, and the onset of some nonspecific signs of the virus in wild grouper (*Epinephelus* spp.) and farmed Sea bass (*Lates calcarifer)* fish, prompted fish screening hypothesis by molecular methods. This is the first report on VNN monitoring in fish from the Persian Gulf of Iran.

Material and Methods

This study monitored from two species of fish susceptible to VNN using PCR and Nested PCR. Furthermore, Water temperature was measured during random collection of visibly healthy and asymptomatic fish.

Results

The results of present study, the PCR showed no positive cases but the Nested PCR revealed some positive results. Ultimately, the phylogenetic analysis of the isolates was performed.Isolated sequence analysis showed a high homology of 98% with Red Spotted Grouper Viral Nervous Necrosis (RGNNV) genotype. According to the importance of emerging viral diseases and their irreparable damages, continuous investigation and epidemiological studies of VNN were recommended.

INFLUENCE OF SOLVENT AND ULTRASOUND-ASSISTED EXTRACTION ON PIGMENTS RECOVERY AND ANTIOXIDANT ACTIVITY FROM ALGA *Ulva lactuca*

R. Raos[a], A. Dobrinčić[b], Z. Čošić[b], P. Lisica[b], S. Pedisić[b], V. Dragović-Uzelac[b], R. Čož-Rakovac[c,d] and Z. Zorić[b*]

Introduction

Ulva lactuca is a green macro alga also known as "sea lettuce" belonging to the genus Ulva in which about 50 other species have been described. Due to the high content of biologically active molecules (BAM), *Ulva lactuca* is considered not only as food but also as a dietary supplement.

Extraction is a fast and efficient method of separation and concentration of BAM which differ in chemical structure. For each matrix it is necessary to optimize the extraction conditions considering all the extraction parameters: the availability of the extraction technique, the purity of the extract, the extraction yield and the energy consumption (Rostagno & Prado, 2013). The advantages of new extraction techniques manifest in the extraction rate and yield, lower energy consumption and environmental acceptability when compared to conventional techniques.

Therefore, the aim of this study was to optimize the parameters of ultrasound-assisted extraction (UAE) in order to achieve the maximum yield of carotenoids and chlorophylls as well as antioxidant activity (AOA) from alga *U. lactuca* using two solvents (hexane and 80% acetone) at two temperatures (30 and 50 ºC) and three different times (10, 15 and 20 min).

Materials and methods

U. lactuca samples were collected from the Adriatic Sea, washed with distilled water, frozen at -60 ºC, freeze-dried (CoolSave 55-9 PRO, Labogene Denmark) and ground. UAE was performed using ultrasound bath (Elmasonic 40H, Elma, Germany) according to above mentioned experimental conditions. Determination of carotenoids and chlorophylls was performed using HPLC system (Agilent Infinity 1260 system) with UV/VIS PDA detection. The solvent composition and gradient conditions used were previously described by Castro–Puyana et al. (2017). Identification was carried out by comparing retention times and spectral data with those of the authentic standards (α- and β-carotene, lutein, chlorophyll *a* and *b*). Quantifications were made by the external standard calculation, using calibration curves of the standards. The AOA of the extracts was assessed by ORAC assay according to Elez Garofulić et al. (2020). The ORAC procedure included an automated plate reader (BMG LABTECH, Offenburg, Germany) with 96-well plates, and data were analysed by MARS 2.0 software. The experimental design and statistical analysis were done using STATISTICA v.10 Experimental design (DOE) software (StatSoft Inc., Tulsa, OK, USA).

Results

Results showed that *U. lactuca* contained high amounts of carotenoids and chlorophylls. Lutein was the predominant carotenoid in all obtained extracts, followed by α- and β-carotene. The highest concentration of lutein was determined in extract obtained at 30 °C and 20 min (91.98 mg 100 g^{-1}), while the lowest concentration was detected in hexane at UAE parameters of 30 °C and 10 min (0.03 mg 100 g^{-1}). Chlorophylls were determined only in acetone extracts and the most represented one was chlorophyll *a* with the highest amount (78.11 mg 100 g^{-1}) detected in extract obtained at 30 °C and 20 min of extraction time. All extracts obtained using acetone had higher ORAC values (286.66 – 329.74 μmol TE L^{-1}) in comparison with hexane extracts (77.22 – 117.00 μmol TE L^{-1}).

Discussion and conclusion

The effects of UAE parameters were assessed on pigments recovery from *U. lactuca* by using acetone and hexane as extraction solvents. Obtained results showed that the yields of all pigments, except β-carotene, were significantly higher when acetone was used. According to Martins et al. (2021), this is due to the higher affinity of chlorophylls and xanthophylls for polar *vs*. non-polar solvents and the ability of acetone to better dissolve cell walls.

(Continued on next page)

Statistical analysis showed that the highest concentration of carotenoids was achieved in acetone extraction at 30 °C for 20 min and in hexane extraction at 50 °C for 15 min. This is in accordance with Abd El-Bakya et al. (2008) results. Although Razi Parjiklaei et al. (2014) concluded that temperature increase has a positive effect on the amount of extracted carotenoids, it was observed in this study that temperature of 30 ºC had higher extraction potential for all pigments than temperature of 50 ºC.

ORAC values were significantly influenced by extraction solvent. The highest ORAC values were observed in acetone extracts, what can be linked with higher carotenoids and chlorophylls amounts present in these extracts.

The highest yields and greater stability of pigments during UAE were achieved under 30 °C, 20 min of extraction time and using acetone as solvent.

Introduction

Greater amberjack *Seriola dumerili* (Risso, 1810) is an excellent candidate for aquaculture thanks to its rapid growth, excellent flesh quality and worldwide market appreciation. As other captive-reared fishes exhibiting reproductive dysfunctions (Zohar and Mylonas, 2001), greater amberjack males produced reduced sperm volume with a decreased sperm quality. The present work represents an overview of the results obtained in a comparative research study on the spermatogenesis of wild and captive-reared greater amberjack carried out in the framework of the EU FP7 project Diversify (www.diversifyfish.eu) (Zupa et al, 2017a, b).

Material and Methods

Twelve greater amberjack males caught from the wild and reared in captivity for three years in a sea cage in Salamina Island (Greece) and 14 males caught from the wild around Pelagie Islands (Sicily, Italy), were sampled during three phases of the reproductive cycle: early spermatogenesis (late April-early May), advanced spermatogenesis (late May-early June) and spawning (late June-July). For each fish, biometric data (fork length, FL, in cm; body mass, BM, in kg; testis mass, TM, in g) were registered and gonadosomatic index (GSI = 100 × TM/BM) calculated. Testis samples were chemically fixed and destined to basic histological analysis and to the identification of proliferating and apoptotic germ cells through the immunohistochemical detection of the proliferating cell nuclear antigen (PCNA) and the TUNEL method, respectively. Blood samples were centrifuged and plasma was collected and stored at -20°C for the analysis of 17β-estradiol (E_2), testosterone (T), 11-ketotestosterone (11-KT) and 17,20β-dihydroxypren-4-en-3-one (17,20β-P) by ELISA assays.

Results and Discussion

Captive-reared fish showed lower GSI and smaller seminiferous lobules compared to wild fish in all the three phases of the reproductive cycle.

Anti-PCNA immunostaining was observed in the nuclei of spermatogonia and primary spermatocytes (Fig. 1a). All the captive-reared and most of the wild greater amberjack showed TUNEL-positive germ cells (Fig. 1b). Individuals reared in captivity showed a gradual decrease of germ cell proliferation throughout the three reproductive phases, which led to a precocious cessation of the spermatogenesis as well as a higher germ cell apoptosis in early spermatogenesis. In all three reproductive phases, captive-reared fish showed lower T, 11-KT and 17,20β-P plasma concentrations compared to wild fish; however, captive-reared fish showed a many-fold higher E_2 plasma levels during the early spermatogenesis.

The occurrence of a severe endocrine dysfunction was described in captive-reared greater amberjack males, including low T, 11-KT and 17,20β-P plasma levels during all the examined spermatogenesis phases. Abnormally high E_2 plasma concentrations were associated to an increased germ cell apoptosis during early spermatogenesis. The observed reproductive dysfunction finally led to a lower sperm concentration and quality (Zupa et al., 2017a). A severe impairment of the reproductive function was observed also in females of the same broodstock and involved low steroid plasma concentrations and extensive atresia of late vitellogenic oocytes (Zupa et al., 2017b). Preliminary data obtained within the H2020 project NewTechAqua indicate that hatchery-produced greater amberjack males reared in sea cages in Salamina (Greece) have similar GSI compared with wild fish sampled in the same period of the reproductive cycle (early June 2021). Although further analyses are required, the available data seem to suggest that the reproductive function might be less affected by captivity-induced stress in hatchery-produced greater amberjack than in wild-caught breeders.

Introduction

Production of Atlantic salmon in recirculating aquaculture systems (RAS) is increasing worldwide. RAS provides better environmental control and higher biosecurity compared to traditional flow-through systems (FT). However, RAS is a much more complex system in which metabolites, organic material, hormones, metals, and other elements can accumulate (Davidson et al., 2009; Good et al., 2014; Schumann and Brinker, 2020). In addition to this, salmon is sharing the RAS environment with a dynamic microbial community dependent on physiochemical water properties and nutrient availability (Fossmark et al., 2020). RAS can be used for production of all life stages; however, we know very little about how this environment affects early salmon development. In this study we aimed to assess the effect of hatchery environment (RAS vs. FT system) on early development of salmon skin and bones.

Methods

The experiment was performed at the Nofima Centre for Recirculation in Aquaculture (NCRA), Sunndalsøra, Norway. The experimental trial was approved by the Norwegian Animal Research Authority. Total of 7200 eggs (AquaGen Atlantic QTL-innOva SHIELD) were incubated at 7.8 ◦C and transported to NCRA at 322 degree days (◦d). Eggs were split and stocked into 12 hatchery trays, each with 600 eggs, and continued with incubation on either FT (9 hatchery trays) or RAS (3 hatchery trays) at a mean temperature of 7.7 ◦C. To examine the effect of biologically active water, we chose to use a bioreactor as a part of RAS water treatment. The same freshwater from ground wells was used in the FT system and in RAS. Detailed description of system design and operation is provided in Robinson et al, 2021. Biological sampling was done at three time points prior to start feeding: at 650◦d, 807◦d and 875◦d. Fish from each tank were randomly netted and euthanized (MS-222; FINQUEL®vet, ScanAqua AS, Årnes, Norway) at every time point. Fish were added to RNAlater (Invitrogen) and stored at -20◦C until RNA extraction or fixed in 10% buffered formalin (CellStor™ pots, CellPath) and stored at 4◦C. Length and weight were measured at 875◦d. In total, 40 alevins per hatching tray were weighed, and the length of 9 alevins from each hatching tray was measured. Following analyses were done: histology, micro-CT scanning, RNAseq, differential gene expression analysis and gene ontology enrichment analysis. Detailed description of methods used is provided in Robinson et al., 2021.

Results and discussion

The use of two different production systems affected the expression of genes in pathways related to skin and skeletal development. Genes known to be involved in bone development and mineralisation were significantly up-regulated (inner ear specific collagen, transforming growth factor-beta-inducible early growth response protein 3 and salmon calcitonin) or down-regulated (metalloproteinase inhibitor 2-like, 25-hydroxyvitamin D3 1-alpha-hydroxylase and elongation of very long chain fatty acids protein 7-like) with RAS relative to FT treatment. Genes known to affect skin development, including keratin type I cytoskeletal 13-like and angiopoietin-related protein 7, were down-regulated in RAS compared to FT treated fish. The image analysis revealed less mineralisation of the skeleton (Fig. 1), thinner skin and more pronounced mucous gland development toward the skin surface in fish developing in the RAS.

How environmental factors, or the interaction between abiotic and biotic components in RAS and FT systems influence the development of skin and mineralisation of the skeleton, remain unclear. Further research will be needed to determine potential causes for observations documented in this study.

Introduction

The diets for carnivorous fish species like European sea bass *(Dicentrarchus labrax)* are still heavily dependent on fish oil (FO) as main source of essential fatty acids (FA), such as eicosapentenoic (EPA; 22:5n-3) and docosahexaenoic (DHA; 22:6n-3) acids. But such high levels of FO used by the expanding aquaculture industry have led to major economic and environmental concerns, due to the lack of sustainability of this limited marine resource, making the use of alternative sources imperative. Up to now,the use of animal fats (AF) has still been poorly explored in Europe, but previous studies in European sea bass have shown that their incorporation into aquafeeds could be a sustainable alternative to the conventional FO (Monteiro et al., 2018; Campos et al., 2019). However, since these fats present low levels of EPA and DHA, their inclusion levels should be carefully assessed in order to produce feeds capable of meeting the fish dietary requirements while preserving the fillet nutritional value. In this context, the maingoal of this work was to assess the effect of two distinct AF, poultry fat (PF) and mammal fat (MF), with or without an emulsifier, on European sea bass growth performance and fillet quality.

Materials and methods

Four extruded isoproteic (45%) and isolipidic (21%) diets were formulated. The lipid fraction of all diets comprised 55% FO and either 45% PF or 45% MF. For each experimental diet, containing each of the aforementioned fat types, an emulsifier was added at 0.01%, resulting in the following experimental diets: FOPF (PF without emulsifier), FOPFe (PF with emulsifier), FOMF (MF without emulsifier) and FOMFe (MF with emulsifier). A growth trial was carried out with European sea bass (initial body weight of 255.7 ± 15.2g), in an open system aquaculture facility, for 12 weeks. At the end of the trial, growth performance,feed efficiency, whole body composition, fillet FA profile, instrumental texture and colour were evaluated.

Results

All diets were equally well-accepted by European sea bass and fish reached a final body weight between 380-417g, without significant differences in daily growth index or feed efficiency among groups. The inclusion of the emulsifier led to increased whole body lipid and energy contents, regardless of the type offat, but retention and nutrient gain remained unaffected by the dietary treatments. EPA and DHA retentionand gain were not significantly affected by the type of fat or the use of emulsifier, though there was a trendtowards increased gain of these fatty acids in fish fed mammal fat diets.

The dietary fat source did not affect significantly muscle total SFA, total MUFA and n-3/n-6 PUFA ratio. In fish fed diets including MF, muscle lipid content reached the highest levels (Fig.1A), whilst total PUFA,namely n-6 PUFA, were the lowest; The use of MF in the diets resulted in a significantly higher amount ofEPA and DHA in the muscle (0.26-0.27 g/100g fillet), when compared to the diets comprising PF (0.21-0.24 g/100g fillet) (Fig.1B). Fish fed diets with MF without emulsifier also demonstrated an increase of

(Continued on next page)

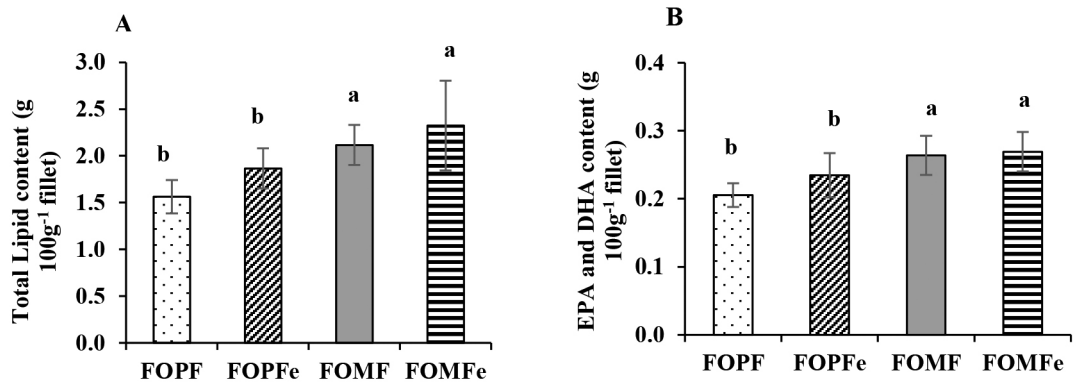

Fig. 1. Total lipid content (A) and muscle EPA and DHA (B) of European sea bass fed the experimental diets for 12 weeks

Discussion and Conclusion

The present study shows that is equally feasible to include poultry fat or mammal fat in diets for Europeansea bass without compromising fish growth performance or feed utilisation. Although diets did not affect muscle SFA and MUFA content, total PUFA were lowest in fish fed MF, suggesting a fillet that will be less subject to rancidity, since PUFAs are more prone to lipid peroxidation. European sea bass fed with MFproduced fillets with a higher lipid content, and had also a tendency to retain higher levels of EPA + DHA.This resulted in muscle EPA + DHA values above those recommended by WHO for human consumption (> 0.25g $100g^{-1}$), but the same could not be observed in fish fed with PF.

Overall, this study suggests that land mammal fat should be considered a sustainable lipid source for European sea bass diets, contributing to a circular economy concept, and diminishing the carbon footprintof the aquafeed sector, since this ingredient can be obtained by rendering locally produced by-products.

Introduction

The greater amberjack *Seriola dumerili* is a fast-growing fish, for which commercial production has been recently achieved in the Mediterranean. It is a gonochoristic species, that completes sex differentiation at the end of the first year of life (Marino et al., 1995). The study of its sex differentiation process during on-growing in sea cages is essential, in order to investigate for possible sex-related growth differences and eliminate the possibility that the rearing method would have an effect on the final sex ratio of the populations. Moreover, the study of the plasma levels of sex steroids and corticosteroids can help reveal the role of these hormones in the process of sex differentiation. Differences in the hormonal levels between sexes can be used for sex identification in greater amberjack before puberty or during the non-reproductive period, in order to ensure optimal broodstock sex ratios and facilitate selective breeding programmes.

Materials and Methods

Fish used in the present study were produced from eggs obtained after spawning induction of wild-caught breeders with gonadotropin releasing hormone agonist (GnRHa) implants (Fakriadis et al., 2020). Eggs were transferred to the facilities of the Institute of Marine Biology, Biotechnology and Aquaculture (Hellenic Center for Marine Research, HCMR) and reared until 50 days post-hatching (dph). At 50 dph, fish were moved to the pilot sea cages of HCMR at Souda Bay, Chania, Crete, Greece, where they were maintained until the end of the experiment.

Seven samplings were conducted from 101 until 408 dph (n=17-23), during which total length (TL) and wet weight (WW) were measured, and gonads and blood were collected, the former for histological analysis and the latter for the measurement of sex steroid (adrenosterone (Ad), androstenedione (Δ4), 11-ketotestosterone (11-KT), testosterone (T), estradiol (E_2), progesterone (P4) and 17,20β-dihydroxyprogesterone (DHP)) and corticosteroid (cortisol and cortisone) plasma levels with the use of liquid chromatography/mass spectrometry (LC-MS/MS).

Results

Growth of greater amberjack was similar for both sexes and females had the same size as males at all samplings. Moreover, the sex ratio in all the samplings was 1:1.

As regards the histological description of sex differentiation, in females at 101 dph (14.98 ± 6.20 cm TL), the ovarian cavity was already formed, and germ cells were visible around it. At 198 dph (25.8 ± 0.14 cm TL) the first primary oocytes were visible. Complete ovary differentiation was achieved at 408 dph (41.22 ± 3.83 cm TL). In males, at 101 dph the gonads contained mostly somatic cells and connective tissue and no germ cells were present (14.47 ± 6.60 cm TL). The first germ cells were apparent at 150 dph, when spermatocytes could be found in the gonads (24.71 ± 3.09 cm TL). The typical testicular structure featuring all types of male germ cells, was observed at 260 dph (28.63 ± 2.85 cm TL). This structure was obviously maintained until the last sampling (357 and 408 dph, 34.25 ± 2.98 cm and 41.7 ± 1.99 cm TL, respectively).

Of the nine measured hormones in greater amberjack females and males during the sex differentiation process, the ones that exhibited statistically significant changes in time were cortisol, Ad, Δ4, 11-KT, T and P4 in females and Ad, 11-KT, T, P4 and DHP in males. Cortisol and Ad exhibited lower values as the sex differentiation period was progressing in females; on the other hand, Ad, 11-KT, T and P4 in both sexes and DHP in males presented higher values at the end of the sex differentiation period.

The 11-KT/E_2 ratio was significantly different between the sexes from the second sampling at 150 dph until the last sampling at 408 dph (Figure 1).

(Continued on next page)

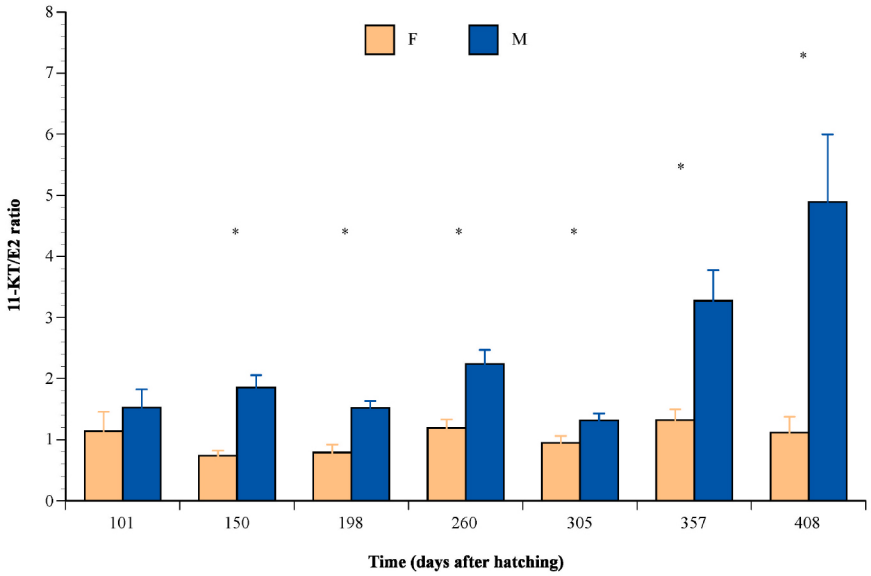

Figure 1. Evolution of the 11-ketotestosterone (11-KT)/estradiol (E2) ratio in hatchery produced greater amberjack in relation to time. Differences in the ratio between males and females are indicated with an asterisk (one-way ANOVA, Tukey HSD, $P < 0.05$)

Discussion

The absence of sex-related growth dimorphism and the constant 1:1 sex ratio in greater amberjack populations reared in sea cages suggest that both sexes can be equally preferable in aquaculture production and that there is no effect of the rearing method on the sex differentiation of the species. No sex ratio fluctuations are to be expected in cage-reared populations. Moreover, using LCMS/MS, nine sex- and cortico-steroid hormones of the cholesterol metabolism pathway can be detected, enabling the study of the biochemical pathway involved in the teleost sex differentiation process. Sex identification was possible in juvenile fish from 150 dph, with the use of the 11-KT/E_2 ratio.
