POLYCHAETE *Nereis virens* MEAL CAN INCREASE FEED EFFICIENCY IN FARMED ATLANTIC SALMON

Turid Synnøve Aas[1]*, Lars Thoresen[2], Aleksei Krasnov[3], Lene Sveen[3], Gunhild Johansson[4], Katerina Kousoulaki[2]

[1] Nofima, Sjølsengvegen 22, NO-6600 Sunndalsøra, Norway
[2] Nofima, Kjerreidviken 16, NO-5141 Fyllingsdalen, Norway

[4] Nofima Muninbakken 9-13, NO-9019 Tromsø, Norway
E-mail: synnove.aas@nofima.no

Atlantic salmon were fed practical diets containing 0 (control), 7.5% (7.5PC) or 15% (15PC) spray dried polychaete meal replacing fish meal in the control diet. The experimental diets were formulated to be balanced for total protein, lipids and EPA+DHA, and Lys, Met, His and Thr were balanced with crystalline amino acids. Y_2O_3 was added as an inert digestibility marker. The diets were fed to triplicate groups of salmon (salt water 32 ‰, 12 ˚C) for 63 days. Mean initial body weight was 70 g and mean final body weight was 204 g.

Feed intake was significantly higher in salmon fed the control diet than those fed 15PC, with those fed 7.5PC in an intermediate position. Specific growth rate (SGR) followed the same pattern (not significantly different). Interestingly, the feed conversion ratio (FCR) was 0.73, 0.70 and 0.68 in salmon fed control, 7.5PC and 15PC, respectively. This indicates effective utilization of the polychaete meal in salmon feed.

Apparent digestibility of energy and main nutrients was measured. The body composition was analyzed for estimation of retention of energy and main nutrients. Intestinal tissue was sampled for histologic evaluation, and for micro-array analysis of gene expression. The results from these analyses will be presented.

The polychaete meal was a nutritionally excellent feed ingredient for salmon in the present trial. Polychaeta can be produced from waste material and is therefore interesting in the context of circular economy. However, the available produced polychaete meal volumes are still low and come to a higher price as compared to fish meal. Thus, to become a commercially interesting feed ingredient, methods for production of large volumes at a competitive price need to be developed.

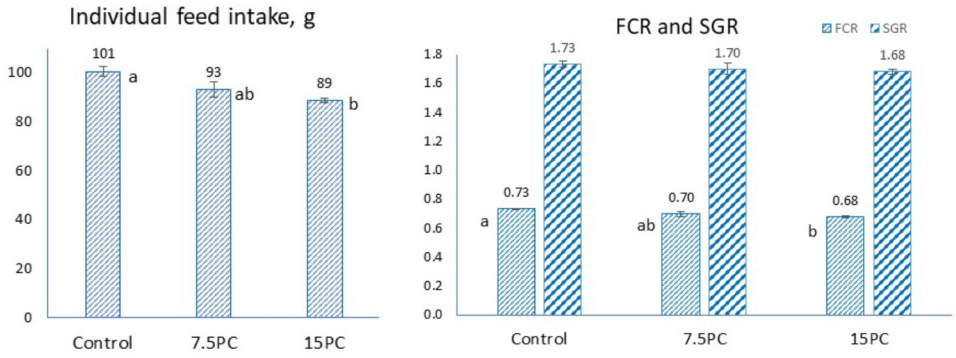

Figure 1. Individual feed intake (g; left panel), feed conversion ratio (FCR) and specific growth rate (SGR; right panel) in Atlantic salmon fed diets containing 0 % (control), 7.5% (7.5PC) or 15% (15PC) polychaete meal.

TOWARDS SUSTAINABLE JELLYFISHERIES IN EUROPEAN WATERS WITH SPECIAL EMPHASIS ON THE TRONDHEIMSFJORD AS A CASE STUDY

***Introduction**:*
Jellyfish are an essential pelagic ecosystem component that can form dense blooms over large spatiotemporal scales. Intensity, frequency, and duration of jellyfish blooms vary, show strong species- and site-specific differences and are often considered to have negative impacts on local industries, tourism and artisanal fishery1. Demands for jellyfish products for e.g. aquaculture feed, food, cosmetics or pharmaceuticals, are increasing thus providing an opportunity to turn them into a resource2. But, a lack of ecological knowledge on the drivers of jellyfish blooms limits a sustainable, cost-efficient harvesting and management of jellyfish. Within the EU-project GoJelly, the aim was to provide a basis for ecosystem-based management taking the knowledge gaps related to jellyfish ecology, bloom dynamics, and origin of seed populations into account. More reliable predictions on jellyfish blooms and tools for more sustainable harvesting of jellyfish should be achieved by focusing on the biotic and abiotic drivers that promote jellyfish blooms.

***Material & Methods**:*
From 2018-2020, seven target jellyfish species with broad spatiotemporal distribution ranges in European waters were harvested in several GoJelly study areas (Norwegian Sea, Baltic Sea, Mediterranean Sea and Eastern Atlantic). Data on the fishing methods (e.g. vessel, fishing gear, fishing effort) and activities (e.g. harvesting period, fishing duration, target species and life-stages, post-harvesting biomass processing) were recorded evaluating jellyfish fishery processes.

***Results**:*
Overall, three tons of jellyfish were harvested and 60% of the total biomass was harvested in the Trondheimsfjord, Norway. Interannual variation in harvested biomass occurred due to differences in harvesting efforts and bloom intensities of the target species (Figure 2A).

Nine jellyfish species were harvested (Figure 2B), three of them representing 80% of the total catch (44% *Periphylla periphylla,* 18% *Rhizostoma pulmo,* 17% *Aurelia* spp.). Different types of fishing vessels were used (from small-sized open boats to medium-sized research vessels). Jellyfish were harvested using six gear types (gillnets, bottom trawls, pelagic trawls, landing nets, hand nets, 20-L buckets). The mesh size varied from 0.35 to 50 mm. The gear type reflected the harvesting depth as well as the vessel type.

Discussion & Conclusion:
Jellyfish resources in Europe are currently not managed, in comparison to e.g. finfish fisheries thus hampering the sustainable, cost-effective harvesting of this biomass. In GoJelly we employed an ecosystem-based management approach based on jellyfish ecology, bloom dynamics, and the origin of seed populations. The aim was to analyse biotic/abiotic drivers that promote jellyfish blooms (e.g. in Trondheimsfjord), establish bloom predictions and sustainable harvesting tools. In this study, we address the knowledge gaps related to jellyfish fisheries and demonstrate future needs towards ecosystem-based management of local jellyfish resources.

Introduction

Accessibility to marine space is one of the major bottlenecks for the marine aquaculture sector. A methodology was defined for the implementation of MSP processes associated with marine aquaculture facilities in two Eastern Atlantic archipelagos: Madeira & the Canary Islands. The search for the most suitable marine locations is linked to 5 parameter clusters: oceanographic potential; environmental sensibility; restrictions related to marine conservation; Land-Sea interactions and avoidance of potential conflicts with extant maritime and coastal activities.

Materials and methods

A methodological approach has been designed to identify suitable marine areas with significant potential considering physical oceanographic parameters (temperature, depth…), minimizing impact on the marine environment (structured as Good Environmental Status defined by Marine Strategy Framework Directive 2008/56/EC), (in)compatibility with marine conservation (marine protected areas under the Natura 2000) and avoiding conflicts with operative maritime and coastal sectors (as coastal tourism, fisheries, aquaculture, maritime transport, etc.). We have applied this framework in the cases of Madeira (Portugal) and Canary Islands (Spain) in the Eastern Atlantic Ocean.

Results

Aquaculture Suitability maps were developed based on the outputs of the Decision Support System of INDIMAR, which analyzed potential aquaculture production sites in relation with each of the 5 cluster parameters, introducing weights as appropriate calculated using an Analytical Hierarchy Process. The applied approach strikes a balance for all the five clusters reflecting on Ecosystem Based Management components that should be mirrored in the Maritime Spatial Planning strategy, including options with trade-offs regarding sectoral growth, conflict prevention and environmental protection and conservation.

Finally, results are compared with the extant aquaculture areas included in both the Madeira Zones Areas of Interest for Aquaculture that were adopted by the National Spatial Maritime Plan, based on the study delivered by Torres and Andrade (2010), and the Regional Plan of Management of the Canarian Aquaculture approved in 2018.

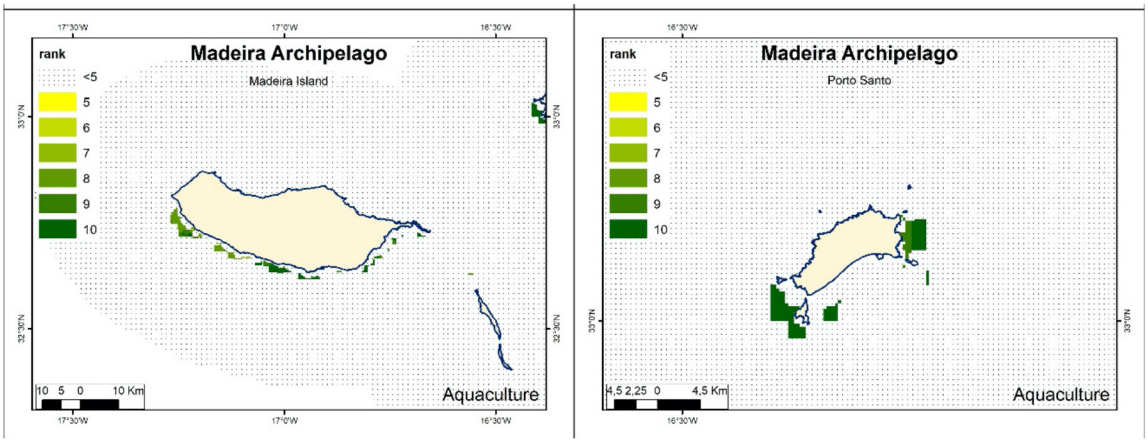

Figure 1: Aquaculture suitability maps for the Madeira and Porto Santo. Analysis delivered by INDIMAR Decision Support System considering physical oceanographic parameters, marine environment & conservation, avoiding conflicts with operative maritime and coastal sectors.

Introduction

The operation of open sea aquaculture (OSA) should be ecosystem-based, balancing ecological, economical, and social objectives for sustainable development. To tackle these issues we formed a consortium of six partners in a project that will and lay the groundwork of OSA in Cyprus. The project (OS-AQUA, 2020-2023) addresses marine spatial planning, the legislation framework, location selection through modeling, offshore aquaculture technologies, finfish species selection, environmental monitoring, and business development. The overall aim is to lead the way to economically and ecologically sustainable OSA business in Cyprus. This document discusses the milestones and developments of the project.

Setting the Scene: Marine Aquaculture in Cyprus

The first commercial-scale marine aquaculture unit in Cyprus was opened in 1989. Increased water temperatures allow the faster development of farmed species and production cycles can cover all seasons. The ultra oligotrophic waters of the Eastern Mediterranean Basin offer excellent water quality conditions. Cypriot coastline is unaffected by human nuisance or pollution and provides natural weather protection to OSA operations as opposed to the southern rim of EMED. Today, aquaculture in Cyprus accounts for about 85% of the total amount of Cypriot fishery production both in quantity and value.

Marine Spatial Planning and Legal Framework

National authorities use marine spatial planning to allocate space among the multiple users of the sea. The project sourced geospatial data of and planned project in the coast of Cyprus. The information was incorporated into a customized geographic information system. The system will be the basis of a reviewed National Marine Spatial Plan which will pave the way to a legal and regulatory framework to designate zones and facilitate the operation of OSA.

Ecological implications of OSA development

The HCMR Aquaculture Integrated Model (AIM) has been used to improve planning and management of OSA in Cyprus. Three nested submodels at 500m resolution were implemented to evaluate the effect of existing fish farms on the coastal environment of Cyprus (Kalaroni et al. *in-prep*). A finer-scale sub-model of targeted areas will be implemented to assess the future OSA units. The area most suited for the installation of an OSA unit in Cyprus will be further studied. An onsite survey will collect data in-line with the national regulation for aquaculture environmental assessment. A deep-water buoy will be placed as part of the suggested ongoing monitoring network for the development of OSA in Cyprus. In situ data will be used to ground truth modeling and satellite data.

Aquaculture unit design

Husbandry, robotics, artificial intelligence, and innovative materials have aided in advancement of OSA operation. Existing and new finfish species, cage and mooring designs, feeding systems, operational vessels, as well as innovative cage and fish monitoring systems, along with a new cage designed for the local conditions will be assessed for their use in Cyprus. The final proposals from this exercise will be taken into consideration in the bankable projects.

Bankable Projects

A risk analysis will reveal the economic performance of varying input parameters from sections 3, 4 and 5. A selection of the bankable demonstration projects will become the basis of detailed Business Plans which would inform industry and financing institutions interested in investing in the OSA in Cyprus.

(Continued on next page)

Challenges and Opportunities

The European Union supports sustainable aquaculture development financial and regulatory incentives. In line with these strategies, Cyprus includes open sea aquaculture and the opening of new markets as priority goals for the next decade (DFMR 2020). Nevertheless, the interdependency of parameters and the interests of multiple marine users need to be taken into consideration. To bridge this gap, stakeholders, regulatory bodies and investors will be brought together to discuss, offer opinions and solutions to this complex issue.

Conclusion

Given proper planning and encouragement, growth of the aquaculture sector in Cyprus will generate jobs and strengthen small companies that will design, install, operate, maintain and monitor the marine facilities, and attract investors to the island. Succeeding in this endeavor would significantly expand a profitable business sector leading to significant increase in food exports. The EAS conference is an excellent forum to gain insight and inform project outcomes.

Trichoderma viride PEPTAIBOL ACCELERATES APOPTOSIS IN *Aspergillus niger* INFECTING FISH IN AQUACULTURES

Iman Kamel Abumourad[1], Marwa Gamal[2], Mohamed Abou Zaid[2], Al-Zahraa Ahmad Karam El Deen[3], Hussein Abd El Kareem[2], Ola M. Gomaa[2*]

[1]Veterinary Division, National Research Center, [1]Microbiology Department, National Center for Radiation Research and Technology (NCRRT), Egyptian Atomic Energy Authority (EAEA), [3]Microbiology Department, Faculty of Science, Ain Shams University.

Introduction

aquaculture fish activity encounters many environmental problems. Two of environmental challenges fish farming faces are 1) fungal infection of fish and 2) lead contamination of aquaculture water.

Materials and methods

Trichoderma viride isolated from soil was used to produce peptaibol under shaking conditions at pH 6, temperature 30°C for 7 days in malt extract media.

Results

Incubating the extract with the *A. niger* induced catalase production, protein content and lipid peroxidation. The caspase 3 level was increased in fungus incubated with the fungal extract. The extract was characterized by boiling, Fourier Transform Infra-red Spectroscopy (FTIR) and Liquid Mass (UPLC/MS/MS) Chromatography 1294 m/z, the results show that the extract is a non-enzymatic protein that closely resembles peptaibol in structure. The extract was incubated with fish cell line and the results of DNA showed that 20 μl of the extract was effective in inducing apoptosis in *A. niger* and at the same time no changes were induced in the fish. This proves that the extract is safe to use in aquacultures.

Conclusion

The extract of *Trichoderma virde* has proved an efficacy in causing apoptosis, not mycostatic effect, in *Aspergillus niger* which is one of the main pathogens infecing fish in aquaculture. The results show that the extract defined as peptaibol was effective under optimized conditions. The extract also did not affect the fish or caused any toxicity which is a very important aspect when using a biocontrol agent. This work is part of another work that involves the use of *Trichoderma virde* in removal of lead in aquaculture which is another major problem that causes loss of fish in Aquaculture in Egypt.

Introduction
Nocardiosis caused by diverse, cosmopolitan aerobic actinomycetes species of the genus *Nocardia* is a common disease in several aquaculture species. In the Canary Islands, Spain, variated internal granulomas resembling those produced by nocardiosis were unexpectedly observed in cultured meagre (*Argyrosomus regius*). Hence, we aimed to identify the causative species and experimentally reproduce the disease.

Material and Methods
Following classical methods, the bacterium was isolated from granulomas in the liver of several specimens and identified using 16S-rRNA gene sequencing and MALDI-TOF MS. The local *in silico* alignments with known 16S-rRNA sequences revealed the target identity as *Nocardia brasiliensis*, a species never before reported affecting fish. The virulence of this species was experimentally characterized *in vivo*. Juvenile meagre intraperitoneally infected with *N. brasilensis* develop internal micro granulomas without gross external sign or significant mortalities. Fish exposed to concentrations lower than 10^6 CFUs did not die at all within the two months trial. Five types of microscopic granulomas with classic necrotic centers and macrophages arranges were recorded in a dose-dependency fashion. Besides, immunofluorescence revealed the presence of live bacteria withing some granulomas.

Results and Conclusion
To our best knowledge, this is the first report of *Nocardia brasilensis* as disease agent in marine cultured fish. Besides, these results show that *N. brasilensis* successfully colonizes internal fish organs and is sufficient to develop chronic granuloma disease in meagre.

THE RESPONSE OF MACROZOOBENTHOS ASSEMBLAGE ON LONG-TERM EXTREME FLOW RATE FLUCTUATIONS IN A CARP POND INFLOW CANAL

Introduction

Between 2014 and 2019, Central Europe was subject to unusually high temperatures and periods of drought due to climate change, with a subsequent negative impact on stream flow regimes, including the canals, providing water inflow to carp ponds. We examined changes in macrozoobenthos community composition and diversity in a small fishless brook (Němčický potok) supplying water to 0.5 ha carp pond in highland during the last decade. As temperatures rise and rainfall declines, many small water courses are likely to shift from permanent streams to intermittent (riffle-pool sequences replaced by isolated pools) or ephemeral (periods characterised by regular occurrence of dry riverbed) streams during periods of drought, often for periods of several weeks or longer (Bonada et al. 2006).

Material and Methods

While flow rates were relatively constant prior to 2014, the hydrological regime was significantly influenced by periods of severe drought between 2017 and 2019, with periods of zero discharge (ZD) and dry riverbed (DR) days. As this time period was characterized by dramatic decline of flow rates and by onset of atypical events of flow cessation and dry riverbed, the community of benthic macroinvertebrates (MIV) passed significant changes.

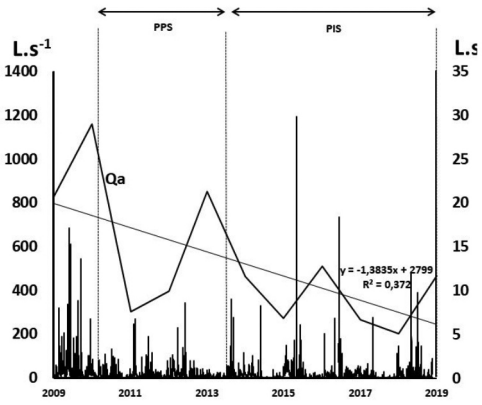

Fig 1. The course of recorded discharge rates (L.s^{-1}, left y axis) and mean annual discharge rates (Qa in L.s^{-1}, right y axis) during the periods of perennial (PPS) and intermittent stream (PIS – ZDs and DR days occurrence).

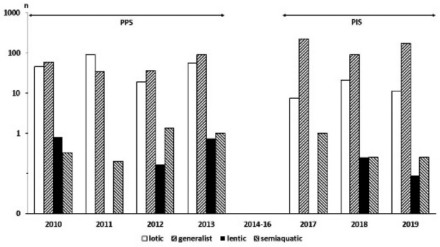

Fig. 3. Abundance (n) of habitat-associated groups during perennial (PPS) and intermittent (PIS) stream periods. Note: x axis in $\log_{10}$ scale.

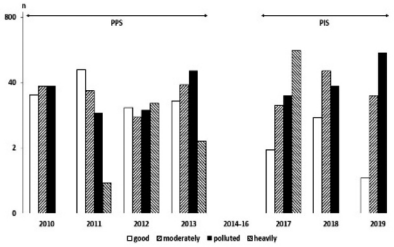

Fig. 4. Abundance (n) of water quality (saprobity) associated groups during perennial (PPS) and intermittent (PIS) periods. Note: x axis in $\log_{10}$ scale.

(Continued on next page)

Benthic MIV samples were obtained semi-quantitatively using a 1-minute hand-disturbance and sweep approach using a 0.5 mm mesh hand net (200x100 mm aperture). After laboratory processing, each taxon was assigned to one of four groups based on hydrological preferences, i.e. lotic, generalist, lentic or semi-aquatic. The classification by Sládeček [16], expressed as a saprobic index (S_I) was applied for assigning taxa into appropriate water quality (saprobity) categories in accordance with Czech National Standard [38], i.e. good, moderately polluted, polluted and heavily polluted.

Results

Hydrological patterns

We recorded no ZDs during the period between 2010 and 2011, with the first events being recorded in 2012 and 2013, though still with no DR occurrence - this was considered as a period of a perennial stream (PPS). The first eleven DR days occurred in 2014, persisting throughout the whole period until 2019. The highest DR frequency was recorded in 2015, with 110 ZDs and 81 DRs, and 2017, with 108 ZDs and 57 DR days which represented a period of an intermittent stream (PIS).

The average annual discharge rates (Qa) ranged between 7.57 to 28.96 $L.s^{-1}$ during the period 2010–2013, and 5.06 to 12.78 $L.s^{-1}$ during the period 2014–2019 (Fig. 1). Overall, Qa showed a declining trend ($R^2 = 0.372$, $p = 0.046$) between 2010 and 2018 with Qa dropping from 28.96 $L.s^{-1}$ to 5.06 $L.s^{-1}$ (Fig. 1).

The response of benthic MIV in the NEM brook was clearly dependent on the flow regime, and particularly on the frequency and duration of the ZD period. Taxa associated with lotic-habitats (e.g. *Gammarus fossarum*, *Baetis vernus* and *Micropsectra* sp.) dominated during the PPS period without ZDs (Fig. 2). During the dryer PIS period, however, lotic-habitat indicators had dropped, while the number of generalist taxa increased.

Conclusion

The macroinvertebrate community structure in a small fishless pond inflow canal was shaped by a transition from permanent to intermittent discharges resulting in waterless periods. The clearest impacts of this transition were a dramatic reduction (almost disappearance) in the population of *G. fossarum* and the prevalence of oligochaetes and dipteran larvae. Overall, the structure of the benthic macroinvertebrate assemblage shifted from being dominated by lotic taxa and good water quality indicators to one dominated by generalists and more tolerant taxa associated with more polluted environments.

GREAT CORMORANT (*Phalacrocorax carbo sinensis*) OCCURRENCE PATTERN IN CARP POND AQUACULTURE: CASE STUDY FROM THE SOUTH BOHEMIA (CZECH REPUBLIC) POND REGION IN 2019

Zdeněk Adámek

University of South Bohemia in *České* Budějovice, Faculty of Fisheries and Protection of Waters
South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses
Zátiší 728/II, 389 25 Vodňany, Czech Republic
zadamek@frov.jcu.cz

Introduction

The great cormorant (*Phalacrocorax carbo sinensis*) has fully recovered from an endangered status in 1980s and is now present throughout Europe. As fish are its almost exclusive prey, cormorant is considered as a conflict species in concern to fisheries, both to the management of open waters and aquaculture enterprises.

Carp ponds, which usually replaced the original wetlands, create a complex mosaic of habitats which often represent unique refuges for both plant and animal communities. As such, they are often considered to be 'hotspots' of aquatic biodiversity and cormorants are to be seen as an integral part of their ecosystems. On the other side, however, cormorant predation on ponds which are primarily destined for commercial culture of common carp (*Cyprinus carpio*) under specific conditions of carp pond aquaculture, is steadily considered as one of substantial negative factors influencing the production profits.

Currently, the numbers of cormorants in the Czech Republic were estimated as 813 breeding and 13148 migrating and wintering birds in 2019 (CFFU, unpubl.), which caused a loss in aquaculture production amounting to approximately ~ 4 million EUR. While birds in breeding colonies contribute ~ 0.5 million EUR to the damage, the losses caused by non-resident cormorants amount to ~ 3,5 million EUR.

The 2019 data on cormorant occurrence on carp aquaculture ponds in the Třeboň Biosphere Reserve were elaborated with respect to various aspects – namely pond size, annual course of occurrence, distance from the cormorant breeding colony and economic issues.

Material and Methods

Study area

The Třeboň Biosphere Reserve represents an old pond district with ca. 600 fishponds surrounded by agricultural and forrested landscape. Currently, one regularly occupied breeding colony with 139 nests (3.4 chicks per nest) exists in the reserve.

Data resource

The data on cormorant numbers were regularly monitored by the Třeboň Fisheries Co. as the maximum current daily counts for the purposes of the request for recompensation. The average daily numbers, expressed as cormorant/days (corm/d), in weeks 1 – 52 of the year 2019 were applied for further evaluation in this study. Altogether, data from 118 monitored ponds were elaborated. The ponds were divided into 5 groups according to their area - < 5 ha (24 ponds, 0.58 – 4.58 ha), 5 - 20 ha (44 ponds, 5.09 – 18.54 ha), 20 – 50 ha (24 ponds, 20.12 – 46.24 ha), 50 – 100 ha (15 ponds, 50.38 – 99.97 ha) and > 100 ha (11 ponds, 104.71 – 644.74 ha). Pond stocks consisted of carp pond polyculture species with the dominance of one- to three-year-old scaly and mirror common carp, which share ranged mostly between 80 – 100 %.

Table 1. Average numbers and economic losses in 2019. Note: n – number of ponds, Σ c/d – total number of cormorant/day, Σ kg – total fish losses in kg, Σ EUR – total losses in EUR, p – per pond, ha – per 1 ha of a pond

pond area	n	Σ c/d/p	Σ c/d/ha	Σ kg/p	Σ kg/ha	Σ EUR/p	Σ EUR/ha
< 5 ha	17	1327	475	663	238	1599	515
5-20 ha	44	1058	89	528	44	1255	105
20-50 ha	24	1031	32	515	16	1162	37
50-100 ha	15	2074	29	1037	15	2237	32
> 100 ha	11	5091	19	2544	10	6031	23

Results and Discussion

The annual pattern of cormorant abundance differed with respect to the pond size. While its course is rather even at ponds < 5 ha nearby the colony, the occurrence of spring and autumnal migratory birds is of increasing importance with increasing pond size. However, when taking into account the percentage distribution of annual occurrence, a smaller summer peak is also noticeable at all ponds due to appearance of young birds leaving the nests (Fig. 1).

The distance of a pond from the breeding colony proved to be another important factor influencing the attendance by cormorants. In this respect, the heaviest hunting pressure was focused on the ponds <50 ha within the 10 km distance while it was rather more evenly distributed at bigger (>50 ha) ponds (Fig.2).

Total numbers of cormorant appearance per day (corm/day) were highest on biggest ponds (> 50 ha) but when considering their counts per ha, small ponds (< 5 ha) were under strongest hunting pressure. The same applies to values expressing the losses both in fish biomass and, in particular, in financial consequences. Economic losses in smaller ponds were increased evidently due to the higher price of young fish cultured in them (Table 1).

Introduction

Oysters are among the most appreciated seafood products and there has been an increase in their production worldwide, being among the five most valued species farmed in the EU (FAO, 2019). The culture of bivalve molluscs is an activity with high expression in Portuguese aquaculture. It represents 55% of the whole production, being the main species, clams, oysters and mussels (INE, 2019). The Portuguese oyster, *Crassostrea angulata*, is a very important resource, not only because of its socioeconomic value but also because of its genetic heritage. This species declined and disappeared from the estuaries on 1970s due to massive mortalities, but currently this resource seems to be recovering and is mainly found in wild beds, with particular edaphoclimatic conditions.

The marine environment is known to provide several sources of stress to oysters during their life cycle, including changes in environmental parameters, changes in the availability of food and the display of various toxic pollutants (Lacoste *et al*., 2001; Kennedy *et al*., 1996; Garnier *et al*., 2007). Aquatic ecosystems can be modified by human activity, namely due to overharvesting and destruction of substrates (Pogoda, B 2019). Also, transfers of oysters between countries and regions can spread diseases and invasive species.

Aquatic animals can transmit infection to the consumer. Nowadays, zoonosis have a worldwide distribution and the consumption of aquatic animals, including oysters, has been growing. There are parasites that are responsible for zoonosis and other species that are not transmissible to humans but can have repugnant aspect and will not be consumed.

The identification of lesions and pathogenic agents in aquatic animals, namely in oysters, for human consumption represent an important information for sanitary control. For the study of pathologic lesions it is necessary to perform necropsies of animal samples to identify lesions and etiologic agents. This work shows the importance of necropsy and the anatomohistopathological exam for the sanitary control, to identify lesions and pathologic agents that wouldn't be recognized and observed by the consumers.

Materials and Methods

Oysters were sampled from four different sites of the Portuguese coast. Portuguese oyster from Sado estuary (n=30) and Mira estuary (n=30) and Japanese oyster from Alvor lagoon (n=30) and Aveiro lagoon (n=30). Oysters were collected from populations of Japanese oyster cultivated in a strong ocean-influenced environment and from populations of Portuguese oyster cultivated in wild-beds with distinct edaphoclimatic conditions than those found in production nurseries. To survey the presence of lesions and diseases anatomo and histopathological examinations were used as main diagnostic methods. Tissue samples were prepared for histopathology processing, following the protocol used in Pathology laboratory of IPMA. Samples were fixed in Davidson's fixative for 48h, dehydrated and embedded in paraffin. Sections with 5μm thick were stained with Hematoxylin-Eosin and mounted on a microscopic glass slide.

Histological preparations were carefully examined under light microscopy (Motic BA-410), looking for the presence of lesions and pathogens in oysters.

(Continued on next page)

Results

The macroscopic lesions and microscopic lesions were recorded in the specimens collected in wild beds (*C. angulata*) and farmed oysters (*C. gigas*). Samples of *C. angulata* from Sado Estuary show the following results: 20% presented mud blisters, mainly caused by *Polydora sp.*; 33% with gills lesions; 10% had shell disease associated with the presence of the fungus *Ostracoblabe implexa*. Samples from Mira Estuary showed mud blisters (96%), 50% had gills lesions, 10% presented edema and 10% shell disease. In samples of *C. gigas* from Aveiro Lagoon, it was observed only 3% of oysters with edema and 3% with shell disease. Finally, in samples of *C. gigas* from Alvor Lagoon 10% presented mud blisters.

Discussion and conclusion

The aim of the present work was to study the evolution of the sanitary condition in oyster production in four different populations of oysters were sampled. Lesions of the internal organs, such as metaplasia, may reflect physiological stress, contaminants or the presence of large parasitic loads (Ruano, 1997). Hemocytosis and edema was mainly present in the interstitial connective tissue. The lesions observed in the epithelium of the diverticula of the digestive gland, the hemocytic infiltration and necrosis were usually associated and could be related with the presence of the observed pathogenic agents. The low number of lesions found in oysters reflects the good sanitary condition.

The lesions observed in the epithelium of the diverticula of the digestive gland, the hemocytic infiltration and necrosis were usually associated and could be related with the presence of pathogenic agents observed. No organisms potentially pathogenic to humans were identified. The identification, characterization and registration of pathologic processes in oysters constitutes important measures for sanitary control and an appropriate for the sustainability of oyster populations management.

Introduction

Total or partial replacement of fishmeal (FM) with black soldier fly (BSF) pre-pupal meal induced a growth reduction in many species such as Nile tilapia (*Oreochromis niloticus*), African catfish (*Clarias gariepinus* and zebrafish (*Danio rerio*) (Zarantoniello et al., 2019; Adeoye et al., 2020; Agbohessou et al., 2021). In our previous experiment, total substitution of FM and fish oil (FO) with BSF larval meal enriched with long-chain polyunsaturated fatty acids (LC-PUFAs) combined with palm oil improved the essential fatty acid content of the whole body of the fish, but decreased the protein digestibility and consequently the growth rate of Nile tilapia (Agbohessou et al., 2021). Chitin in insect meals may affect protein availability and digestibility and thus growth performance. Fish consuming insects have an important adaptation that relates to the digestive tract system of carnivorous and omnivorous fish; the gastrointestinal tract of many fish displays chitinase activity to facilitate insect consumption (Nogales-Mérida et al., 2019). Chitinase can hydrolyze chitin into chitin oligosaccharides, including oligomers, chitobiose and N-acetyl-glucosamine, which may play the role of antibacterial agents, lysozyme inducers and immunostimulators (Zhang et al., 2012). The present study aimed to determine the combined effects of LC-PUFAs and/or chitinase enrichment of BSF-based diets on the growth, digestibility, digestive enzymes, gut microbiota and immune status in Nile tilapia juveniles.

Materials and methods

Two types of BSF meals enriched with either a-linolenic acid (ALA) or ALA + eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) were produced using BSF pre-pupae cultured on vegetable substrates (VGS) or fish offal substrates (FOS), respectively. Seven diets were formulated, namely a control FMFO diet and two other control diets BSF/VGS0 and BSF/FOS0 containing the meals of each type of BSF meal as total replacement for FM and FO, as well as four diets supplemented with chitinase. Two doses of commercial chitinase from *Aspergillus niger* (Creative Enzymes, USA) (2g/Kg and 5g/Kg of feed) were supplemented to the other diets containing BSF/VGS and BSF/FOS meals to formulate BSF/VGS2, BSF/VGS5, BSF/FOS2 and BSF/FOS5 diets. Extruded pellets were prepared and a set of 630 sex-reversed male Nile tilapia juveniles (5.57 ± 0.05g) were randomly distributed in 21 tanks with a density of 30 fish per tank, and three tank replicates per feeding treatment. Fish were hand-fed to apparent satiation three times daily for 53 days to evaluate growth performance and feed utilization.

Table 1. Growth performance and feed utilization of juvenile Nile tilapia fed with FM and FO or BSF meals enriched with (LC)-PUFA and supplemented with chitinase for 53 days (mean ± S.D., n = 3). Values from the same line with different superscript letters are significantly different ($P < 0.05$).

Parameters	FMFO	BSF/VGD0	BSF/VGD2	BSF/VGD5	BSF/FOD0	BSF/FOD2	BSF/FOD5
Specific growth rate (SGR, % d^{-1})	3.61 ± 0.14^{a}	2.98 ± 0.19^{c}	3.11 ± 0.16^{bc}	2.96 ± 0.17^{c}	3.20 ± 0.06^{bc}	3.17 ± 0.12^{bc}	3.43 ± 0.26^{ab}
Feed intake (FI, g/fish/day)	0.63 ± 0.05	0.55 ± 0.03	0.58 ± 0.06	0.53 ± 0.02	0.63 ± 0.08	0.59 ± 0.06	0.61 ± 0.09
Feed efficiency (FE)	0.96 ± 0.05^{a}	0.74 ± 0.10^{b}	0.77 ± 0.03^{b}	0.75 ± 0.08^{b}	0.74 ± 0.06^{b}	0.78 ± 0.03^{b}	0.91 ± 0.06^{a}
Protein efficiency ratio (PER)	3.03 ± 0.02^{a}	2.32 ± 0.31^{b}	2.43 ± 0.12^{b}	2.37 ± 0.26^{b}	2.33 ± 0.20^{b}	2.45 ± 0.09^{b}	2.87 ± 0.20^{a}

(Continued on next page)

A digestibility test was performed on the same fish used for the growth test, but three weeks after feeding the different diets. Fish were fed a diet containing chromium oxide (Cr_2O_3) as an inert marker at a level of 1% compared to the previous formulation, and the fish were fed under the same conditions as the growth experiment. At the end of the feeding trial, the total number of fish and their body weight were recorded to determine the survival (SR) and growth rates. Blood, kidney and spleen samples were collected from 6 fish per aquarium and stored at -80°C for immune analysis. Stomach and intestine samples were collected for digestive enzymes, microbiota and histopathology analysis. A challenge test with bacterial lipopolysaccharide (LPS) was performed and 24 h later, blood, kidney and spleen samples were collected to evaluate the response of fish after LPS stimulation. Lysozyme activity, total peroxidase activity and plasma hemolytic alternative complement (ACH50) activity will be assessed in plasma before and after LPS stimulation. Immune gene expressions will be analyzed by Real-time qPCR in kidney and spleen samples before and after LPS stimulation while chitinase gene expressions will be analyzed in the intestines. The activities of digestive enzymes such as pepsin, amylase and chitinase will be analyzed in the stomach, and trypsin, alkaline phosphatase and aminopeptidase will be analyzed in the intestine. For histopathological analysis, the samples of anterior intestine were fixed in 10% neutral buffered formalin. Histological images will be acquired using a digital color camera combined with the microscope. For the description of the gut microbiota, we will use the next generation sequencing (Illumina HiSeq 2500). The hypervariable V1-V3 region 16S rRNA gene will be sequenced to assess the taxonomic composition and diversity index of bacteria.

Results and discussion

After 53 days of feeding, the BSF/FOD5 diet induced a growth performance (SGR) similar to the one of the FMFO control diet, while a significant decrease ($p < 0.05$) was observed for the other insect-based diets in relation to a lower feed efficiency (FE) and protein efficiency ratio (PER) ($p < 0.05$). However, the feed intake (FI) and the survival rate which varied from 82.22 to 93.33% were not significantly affected by the different diets (Table 1).

Fish fed the BSD/FOD5 diet, rich in ALA, EPA and DHA and supplemented with 5g of chitinase per Kg of feed showed growth rates comparable to those of fish fed the FMFO control diet, with higher values than those of fish fed other BSF meal diets. The combined effect of 5g of chitinase per Kg of feed and LC-PUFA enrichment of BSF meal improved the growth and feed efficiency of fish consuming the BSF/FOD5 diet.

Subsequent biochemical analyses are in progress, including diet digestibility, digestive enzymes, gut microbiota, gut histopathology, immune defense capacity and the response after LPS injection of fish fed the different diets. The results of these different analyses will be available for the oral communication.

YEAST AS A PROTEIN SOURCE WITH HEALTH BENEFICIAL EFFECTS IN DIETS FOR ATLANTIC SALMON (*Salmo salar*)

J. O. Agboola*, B. Morales-Lange, J. Ø. Hansen, L. T. Mydland, M. Øverland

Department of Animal and Aquaculture Sciences, Faculty of Biosciences, Norwegian University of Life Sciences, P. O Box 5003, NO-1432, Ås, Norway
Jeleel.opeyemi.agboola@nmbu.no

Introduction

Yeasts are gaining increasing focus as major protein ingredients in fish feeds. This is in part due to their ability to convert non-food biomass of low industrial applications into high valuable resources. In addition, yeast cell wall contains bioactive components such as β-glucan, mannan and chitin, which are known for their health beneficial effects in fish. Yeasts also contain about 50-60% of crude protein with favourable amino acid composition. Therefore, in the present study, we examined the nutritional value and health effects of three non-*saccharomyces* yeasts exposed to different down-stream processing conditions in diets for Atlantic salmon.

Materials and methods

Cyberlindnera jadinii (CJ), *Blastobotrys adeninivorans* (BA) and *Wickerhamomyces anomalus* (WA) yeasts produced from wood sugars and chicken hydrolysates were either heat inactivated (I) or autolyzed (A) and the feeding quality of the resulting yeast products were evaluated through two studies with Atlantic salmon. The first trial assessed the ability of yeasts to restore intestinal health in Atlantic salmon fry exposed to a dietary soybean meal challenge. The experimental diets consisted of a fish meal-based control (FM), a challenge diet with 40% soybean meal (SBM), and 6 test diets with 40% SBM and 5% of each of the yeast products (ICJ, ACJ, IBA, ABA, IWA and AWA). Fish were fed one of the experimental diets for 37 days, after which distal intestine, head-kidney and spleen were collected for histological and immune response analyses. The second trial evaluated the nutrient digestibility of the different yeast products using experimental diets containing 700g kg^{-1} of a FM reference diet and 300g kg^{-1} of each of the yeast products.

Results and discussion

The crude protein content of the three yeasts ranged from 38-53% and the yeasts contain cell wall components that support growth and health of Atlantic salmon. Autolysis modified the ultrastructure layers of the yeast cell wall (Figure 1a). Atomic force microscopy analysis demonstrated that the ability of yeast mannoprotein to bind to cell surfaces changed with the autolysis process. Histological evaluation of distal intestine based on widening of lamina propria, showed that AWA was effective in restoring gut health, while only limited effects were observed for the other yeasts (Figure 1b). As determined by indirect ELISA, inclusion of yeasts in Atlantic salmon diets induced production of TNFα and a concomitant reduction in Annexin 1 level compared to SBM fed fish (Figure 2a), which suggests a modulation of the immune response. Protein digestibility in inactivated yeast ranged from 63-72% and increased by 9-12% after autolysis (Figure 2b).

Conclusion

Based on the results of this study, yeast has a high nutritional value and can give positive health effects, and could thus be used as major protein ingredient in fish feeds. Ongoing analyses will evaluate the ability of the different yeasts to modulate gut microbiota of Atlantic salmon.

The immunological markers are presented as fold change relative to SBM, and the digestibility as percentage.

BUILDING A GROWTH MODEL FOR *Hediste diversicolor* AQUACULTURE

F. Aguado-Jiménez[1*], B. García-García[2], I. E. Martín-Montero[1] and I. Rasines-Pérez[1]

[1] Spanish National Research Council. National Center Spanish Institute of Oceanography. Oceanographic Centre of Santander. "El Bocal" Marine Aquaculture Station. Monte-Corbanera, 39012, Santander, Spain
E-mail: felipe.aguado@ieo.es

Introduction

The "ragworm" *Hediste diversicolor* is a euryhaline and eurytherm polychaete with a great feeding plasticity. Its demand for baitfish and as food for fishes and crustaceans makes him a good candidate for the aquaculture industry (Batista et al., 2003). Modelling growth is basic for aquaculture purposes from a husbandry point of view, in order to establish a correct planning and optimization of production performance. In this work we show the results obtained to date of an experience in progress whose main objective is to build a growth model of *H. diversicolor* with the body weight and water temperature as descriptive variables.

Material and methods

Ragworms of nine different size classes (< 25 mg; 25-50 mg; 50-75 mg; 75-100 mg; 100-150 mg; 150-200 mg; 200-250 mg; 250-300 mg; 300-400 mg) coming from a captive population stock were placed in experimental units (EU) which consisted of a cylindrical PVC structure (height: 20 cm; internal Ø: 11.3 cm) whose wall and base were 335 μm mesh. EUs were filled with sifted sand (0.25-1 mm grain size) to a height of 12 cm. The substrate was always submerged. Ragworm density was about 1,000 ind m^{-2} (10 ind. per EU). Each size class was in triplicate. Groups of 6 EUs were placed inside polycarbonate trays (width: 35 cm; height: 30 cm; length: 54 cm) which were part of a Recirculating Aquaculture System (RAS) with a daily water renewal rate of around 10 %. The RAS had biological and mechanical filtration, UV sterilization and temperature control. Salinity was around 36 ‰ and photoperiod was 16L:8D. Ragworms were weighed (wet body weight: *BW*) to the nearest mg at the beginning (BW_i) and at the end (BW_f) of the experimental period of 15 days during which they were fed to apparent satiety with sole (*Solea senegalensis*) weaning feed pellets (0.35-0.50 mm in size) once a day. Dissolved oxygen was always close to 100 % saturation, and ammonium level below 0.1 ppm. The assay was conducted at three different temperatures (*T*): 10-11 °C, 15-16 °C, and 19-20 °C. Absolute growth rate ($AGR = \frac{BW_f - BW_i}{t}$) was calculated for each EU. A natural-log relationship between *BW* and growth has been clearly established for most animals (Aguado-Giménez & García-García, 2002). In order to explain variations in growth according to *BW* and *T*, data were empirically fitted by mean of multiple regression analysis (MRA) to equations such as the following:

$$LnAGR = Ln\ a + b \times LnBW + c \times LnT \quad \text{(Eq. 1)}$$

$$LnAGR = Ln\ a + b \times LnBW + c \times T \times LnBW \quad \text{(Eq. 2)}$$

Eq. 1 predicts that maximum *AGR* will occur around an optimum *T* and it is independent of *BW*, while Eq. 2 predicts that the optimum *T* for *AGR* changes with *BW*. Estimations of *AGR* were carried out with both models. Residual analysis was performed by linear regression to compare the goodness of fit of both models.

Results and Discussion

Variability explained by both models was very high, and the estimation error was low for both models (Table 1). As it was expected, MRA showed that *BW* and *T* have a strong influence on *H. diversicolor* growth: the larger the ragworm and the higher the temperature, the higher the growth. The coefficient of determination R^2_{adj} and the goodness of fit were slightly better for Eq. 1 (Table 1; Figure 1C), but the differences in estimating *AGR* were minimal (Figure 1 A-C). We go on conducting trials with worms of the same size classes and higher, and at temperatures above and below those set out in this communication. It would be expected that expanding the range of *BW* and *T*, the combined effect of weight and temperature on growth may be highlighted, being able to define the optimum *T* for growth depending on the worms size.

INTERANNUAL VARIATION IN ENERGY CONTENT OF MARINE COSTAL SESTON DETERMINED BY DIRECT CALORIMETRY

T. Strohmeier*, R. Filgueira, P. J. Cranford, L. E. Steeves, A. Aguera, C. Krogness and Ø. Strand

*Institute of Marine Research, PO Box 1870 Nordnes N-5817 Bergen Email: tores@imr.no

Suspension feeders (mollusks) are currently by far the world's largest marine non-fed cultured production of animals [14]. This vast production capacity relies on their capacity to exploit the largest trophic resource in the marine environment, the seston. The seston comprises plankton and inorganic and organic matter in suspension. This multifaceted food resource varies on spatial and temporal scales with respect to concentration, biopolimeric composition, energy content and nutritional value [2-7, 9].

The seston food source, and the ecological and physical processes that control this food supply, fuels growth, sets the production capacity and determines the ecological carrying capacity of low trophic animal aquaculture [7, 8, 10, 11]. However, a unifying approach for quantifying this food resource that can explain growth, production and ecological carrying capacity is currently lacking.

Proxies of seston abundance and nutritional quality are typically converted to energy content units (J g^{-1}) using a constant factor to estimate the capacity of the food supply to support bivalve production. The factors commonly used are 47.7 J mg^{-1} for phytoplankton carbon [16] and 23.4 J mg^{-1} for living organic "particle" [15]. There are few published studies on the energy content of mixed seston [1, 6, 12, 13, 17, 18] and to our knowledge none that has directly measured the temporal energy content of seston. Since the temporal variation in the relationship between the food proxy and the actual energy content of the seston is not known, there is a large potential for erroneous interpretation of the capacity of the ambient food resource to support aquaculture.

The presentation will summarize the temporal (interannually) variation in energy content of marine costal seston as determined by direct calorimetry.

Blue mussels, *Mytilus edulis* L., are an important natural and cultured resource in coastal areas around the world. As such, there has been a wide interest in describing the physiological performance of blue mussels in varying environments. However, our understanding of the individual plasticity as environmental conditions change is still limited.

High temporal resolution measurements of feeding physiology and metabolism are necessary to gain further insight on how sensitive blue mussels are to natural changes. Key physiological aspects such as the adaptation to different seasons, plasticity under variable combinations of food and temperature or individually predetermined physiological performance are still poorly understood. To increase our knowledge in these aspects we measured growth, feeding physiology (clearance, retention rates) and metabolism (respiration rate) of the same 20 mussels exposed to the natural variation of food, temperature and salinity. An automatised system performed measurements of feeding every 2 hours and respiration every 4 hours during one year.

Over 17000 respirometries and 34000 measurements of clearance and retention were collected over that year. Preliminary results show that mussels exhibited a wide variability in both metabolism and feeding physiology that reflected in growth and overall performance. Individuals could not be classified as either slow or fast growers/feeders but a continuous range of performance was observed that resulted in larger variability of measured growth, feeding and metabolism as the experiment progressed. Food was the main driver of both feeding physiology and metabolism variability during the year, with little effect of temperature in modulating these within the observed temperature range (5 - 18°C).

BEHAVIOURAL FEVER PROMOTES AN INFLAMMATORY REFLEX CIRCUIT IN ECTOTHERMS

Andrea Aguilar[1], Nataly Sanhueza[1], Sebastian Boltaña[1]

[1]Centro de Biotecnología, Departamento de Oceanografía, Universidad de Concepción, Concepción 4030000, Chile

The communication between the brain and the immune system is a cornerstone in animal physiology. This interaction is mediated by immune factors acting in both health and pathogenesis, but it is unclear how these systems molecularly and mechanistically communicate under changing environmental conditions. Behavioural fever is a well-conserved immune response that promotes dramatic changes in gene expression patterns during ectotherms' thermoregulatory adaptation, including those orchestrating inflammation. However, the molecular regulators activating the inflammatory reflex in ectotherms remain unidentified. Methods: We revisited behavioural fever by providing groups of fish a thermal gradient environment during infection. Our novel experimental setup created temperature ranges in which fish freely moved between different thermal gradients: (1) wide thermoregulatory range; $T^{o} = 6.4\ ^{o}C$; and (2) restricted thermoregulatory range; $T^{o} = 1.4\ ^{o}C$. The fish behaviour was investigated during 5-days post-viral infection. Blood, spleen, and brain samples were collected to determine plasmatic pro- and anti-inflammatory cytokine levels. To characterize genes' functioning during behavioural fever, we performed a transcriptomic profiling of the fish spleen. We also measured the activity of neurotransmitters such as norepinephrine and acetylcholine in brain and peripheral tissues. Results: We describe the first set of the neural components that control inflammatory modulation during behavioural fever. We identified a neuro-immune crosstalk as a potential mechanism promoting the fine regulation of inflammation. The development of behavioural fever upon viral infection triggers a robust inflammatory response in vivo, establishing an activation threshold after infection in several organs, including the brain. Thus, temperature shifts strongly impact on neural tissue, specifically on the inflammatory reflex network activation. At the molecular level, behavioural fever causes a significant increase in cholinergic neurotransmitters and their receptors' activity and key anti-inflammatory factors such as cytokine Il10 and Tgfβ in target tissues. Conclusion: These results reveal a cholinergic neuronal-based mechanism underlying anti-inflammatory responses under induced fever. We performed the first molecular characterization of the behavioural fever response and inflammatory reflex activation in mobile ectotherms, identifying the role of key regulators of these processes. These findings provide genetic entry points for functional studies of the neural–immune adaptation to infection and its protective relevance in ectotherm organisms

EFFECT OF DIFFERENT DOSES OF DIETRY EUROPEAN OLIVE OIL PROCESSING BY-PRODUCT ON THC AND DHC OF PACIFIC WHITE SHRIMP (*Penaeus vannamei*)

Introduction

Pacific white shrimp as a commercial resources in aquaculture has been always effected by many infectious diseases. The use of the plant immunostimulants in compare with antibiotics, which are harmful for human, animals and also environment, is an alternative for disease management and has become a common practice recently. Phenolic compounds in olive oil processing by-products, regarding to phytotoxic and antimicrobial activities can be a great risk for the organisms in the case of sludge accumulation in the environment (Jerman Klen et. al., 2015). Thus using them in animals diet can profited them from antioxidant properties (Artajo et. al., 2006) and reduce the damaging organic load to the environment. The innate immune system of the shrimps mostly involve hemocytes and are consist of hyalinocytes, granulocytes and semi-granulocytes which have biological functions against pathogens. Hyaline and semi-granular cells are in charge of phagocyte activity (Johansson et. al., 2000), while granular cells are more responsible for prophenoloxidase and cytotoxicity functions. One part of this comprehensive study has been specified to study the innate immune system and the levels of THC and DHC of the shrimps using different amounts of olive pomace in the diet.

Materials and Methods

For this purpose 225 shrimps weighing 8.09±0.04g divided into 5 groups in triplicates after adaptation at 28 °C, pH 7.55, dissolved oxygen 7.37. Five experimental diet consisting 0, 3.5, 7, 10.5 and 14 percent olive pomace (OP), were formulated to be iso-nitrogenous (421 g/kg crude protein) and iso-lipidic (121 g/kg crude lipid) according to NRC nutrient values of Pacific white shrimp. Approximate composition of diets were determined by AOAC, 2000.After 60 days, THC and DHC of each treatments were determined. For this purpose sterile syringe were used to withdraw 1-ml of haemolymph from the ventral sinus of shrimps and were diluted individually in Alsever anticoagulant solution (ratio 1:1). A drop of this mixture was loaded on a haemocytometer to count the THC and DHC.

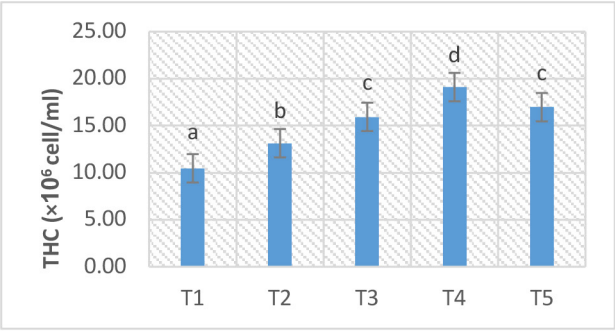

Fig 1- Total Hemocyte Count (THC) of five different doses of the five treatments

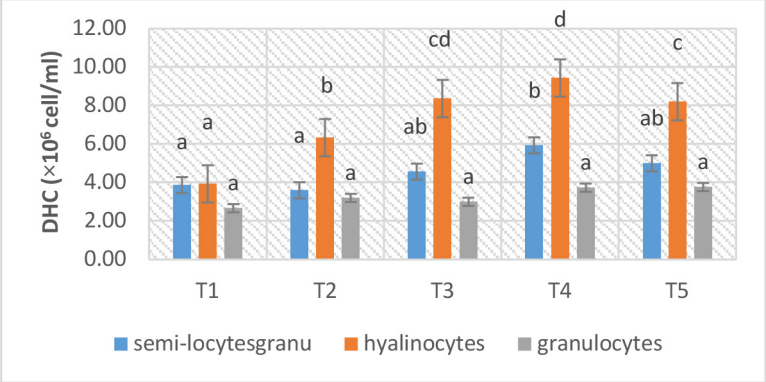

Fig 2- Differential Hemocyte Count (THC) of the five treatments

(Continued on next page)

Result

The results show that the control treatment which consisted no amount of olive pomace had the lowest level of THC (10.47×106cell/ml) sixty days after consuming the diet, while the highest level of THC belonged to the fourth treatment, OP10.5 (19.1×d106cell/ml) with a significant difference ($P<0.05$)(fig. 1). Comparing the amount of different hemocytes revealed that hyalinocytes are the most abundant cells while the granulocytes are the least cells in each treatment. Differential hemocyte count (DHC) showed the most level of hyaline cells and semi-granular cells in the treatment of 10.5% OP (treatment 4) with 9.43×106 and 5.93×106 cell/ml respectively and the least hyaline cells and semi-granular cells in the control treatment with no olive pomace (fig. 2). Granular cells however are almost the same in every group with no significant difference ($P>0.05$). Considering the hemocytes in this survey, using 10.5% of olive pomace in the diet of the shrimps had the best effect in boosting its immune performance.

Introduction

Tilapia farming is one of the most important finfish species cultured worldwide with a total global production estimated at more than 6.6 million tonnes (in 2016 ;FAO 2018). Recently, a novel strain of infectious spleen and kidney necrosis virus (ISKNV) has been identified that is an agent of high morbidity and mortality threatening tilapia aquaculture. In tilapia farms in Lake Volta, Ghana, molecular diagnostics of regional fish farms have suggested rapid spread of the disease (in a matter of months), with losses of more than 10 tonnes of fish per day following infection (Ramírez-Paredes et al. 2019). A primary objective of this work in this study is developing methods for long read sequencing to enable field-based, real-time genomic surveillance of ISKNV phylogeography, adopting a similar approach to the recent work by the Artic Network group on Ebola, Zika virus and SARS-CoV-2. Whole genome sequencing captures all variation across the full genome, providing greater resolution of emerging diversity. Phylogeographic analysis can be used to reconstruct a detailed spatial history of virus spread from the origin of an outbreak. With the information obtained from genomic surveillance and epidemiological data, it is possible to reconstruct chains of transmission (Quick et al. 2020), (Gardy et al. 2015).

Materials and methods

This study was performed on samples collected by the Centre for the Environment, Fisheries and Aquaculture Sciences (Cefas), from seven farms in Lake Volta/Ghana, during an outbreak of ISKNV between October/2018- July/2019. We performed whole genome sequencing of ISKNV from infected fish using a tiled PCR approach, with 2000 nt amplicons spanning the genome. Library preparation was conducted on the generated amplicons. Samples were multiplexed and sequenced using the MinION sequencer. High accuracy base calling was carried out after sequencing from the fast5 files using the Oxford Nanopore Guppy tool *(v.* 5.0.7*)*. A consensus genome was generated according to the ARTIC bioinformatics pipeline (artic.network/ncov-2019/ncov2019-bioinformatics-sop.html). Geneious Prime software (Biomatters, Auckland, New Zealand) was used to explore the ISKNV strains collected from Ghana, and visualise gene variability and single nucleotide variants (SNV). The generated consensus sequences were aligned with previously ISKNV published genomes to create a phylogenetic tree.

Results and discussion

In this study, we were able to recover 85%- 89% of the ISKNV genome, directly from fish samples collected from Ghana during an outbreak, using the tiled PCR protocol. Approximately 125 SNVs were detected, when compared with the original reference genome, and it has shown that changes were sufficient to detect a phylogeographic signal during this outbreak. This work shows that PCR tiling approaches used successfully to track the evolutionary rate, signatures of host adaptation, and transmission patterns of **RNA viruses** (Quick et al. 2016) can also be applied to monitor infections of a **large dsDNA** fish viruses. Thus, this method can be utilised as a surveillance tool for other viral infections threatening the growth of the aquaculture industry. RAMPART (Artic Network), (https://artic.network/rampart) software was used to determine coverage in real-time for samples collected from four different farms.

Future research

Further studies will include determining the sensitivity of the Artic-Network protocol across a range of viral loads. We aim to use the qPCR to monitor viral concentration in the surrounding water bodies, and neighbouring aquaculture sites to assist in the monitoring and management of viral outbreak threats. Through detecting the gradient of virus concentration in the water, moving away from infected farms we propose to evaluate the possible threat to stocks to other farms and to assess whether the spread of the virus is operating through water flow or movement of livestock. Determining the concentration of ISKNV from water samples, and via amplicon sequencing, may enable us to monitor the ISKNV variants present in a farm without destructive sampling. Finally, we aim to adapt this protocol to track other important fish viruses threatening aquaculture, and establish how this method may be applicable in the field.

halberts@awi.de

Introduction

In aquaculture, marine specimens from lower trophic levels have the potential to serve as alternative food source for farmed fish and invertebrates, replacing traditional meal and fish oils. Marine amphipods are a natural food source for many marine fish and thus became of increasing interest for feeding fish in aquaculture (Alberts-Hubatsch *et al*. 2019).

In the amphipod *Gammarus locusta*, diet can heavily impact the nutritional composition such as fatty acid profiles. This low-trophic species also produces other compounds valuable for feeding in aquaculture such as pigments, i.e. astaxanthin. This study investigated the impact of feed type on the pigment profile and content of *G. locusta* in relation to changes in feed type.

Material and Methods

Freshly hatched juvenile *Gammarus locusta* were extracted from a steady culture and raised on *Fucus* spp. for two weeks to produce a baseline in feeding status. Four treatments in quadruplicates were designed to reflect successive changes in feeding between a marine control diet, consisting mainly of dried *Fucus serratus*, and a terrestrial diet consisting of dried leaves of the carrot *Daucus carota*. The specimens in the first treatment (A) were exclusively fed with dried algae for 28 days, the second treatment (21/7) was fed with algae for 21 days, followed by 7 days of feeding with carrot leaves, the third treatment (14/14) were fed algae for 14 days, followed by carrot leaves for 14 days and the fourth treatment (C) was exclusively fed with carrot leaves. Feeding was carried out in excess twice a week, remaining feed was removed from the containers and replaced with fresh feed.

At the end of the experiment three individuals of each replicate were pooled and stored at - 80°C for pigment analysis. Pooled samples as well as triplicate samples of the diets were then analyzed on a Hitachi La Chrome Elite™ RP-HPLC with diode array detection at 475 nm and astaxanthin as standard.

Results

We found varying contents of carotenoids in the four treatments with highest amounts of carotenoids in gammarids fed the carrot leaf diet (1.04 ± 0.12 mg/kg dry weight) and lowest content in the *Fucus* diet (0.47 ± 0.13). In total, six major different carotenoids were detected in the four treatments (Table 1). A shift in pigment profile in correlation to the diet could be observed, with the algae treatment resulting in five major carotenoids shifting to only three major pigments in the carrot treatment.

No differences were observed in the astaxanthin content between the treatments ($p \geq 0.05$, $F(3, 17) = 0.8996$; $p = 0.4659$), but distinct differences were observed in lutein content ($p \leq 0.05$, $F(3, 17) = 7.562$; $p = 0.003$), with the gammarids fed carrot leaves showing highest levels of lutein (0.73 ± 0.10) and specimens from the *Fucus* diet having lowest amounts.

Table 1 Total amount (mg/kg) of major carotenoids of *Gammarus locusta* in relation to type of feeding. C indicates feeding with carrot leaves, F indicates feeding with *Fucus* spp., 14/14 and 21/7 indicate intermediate feeding regimes (see text).

Carotinoid	C	F	14/14	21/7
Fucoxanthin	---	1.11 ± 1.63	---	0.10 ± 0.10
Violaxanthin	---	0.13 ± 0.04	---	0.05 ± 0.05
Astaxanthin	0.11 ± 0.01	0.18 ± 0.07	0.23 ± 0.06	0.21 ± 0.02
Zeaxanthin	---	0,04 ± 0,01	---	---
n.n.	0.19 ± 0.02	---	0.18 ± 0.05	0.10 ± 0.01

Σ	1.04 ± 0.12	0.47 ± 0.13	0.98 ± 0,17	0.78 ± 0.13

(Continued on next page)

Discussion

The pigment profile of *Gammarus locusta* was strongly affected by the pigment profile of the feed type. The pigment profile completely changed within 28 days, with intermediate profiles reflecting both diets. Astaxanthin content was surprisingly highest in the intermediate treatment, whereas pure *Fucus* as well as pure carrot leaves diet did not show differences. The most apparent difference was observed in lutein content with the highest content in the carrot leave treatment and lowest in pure *Fucus*. Since no cantaxanthin was detected in any samples, we suggest the biosynthetic pathway through zeaxanthin (Gaillard et al. 2004). Both feeds contain similar amounts of β-carotin, which - as a precursor in the biosynthetic pathway - may result in similar amounts of astaxanthin in the gammarid. Even though astaxanthin content did not change with the diet, amount of lutein was six-fold higher than in the control diet.

Even though the astaxanthin content did not change between these diets, it is available in biologically significant amounts. In relation to dry mass, the astaxanthin content in our study varied from 20 to 100 mg/kg dry weight. Aquaculture species already benefit from an astaxanthin content as low as 50 mg/kg in their diet (Olsen & Baker, 2006; Wade *et al*. 2017).

The effect of lutein for aquaculture species has been hardly studied, but it is already known, that is has positive effects in the coloration of yellow croaker (Yi *et al*., 2015. However, effect of lutein on the metabolism of other aquaculture species needs to be investigated. Besides their valuable nutritional composition, marine gammarids can harbour pigment profiles that can benefit aquaculture species

Introduction

The smoltification process in combination with pumping and handling of salmon during seawater transfer may easily cause physical damage and stress in fish. This may result in poor appetite, and it can take weeks to get the smolts to eat properly. Increased susceptibility to pathogens and infectious diseases in salmon after transfer, accompanied by high annual production losses of smolt, have been reported. This has been associated to poor skin quality and impaired immunity of fish. The aim of this project was to study the effect of a krill hydrolysate (OlyPep, Rimfrost AS) as attractant in transfer feed for Atlantic salmon (*Salmo salar* L.), and to reveal impacts on feed intake, growth efficiency, skin quality and robustness of the smolt.

Materials and methods

A practical formulated diet with 15 % fishmeal (FM) was used as control diet (D1), while all other diets were added variable levels of krill hydrolysate (KH) or krill meal (KM). The KH was added at two dietary levels (2.5 %, 5.0 %), exchanging respectively 1.08 % and 2.15 % of the FM protein in D1, and it was added either prior to extrusion (D2, D3) or by top-coating on the extruded and final coated pellets (D4, D5). A KM with low content of water-soluble compounds exchanged 4.3 % of the dietary FM protein in another diet (D6). Dietary plant ingredients were similar in all diets, except wheat that was used to balance the diets. The diets were iso-caloric and with mean energy contents of 22.9 ± 0.2 MJ kg^{-1}. Dietary protein and lipid levels were average 446 ± 6 g kg^{-1} protein and 263 ± 5 g kg^{-1} lipid. Atlantic salmon (mean weight 91.9 ± 0.3 g) were starved for one day and randomly distributed to 18 fiberglass tanks (1m^2), each with 80 fish. The fish were fed one of six diets in triplicate tanks for a feeding period of 84 days, starting out from the first day of feeding after seawater transfer. The fish were fed in excesses of appetite (10 – 15 %) by automatic feeders and exposed to continuous light (24h) and ambient water temperature (mean temperature 11.7 ± 1.6 °C) during the trial.

Results

In the first feeding period (Week 0 – 6), fish fed diets added KH by top-coating (D4, D5) both showed significant higher feed intake (total FI (%), daily FI (%/mean BW/d)) and growth rate (SGR, %) as compared to all other groups ($P < 0.05$), Fig. 1. Fish fed diets added KH prior to extrusion (D2, D3) also showed higher FI and SGR compared to fish fed the control diet (D1), but significant differences in FI was only found in fish fed D3 ($P < 0.05$), Fig. 1. The KM diet (D6) did not promote increased FI in the first few days/weeks after transfer. However, within 6 weeks of feeding, the KM increased the FI in salmon to a level in between fish fed D2 and D3, followed by moderately increased growth similar to fish fed D2, Fig. 1. Results may suggest higher quality of KM relative to the substituted FM. In the last feeding period (Week 6 – 12), all dietary groups showed efficient FI and growth.

For the complete feeding period (Week 0 – 12), significant higher FI and SGR was found in fish fed the two KH top-coated diets ($P < 0.05$). Fish fed the highest level of KH added into the diet (D3) also showed significantly higher FI and growth as compared to the control diet and the KM diet ($P < 0.05$). A significant linear relation between FI and growth ($P < 0.05$), while no significant differences in feed conversion ratio (FCR) ($P > 0.05$) was observed. No or small differences in nutrient and total energy digestibility, and protein utilization efficiency (PER, PPV, BV) were found, while fish fed D3, D4 and D5 showed the best results. Apparent amino acid digestibility was significantly increased in fish fed all KH diets ($P < 0.05$) as compared to the control group, while fish fed the krill meal diet performed similar as control fish ($P > 0.05$). Higher plasma phospholipids were found for all krill products and levels relative to the control diet ($P < 0.05$). Twelve weeks post-transfer, the mean final weight of fish fed KH added by top-coating (D4, D5) was 130 g higher than in fish fed the control diet, equivalent to 32 % higher SGR (%). The results suggest that the amino acids and soluble N-compounds in KH that leaks into the water following top-coating of KH on extruded pellets induce a more efficient appetite triggering impact than by adding KH to the feed prior to extrusion.

(Continued on next page)

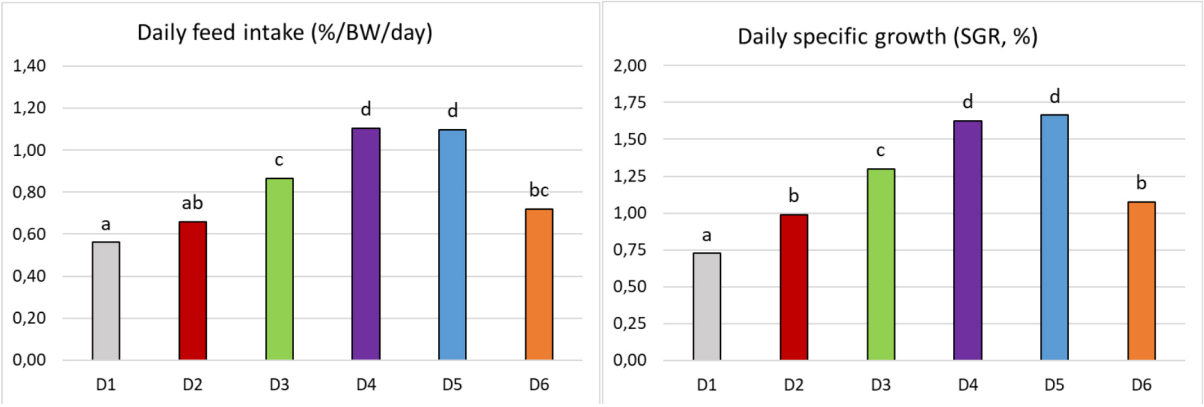

Fig. 1. Daily feed intake (%/BW/d) and growth (SGR, %) of A. salmon in the first feeding period (Week 0 – 6) after seawater transfer. A FM formulated diet served as control (D1), while KH was added to the feed at two dietary levels (2.5 %, 5.0 %) either prior to extrusion (D2, D3) or by top-coating to the extruded pellets (D4, D5). The KH exchanged respectively 1.08 and 2.15 % of the dietary FM protein. In addition, a krill meal exchanged 4.3 % of the dietary FM protein in another experimental diet (D6).

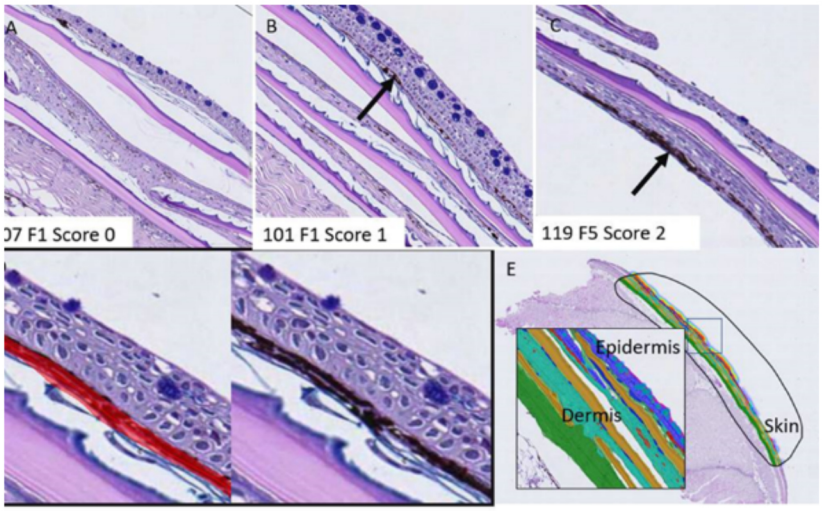

Fig. 2. Histological examination (Aiforia®) of the upper dorsal skin layers of experimental fish with OWI's skin score values of respectively 0 (A), 1 (B) and 2 (C), representative for Atlantic salmon with no, low or medium skin quality measured for scale loss.

Improved FI and growth of fish fed top-coated KH diets after seawater transfer was verified in another 6 week's feeding trial with A. salmon. Visual recorded differences in skin quality as observed in the first trial was followed up by visual (FishWell Operational Welfare Indicator scores (OWI's)) and histological (Aiforia®) examination of the dorsal skin quality of fish in the second trial. The visual skin quality, i.e. number of fish with scale loss, wounds or bleeding (n = 90 fish/diet) ranged on a scale (score values 0, 1, 2, 3) suggested better skin quality in the larger size fish fed the KH. The mean OWI scale loss score was lower in fish fed KH added by top-coating (mean score = 1.28) as compared to control fish (mean score = 1.70), but no significant differences were detected (Chi square P = 0.18, ANOVA p = 0.069). Significant higher values for dark pigmentation (melanin) in the upper dorsal skin layer were, however, found in fish with skin score = 2, as compared to fish with skin score = 1, Fig. 2. According to 2-way ANOVA, a significant dietary difference in skin quality was detected ($P < 0.05$). Dark pigmentation in the skin is consider a normal response to stress and skin damage in salmon.

Summary and conclusion

The positive FI and growth responses observed in fish fed the KH added by top-coating may be explained by efficient release of appetite triggering amino acids and N-compounds that leaks from the KH into the water and stimulate the FI of fish in the first period after seawater transfer. The increased FI was accompanied by equivalent increased growth. The FI stimulating effects of KH was less efficient when KH was added to the diet prior to extrusion. Visual and histological examination of the upper dorsal skin layer suggested improved quality with lower scale loss and less wounds in fish fed top-coated KH diets relative to fish fed the control diet. It is expected that the nutritional more well fed and larger fish fed KH will be able to grow a thicker and more robust skin. The observed improved quality of the dorsal skin is therefore considered a secondary response to the improved FI and growth of salmon. In conclusion, the KH significantly improved FI and growth of salmon in the first period after transfer and resulted in production of a more robust smolt with lower scale loss and more normal pigmented skin.

TRANSITIONING TO A CIRCULAR ECONOMY IN THE SEAFOOD SECTOR: BEST MANAGEMENT PRACTICES UNDER A NEXUS LIFE CYCLE NEXUS THINKING APPROACH

R. Aldaco*, I. Ruiz-Salmón, J. Laso, A. Quiñones, M.F. San Román, F.J. Amo-Setién, J. Cristobal, A. Fernández-Ríos, A. Irabien, M. Margallo

Department of Chemical and Biomolecular Engineering, University of Cantabria, Cantabria (Spain)
E-mail: aldaco@unican.es

Introduction

Transitioning to a circular economy in a seafood context requires "nexus thinking", which adopts a lifecycle approach to water-energy-food connections. This is essentially a transformative approach to governance, and also requires substantial changes in the way people behave. This work package focuses on how to govern such transformations, and the policy tools that will be required, including behavioral change interventions that go beyond mere education to influence how people make decisions about buying and consuming marine products.

Consequently, a new approach to assess seafood lifecycle is proposed based on the nexus of water-energy-food systems. The term "nexus" implies that the action in one of the systems has impacts on the others. Therefore, any strategy that focuses on one system without considering its connections with other systems may lead to acute unpremeditated consequences.

The water-energy-food nexus allows assessing the lifecycle of seafood products under a holistic manner considering the whole supply chain. Currently, there is no universally recognized methodology for nexus analysis. However, Life Cycle Assessment is particularly important for understanding the interconnections in the nexus, as it enables the consideration of entire supply chains. The definition of an integrated nexus eco-label facilitates the decision-making process to stakeholders and allows the development of strategies based on the circular economy concept (Ruiz-Salmón et al, 2021).

Materials and Methods

The work develops a methodology that combines water (WF), energy (EF), carbon (CF) and (NF) nutritional footprints to define an integrated nexus eco-label. The NEXUS Water-Energy-Food calculation comprises the following stages (Benini et al., 2014; He and Gu, 2016):

i. Selection of product environmental footprints: Establishment of representative environmental footprints to be included within the NEXUS eco-label. In this case, the WF, EF, CF and NF were selected to be included.

ii. Calculation: The assessment of the different environmental footprints is carried out following the guidelines and procedures based in the life cycle assessment tools.

iii. Normalization: Normalization is used to express the indicator data in a way that could be compared among all types of product environmental footprints. An internal normalization is considered in this methodology. In this way, the product with the lowest footprint in terms of WF, EF and CF is assigned a value of 100 and the rest of the products decrease in proportion. On the other hand, since the NF should be as good as possible, the product with the highest value will be assigned the value 100. In this way the value of the 4 variables for the different products are normalized on a scale of 1-100 (WFn, EFn, CFn and NFn), easily interpretable by the general population.

iv. Weighting: Assign weights to the different types of product environmental footprints based on their perceived importance to emphasize the most important potential impacts with the consideration of design requirements. It would obviously alter the results with different weights. As first assumption, all the indicators are given equal importance, so the weight by which they are multiplied would be 0.25, so that the final result of the NEXUS indicator for the product will be in the desired range between 1-100.

v. Aggregation: The resulting multi-criteria value of the NEXUS is obtained as follow:

$$NEXUS_i = w_1 \cdot WFn_i + w_2 \cdot EFn_i + w_3 \cdot CFn_i + w_4 \cdot NFn_i \quad [1]$$

Where WFn_i, EFn_i, CFn_i and NFn_i represent the value of the normalised footprints (water, energy, carbon and nutritional, respectively) for the analysed product (i). w_i is the correlative weight.

vi. Communication and dissemination of results: Once the NEXUS results are obtained, it is just as important to carry out good communication to disseminate the information to the interested audience in an effective way.

vii. NEXUS eco-label design

Once the NEXUS value has been obtained for each case study, it is necessary to design the ecolabel that will be used to communicate the results of the project to potential consumers and stakeholders.

(Continued on next page)

Results

This study will address the environmental analysis of the *Siberian sturgeon* (*Acipenser baerii*) from a fish farm in Teruel, Spain). The function was to evaluate the environmental impact of an aluminium can that sturgeon with sunflower oil. Based on the function, the selected functional unit (FU) was one can of 15.6 g containing the product. The production of the aluminium packaging, the electricity and fuel requirements and the production of sunflower oil are the main contributors in the Nexus footprint. The packaging represents between 50-70% of the total impact sturgeon, diesel production and consumption ranges from 21% to 40% and sunflower oil around 5%.

Conclusions

Measures to improve the environmental performance of canning products include the use of renewable energies, the eco-design of the packaging and the use of more sustainable materials, promoting circular economy approach. However, it should be also considered the preferences and behavior of consumers. These socials issues, as well as economic aspects, should be analysed for the packaging improvement.

The outcomes of the study will help to determine the environmental impacts and hotspots of canning products, proposing improvement measures regarding the process efficiency and the packaging. This will contribute to a more sustainable canning industry.

Nexus eco-label will help producers to introduce their seafood products in new green markets and consumers to identify more sustainable seafood products.

AQUACULTURE IN THE TIME OF COVID-19: CONSIDERATIONS FOR LOCAL AND GLOBAL OPPORTUNITIES AND RESPONSES

Introduction

Pollution, overfishing and the impacts of climate change are the main damages for oceans and, consequently, for fishing and the whole supply chain. To deal with these issues, the 14th Sustainable Development Goal (SDG) promotes the conservation and sustainable use of the oceans, seas and marine resources, which links to Zero Hunger (2nd SDG), Sustainable Consumption and Production (12th) or the urgent action to combat climate change and its impacts (13th), among others. The COVID-19 pandemic, unexpected target in the 3rd SDG (health), clearly damages the commitments proposed by the United Nations, adding an important handicap. Nevertheless, it also open the window to rethink the current status of the aquaculture, which are the challenges and opportunities and how to deal with them.

Some tools may improve the fish system (Aldaco et. Al, 2020). For instance, a robust inventory to improve the initial design of products, processes and services and to apply preventive and corrective actions would minimize the environmental impact associated to the life cycle phases, including some of the most relevant in each phase: food waste and discards in the process, distribution, packaging in the use, or final residue treatments. This approach is in progress on Neptunus Project (Neptunus Project, 2019), focused on the species farmed in European Atlantic region.

Year 2020: when the sector changed

The COVID-19 pandemic in 2020 has caused a global change. Particularly, in the fishing sector, several policies have been forced to be implemented to deal with health and environmental effects and socio-economic implications that have been triggered. In view of all these problems, it is necessary to adopt certain guidelines that will facilitate this situation in the near future.

Learnings and opportunities in the near future

Despite the clear negative consequences that COVID-19 has had on the fishing sector, the pandemic presents an opportunity to transform the food system to be greener, more inclusive, and resilient (Love et al., 2020).

1. The use of alternative networks (ANs), i.e. fish distribution models that serve local and regional food systems and deliver fish directly to consumers, present a segment of the food system that has not been fully taken advantage of it before. ANs have implications with respect to the organization of production and distribution of food, as well as for policy options for enhancing the systemic resilience of fish systems moving forward, allowing the sector to respond effectively.
2. The use of technologies can facilitate the adaptation of the commercial sector on the pandemics, allowing companies to promote their products and connect with consumers. Therefore, maintaining and building diversity and connectivity at the community, company, and country level are ways to build resilience and guard against bad outcomes.
3. With respect to the product, the sale of shelf-stable and frozen fish, instead of live-fresh fish, is an important option to consider since it guarantees less food loss and waste but may become unviable the sustainability for small aquaculture companies. Moreover, the promotion of shorter food supply chains, namely fresh meat and fish, under 'zero km' strategies, also minimize the environmental impact associated to the transport. Thus, the lifestyle during pandemic changed, making local purchasing gained importance in the collective thinking. Indeed, mobility restrictions, even in small towns, favor this. These local markets represent a more resilient and sustainable solution, reducing transportation, providing a better supply-demand balance, creating more transparency and tracking and contributing to waste reduction.
4. Finally, regarding the policies, COVID-19 provides an opportunity to integrate wider policies that are more coherent and make sense from an ecological perspective, considering the management and protecting the sector throughout their life cycle. The opportunity presented by the COVID-19 slowdown should be use to encourage inefficiencies within the system to reduce energy use, increasing profit and reducing environmental impacts.

(Continued on next page)

Conclusions

The COVID-19 pandemic has weakened the commitments proposed by the United Nations, making policies related to climate change and other environmental issues in aquaculture sector take a backseat and highlighting other social, health and economic aspects, hindering the improvement of the sector. Economic crisis and poorer material conditions for citizens; concern about COVID infections of aquaculture workers; closure of distribution channels or eventual plastic pollution in oceans from extra personal protective equipment delivery are few examples of what this pandemic has caused in short and long terms. This requires that life and economic derivatives maintain the sustainability and, consequently, it is necessary that the way in which it is produced and consumed is more efficient, reducing raw material and long-distance distribution and assuring food sovereignty by supporting local economies.

Therefore, certain support policies for the aquaculture sector have had to be brought with immediate responses against the economic and social consequences of the pandemic crisis. In addition, in order to deal with the effects on health, fish oils have been used as a nutrient for the sick. Environmentally, the quality of coastal waters has greatly improved and certain socio-economic problems have appeared such as the closure of distribution channels and many fish farms. Despite the clear negative impact of COVID-19 on this sector, the pandemic presents an opportunity to transform the food system to be more environmentally friendly, inclusive and endurable.

Introduction

European sea bass (*Dicentrarchus labrax*) is an important European aquaculture species. Females, performing better than males with later maturation and larger size, are preferred. Unfortunately, in aquaculture conditions, the sex-ratio is typically biased towards males. Thus, deciphering the sex determinism system and finding routes for controlling the sex-ratio of this species has been a long-lasting challenge to support sea bass production and selective breeding programmes. A polygenic threshold sex determination system was demonstrated (Vandeputte et al. 2007), where the genetic sex tendency is influenced by larval rearing temperature to determine the phenotypic sex (Piferrer et al, 2005). In this study, we applied two thermal treatments during early larval stage, a low temperature protocol (16°C, LT), known to favour more balanced sex-ratios, and a high temperature masculinizing protocol (21°C, HT). We used genome-wide SNP genotypes to estimate the genetic parameters and genotype-by-temperature interaction of sex tendency in European sea bass.

Material and Methods

We produced 8 families by mating 8 males with a same female. The progenies were reared in common garden under two thermal treatment in triplicate: a LT (16°C) and a HT (21°C) temperature protocol. 1013 fish were sexed at one year and genotyped for 57k SNPs with the DLabCHIP array (Griot et al., 2021). Pedigree was obtained using a subset of 1,000 highly polymorphic SNPs, using the R package APIS (Griot et al., 2020). After filtering SNPs with a call rate >0.90, a sufficient minor allele frequency (MAF>0.05) and no mendelian transmission errors, 39,607 polymorphic SNPs were retained to estimate genomic-based heritability, estimated sex tendency (with temperature as fixed effect) and the genetic correlation between treatments, with a threshold model using THRGIBBS1F90 (Tsuruta and Misztal, 2006).

Results and Discussion

The proportion of females obtained was 53.4% at LT and 25.3% at HT. As expected, the high temperature induced a marked masculinization, producing half of the females than at LT treatment. Sex tendency at LT (sex_LT) and at HT (sex_HT) were estimated as highly heritable with $h^2_{sex\_LT} = 0.65 \pm 0.06$ and $h^2_{sex\_HT} = 0.51 \pm 0.08$. A strong genetic correlation between sex_LT and sex_HT was observed ($r_G = 0.91 \pm 0.09$). The genomic-based estimation of the sex tendency of the animals is shown in Figure 1. Regarding the estimated sex tendency, as the combination of individual genetic sex tendency and the fixed effect of temperature, we observed that at LT, the mean sex tendency (0.12) is close to the theoretical threshold of zero (above which an animal is more likely to become a female). On the contrary, the distribution of the sex tendency estimated for animals at HT is typically displaced toward negative values with a mean at -0.89.

The lower heritability estimates for HT and the skewing of the estimated sex tendency toward negative values could result from the temperature-mediated impact on the sex at HT. At HT some phenotypically male fish can be considered as “reversed-females”, also known as “neomales”, confirming the hypothesis of a polygenic threshold model of sex determination.

These results confirm the high heritability of sex tendency in European sea bass, show the effect of larval rearing temperature on sex tendency is mostly additive (high genetic correlation between LT and HT), and highlight the efficiency of genomic-based mixed animal models to estimate breeding values for sex tendency in sea bass, with potential applications to identify sex-reversed “neomales” which would be of high interest to increase proportions of females in farmed populations of sea bass.

(Continued on next page)

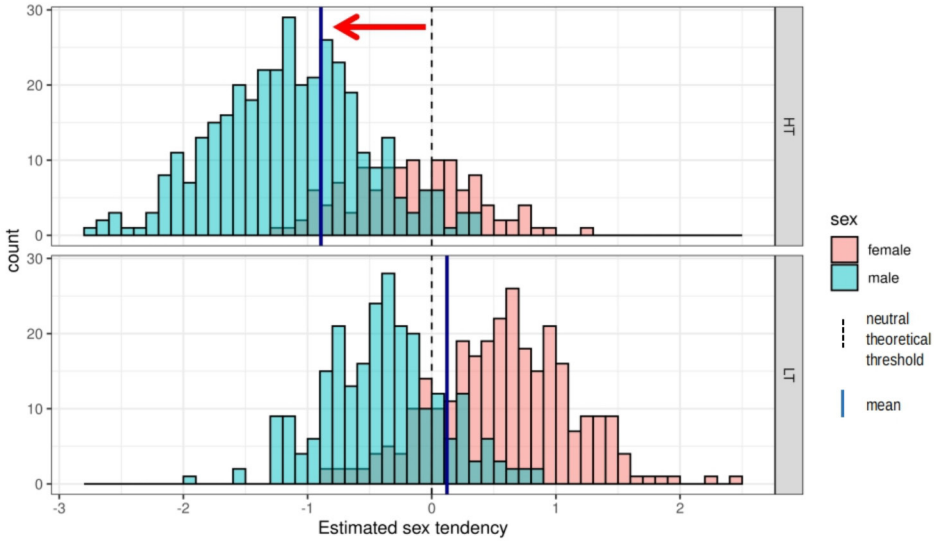

Figure 1. Distribution of the estimated sex tendency of phenotypic males and females reared at high temperature (HT) and at low temperature (LT). The red arrow shows the temperature-mediated shift of the mean sex tendency compared to the neutral theoretical threshold.

AQUACULTURE AND THE PRIMARY SECTOR: IMPACTS ON THE LOCAL ECONOMY

Gouveia, R. *, Machado, L, Almeida, A.

Faculty of Social Sciences, University of Madeira

Email:ricardogouveia@staff.uma.pt

While the idyllic image of islands is linked to a striving and successful tourism sector globally oriented, a sizeable share of the employment and GVA relates to traditional sectors such as the agriculture, fisheries and aquaculture. Such sectors are equally strategic in terms of external image conveyed abroad, cultural heritage and local identity. In this paper we compute based on a simple econometric model we estimate the impact of recent changes in the agriculture and fisheries sector to the regional GDP. The aim of this paper is to highlight the relevance of the primary sector as an alternative to tourism during the times of economic crisis.

MEDITERRANEAN MONK SEAL (*Monachus monachus*): PERCEPTION ABOUT FISH FARMING INTERACTIONS IN THE ARCHIPELAGO OF MADEIRA

Introduction

The sub-population of monk seals from Madeira island, Portugal, is comprised of 21 individuals (aged over 1 year) in 2018, which is distributed across the island of Madeira and the Desertas Islands. It is an extremely vulnerable and endangered population classified under the IUCN red list of threatened species (Karamandilis and Dendrinos, 2015). The monk seals from Madeira may interact with several human activities at sea such is the case of fish farming. In Madeira island there are three aquaculture companies in the open sea (offshore): Marismar (Calheta), Aquailha (Ribeira Brava) and Ilha-Peixe (Machico). Aquaculture systems in an open environment are known for attracting fish-eating predators due to the large number of confined fish (Güçlüsoy, 2003). The aim of this study was to understand the perception from different maritime professional sectors about monk seal - fish farming interactions, in Madeira island.

Materials and methods

Interviews were conducted to fish farm workers (16), whale-watching's workers (14), diving club workers (10) and IFCN's (Institute of Forests and Nature Conservation) workers (6). The questionnaire surveys were conducted along the south coast of the island of Madeira at the workplace of each respondent. Interviews took place between February and May, 2021. Each interview lasted approximately 5 minutes. The questionnaire had question groups in order to understand the perception of the workers on the monk seal-fish farming interactions, the frequency of sighting of monk seals in each fish farm and assess whether the workers opinions were based on real observations or influenced by external factors. Data analysis was performed using *Microsoft Office Excel 2007*™ and *IBM SPSS Statistic 26* for Windows. Descriptive statistics were used and nonparametric tests.

Results

47 surveys were carried out, 74% of respondents didn't mention the monk seal as an animal that would cause any harm to fish farms. It was found that the perception of monk seal-fish farming interactions is independent of the career, the place where the respondents most often work and the respondent's place of residence. Most respondents claimed observing the monk seal close to fish farming rarely (54%) or never (26%), regardless of the frequency of their trips out to sea and the fish farm they passing by. It was considered that most of the respondents have their opinion influenced by external factors, with the main sources of influence being informal conversations, followed by Institute of Forests and Nature Conservation (IFCN) and media. Most respondents don't show animosity towards monk seals. In relation to aquaculture, it was found that there are significant differences between the degree of animosity shown depending on the maritime activity performed.

Discussion

Efforts to study these interactions have been carried out in Turkey, where negative interactions are particularly intense (Güçlüsoy, 2003). A similar sociological study about this monk seal sub-population from Madeira has been carried out by Hale (2011), but only covering the monk seal-fisheries interaction. The majority of respondents didn't mention the monk seal as an animal that would cause any harm to fish farms (74%), despite that this has been reported in Turkey (Güçlüsoy 2003). Nevertheless, in Madeira the majority of fishermen believe that the species doesn't damage fishing gear or catches (67%) (Hale, 2011). Less than 20% of respondents mentioned having seen the monk seal close to fish farming occasionally or always, likewise only 30% of the fishermen interviewed in the Hale's study (2011), claimed to have experienced monk seal – fishing gear interactions.

(Continued on next page)

Tourist/leisure activities and aquaculture are interactions identified as a threat to this species (Pires, 2020). Nevertheless, the perception of the inquiries was that these interactions on fish farms are rare, with no attacks. It should be noted that the presence of the monk seal in Madeira is a source of pride, which leads to greater awareness (Pires, 2020), reflected in some of influenced opinion's respondents who refer to the IFCN as a source of information for the knowledge of the species.

Further studies and awareness, through informal conversations, about this interaction aimed at each maritime activity are needed.

Introduction

Portuguese oyster suffered a major decline on natural populations in the past decades in Europe and strategies for its restoration and management need to be developed. Cryopreservation is a helpful tool for the management of endangered genetic resources through the preservation of genetic material in ultralow temperatures (Martínez-Páramo et al. 2017). In invertebrates, such as oysters, it is possible to preserve the genetic resources of both parents, through sperm and oocytes cryopreservation. However, it is also possible to preserve the offspring by freezing embryos and larvae. The availability of cryopreserved sperm is useful when there is no synchrony between spawning of males and females. However, the cryopreservation of larvae presents several advantages, since it allows the availability of diploid animals upon thawing, which simplifies its application for aquaculture purposes (Labbé et al. 2018). Cryopreservation methodologies needs to be adapted according to the species and type of biologic material, being necessary to explore the type and toxicity levels of cryoprotectants and use of single or combined freezing solutions. The main goal is to achieve the conditions that produce the lowest levels of cryodamage, improving post-thaw quality. The objective of this work was to develop conservation strategies of Portuguese oyster through sperm and larvae cryopreservation to support this species management.

Materials and methods

Samples from 10 males of Portuguese oyster were collected by gonadal incisions following the protocol described by Riesco et al. (2017). Each sperm sample was cryopreserved with three cryoprotectant medium in a programed biofreezer at -6ºC/min. Cryoprotectant solutions were prepared in filtered seawater containing 20% dimethyl sulfoxide (DMSO) and 20% DMSO added with 0.9 M trehalose or sucrose. Post-thaw sperm motility was analyzed with CASA software. Flow cytometry was applied to determine the cell viability using PI and to detect levels of reactive oxygen species in live post-thaw sperm by combination of DHE and Sytox dyes. MDA quantification was used to assess lipid peroxidation.

Portuguese oyster larvae were produced by broodstock gonadal incisions to collect the gametes followed artificial fertilization and incubation until D stage. Pools of 60,000 D-larvae/mL (n=7-8) were divided in five aliquots, one used as control and the others exposed and cryopreserved to two cryoprotectant solutions. The solutions were composed by 20 % (v/v) ethylene glycol (EG) or DMSO, 2% (w/v) polyvinylpyrrolidone 40000 MW and 0.4 M sucrose in milli-Q water. Larvae samples were exposed for 3 minutes to cryoprotectant solutions in a 1:1 (v/v) proportion to evaluate the toxicity levels of cryoprotectants. For cryopreservation, samples were loaded into 0.5 mL straws and freeze in a programmable biofreezer. Larvae diluted in filtered seawater (FSW) was used as control. D-larvae quality was evaluated before and after cryoprotectant exposure and post-thawing, according to morphology, motility rate and velocity. Moreover, the whole transcriptome profile of fresh larvae, larvae exposed to DMSO solution, and post-thaw larvae were compared.

Results and discussion

Sperm cryopreserved with DMSO supplemented with sugars significantly improved post-thaw sperm viability and reduced levels of lipid peroxidation and ROS in comparison with DMSO treatment. This can be related with the fact that combination of permeable and non-permeable cryoprotectant interact as membrane fluidity regulator and increase the membrane hydrophobicity (Hassan et al. 2017). The supplementation with sugars was successfully applied in other oyster species such as Pacific oyster (Adams et al. 2004) and Australian flat oyster (Hassan et al. 2017).

(Continued on next page)

The toxicity tests showed that larvae exposed to cryoprotectant solutions containing DMSO had no significant differences in morphology and motility when compared to control. Larval movement (VAP) was significantly higher in DMSO treatment than EG treatment, suggesting that DMSO promoted lower toxicity. Cryopreservation reduced larval quality parameters when compared with control. This effect was also described for Pacific oyster by Labbé et al. (2018). Oyster larvae cryopreserved with DMSO solution showed a significant improvement of larval movement when compared to EG treatment. In this way, DMSO as internal cryoprotectant was beneficial in maintaining post-thaw larvae quality. The transcriptomic analysis of Portuguese oyster larvae did not show many differences in gene expression between fresh and cryoprotectant exposed larvae. Contrarily, after cryopreservation there was a significant number of genes in larvae up and down regulated compared with the ones in fresh larvae. This supports the results previously described, which suggested that quality reduction of D-larvae was related to cryopreservation or cold damage.

Conclusion

The current work provided methodological tools to set up a Portuguese oyster gene bank through the establishment of cryopreservation protocols for sperm and larvae to support the aquaculture and restoration programs.

Introduction

The occurrence of skeletal abnormalities is a significant problem for aquaculture industry (Boglione *et al*. 2013), as well as for laboratory fishes (e.g. zebrafish, Martins *et al*. 2018; Printzi *et al*. 2021). Skeletal abnormalities have severe consequences not only on the production cost but also on the welfare of the fish (Boglione *et al*. 2013). Most of the skeletal abnormalities develop during larval rearing and early juvenile period (Koumoundouros 2010). Main factors that trigger the development of skeletal abnormalities are the adverse abiotic conditions, genetic factors and nutrition (Boglione *et al*. 2013).

In this study, we examined the effect of different starter diets on the development of skeletal abnormalities and survival rate in zebrafish *Danio rerio*.

Material and Methods

Four commercial (A-D) and one experimental (CTRL) starter diets were tested. Of the commercial, two are formulated specifically for zebrafish rearing (A and D), one for freshwater ornamental fish (B) and one for marine fish larvae (C). Larvae were initially fed with *Artemia* nauplii (4-7 days post fertilization, dpf), then with *Artemia* nauplii and dry diets (8-11 dpf), and finally with dry diets only (12-20 dpf). Larvae were fed five times per day. Trials were performed in triplicate, in a closed recirculation system, at 28^{o}C water temperature.

At 18-20 dpf, a random sample of fifty specimen were taken from each experimental population anaesthetized, formalin fixed and double-stained for the examination of skeletal abnormalities (Walker and Kimmel 2007). For the survival rate, the total number of fish in each diet was counted at the end of the larval rearing. The significance of the differences in the abnormality rates and survival rate among the dietary regimes was tested by G-test (Sokal and Rohlf 1981).

All diets were analyzed with respect to their proximate composition (Table 1).

Results & Discussion

Our results showed that starter diets had a significant effect on the development of caudal scoliosis ($p<0.05$, 19.3-54.7%, Fig. 1B, B') and gill-cover abnormalities of either light ($p<0.05$, 11.3-36.7%, Fig. 1C, C') or severe ($p<0.05$, 1.3-11.3%, Fig. 1D, D') intensity. Similarly, the survival rate was significantly affected by the nutritional regimes applied ($p<0.05$, 63.1-90.3%, Fig. 1A) in the different diets.

Existing literature demonstrate that larval diet has significant effects on the development of zebrafish skeleton (Martins *et al*. 2018, Printzi *et al*. 2021). Our results showed that the use of specialized zebrafish diets (A, D, CTRL) may comparatively decrease the incidence of skeletal abnormalities and increase fish survival rate. More research is required to fine-tune the nutritional composition of zebrafish starter diets whilst taking into account critical rearing parameters on zebrafish skeletal development.

Table 1. Proximate composition of each starter diet.

Feed	DM (%)	Ash (%)	Proteins (%)	TL (%)	NL (%)	PL (%)
Artemia	94.8	6.5	61.7	19.2	9.2	6.6
Control	94.0	12.0	54.7	16.7	4.7	11.7
A	93.9	13.9	66.8	18.5	4.0	8.8
B	93.9	12.0	63.5	12.6	5.7	4.6
C	93.2	14.0	67.3	16.8	6.8	5.5
D	91.0	12.7	67.7	13.0	4.0	6.3

DM, dry matter; TL, total lipids; NL, neutral lipids; PL, phospholipids.

Introduction

In aquaculture a period of starvation is a common practice prior to handling, transportation and harvesting, in order to ensure good water quality and to reduce metabolic rate and stress (Waagbø *et al*. 2017). *Origanum vulgare* and *Cinnamomun zeylanicum* have proved their growth-promoting, genoprotective, antistress, antioxidant, antidiabetic, anti-inflammatory, antimicrobial, antiviral, antiparasitic, antineoplastic and immune modulatory effect (Khafaga *et al*. 2020). Very few studies have examined *Cannabis sativa* oil effects in fish as dietary additive, despite the fact that hempseed oil attracts the interest of scientific community. This study attempts to investigate the effect of *O. vulgare*, *C. zeylanicum* and *C. sativa* essential oils as phytogenic feed additives (PFAs), on plasma cortisol levels in *Sparus aurata* under starvation, in order to highlight the beneficial use of medicinal plants by the aquaculture industry.

Materials and methods

All the procedures involving fish were performed according to the EU guidelines on the protection of animals used for scientific purposes (Directive 2010/63/EU). Seven isonitrogenous and isoenergetic diets were applied in gilthead seabreams (n=630, 5±0,12g) (*S. aurata* L.) in three replicates: two with cinnamon essential oil (*C. zeylanicum*) (CIN1%: 1% and CIN2%: 2% of the aquafeed), two with oregano essential oil (*O. vulgare*) (OR1%: 1% and OR2%: 2% of the aquafeed), two with hempseed oil (*C. sativa*) (CAN1%: 1% and CAN2%: 2% of the aquafeed) and one control diet (no supplementation). The feeding trial lasted 84 days and each diet was applied in six tanks. At the end of the feeding trial a 14 days starvation period was applied, in three of the six tanks for each feeding group. At the end of the starvation trial, fish were anesthetized and blood samples were obtained from the caudal vein. Plasma cortisol was measured using commercial Cortisol Elisa Kit, Cayman Chemical, USA (No. 500360) and the FLUOstar Omega microplate readers from BMG LABTECH.

Results

Significantly lower cortisol levels ($p<0,05$) were observed in normally feeding groups compared to groups that food deprivation was applied. Between groups that sustained the starvation challenge, significantly higher cortisol levels ($p<0,05$) were measured in OR1% and control groups, while OR2% and CIN1% were the groups with the statistically significant lower values ($p<0,05$). CIN2% and CAN2% supplemented groups presented higher cortisol levels compared to CIN1% and CAN1%, respectively. Group fed with OR1% incorporated diet showed significantly higher cortisol level than the group fed with OR2%.

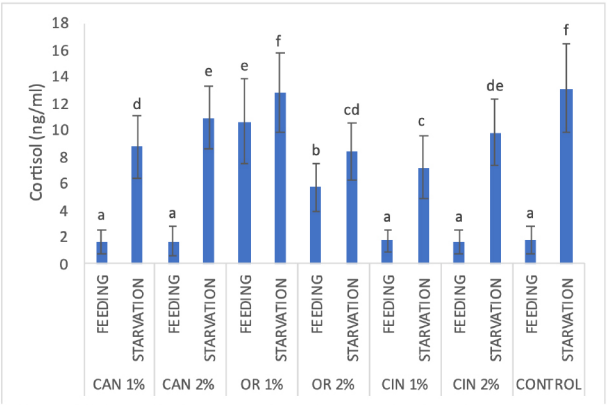

Fig. 1. Effect of *C. sativa O. vulgare* and *C. zeylanicum* incorporated diets on plasma of gilthead seabream (*S. aurata*) after feeding and starvation challenge. Letters a, b, c, d, e, f indicate significant differences between treatments (ANOVA; $P<0.05$).

(Continued on next page)

Discussion

Presently, starvation challenge proved to be a stress promoting factor compared to normally feeding process. All the experimental starvation groups supplemented with PFAs, except for the OR1%, revealed statistically significant lower cortisol levels, compared to control group, indicating that these additives maybe capable of restraining the elevated cortisol levels triggered by starvation stress. Fishfeed supplemented with 1% *C. zeylanicum*, proved to be the most effective, combining low cortisol level during feeding and reduced cortisol level under stress promoting practices. *O. vulgare* and *C. zeylanicum* incorporated diets consider to be welfare promoters under stress conditions reducing cortisol secretion (Santos *et al*. 2016, El-Hawarry *et al*. 2018). In conclusion, the current study revealed that PFAs reduced stress response in *S. aurata* exposed to starvation challenge, indicating that they maybe promising anti-stress agents used under stressful aquaculture practices.

Introduction

Handling during intensive fish culture is an unavoidable and stressful practice that should be carried out only when necessary, as it elicits a maximal emergency physiological response. Essential oils of *O. vulgare* and *C. zeylanicum*, as phytogenic feed additives (PFA), have shown various beneficial effects in aquaculture, such as antistress, antipathogen, appetite-stimulating, growth-promoting, tonicity-enhancing and immunostimulatory activities (Abdel-Latif *et al*. 2020, Khafaga *et al*. 2020). *Cannabis sativa* oil is in the interest of scientific community during the last years, however few studies have examined hempseed oil effects on fish production as dietary additive (Pellati *et al*. 2018). The present study aimed to assess the impact of origano and cinnamon essential oils and hempseed oil, on plasma cortisol levels in *Sparus aurata*, after a handling challenge.

Materials and methods

All the procedures involving fish were performed according to the EU guidelines on the protection of animals used for scientific purposes (Directive 2010/63/EU). 315 gilthead seabreams (5±0,72g) were grouped in 21 tanks. Two diets with cinnamon essential oil (*C. zeylanicum*) (CIN1%: 1% and CIN2%: 2% of the aquafeed), two diets with oregano essential oil (*O. vulgare*) (OR1%: 1% and OR2%: 2% of the aquafeed), two diets with hempseed oil (*C. sativa*) (CAN1%: 1% and CAN2%: 2% of the aquafeed) and one control diet (no supplementation), were applied in experimental fish in triplicates. At the end of the feeding trial, which lasted 84 days, three fish from each tank were randomly captured and kept out of water for 5 min using intense netting procedures. Fish were then anesthetized and blood samples were obtained from the caudal vein. Plasma cortisol was measured using commercial Cortisol Elisa Kit, Cayman Chemical, USA.

Results

Plasma cortisol values showed significant differences between experimental groups fed with diets supplemented with PFAs. Statistically significant lower cortisol levels (P<0,05) were observed in all groups fed with *C. sativa* and *C. zeylanicum*, compared to *O. vulgare* and control group. *O. vulgare* supplemented groups presented higher cortisol levels (P<0,05) compared to control group.

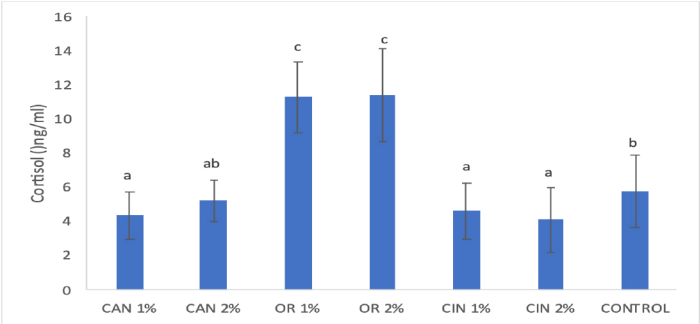

Fig. 1. Effect of *C. sativa*, *O. vulgare* and *C. zeylanicum* incorporated diets on plasma of gilthead seabream (*S. aurata*) after intense netting handling challenge. Letters a, b, c indicate significant differences between treatments (ANOVA; *P*<0.05).

(Continued on next page)

Discussion

PFAs have the ability to prevent increase of plasma cortisol after handling (Teixeira *et al*. 2017). In the present study, *C. sativa* and *C. zeylanicum* proved capable to restrain the elevated cortisol levels triggered by handling stress. Reduction of the cortisol level and insignificant mortalities (Santos *et al*. 2016) have been observed in the case of *C. zeylanicum* incorporated diets, under stressful conditions induced by hypoxia in fish.

Fish fed with *O. vulgare* incorporated diets showed statistically significant higher cortisol values compared to control group. According to Bodur et al. (2018) oregano essential oil, when used as an anaesthetic agent, enhances stress response since it does not block cortisol response. In conclusion, the current study has revealed that *C. zeylanicum* and *C. sativa* dietary supplementation reduces stress response in *S. aurata*, when exposed to handling stress, suggesting their potential use as natural anti-stress agents. More studies are necessary to elucidate the effects of *O. vulgare* essential oil on stress response.

Introduction

Aquaculture industry is increasingly incorporating principles of circular economy and zero waste to find alternative ingredients for aquafeeds. The reduction of fishmeal and fish oil inclusion is an established principle in contemporary fish feed formulations. Hence, by-products from other industries, such as rendered animal proteins, are progressively being used. Aquaculture production is seeking for functional ingredients that may enhance fish resilience and robustness, in face of the suboptimal conditions that may be imposed by the rearing procedures and new dietary formulations.

Fisheries and aquaculture activities, including the associated industrial processing, generate substantial side-streams. Valorization of these resources are of utmost importance. Dietary inclusion of fish hydrolysates in low-fishmeal diets have been shown to promote growth, antioxidant capacity and immune status in several fish species (*e.g.*, Khosravi et al., 2018; Siddik et al., 2020; Chaklader et al., 2021). Therefore, the objective of this work was to assess the benefits of inclusion of fish hydrolysates produced from by-products of the fisheries industry on the growth and physiological status of gilthead seabream (*Sparus aurata*) juveniles fed with low-fishmeal diets.

Materials and Methods

Four isonitrogenous and isolipidic diets (48% crude protein and 16% crude fat) were formulated with practical ingredients: a positive control, a negative control, and two experimental diets containing fish hydrolysates obtained from fisheries biomass previously discarded and nowadays landed due to obligation compliance in the legal framework of the Common Fisheries Policy of the EU. The fish hydrolysates were obtained by enzymatic hydrolysis of *Micromesistius poutassou* whole-body (**FHW**) or from *Trigla* spp. heads (**FHH**). Fish hydrolysates were analyzed and characterized before diet formulation. The positive control (**PC**) was a commercial-like diet, containing fishmeal, poultry meal and plant ingredients as protein sources, and including commercial fish protein hydrolysates. In the negative control (**NC**), fishmeal and soya products were completely removed from diet formulation, through an increase in poultry meal and plant ingredients, and feathermeal hydrolysate and hemoglobin were included instead of the commercial fish protein hydrolysate. The other two experimental diets were based on the NC diet, but feathermeal hydrolysate and hemoglobin were replaced by the experimental fish hydrolysates: **FHW** and **FHH**. Diets were manufactured at SPAROS Lda. (Olhão, Portugal).

Twelve homogenous groups of 90 juvenile gilthead seabream (± 8.0 g) were distributed into 500 L tanks at a density of 1.4 kg/m^3. Fish were supplied with flow-through aerated seawater (temperature: 21.7 ± 1.6 ºC; salinity: 37.3 ± 0.4 psu; dissolved oxygen in water above 85% of saturation) and subjected to natural photoperiod changes through summer conditions (mid-May to mid-July). Each diet was randomly assigned to triplicate tanks and tested over 8 weeks. Fish were fed to apparent satiety by hand, three times a day. Apparent feed intake was recorded daily, and utmost care was taken to avoid feed losses.

At the end of the trial, fish were weighed, as well as liver, viscera, and perivisceral fat from 12 fish per tank. Blood and liver samples were collected for posterior analysis of physiological indicators, antioxidant status and immune parameters. All samples were collected after a 24 h period of fasting. A digestibility trial is ongoing to determine the apparent digestibility coefficients of the dietary nutrients.

Results and Discussion

The fish hydrolysates from the fish whole-body or from fish heads presented differences in molecular weight distribution. In the latter (**FHH**), most of the peptides obtained had a molecular weight between 1-3 kDa, while for the former (**FHW**) a more equative distribution among fractions up to 3 kDa was found. Furthermore, the lipid content in hydrolysates from fish heads (**FHH**) was almost twice that from the whole-fish hydrolysates (**FHW**).

(Continued on next page)

Fish growth was affected by the replacement of dietary fishmeal. Fish fed with the **NC** diet ended the experiment with a significantly reduced final body weight when compared with the **PC** diet and presented the lowest growth rate (expressed as daily growth index or weight gain). The addition of fish hydrolysates (**FHW** and **FHH**) led to a significant increase in the average fish body weight when compared with the **NC** treatment, although still significantly lower than fish fed with the **PC** diet. However, growth rate was not significantly different in fish fed the **FHW** and the **PC** diets. These results indicate that experimental fish hydrolysates were able to partially mitigate the negative effects of fishmeal replacement.

Voluntary feed intake was similar among treatments, but dietary effects were found in feed efficiency. Fish fed the **NC** diet presented higher feed efficiency ratio (FCR) and lower protein efficiency ratio (PER) than fish fed the **PC diet**. The inclusion of fish hydrolysates had a positive effect on feed efficiency, resulting in FCR and PER values not significantly different from the **PC** treatment.

No significant differences were found in the hepatosomatic and viscerosomatic indexes among treatments. However, fish fed low-fishmeal diets (**NC**, **FHW** and **FHH**) ended the experiment with a significantly lower percentage of perivisceral fat when compared with fish fed with the **PC** diet. Fish survival (>96%) was high and not significantly affected by the dietary treatments.

Plasma and liver samples are still under analysis. These results will provide indications on the potential of fish hydrolysates as functional ingredients in diets for seabream juveniles. Up to this moment, it is clear that these hydrolysates were able to mitigate some negative effects of the total dietary fishmeal replacement by rendered animal and plant proteins. Thus, preliminary results suggest that these by-products from marine fishery activities are an interesting ingredient for aquafeeds, contributing to the sustainability of the fisheries and aquaculture industries through principles of circular economy.

Introduction

Nutrition has a pivotal role in aquaculture production, since it provides direct advantages on fish growth, health condition, and flesh quality. Functional amino acids regulate key metabolic pathways that may improve the animal's immune response and health. Therefore, functional amino acids are gaining *momentum* in aquaculture production, where few therapeutic possibilities are available against infectious episodes. Tryptophan is an essential amino acid with recognized roles in both neuro-endocrine and immune systems. Hence, it is crucial to understand how its availability will influence the metabolic changes associated with inflammation.

Tracer methodologies allow to understand how nutrients are metabolised by the animals under different situations. Through the labelling technique it is possible to assess in a time-course set-up changes in metabolism and *in vivo* nutrient utilization.

The objective of this study was to assess the absorption and metabolic utilisation of dietary tryptophan during the onset of inflammation in European seabass (*Dicentrarchus labrax*) juveniles.

Materials and Methods

European seabass juveniles (± 20 g) were reared in a recirculating aquaculture system following standard procedures. Fish were hand-fed one of the two experimental diets, formulated to contain tryptophan at the requirement (1xTrp) or at twice the requirement (2xTrp) level. Fish were fed the experimental diets for one or two weeks (referred thereafter as feeding periods).

After each feeding period, fish were transferred to the nutrient flux laboratory at CCMAR, after fasting overnight. Fish were then injected with Freund's Incomplete Adjuvant (FIA), a phlogistic agent widely known to boost the fish inflammatory response. After this procedure, fish were tube-fed with the corresponding diet (1xTrp or 2xTrp) labelled with ^{14}C-tryptophan and were then transferred to individual metabolic chambers, for 1, 2, or 4 h (n = 6-7 fish for each diet, incubation time, and feeding period). The tracer technique allowed to estimate the amount of tryptophan that was unabsorbed (water), catabolised (chemical trap) or retained in selected fish tissues (liver, head-kidney, posterior intestine, brain, and muscle), after the inflammatory insult. Furthermore, through chemical separation, the amount of free or bound tryptophan was assessed in each fish tissue, in order to obtain a more comprehensive indication of tryptophan's metabolism.

Results and Discussion

The preliminary results indicate that tryptophan is readily available for metabolic utilisation at the different tissues analysed. Furthermore, different patterns of tryptophan absorption were found at the diverse tissues and feeding periods. Tryptophan metabolism presented differences according to the tissue analysed and the differences observed at the different feeding periods indicate that metabolic adaptations occur with time.

Dietary tryptophan supplementation (2xTrp) resulted in higher tryptophan availability at important tissues involved in inflammatory and immune responses, which may suggest a potential benefit for the fish.

In conclusion, the *in vivo* tracer methodology was successful at unravelling the metabolic role of tryptophan during inflammation.

Introduction

Europe is a major contributor of mussels by supplying over a third of the world total production. It is known that inland hatchery cultures can support the extensive farming of this bivalve, by ensuring known quantity and quality of spats each year. However, these systems are still not economically viable, due to the high costs of conventional live microalgae feeds. For this reason, new alternative microencapsulated inert diets have been developed (Willer & Aldridge, 2019). The aim of the present study was to test microencapsulated feeds containing *Schizochytrium* sp. as alternatives or supplement to a live microalgal diet and evaluate their effect on *Mytilus galloprovincialis* spat and adult microbiota, with the subsequent link of the microbiota structure of mussel with growth rate, proximal composition and gametogenesis.

Material and Methods

Mytilus galloprovincialis spats and adults were cultured at hatchery semi-industrial scale for 8 and 6 weeks, respectively, with different feeding conditions: 1) NC (Negative Control: no food supplied); 2) A (commercial microalgae: 100% ShellfishReed); 3) B (BioBullets as alternative singular diet: 100% *Schyzochytrium*); 4) ABL (Alternative mixed diet: 40% A + 60% B; 5) ABM (Alternative mixed diet: 20%A + 80%B). To investigate their effect on gut microbiota, spat and adult mussel bacterial DNA from the digestive gland was sequenced (MiSeq Illumina) by targeting the V3-V4 16S rRNA gene. Sequences were processed with MOTHUR v1.44.0 (Schloss et al., 2009) and taxonomically affiliated by BLAST against SILVA database (Release 138.1). Alfa diversity estimators were calculated using Past 4.05 software (Hammer, Harper, & Ryan, 2001). Beta diversity analyses including hierarchical clustering analysis (based on Bray-Curtis dissimilarity coefficients), non-metric multidimensional scaling (NMDS) and permutational analysis of variance (PERMANOVA) were performed with R software using the "vegan" package (Oksanen et al., 2020) in order to investigate significant (p-value <0.05) differences of gut microbial community structure between different treatments and over time. Finally, indicator species and metabolic predictions of microbiota were investigated for each diet using LEfSe and PiCRUST programs.

Results and conclusions

Microbial diversity of adult and spat gut microbiota were composed of 11682 and 5083 OTUs (after quality control and data normalization), respectively. Overall, mussel gut microbiota was dominated by phyla Proteobacteria (representing 63% of the reads) and Bacteroidetes (25%), followed by other significant phyla such as Firmicutes (4 %), Campylobacteria (1.5 %), Planctomycetes (1.3 %) and Verrucomicrobia (1.1 %). As expected, differences were observed between adult and spat taxa composition, and different feeding conditions resulted in disparate proportions of bacterial community composition. Alpha diversity (Shannon, Simpson, Chao1 and Berger-Parker) for gut microbiota revealed no statistical significances (p-value > 0.05) between diet treatments. Hierarchical cluster analysis, based on Bray-Curtis dissimilarity, showed that samples were primarily clustered according to the diet and then according to time of exposure. However, mixed diets (ABL and AMB) were clustered together according to time. These results correlate with the NMDS, where significant differences (p =0.00099) were recorded across microbial communities from different feeding conditions and time exposure. Next steps will be to search for indicator species and perform metabolic predictions of microbiota using LEfSe and PiCRUST programs. The whole analysis would help to link of the microbiota structure of mussel with growth rate, proximal composition and gametogenesis.

Introduction

BIOGEARS addresses the challenge of minimizing the use of plastics in the sea by developing prototypes of biobased and compostable ropes, **biogears**, and examines their use in culture of mussels and seaweed Integrated Multi-Trophic Aquaculture (IMTA) systems. The goal of the biopolymers used in the development of the biogears is to achieve competitive manufacturing of aquaculture ropes with adequate durability for mussels and seaweed offshore productions. At the end of life of biogears will enter in-land organic recycling circuits, hence greatly reducing carbon footprint along the whole value chain and generating new local biobased value chains. The aim of this study is to assess the acceptability and potential use of biogears (biobased ropes) by the European aquaculture sector to be more eco-friendly and create circular economy, by identifying the main drivers for this change.

Material and methods

To assess this, a preliminary **value chain description**, a **market study** and an **online survey** were conducted. In the market study, the need of ropes of the European mussel and seaweed sectors were estimated, and social, economic and technology drivers and current trends in aquaculture value chains were identified. To assess the impact of the main drivers identified, they have been categorized as: TECHNOLOGY, (TECH) SUSTAINABILITY (SUST), SOCIAL/POLICY (SOCP) and MARKET/ECONOMY (MARK). An online survey was elaborated and distributed at EU level. The results obtained in the questionnaire are used to complement the market analysis and to identify the pros and cons for the acceptability and implementation of biogears as solutions towards an eco-friendlier European aquaculture sector.

Results and discussion

The value chain has been analysed under circular economy umbrella identifying all stakeholders involved: raw material, bioplastic, biogears, aquaculture, wholesaler, retailers and consumers. The market study pointed out that the aquaculture rope demand in Europe for mussels and seaweed is estimated to be from 1 600 000 m to 3 300 000 meters, approximately. Seaweed market is a new market and is more oriented to sustainable and eco-friendly products. In this case the biobased rope is more in line with the philosophy of the seaweed business.

The preliminary results of the survey are shown in Figure 1. Respondents consider SUST, MARK, SOCP and TECH drivers, the order of driver impact on biogears acceptance and use. Regarding the intensity of agreement in the answers received, in SUST: respondents considered that aquaculture, as food producing sector, should be one of the first marine sectors to avoid plastic use, and that currently used plastic materials (100% petrol based) should be substituted by biogears made of more eco-friendly materials, that could potentially not affect as negatively on seabeds as those currently used if they are lost or abandoned. In MARK: stakeholders consider that they will buy or use biogears because they are compostable at the end of use, promoting also circular economy, and because they are made of biomaterials that come from natural resources that do not compete with food market, and will pay a competitive price for them. In SOCP: a remarkable awareness of current strategies for the development of aquaculture has been observed among respondents (Circular Economy Strategy and Farm to Fork Strategy) who consider that biogears can be drivers for the generation of new value chains, the production of healthy foods (minimizing use of plastic in productions and microplastics in food) and generation of new value chains and circular economy in the European aquaculture sector. In TECH: respondents consider that IMTA productions, can increase the positive perception and acceptability of aquaculture and can contribute to an environmentally sustainable development of aquaculture. Results will be further analyzed and discussed in the presentation.

Introduction

The global production and the use of plastic materials have increased exponentially being the estimation to exceed 1 billion tons by 2050. Microplastics are usually defined as plastic items which measure less than 5 mm in their longest dimension. This material has been found in several habitats, including the sea surface, water column, benthos, estuaries, beaches and aquaculture facilities (FAO, 2017). One of the challenges that result from the growth of human population is the need to increase food production by better managing and sustainably exploiting biological and other resources from the ocean without threatening its quality. The potential of Integrated MultiTrophic Aquaculture (IMTA), a cultivation of aquatic animal species fed in combination with extractive species (organic and inorganic) in earthen ponds (Cunha et al., 2019) has been pointed out as a viable practice to contribute for this goal. Therefore, it is crucial to investigate the impact of microplastics in the aquaculture production. The aim of this study was to identify and quantify the plastics used in IMTA culture in earthen ponds.

Materials and methods

The IMTA procedure used in this study was undertaken in Portugal at the aquaculture research station in Olhão, Portugal (EPPO-IPMA), in earthen ponds with 2500 m^3 and 200% day^{-1} water renewal. The production system included: meagre (900kg), white seabream (240 kg) and zebra seabream (300kg). In addition, 425 kg of gigas oysters were distributed in 2 longlines, totalizing 85 bags of oysters, floats, ropes and other structures. The pond had a paddle aerator attached with the help of ropes and was entirely covered with a marine crow protection net measuring 58.6 x 37 m.

Results

Six types of plastics were found in the integrated cultivation ponds, polyethylene (PE); fibre-reinforced plastic (FRP); polyamide (PA); polystyrene (PS) and polyvinyl chloride (PVC). The total plastic weight per pond was 205.36 kg. The most abundant were PE (43%) and PA (36%), followed by PS (13%), FRP (6%) and PVC (2%). Polyurethane (PU) exists inside the aerator floats, but it was not accounted in this study.

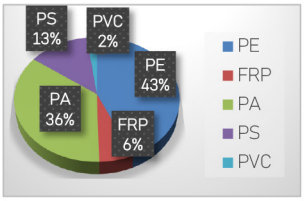

Figure 1 - Types of plastics in integrated aquaculture. **PE**: polyethylene; **FRP**: fibre-reinforced plastic; **PA**: polyamide; **PS**: polystyrene and **PVC**: polyvinyl chloride.

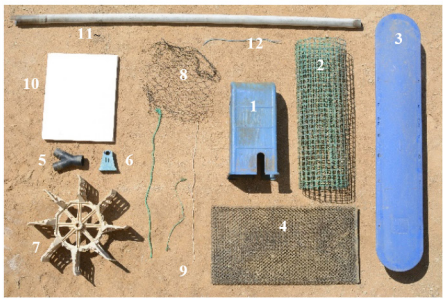

Figure 2 - Types of plastics by equipment. **PE**: 1- aerator cover, 2- output net, 3- aerator float and 4- oyster bag. **FRP**: 5- feeder part, 6- support aerator and 7- wheel aerator. **PA**: 8 - marine crow protection net and 9- ropes. **PS**: 10- oyster float plate. **PVC**: 11- feeder tube and 12- oyster bag holder.

(Continued on next page)

Discussion and conclusion

High levels of solar radiation and temperature are factors that contribute to the degradation of all types of plastics in the Mediterranean. Most of PA and PVC are not in contact with water, so they are degraded exclusively during sunlight. Although PS accounted for 13% of the total plastics in the pond, the degradation of this type of material is the fastest due to bream bites when trying to eat organisms encrusted in the oyster float plates. PE is mostly degraded by the encrustation of marine organisms and also by their removal through maintenance routines. The FRP, which is mostly present on the wheel aerator, wears out by water friction. It is possible to test solutions to reduce microplastics in aquaculture, such as: replacing feeder tubes (PVC) with aluminum tubes; use of sound systems and/or birds of prey to avoid the marine crow and thus reduce the plastics of the protection nets, the current ropes (PA) can be replaced by ropes of organic origin; oyster float plate (PS) can be covered with marine wood to avoid wear and tear and direct contact with water; PE and FRP materials must be studied to be replaced by alternative or biodegradable material. Further studies will be necessary on microplastics, such as degradation, quantification, bio-accumulation among others, to find ways to reduce their impact.

Introduction

Enhancing innate (non-specific) immune response known as immunostimulation has an emphasized importance in the intensification of aquaculture, as a promising method of preventing fish diseases (Sakai, 1999). Excessive use of antibiotics to prevent and treat bacterial diseases leads to the development of resistant bacteria and environmental pollution, therefore it is very important to develop new methods of disease prevention (Dawood et al., 2018). Immunostimulation by the application of microalgae can be such a new and innovative solution (Cerezuela et al., 2012; Messina et al., 2018). As a result, fish can be a safe, antibiotics-free food and this method can contribute to the reduction of antibiotic and chemical residues getting into the environment as well.

In this study we examined new microalgal strains isolated from Hungarian water courses. These strains were selected based on their growth capacity and content of potential immunostimulant substances (e. g. β-glucans, carotenoids or poly-unsaturated fatty acids (PUFA)).

Materials and Methods

Selected and cultured microalgal strains (named ST3i, ST4i, ST5i, ST6i, ST8i) were tested in vitro, on pikeperch (*Sander lucioperca*) and common carp (*Cyprinus carpio*). Leukocytes were isolated from the head kidney of the fish by gradient centrifugation (Secombes, 1990), and they were cultured in L-15 medium on microtiter plates at 18 °C. Suspensions of algae were diluted 10x, 50x, 250x and 1000x with L-15 (common carp) or the concentrations were set to 10; 20; 5 and 1 mg/l using L-15 (pikeperch). Leukocytes were incubated with these media for 48 (pikeperch) or 72 (common carp) hours. L-15 containing 50 μg/ml lipopolysaccharide (LPS) was used as a positive control. Respiratory burst activity (pikeperch) or nitric-oxide production (common carp) of the cells were then measured using photometric methods (Secombes, 1990; Green et al., 1992). Four fish were used from both species, and their average values were calculated for the statistical analysis (one way analysis of variance). Measurements were done with three replicates and each algal strains were tested on separate plates.

Results and Discussion

In the experiments with pikeperch leukocytes, all examined algae significantly ($p<0.05$) enhanced the respiratory burst activity of cells, when they were applied in lower (1 or 5 mg/l) concentrations (Table 1). However, leukocytes isolated from common carp had a significantly ($p<0.05$) higher nitric-oxide production when they were stimulated by the higher concentrations of algae (250x, 50x or 10x dilutions) (Table 2). Based on these *in vitro* results we can conclude that all five algal strains can be potential immunostimulants. However, the correct dose and time of application has to be determined by *in vivo* experiments.

STRUCTURAL ENRICHMENT IN GILTHEAD SEABREAM AQUACULTURE: FUNDAMENTALS AND APPLICATIONS

P. Arechavala-Lopez*, A.R. Oliveira, C.M. Maia, M. Cabrera-Alvarez, J.L. Saraiva

Fish Ethology and Welfare Group, Centro de Ciências do Mar (CCMAR), Faro, Portugal
*E-mail: pablo@fishethogroup.net

Introduction

Environmental enrichment is considered as a tool to guarantee or improve the welfare of captive fish. The deliberate addition of physical complexity to captive conditions allows the animals to have a greater control over their environment,and provides the opportunity to experience new situations while performing behaviours typical of their species in the wild. Well-designed structural EE may provide sensorial and motor stimulation that meet the animals' behavioural and psychological needs, while increasing the behavioural options and putatively reducing the stressors. We demonstrated experimentally that simple structural enrichment can be applied at different production stages of gilthead seabream (*Sparus aurata*) aquaculture, from broodstocks to on-growing sea-cages, not only improving the welfare conditions of captive seabream, but also providing benefits to the farmers. Here, we review the experimental and structures designs, results and conclusions from previous studies carried out on captive gilthead seabream at different life-stages.

Material and Methods

Four different experiments were carried out exposing gilthead seabream juveniles, adults and broodstocks, assessing the effects of structural enrichment of fish welfare with different tools and from different perspectives. However, structural enrichment was similar among experiments, which consisted on plant-fibre ropes, vertically positioned and equally distant, attached to the bottom or to the top of the rearing system and adapted to the appropriate size. First, we studied the effects of structural enrichment on 80 juvenile seabream (weight: 3.8 ± 0.1 g), randomly distributed in eight experimental floating cages within a larger tank. Half of the fish (four tanks) were exposed for 35 days to enrichment. Body condition, growth parameters, fins erosion and brain monoamines were assessed, together with the spatial distribution of the fish during the experiment (Arechavala-Lopez et al. 2019). Second, we explored the effects of structural enrichment on cognition, exploratory behaviour and brain physiological functions of 90 seabream juveniles (weight: 21.9 ± 0.8 g). Fish were distributed in six experimental tanks, half of them (three tanks) reared with the structures for 60 days. During last days, fish were moved into a new-designed experimental maze and video-recorded from above for 1 h, during four different days each group. Fish behaviour, brain monoamines and oxidative stress were assessed (Arechavala-Lopez et al. 2020). A third study was carried out on bigger seabream (weight: 217.58-55.96 g) in a floating sea-cage. Ten fish were tagged with "accel-tag" acoustic transmitters, and reared for one month together with 300 seabream in the same cage. Structural enrichment were deployed during the last two weeks of the experiment. Fine-scale daily activity and spatiotemporal distribution of tagged fish were assessed (Muñoz et al. 2020). A fourth experiment is being carried out on seabream broodstocks (weight ~1 kg), reared in six tanks of 2000 L at commercial densities. Three tanks were enriched with vertical structures (hanging ropes). The aim of this experiment is assessing the physiological and behavioural stress response of broodstock to common aquaculture procedures, such as handling, netting or crowding, as well as the potential effects on spawning and off-spring production (Oliveira, in process).

Results

Results from the first experiment showed that EE modified distribution of seabream inside the experimental cage, entailing a higher use of the inner area of the cage. In addition, a lower interaction with the net and lower aggressiveness among individuals was shown, which consequently, improved pectoral and caudal fins conditions. No effects of growth or brain monoamine levels were observed (Arechavala-Lopez et al. 2019). In the second experiment, we evidenced that deliberate addition of simple enrichment structures enhances welfare status of captive seabream juveniles, influencing positively on cognitive processes, behavioural responses such as exploratory behaviour, and brain-physiological functions. Improvements on spatial cognition and exploratory behaviour may be associated with changes in monoaminergic activity in telencephalon, and serotonergic activity in cerebellum, and are well reflected on antioxidant enzyme activities (Arechavala-Lopez et al. 2020). The third experiment exhibited differences in day vs. night patterns both on swimming activity and vertical distribution throughout the experiment mostly due to the presence of enrichment structures, enhancing the spatial use of fish in the sea-cage (Muñoz et al. 2020). The last experiment is in process, but we hypothesised that the presence of structural enrichment may help seabream broodstocks to cope with common aquaculture procedures, such as handling, netting or crowding, enhancing their physiological and behavioural stress response. It is also expected some positive effects of structural enrichment on spawning and off-spring production, due to the reduction of overall stress (Oliveira, in process).

(Continued on next page)

Discussion

We experimentally demonstrated that simple structures improve the welfare conditions of farmed seabream, and therefore, can be suggested as potential tools to be applied in seabream aquaculture. Moreover, results not only showed that structural enrichment promote positive welfare of seabream, but also that are not detrimental to the growth of the fish and might be used safely by the aquaculture industry. Together with environmental enrichment, innovative technological tools (e.g. acoustic telemetry and underwater cameras), may represent an advancement to monitor fish farming procedures and conditions, helping to promote fish welfare and product quality. Nevertheless, before implementing any environmental enrichment at commercial scale, structures must be appropriated designed and validated, to demonstrate on-farm the applicability and feasibility of these kind of strategies (Arechavala-Lopez et al. 2021).

Introduction

Understanding the basic biology of fish species is crucial for livestock production, and the integration of technological solutions can help to improve accuracy, precision and repeatability in farming operations, but also to improve the decision making in aquaculture management plans. In this sense, the use of accelerometer acoustic transmitters calibrated with oxygen consumption and body motion in swim-tunnels as a proxy of energy expenditure can be seen as a promising tool for production and welfare assessment in the aquaculture industry. Nevertheless, more studies are required to improve methodologies in this field of research, with issues arising from the complex interpretation of data acceleration, but also developing species- and life-stage-specific before acceleration transmitters can be extensively applied to reliably assess fish swimming activity. Therefore, we compared accelerometer acoustic transmitter outputs with swimming performance and body motion of gilthead seabream (*Sparus aurata* L.) in swim-tunnels at different flow speeds, which allowed us to characterize the swimming activity of this fish species of high aquaculture interest. In addition, we assessed the potential surgical/tagging effects through the comparison of oxygen consumption, cost of transport and body motion parameters between tagged and non-tagged gilthead seabream.

Material and Methods

A total of 50 seabream (20 cm in length and 200 g in weight, aprox.) were held in a 600L circular tank for two weeks before use in the swimming experiment. Swimming tests were performed in four Blâzka-type swim-tunnels. The flow in the swim tunnels was set at six different speeds during the experiment, from the lowest speed (flushing only, propellers not active) and increasing stepwise by 0.2 m s^{-1} per hour up to 1 m s^{-1} (Palstra et al. 2020) while accelerations, oxygen consumption and locomotion were assessed within each interval (Arechavala-Lopez et al. 2021). Acoustic transmitters equipped with accelerometer sensors (ThelmaBiotel Ltd., Trondheim, Norway; model A-LP7; AccelTag) were surgically implanted to 10 seabream individuals, which were allowed to recover for five days before the swimming experiment. A passive acoustic receiver (ThelmaBiotel Ltd.; modelTBR700) was positioned at the back end inside each tunnel, to record the accelerometer transmitters signals during the experiment. The accelerometers provided root mean square values of the three acceleration axes (ARMS, in m $cots^{-2}$), averaged overall samples in the sampling window, and were transformed into real accelerations (in m s^{-2}). The swim-tunnel system included a bypass with an oxygen probe in a four-channel respirometry system (DAQ-PAC-G4; Loligo Systems Aps, Tjele, Denmark) to measure total oxygen content of the water in percentage, which drops due to oxygen consumption of the fish (ΔO2%). Then, oxygen consumption rate (MO_2; in mg O_2 kg^{-1} h^{-1}) and cost of transport (COT; in mg kg^{-1} km^{-1}) were calculated for each individual and swimming speed. Additionally, critical speed (Ucrit), optimal speed (Uopt), and minimum cost of transport (COTmin) were estimated. Seabream locomotion was filmed with a camera positioned one meter below the center of the tunnel (Basler 2040-90um NIR USB3 camera; frame rate: 25 frames s^{-1}, exposure time: 15 ms). The following parameters were estimated: head orientation position (HO), head orientation frequency (HOF) and amplitude (HOA), tail beat frequency (TBF) and amplitude (TBA). Difference between tagged and non-tagged fish on respirometry and locomotion parameters were tested using a generalized linear mixed model (GLMM). In addition, the paired relationships between estimated parameters were also tested using a GLMM (for further details see Arechavala-Lopez et al. 2021).

Results

Tag implantation in the abdominal cavity had no significant effects on swimming performance and body motion parameters. Accelerations, cost of transport (COT) and variations on head orientation (angle with respect to flow direction) were negatively related to flow speed in the tunnel, whereas oxygen consumption (MO_2) and frequencies of tail-beat (TBF) and head movements (HOF) increased with flow speed (Figure 1).

(Continued on next page)

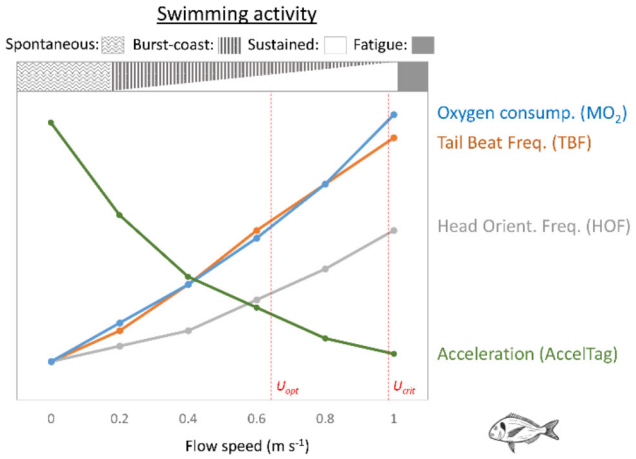

Fig. 1. Representation of the main results obtained in this study.

Discussion

These results show that accelerometer acoustic transmitters mainly recorded deviations from sustained swimming in the tunnel, due to spontaneous and explorative swimming at the lowest speeds or intermittent burst and coast actions to cope with water flow. In conclusion, accelerometer acoustic transmitters applied in this study provided a proxy for unsustained swimming activity, but did not contemplate the high-energy cost spent by gilthead seabream on sustained swimming, and therefore, it did not provide a proxy for general activity. Despite this limitation, accelerometer acoustic transmitters provide valuable insight in swim patterns and therefore may be a good strategy for advancing our understanding of fish swimming behaviour in aquaculture, allowing for rapid detection of changes in species-specific behavioural patterns considered indicators of fish welfare status, and assisting in the refinement of best management practices.

Introduction

Structural enrichment is considered an useful tool to guarantee or improve the welfare conditions of captive fish (from a behavioural, physiological and psychological perspective) by increasing the heterogeneity and complexity of captivity environments (Arechavala-Lopez et al. 2021). However, the potential effects of structural enrichment to reduce growth variability among tanks has not been reported before. High growth heterogeneity (different individual growth) within the same stocking fish group leads to a greater investment and effort on the part of the fish-farming companies to try to reduce this variability, either through several grading or continuous feed adjustments, which consequently leads to higher stress to captive fish. Growth heterogeneity on European seabass (*Dicentrarchus labrax*) can be caused by sex differentiated growth (females growth faster than males) or due to indirect effects of social hierarchies and behavioural traits. In this study, we assessed the effects of suspended vertical structures (U-shaped ropes) on growth performance and tank-to-tank homogeneity of juvenile seabass.

Material and Methods

A total of 420 seabass (mean standard length ±SD: 9.8 ±1.1 cm; mean body mass ±SD: 16.5 ±5.6 g) were obtained from a commercial hatchery (Aqüicultura Balear S.A.- Culmarex; Mallorca, Spain) and acclimated to the laboratory conditions for one week at the Laboratory of Marine Research and Aquaculture (LIMIA) in Port d´Andratx, Mallorca, Spain. Then, seabass were randomly distributed in 6 circular tanks (water volume 150 L) in groups of 70 individuals. Three tanks were enriched with 3 plant-fiber ropes hanging from one edge of the tank to the other, two parallel (130 cm) and one perpendicular larger (170 cm), all of them at different depths and similar distances among them. The other three tanks did not present structural enrichment and were considered as the control or non-enriched (NE) treatment. They were daily fed by hand at 13:00 P.M. a commercial pelleted diet (sinking pellets; 2% of their body mass) specific for seabass (Skretting® 106 Perla MP). All tanks were thoroughly cleaned daily by siphoning faeces and uneaten pellets. The seabass juveniles were maintained under these experimental conditions for 30 days (11/03/2019 - 11/04/2019).

In order to assess the effect of structural EE on seabass body condition and growth performance, fish were anesthetized (Tricaine methanesulfonate, MS-222; 0.1 g L -1) at the beginning (Tinitial) and after a period of 30 days (Tfinal). Then, the standard body length (SL, cm) and total body weight (BW, g) were measured, and the Fulton´s condition factor (K = 100 x BW x SL-3) was calculated for each individual for both sampling times (initial and final). The heterogeneity of each parameter in each treatment (among tanks) was analysed by estimating Pearson's coefficient of variation in percentage (%CV), as the parameter standard deviation divided by the mean, and visually assessed for each treatment by plotting the distribution or frequency of each parameter.

Results

No statistical differences were found between EE and NE treatments at the beginning of the experiment regarding standard length, body weight and condition factor. Similarly, no significant differences were detected at the end of the enrichment experiment (30 days) on these fish condition parameters. Regarding distribution of data frequency, fish condition parameters differed visually between treatments. Frequency of final SL and final K of EE-fish group presented normal distribution curves narrower and less dispersed than the normal curve of NE-fish group. Similarly, distribution of final BW data also differed between treatments, but in this case EE-fish group showed a normal distribution, whereas NE-fish group showed a bimodal distribution (Figure 1). Additionally, group heterogeneity among tanks, assessed through the coefficient of variation (%CV), was higher in NE fish tanks compared to EE tanks for every estimated parameter.

(Continued on next page)

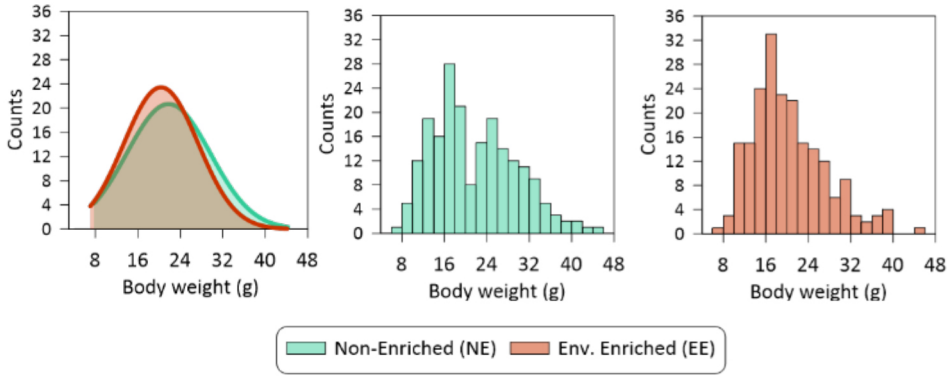

Fig. 1. Distribution of frequency of final body weight from European seabass individuals reared in enriched (EE, in red) and non-enriched (NE, in green) conditions under 30 days in experimental tanks.

Discussion

We demonstrated for the first time that suspended vertical structures (U-shaped ropes) can provide short-term benefits increasing the homogeneity (i.e. reducing CV) of body condition and growth performance of seabass juveniles reared in tanks. Indeed, one of the main effects of the suspended structures was the modification of BW distribution into a single curve, eliminating the undesirable "bimodal distribution" within a stocked fish group/tank. Coefficient of variation (CV) is widely used by aquaculture industry, as a relevant indicator of growth performance and development of farmed fish. High growth heterogeneity (different growth potential) within the same stocking fish group leads to a greater investment and effort on the part of the fish-farming companies to try to reduce this variability, either through several grading or continuous feed adjustments. Consequently, the fish handling and management procedures increase due to high heterogeneity, which can create more stressful situations, negatively affecting the welfare of the fish, with direct consequences to the companies. Therefore, suspended structural enrichment can positively affect the welfare of captive fish in aquaculture, providing not only ethical but economic benefits to fish farmers.

ANTIBACTERIAL ACTIVITY OF THE *Sea cucumber holothuria leucospilota* WHOLE BODY EXTRACT AGAINST *Staphylococcus aureus* STRAINS MRSA, SEA AND SEB

Noushin Arfatahery

Freie University Berlin. Institute Biology/Evolutionsbioloy

Correspondence to: arfa.n@fu-berlin.de (Noushin Arfatahery)

Introduction
Aquatic organisms are a source of organic compounds that hold various features such as medical and nutritional activities. Within the framework of an antimicrobial activity study of marine macro-organisms from the Persian Gulf, bioactive compounds of the sea cucumber *Holothuria leucospilota* were extracted from the whole body using chloroform and methanol. *Staphylococcus aureus* is one of the most common causes of seafood-borne diseases worldwide, attributable to food contamination by preformed enterotoxins. The extracts were evaluated for their antibacterial effects against methicillin-resistant (MRSA) and staphylococcal enterotoxins producing (SEA, SEB) *Staphylococcus aureus* strains.

Materials and Methods
Activities have been determined using three methods: disk diffusion tests, minimum bactericidal concentration (MBC), and minimum inhibitory concentration (MIC). The results demonstrate that methanol and chloroform extracts have an inhibitory effect on the growth of all strains at MIC concentrations up to 100 mg/ml. Also, chloroform extracts demonstrate bactericidal activity against SEB in concentrations of about 100 mg/ml. The extracts also show bactericidal effects against MRSA and SEB below 100 mg/ml concentrations.

Results
The highest antibacterial activity was found in methanol extract. Therefore, sea cucumber extracts are good candidates for the identification of new antimicrobials. Yet, comprehensive investigations are needed to separate and identify the active components for *Holothuria leucospilota* from the Persian Gulf.

Table 1. Antimicrobial activity of whole body of *H. leucospilota* methanol and chloroform extracts

Staphylococcus aureus	extracts	MIC	MBC
MRSA	Methanol 40 µg/mL	100 mg/ml	100 mg/ml
SEA		100 mg/ml	-
SEB		50mg/ml	100 mg/ml
MRSA	Chloroform 40 µg/mL	50 mg/ml	-
SEA		50 mg/ml	-
SEB		50 mg/ml	100 mg/ml

CHARACTERIZATION OF TOXIN GENES AND ANTIMICROBIAL SUSCEPTIBILITY OF STAPHYLOCOCCUS AUREUS ISOLATES IN FISHERY PRODUCTS IN IRAN

Noushin Arfatahery

Freie University Berlin, Institute Biology/Evolutionsbioloy

Correspondence to: arfa.n@fu-berlin.de (Noushin Arfatahery)

Introduction
Staphylococcus aureus is one of the most common causes of seafood-borne diseases worldwide, which are attributable to the contamination of food by preformed enterotoxins.

Materials and Methods
In this study, a total of 206 (34.3%) Staphylococcus aureus strains were obtained from 600 fish and shrimp samples and were tested by PCR for their antimicrobial susceptibility. We assessed the prevalence of the genes responsible for the staphylococcal enterotoxins (SEA, SEB) and toxic shock syndrome toxin 1 (TSST-1) genes.

Results
The results indicated that 34% of aqua food samples were contaminated with S. aureus, and 23.8% of these isolates were mec-A-positive. Sixty-four percent of the strains isolated from contaminated seafood was enterotoxigenic S. aureus, and 28.2% of SEs were MRSA-positive. The most prevalent genotype was characterized by the presence of the sea gene (45.2%), followed by the seb gene (18.5%), and the tst gene encoding TSST-1 was found in eight strains (3.9%). Of the 206 S. aureus isolates, 189 strains (84.9%) were resistant to at least one antibiotic. Given the frequent outbreaks of enterotoxigenic MRSA, it is necessary to make revisions to mandatory programmes to facilitate improved hygiene practices during fishing, aquaculture, processing, and sales to prevent the contamination of fishery products in Iran.

Studied genes of *Staphylococcus aureus*	Genes: positive		Genes: negative		Total

Introduction

The finfish aquaculture industry is presently the main supplier of fish for human consumption worldwide. With the increase in demand and the development of technologies that allow the intensification of fish rearing, welfare issues are deemed to increase. One of the main measures to improve the life of farmed fish is implementing environmental enrichment (Arechavala-Lopez et al. 2021). Within structural enrichment, the provision of tank covers is suggested to be a suitable option to provide shelter, with the advantage of being cheaper and easier to maintain than underwater structures, while also reducing external stressful stimuli. This would make tank covers a potentially suitable enrichment strategy for small scale fish farms. In this study we tested the welfare effects (using behavioural and physiological welfare indicators) of three levels of tank cover (fully covered, 50 % covered and uncovered) in an all-male population of Nile tilapia *Oreochromis niloticus*, a fish species with high farming interest world-wide.

Material and Methods

A total of 135 Nile tilapia males (Silver Natural Male Tilapia™ , Til-Aqua International
B.V., Netherlands) were distributed through 15 cylindroconical tanks of 100 L in a recirculating system. These fish were kept for seven days in the tanks prior to the experiment and exposed to different treatments (i.e. tank covers) during the following 21 days. Each tank held nine individuals of 35.27 ±0.54 g (mean ±SEM) at an initial density of approximately 3 kg/m^3. Tank covers were made of extruded polystyrene (Roofmate ™) and were disposed on the top of the tanks (approximately 10 cm above the water surface) and the cover effect on light intensity inside each tank was measured with a luxmeter. Three treatments were used: 100 % covered (corresponding to 18.8 ±1.5 lx), 50 % covered (94.2 ±2.6 lx) and uncovered (169.6 ±8.0 lx) (Fig. 1).

Five of the nine fish in each tank were tagged with individual Floy Tags ™ to allow visual discrimination and behavioural assessment. Each day, five tanks of different treatments were video recorded with a Go-Pro Hero 5 digital camera, slightly submerged, placed at the top centre of the tank aiming down and using the maximum wide angle possible for this model. The recording time for each tank was 25 min after 1-2 min for habituation. By the end of the experiment (21 days), each tank was observed three times, the interval between recordings was three to six days, and each marked fish within the tanks was observed for an accumulated total of 15 min. The Observer XT ™ (Noldus, the Netherlands) software was used to quantify behavioural states (i.e. freezing on the bottom, fast swimming, hovering) and events (chases and bites). At the end of the experiment, tagged animals were anaesthetised with a solution of MS-222 (Sigma) buffered with sodium bicarbonate at 1:2 and had a blood sample taken through punction of the caudal vein with a heparinised needle. Samples were centrifuged and supernatant plasma was analysed for cortisol through radioimmunoassay.

Results

The percentage of time that fish were in the freezing state was significantly higher in the 50 % covered tanks than in the open tanks. Tank coverage did not influence time spent in fast swimming. Fish reared in the open tanks spent a significantly higher percentage of time hovering compared with fish reared in the 50 % cover treatment. While the frequency of chases per min was significantly lower in the partially covered compared with the open tanks, the 100 % cover displayed intermediate values and did not differ significantly from any other treatment. Concerning frequency of bites per min, no significant differences were detected among treatments. Additionally, cortisol was significantly higher in 50 % than the 100 % cover while fish reared in the open tanks had intermediate levels and did not differ from the other treatments.

(Continued on next page)

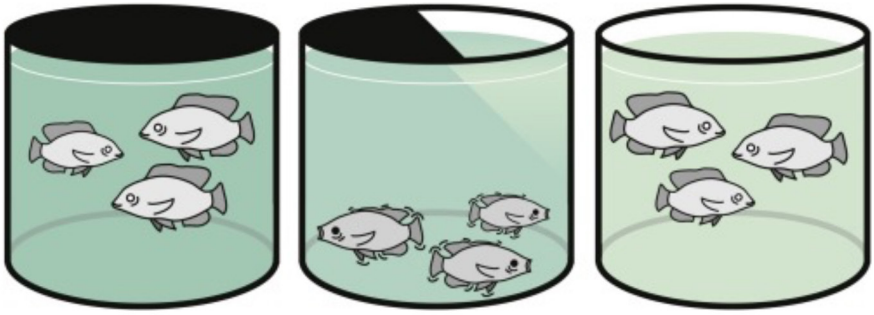

Fig. 1. Graphical summary of the experimental design and the effects of tanks covers (fully covered, 50 % covered and uncovered) on welfare of Nile tilapia (taken from Saraiva et al. 2021).

Discussion

Providing tank covers can improve welfare conditions of farmed fish in captivity, but poor environmental enrichment (EE) strategy or wrong designs can lead to fish welfare impairments. Contrary to our initial predictions, this work clearly demonstrated that fish under the 50 % cover treatment presented the worst welfare according to our chosen indicators. Fish under partially covered tanks spent the longest time frozen on the bottom, the least time hovering in the water column and had the highest cortisol levels. They also presented the least frequency of chases, which can be explained by the fact that if they are frozen on the bottom, they cannot be chasing conspecifics. In fact, freezing behaviour impairs the performance of many fundamental behaviours. We expected that there would be a progressive increase in good welfare indicators from the open to fully covered treatment, possibly due to protection from external disturbances, yet our data suggests otherwise. These results do not undermine the need to pursue better welfare solutions for fish, of which environmental enrichment and complexity is a promising avenue. Yet, they highlight the need to thoroughly test and conduct exhaustive trials when implementing EE measures, even as simple as tank covers, as well as the importance of species-specific knowledge when implementing environmental enrichment strategies.

Introduction

Climate change is having a significant impact on the biology and ecology of aquaculture species and will affect the productivity within seafood supply chains in the future. The challenges are further amplified when actors within the aquaculture sector have very different ideas and assumptions about climate change, and what risks and opportunities they entail. In order to address the challenges of climate change, several countries have developed national adaptation plans. However, aquaculture is rarely included in these plans, resulting in a general lack of documented adaptation strategies within the sector in most countries.

This study introduces guidelines for the development of climate adaptation plans (CAPs) for aquaculture, which are part of the recently published CEN[1] Workshop Agreement voluntary standard on "Good practice recommendations for making climate adaptation plans for fisheries and aquaculture" (CWA 17518:2020) and supported by the recent paper (Pham et al. 2021). The objective is to provide a stepwise process using a co-creation approach to facilitate stakeholders to plan strategies for climate adaptation. The three-step process is part of a cycle, including implementation, monitoring, and evaluation, generating iterative feedback loops over time. The guidelines are discussed in the light of other existing adaptation tools and highlight the advantages and challenges of developing CAPs within the aquaculture sector.

Framework for developing CAPs

The CAP guidelines were developed using two main approaches: the social-ecological approach and the co-creation approach. The former was employed to identify relevant key components of the sustainable aquaculture system. The latter was used to determine the level of stakeholder participation in the development of CAPs. After devising a prototype, the guidelines were applied to six aquaculture case studies within Europe including species from multiple trophic levels. The methodology and the CAP development process were modified and improved through iterative feedback loops. The CAP guidelines also followed the standardization process devised by the European Committee for Standardization (CEN).

Guidelines for developing CAPs for aquaculture

The guidelines consist of three main tasks: T1, assessment of risks and opportunities; T2, identification of adaptation measures; and T3, operationalization of the CAP. These tasks are conducted through seven steps (S1-S7) in conjunction with three stakeholder meetings. The tasks, steps, and stakeholder meetings are described below, in chronological order (Fig. 1).

Discussion and conclusion

Each CAP development process will be unique. A CAP for an aquaculture system may be developed and applied at local or at national level. To be effective, CAPs should be aligned with strategy and policy processes that are in development, under evaluation and/or revision. The "Strategic Guidelines for the sustainable development of EU aquaculture" are being reviewed by the Commission to support Member States and the sector in further developing aquaculture production. These revised Strategic Guidelines also suggest management measures as well as funding opportunities for climate adaptation in line with the CWA17518:2020.

(Continued on next page)

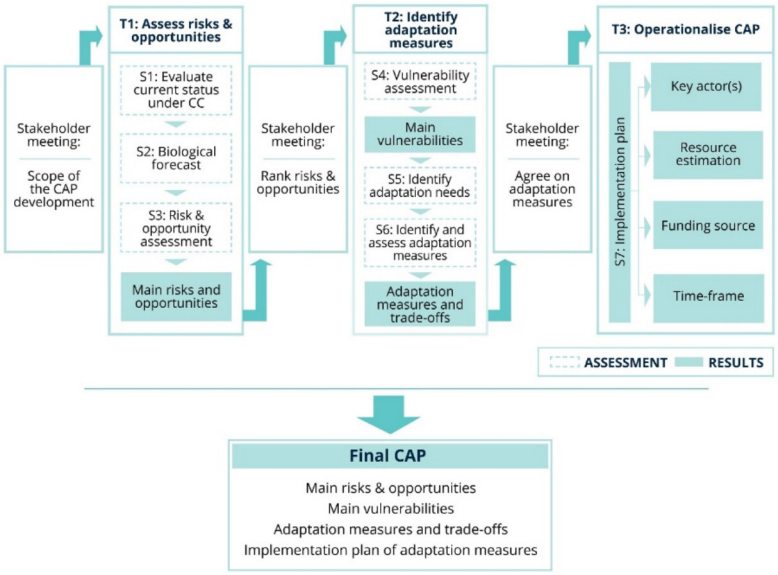

Figure 1: Flowchart of guidelines for developing a Climate Adaptation Plan (CAP). The CAP development consists of three tasks (T1-3) and seven steps (S1-7).

Fernandes, Tarub Bahri, Sigurður Ö Ragnarsson, and Michaela Aschan. 2021. "Guidelines for Co-Creating Climate Adaptation Plans for Fisheries and Aquaculture." *Climatic Change* 164 (3): 62. https://doi.org/10.1007/s10584-021-03041-z.

A CEN workshop for developing fisheries and aquaculture CAPs was established to ensure representability and involvement of a broad set of stakeholders. Throughout this process, the guidelines were evaluated, reviewed, and revised on several occasions based on the input and feedback of the CEN workshop participants. At the end, consensus was reached, and a CEN Workshop Agreement (CWA) was established, ensuring that the guidelines will be available through national standardization bodies for at least three to six years after they were published.

Introduction

Pacific oyster (*Crassostrea gigas*) is a highly important shellfish species accounting ~98% of global oyster production. Infectious diseases present a significant threat to the sustainability of aquaculture production with high economic losses due to mortalities caused by diseases. Ostreid herpesvirus (OsHV-1-μvar) originates highly contagious viral disease to Pacific oysters which is serious concern for oyster farmers globally. OsHV-1 may cause massive mortalities (~100%) especially in susceptible phase (larvae and small size oysters). Selection and breeding for resistance against infectious diseases is highly valuable tool to help prevent or diminish disease outbreaks, and currently available advanced selection methods with the application of genomic information could pace up response to selection. Current study was designed to estimate genetic variation for resistance against OsHV-1, map quantitative trait loci (QTL), and explore potential of marker assisted and/or genomic selection [1].

Material and Methods

This study comprises of a resource population of subsided 1520 offspring belonging to ~8 F_2-families produced from a cross of highly resistant grand-parents and susceptible lines (kept free of OsHV-1 infection since 2010). These offspring were selected from a large size population of ~16,000 offspring which experienced natural field outbreak of OsHV-1 in summer 2017. F_2 individuals were recorded twice a day to check their status (alive vs. dead). Tissue sampling was performed for early dead individuals (i.e., mortalities in early phase of infection) and the late survivors (two months later). The tissue samples of F_1 parents and grand-parents were also collected for further genomic work.

Additionally, the whole genome re-sequencing (WGS) was performed on 67 individuals including grand-parents, F_1 parents and 5 individuals per F_2 family (4 survivors and 1 dead) using Illumina HiSeq 2500 platform. Genotyping calling using sequence data produced a quality genotypes for 1,684,660 SNPs. The genotype data from the sequenced individuals (grand-parents, F_1 parents and ~5 offspring per F_2 family) was used for the construction of linkage map. Linkage mapping was performed with Lep-MAP3 [2] using all the informative markers in VCF file.

The survival recorded F_2 individuals (n~1520) were genotyped using 40,625 SNP array (Thermo-Fisher, AXIOM), and 14,245 markers remained after quality filtering. Out of 14,245 array markers, 14,218 were in common with the markers discovered from sequence data which were allocated linkage positions using map developed from sequenced individuals.

Estimates of genetic variation and the breeding values were obtained using ASReml 4.0 [3] implementing genomic or pedigree-based relationship matrices (G-matrix and A-matrix, respectively) with the following mixed model,

$$y=\mu+Zu+e$$

where is a vector of 'n' phenotypic records, is an overall mean, is a vector of additive genetic effects distributed as or is the incidence matrix for additive effects, and is the vector of random residual effects with . Accuracy of prediction was computed using a cross validation scheme by masking the phenotypes of ~ 20% of the offspring. The cross validation process was repeated 20 times and the accuracy was computed as the correlation of the estimated breeding value (pedigree/genomic, PEBV/GEBV) with the phenotype scaled by the square root of heritability.

GWAS was performed by applying the same above model in GCTA program [4] with first 4 PCAs included as covariate and the SNP effects were also computed.

(Continued on next page)

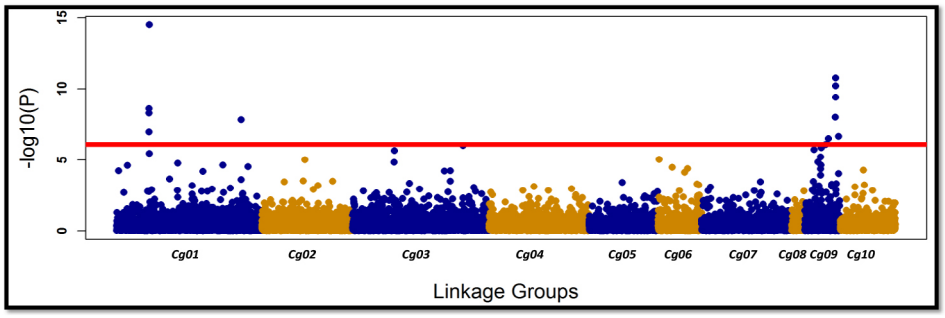

Figure. 1: Manhattan plot presenting association of SNPs with the trait.

Results and Discussion

We developed a linkage map ~1.18 million markers grouped into 10 linkage groups (*Cg*) which are consistent with the karyotype of this species. The estimated heritability for resistance to OsHV-1 (binary, dead/alive trait) using pedigree vs. genomic information was moderate to high (0.23 vs. 0.63, respectively). GWAS revealed strong signals of QTLs on two different linkage groups (*Cg01* and *Cg09*, including 6 and 10 SNPs respectively), presenting significant association to the trait with P-value crossing genome-wide Bonferroni corrected threshold (Figure 1). The proportion of total genetic variance explained by the top two SNPs (with single top-most SNP taken from each of the QTLs) was ~50% of the total genetic variance. The prediction accuracy for breeding values using genomic models exhibited 113% increase over the use of pedigree information.

In conclusion, results revealed moderate to high genetic variation for survival against OsHV-1 with two quantitative trait loci affecting resistance. The estimated breeding values using genomic information presented more than double accuracy compared to pedigree information, which should ultimately be reflected in overall genetic gain.

Introduction

Contagious diseases are a major threat in aquaculture due to losses caused by high mortalities and the reduced growth of surviving fish. Viral nervous necrosis (VNN) is an infectious disease caused by nervous necrosis virus (NNV, red-spotted grouper nervous necrosis virus, RGNNV in European sea bass) which is considered a serious concern for European seabass producers, with fry and juveniles being highly susceptible. The outbreak of VNN may cause up to 100% mortalities at larval and around 20% mortalities at advanced juvenile stages[1, 2]. Moreover, the surviving fish present poor growth rate and ultimately high economic losses for the producers.

Selection and breeding for resistance against infectious diseases is highly effective tool to prevent and/or diminish disease outbreaks. Currently available advanced selection methods with the application of genomic/marker(s) information could pace up response to selection. The genetic variation for resistance against VNN obtained from the challenge tested population was presented previously [3]. The aim of current study was to further look into the genomic architecture of the trait and explore potential of marker assisted and/or genomic selection and obtain realized validation of QTL effects.

Material and Methods

This study comprises of a resource population belonging to multiple year classes (YC2016, YC2017, and YC2019) derived from the Nireus SA's breeding nucleus of European seabass. Families from each of these year classes were gone through the challenge test against VNN, and the subset of the families and individuals from year classes YC2016 and YC2017 including 30 (~27 individuals/family) and 92 (~8 individuals/family) families, respectively were genotyped. Additionally, 536 breeding candidates from multiple year-classes (YC2011-2016) pre-selected according to selection criteria defined in the commercial seabass nucleus work and linked to YC2016 and YC2017 through pedigree were genotyped. The tested individuals and the candidates from YC2016 and YC2017 were genotyped using SNPs based ~57K Affymetrix Axiom array (DlabCHIP) [4]. The detection of QTL was performed using survival phenotype and the genotype information on YC2016 and YC2017 whereas validation of QTL effects was performed using genotype information on candidates (YC2011-2016) and the phenotype of descendent year class, YC2019. For the purpose of validation, additional specific crosses were made in YC2019 using QTL information to produce resistant ("RR", homozygous for favorable allele), moderate ("Rr", heterozygous) and susceptible ("rr", homozygous for alternative allele) families.

Analyses: Genome wide association analysis was performed using following linear mixed animal model implemented in GCTA program with "--mlma-loco" function [5].

$$y=\mu+Xb+Ma+Zu+e$$

Where is the vector of phenotypes (0 dead or 1 alive); is the overall mean; is an incidence matrix for fixed effects and is a vector of fixed effect of year class; is the incidence matrix for SNP containing marker genotypes coded as , is the allele substitution effect of SNP, is a design matrix to relate the records to genetic values and is a vector of random additive genetic effects, it is assumed that , where is the genetic variance and is a genomic relationship matrix computed using VanRaden's method 1. The is the vector of random residual effects with .

Moreover, the accuracy of genomic prediction was evaluated using different models (GBLUP and Bayesian) to assess and compare the potential of genomic and/or marker assisted selection.

(Continued on next page)

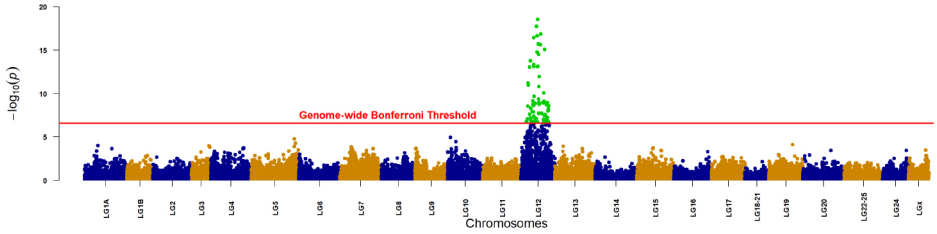

Figure. 1: Manhattan plot presenting association of SNPs with the trait.

Results and Discussion

The GWAS analysis revealed a strong signal of QTL at LG12 with 72 SNPs presenting significant association to the trait with P-value crossing genome-wide Bonferroni corrected threshold (Figure 1) The proportion of the genetic variance explained by the highest significant SNP was ~33% of the total genetic variance. Multiple genes were identified within the QTL region with *REEP1* gene located immediately at the upstream of the highest significant SNP which seems to be more pronounced with functions involving nervous system. The mean accuracy of prediction for resistance against VNN obtained using different genomic models (GBLUP and Bayesian) was 0.72 with Bayesian models worked either better or equally well as GBLUP.

The validation results for survival of "RR", "Rr" and "rr" families which were specifically produced using QTL information on parents revealed >30% higher survival of "RR" over "rr" families and 7% higher survival over "Rr" families.

In conclusion, the tested realized effect of QTL showed >30% higher survival of families carrying homozygous favorable genotype over families containing homozygous unfavorable genotype. Hence, marker assisted selection using QTL information has a shown strong potential for improving resistance against VNN.

Introduction

A selective breeding program for growth rate of tilapia in brackish water is conducted in Indonesia. While focusing on growth trait, the reproductive performance of tilapia in brackish water is also considered important. To avoid the potential threat to the saline aquatic ecosystem, reduced or even repressed reproductive performance of tilapia in brackish water is desired. However, studies comparing reproductive performance between environments and estimates of genetic parameters for reproduction traits are very limited in any aquaculture species. Objective of this study were to investigate: 1) the reproductive performance of tilapia in brackish water and freshwater and 2) the genetic parameters of tilapia reproduction traits.

Materials and methods

Offspring of 91 full sib families were produced and per family 20 fingerlings were randomly chosen for communally grow-out in a brackish water (20-25ppt) and another 20 in freshwater. After the grow-out period of 120-147 days, fish were harvested and 6 fish per family were recorded for gonad weight and maturation score in each environment. Gonads were weighed and maturation stage was macroscopically determined according to Legendre & Ecoutin (1989). Gonadosomatic index was determined as GSI = gonad weight*100/BW. Gonad weight (GW) and GSI were analyzed separately for each sex. Genetic parameters were estimated from bivariate animal models in ASReml version 4.1 (Gilmour *et al*., 2015) accounting for fixed effects of pond and harvest weight. For genetic analysis maturation was reclassified as mature (1) or immature (0) (Legendre & Ecoutin, 1989) and analyzed for males and females together with sex as additional fixed effect.

Results

At harvest time, the mean weight was higher in brackish water (300.84±67.48) and significantly different ($P<0.05$) compared with the freshwater (238.13±56.65). Gonad weight for male and female and GSI for female in brackish water were higher and significantly different compared to freshwater ($P<0.05$). GSI of males showed no significant difference ($P>0.05$) between brackish water and freshwater (Table 1).

Most males were mature (~80% were stage 3) in both brackish water and freshwater (Table 2), while for the female, about half the fish were mature fish (stage 4-5) in both brackish water and freshwater. For males, heritabilities of GW and GSI were higher in freshwater, than brackish water and the genetic correlations were high. For females the opposite was found with higher heritabilities in brackish water and a moderate genetic correlation for GW (Table 3). The genetic correlation for GSI in females was high, but estimated with a very high standard error. Maturation was analyzed for both sexes combined and found to have a low heritability in brackish water and freshwater, 0.12 ±0.07 and 0.04 ± 0.07, respectively and a moderate genetic correlation, 0.47 ±0.74.

Table 1. Means ($\bar{x}$), standard deviations (σ), coefficients of variation, % (CV) of gonad weight and GSI male and female from brackish water and freshwater

Traits	N	Brackish water			n	Freshwater		
		$\bar{x}$	Σ	CV		$\bar{x}$	σ	CV
Gonad weight male	299	1.03	1.50	145.1	280	0.70	0.76	109.7
Gonad weight female	177	4.52	3.56	78.6	198	2.42	2.16	89.2
GSI male	299	0.31	0.50	159.7	280	0.28	0.31	111.1
GSI female	177	1.82	1.40	77.2	198	1.26	1.54	91.2

(Continued on next page)

Discussion

The final weight in brackish water was higher (P<0.05) compared with the freshwater and can explain the higher GW and GSI in brackish water. Males showed higher maturation stages compared to females, both in brackish water and freshwater. This was expected from comparing them at the same age. Heritability of maturation traits in brackish water was higher for males and lower for females in comparison to freshwater. The heritability of maturation in brackish water (0.12) was in good agreement with an earlier report from Egypt, 0.13 (Charo-Karisa *et al*., 2007). Our estimate from freshwater was however much lower at 0.04±0.07. Heritabilities for maturation were lower than the result from Thoa *et al*. (2015) who reported heritabilities of 0.40±0.06 in saline water and 0.32±0.06 in freshwater. Genetic correlations estimates had high s.e. because of the limited size dataset.

Conclusions

All reproductive traits showed higher values in brackish water compared to freshwater. Tilapia is a species with a high reproductive rate and their maturation was not compromised by the brackish water environment. To reduce the potential threat from escapees to the brackish water ecosystem, selection for reduced maturation in brackish water environment is most promising for the female reproductive traits that have the higher heritabilities and lower genetic correlations with reproductive traits in freshwater.

CHARACTERIZATION OF MOLECULAR, CELLULAR AND HUMORAL IMMUNE MARKERS IN THE EUROPEAN SEABASS (*Dicentrarchus labrax*) UNDER CHRONIC INFLAMMATORY CONDITIONS

R. Azeredo[1*], M. Machado[1], D. Peixoto[1,2], B. Costas[1,2]

Introduction

Fish health and welfare are among the top priorities in what aquaculture research is concerned. Stress-inducing husbandry and rearing conditions (including alternative dietary formulations), bacterial infections or parasitic diseases may all lead to chronic inflammation (1, 2). Such an immune response channels energy away from growth, reproduction and other important physiological processes, to fuel immune-related metabolic responses. Despite a reasonable amount of studies on fish immune response, there is a lack of a solid inflammation model for fish and a battery of biological markers that can more accurately characterize chronic inflammatory responses. The present study aims to gather information on molecular, cellular and humoral parameters of European seabass (*Dicentrarchus labrax*) undergoing chronic inflammation that can be used as health indicators for applications in fish health management.

Material and methods

Juvenile European seabass (300 g ± 71.8) were acclimatized in a recirculating seawater system (temperature 16 ºC; Salinity: 35; Photoperiod: natural summer time; n = 12) for 30 days being fed a commercial diet throughout the whole experiment. At the end of this period, fish were intra-peritoneally injected with either Freund's Incomplete Adjuvant (FIA) to induce inflammation or Hanks Balanced Salt Solution (HBSS) to serve as sham, and distributed in duplicate tanks in the same system. Fish were sacrificed at 24 h, 7 days, 14 days and 21 days post-injection (n = 3 per tank). During sampling, blood was collected from the caudal vein and directly used for total peripheral cell counts, blood smears preparation and respiratoy burst. Plasma was then obtained for the assessment of humoral immune parameters. Peritoneal exudates were collected for total peritoneal leucocytes counts. The head-kidney was sampled for the evaluation of immune-related and opioid receptors gene expression measured by real-time quantitative PCR.

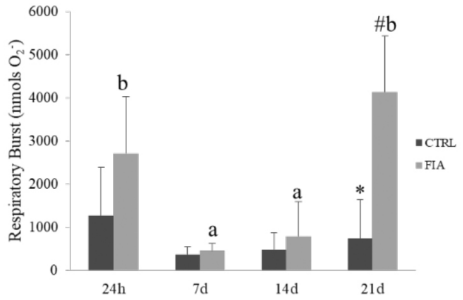

Fig. 1. Respiratory burst activity of circulating leucocytes of European sea bass intraperitoneally injected with HBSS (CTRL) or Freund's Incomplete Adjuvant (FIA). Values represent means ± SD (n = 6). Different letters stand for statistically significant differences between sampling times, within the same treatment. Different symbols stand for statistically significant differences between treatments (Two-way ANOVA; $P < 0.05$)

(Continued on next page)

Results

Though there were no significant differences in total peripheral cell counts between FIA and HBSS groups, FIA-injected fish presented higher total peritoneal leucocyte concentration than the HBSS group at 7, 14 and 21 days post-injection. Peripheral monocytes were also higher in FIA-injected fish than in the HBSS group regardless of sampling time, as well as both lymphocytes and neutrophils at 24h post injection. Total proteases activity and lysozyme activity were also induced in FIA-injected group, compared to the HBSS group, regardless of sampling time. Similarly, increased respiratory burst was observed in FIA-injected fish, though only in fish sampled at 21 days post-injection (Fig 1). Regarding head-kidney gene expression, interleukin 1β (*il1β*) and caspase 1 (*casp1*) were both up-regulated in FIA-injected fish, irrespective of sampling time. Moreover, interleukin 34 (*il34*) did not respond differently between groups or sampling times, but an increasing trend was observed within FIA-injected fish. In what opioid receptors are concerned, no differences were detected between FIA and HBSS groups but mu, kappa and nociceptin opioid receptor (*muor, kor1* and *nopr*, respectively) were found down-regulated in fish sampled at 7 d, 14 d and 21 d post-injection compared to levels measured at 24 h.

Discussion and conclusion

FIA is well-known to trigger and enhance inflammatory responses, thus serving as a very effective adjuvant during vaccination. Indeed, the results here reported are clear indicators of an inflamed peritoneal cavity and an ongoing systemic immune response that persist at least for 21 days. Locally, inflammation was characterized by an intense recruitment of immune cells that was still evident 21 days after injection thus illustrating the chronic character of the immune response. Cellular response was also noticed peripherally with neutrophils, lymphocytes and monocytes numbers rising in the blood of FIA-injected fish. Furthermore, cellular-mediated respiratory burst peaked at 21 days post FIA injection, suggesting that phagocytes were still actively fighting the phlogistic agent. Respiratory burst is a particularly interesting parameter to be seen enhanced at such a late time-point, as it is a key discriminant feature of active phagocytes (3), very much present at the onset of inflammation. Regarding the head-kidney molecular analysis, pro-inflammatory genes (*il1β*, *casp1*) were indeed higher in fish injected with FIA but such effect was regardless of sampling point, making these poor markers of a prolonged response. *il34* expression time-dependent increasing trend poses as good marker of chronic inflammation due to its importance as a second ligand of CSFR1, a pathway with high relevance in chronic inflammation settings (4). In conclusion, peripheral leucocyte counts and respiratory burst analysis seem to be reliable indicators of chronic inflammation easily obtained with a blood sample. Further investigation is nonetheless required to select more responsive and specific molecular markers.

Introduction

One of the main problems associated with any food production value chain is valorisation of by-products and side-streams to reduce the environmental impact, while optimizing the use of resources (Newton et al., 2017). This is especially needed for the aquaculture sector, where circularity principles are key elements to meet sustainability requirements. In the H2020 project "GAIN" , we have used different strategies to address this issue by investigating innovative processes aimed at reusing: fish sludge, generated in Recirculating Aquaculture Systems (RAS), fish mortalities, by-products generated by fish processing (heads, frames and trimmings, skins, etc..), and shells from bivalves generated by the cannery industry. Main results and developments that will significantly contribute to the eco-intensification of this productive sector are presented.

Material and Methods

As a basis for investigating and developing technologies for valorizing aquaculture side-streams we analysed wastewater from land-based Atlantic salmon smolt production farms for its chemical characteristics with respect to its environmental footprint and the underlying valorisation potential. To recover particulate, flocculated matters, the S3 filterdryer system was developed, including a fine meshed filter cloth (mesh size 6 μm) capable to remove particles from aquaculture wastewater. In addition, the S3 filterdryer sanitizes and dries the resulting sludge (DM content 91-94%) without the use of added chemicals (polymers, coagulants, etc.). Besides, an alternative system, adding polymers and drying the sludge using the Waister superheated steam dryer to sanitise it, was also tested.

For the sanitation of fish mortalities, a new superheated steam dryer was developed, the Waister 15 generation.

In order to estimate the potential for valorisation of by-products, the yield of these by-products in salmon, trout, seabream, seabass, turbot and carp were determined. These by-products were used as raw material for performing enzymatic hydrolysis to obtain fish protein hydrolysates (FPH).

The suitability of bivalve shells for being used as filling material of a newly designed biofilter for nitrification and phosphate removal from RAS wastewater was investigated. 10L volume biofilters were used at lab-scale level for compative experiments between plastic material and crushed and whole mussel shells. For phosphate removal experiments, crushed shells biofilters were compared with calcite material, the latter simulating the abovementioned material calcined shells.

Results

The main challenge to purify aquaculture wastewaters lies with the very low levels of dry matter (DM) and the small particle size of solids present in wastewaters. The use of the newly designed S3 filtration system provides a 93 $\pm$ 2.8 % removal of suspended solids (SS) and a 80 $\pm$ 6.4 % removal of organic content determined as chemical oxygen demand (COD) in the treated wastewaters, confirming the utility of the S3 filter dryer as a technology meeting the regulatory demand of a 50% SS and a 20 % COD reduction as a standalone unit. The S3 system dries the sludge in parallel, achieving a DM content of 91-94%, without the use of chemicals and extremely low energy consumption: 300W per cubic meter wastewater for the entire process.

Sludge dried using conventional heating, as a superheated steam dryer, resulted in a product with excellent physicochemical properties and DM contents of 90-95 %, outperforming airdried fish sludge as a bioenergy source in cement production. Analysis of dried fish sludge shows that it is an excellent bio-fertiliser product with high content of N and P, while low level of K. The Zn content is currently the most limiting element for allowed spead of dried fish sludge on farmland.

(Continued on next page)

Waister implemented a novel drying technology of mechanical fluidisation and superheated steam for sludge of typically 10-50 % DM from polymer-based dewatering technologies. This technology can be combined with the S3 dewatering technology. Both systems stabilise the sludge and minimise shipping costs.

Regarding the treatment of fish mortalities, a single loop Waister 15 dryer was installed in Helgeland Smolt, finalising a well-functioning technology for mortalites disposal. The main challenges with the treatment of salmon mortalities were the high fat content and the presence of excess water mixed with the fish. The first problem was solved with the incorporation of additives, such as wood chips or dried spent grain, while the second was solved with manual feeding of the fish into the dryer. The dried product obtained can be used for bio-energy production, biofertiliser, or potential animal feed ingredient depending on the additive used prior to the drying.

The potential volume and economic value of by-products generated by the main aquaculture species in Europe was estimated.

Most by-products present a significant protein content: therefore, the use of proteolytic enzymes to breakdown these proteins and use the resulting peptides for different applications, i.e. as ingredient of aquafeeds was investigated, in order to determine optimal operational, e.g. temperature, pH and other parameters.

Mussel shells were tested as a replacement for plastic filling in a RAS biofilter. Results suggest that mussel shells could be effectively used, as they provide a suitable substrate for nitrifying bacteria and, due to their carbonate content, contribute to stabilize pH. Also, they showed interesting properties to remove dissolved phosphate from water, improving the quality of the effluent.

Introduction

The work on improved sustainability in the aquaculture industry by valorisation of side-streams being performed in the GAIN (Green Aquaculture INtensification in Europe) project has resulted in innovative machines in standardised sizes for processing of fish sludge at hatcheries. Initially, it proved challenging to achieve a stable process for fish sludge drying. However, through a number of improvements Waister has ensured a stable drying process with a predictable processing capacity.

GAIN is a Horizon 2020 project, delivering services and technologies to market within the project period to contribute to the ecointensification of European aquaculture production. Resource efficiency, reduced environmental impact, increased precision and valorisation throughout the production chain are all key elements in the approach to improve seafood self-proficiency and regional stability.

Achievements

Processed with the innovative technology, dried fish sludge from hatcheries has proved to be rich in nitrogen (N) and phosphorus (P), while relatively low on heavy metals. This allows the dried fish sludge, given the correct processing, to be utilised as a potentially valuable bio-fertiliser. By combining a mechanical fluidisation of the fish sludge in the drying chamber, inserting superheated steam with a relatively low temperature, Waister has achieved a significant decrease of N loss in the drying process. Through a number of innovations and improvements to the drying technology, Waister has achieved N levels as high as 7 % in the dried fish sludge.

There is no common EU classification standard of bio-fertiliser products from fish sludge. The Norwegian classification system defines four quality classes determined from the level of heavy metals in the bio-fertiliser product. The dried fish sludge from this innovative drying process produces a bio-fertiliser product in quality class I, which is the second best out of the four classes, allowing spread of up to 4 kg/m^2 over a period of ten years for use in agriculture, private gardens, and parks. Growth trials made on barley has shown up to 45 % better yield than the reference mineral fertiliser. The dried bio-fertiliser product is thereby proved as a well-functioning and safe product for application on lands for productions of both feedstock and crops for human consumption, thereby enabling a circular economy solution to an aquaculture challenge.
We will present the applicability of the dried fish sludge as a bio-fertiliser, as well as the standardised solutions for a stable technology on processing of transforming fish sludge into a valuable bio-fertiliser product.

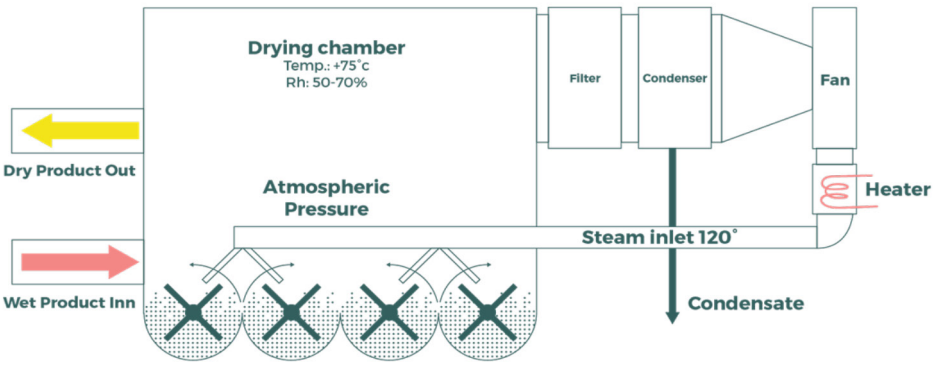

Figure 1: Schematic presentation of the innovative drying technology for enabling the transformation of fish sludge into a valuable bio-fertiliser product

Introduction

Aquaculture is more and more considered as a major contributor to the growing demand in worldwide seafood production. Sustainability has becoming a key question for aquaculture systems.

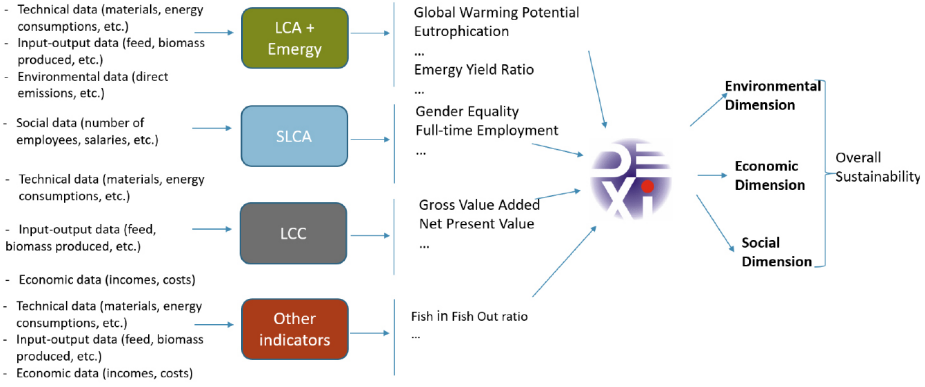
Among the different evolution strategies of aquaculture systems, Integrated Multitrophic Aquaculture (IMTA) goes further in associating complementary species in the same system of production.

The most common IMTA systems are aquaponic systems that use the nutrients present in the waste water from fish to support the growth of plants (Waller et al., 2015). More complex systems appear that, for example, combine polychaete-assisted sand filters and halophyte aquaponics for super-intensive marine fish farms. IMTA systems are designed as potential future solutions to decrease the impacts of fish production on ecosystems.

The SIMTAP project (EU PRIMA 2018) launched in June 2019 with the objective to develop self-sufficient IMTA systems in several Mediterranean countries (France, Italy, Malta and Turkey), with the aim to improve nutrient recycling. Beyond the objectives to develop effective systems of production, the project aims to assess their sustainability performance. Sustainability assessment of food systems needs indeed to merge multiple criteria and. Thus, in this context, environmental, social and economic impacts need to be evaluated together. The assessment of sustainability is also dependent of the context and to the stakes of the concerned people. Therefore, it is necessary to include the participation of different stakeholders from the concerned territories, as it has been shown previously in aquaculture sector. In this objective, the use of a multi-criteria decision analysis (MCDA) method is a relevant option.

Aiming at helping decision makers to make choices towards more sustainable options or scenarios, MCDA was chosen to gather the environmental, social and economic dimensions into a global sustainability assessment method. To simplify this complex and multidimensional issue, the DEXi method was selected as the MCDA method.

This paper presents the DEXi model developed with details on working group, meetings and discussions between stakeholders of the SIMTAP project, in order to obtain an operational model for sustainability assessment of aquaculture systems.



(Continued on next page)

The DEXiAqua model

The developed model is called DEXiAqua. The main steps were to (i) build a conceptual model based to describe the three pillars of sustainability in aquaculture system, according to technical and scientific literature leading to a tree of attributes, (ii) determine ponderation factors for the aggregation of the different attributes, (iii) determine thresholds to convert quantitative and/or qualitative values of indicators into scales for attributes (as for example low/medium/high). A template for data collection has been developed in order to collect the raw necessary data, and calculate first level of indicators.

DEXiAqua uses the DEX method to assess the sustainability of aquaculture systems through several indicators stemming from technical domain and reference methodologies (Life Cycle Assessment, Life Cycle Costing, Social Life Cycle Assessment, Emergy Accounting) selected and organized by the partners involved in the SIMTAP project. The DEX method consists in building a tree of attributes organized to characterize a complex problem. At the end of each branch of the tree, qualitative or quantitative indicators are measured. The value of each indicator is translated into a qualitative scale for the associate attribute by using thresholds values. Weightings – called utility functions – are used to build attributes from sub-attributes until the overall sustainability.

Conclusion

Despite collection of the data required for the model feeding can be money and time expensive, DEXiAqua is able to assess the overall sustainability of aquaculture systems and to help to define ways of improvement by identifying the hotspots. More case studies are required in order to confront DEXiAqua to a variety of systems with technical and contextual disparities, which could lead to changes in weighing of attributes for a better adaptation to contexts. In the second part of the SIMTAP project, the inland IMTA developed systems will be compared with commercial aquaculture systems.

OPEN OCEAN CULTIVATION OF SEAWEED – SCALING UP PROVEN CONCEPTS

U. G. Bak*[1], F. Marsman[1], E. Berg[1], I. Menger[1], Ó. Gregersen[1]

[1] Ocean Rainforest Sp/F, Mjólkargøta 20, FO-180 Kaldbak, the Faroe Islands.

Introduction

We are facing a global crisis. Climate change and loss of biodiversity are a fact (Dasgupta, 2021). At the same time, the global human population is increasing, hence, sustainable, healthy, and tasty food is needed (WFS Webinar, 2021). Sustainably cultivated seaweeds in the open ocean are being mentioned as a blue biomass resource that could amend the negative impact of climate change and loss of biodiversity and add new healthy food and feed products to the market (Lange et al., 2021).

The large brown seaweeds (kelp) are among the fastest-growing crops on the planet. To grow, they only need sunlight, CO_2, and nutrients that are naturally available in the ocean. When this productivity becomes commercially exploited and transferred to the large surface of the open ocean, in sites with sufficient nutrients, large quantities of biomass can be produced. The CO_2 and nutrient mitigation provided by the kelp production improve ocean health and add new kelp-forest-habitats that provide a shelter, feeding chamber, and nursery for various low and high trophic animals.

The open ocean environment has previously been a major challenge for seaweed production due to the high wave exposure and deep waters (Bak et al. 2020). Nevertheless, the SME Ocean Rainforest has developed a MacroAlgal Cultivation Rig (MACR) that is suitable for these harsh ocean environments (Bak et al. 2018). The challenge is immediately to take this proven concept and bring it to a level of 1 Mio tons wet weight of annual production with a high economic, social, and environmental impact in 2030.

This work is part of the ongoing EU H2020-project AquaVitae www.aquavitaeproject.eu and the project SELBREED which is a project collaboration between Ocean Rainforest and Hortimare.

Methods

The main challenge is to reduce operational expenditures (OPEX) and capital expenditures (CAPEX) of production to make the business profitable. The methods investigated to reduce cost are:

- Upscaling operation through further rig development
- Testing re-use of aquaculture equipment
- Developing mechanized seeding, harvesting, and landing technics
- Increase yield through selective breeding
- Make use of multiple partial harvesting and optimize this method

Results

Upscaled macroalgal cultivation in the Faroe Islands was tested by improving the MACR further allowing the rig to hold a production of 40 km seeded grow line in an 8-ha area which has now been tested during winter storms and proven the survivability of the second MACR-version with a total of 100 km grow lines deployed and a productivity of 30 tonnes ww/ha/year.

Discarded anchors and buoys were re-used in the deployment of two new rigs, and the implementation of second-hand equipment was analyzed and found to reduce the CAPEX by 41% and lowered the CO_2-footprint by 46% in an optimal situation. However, the more the seaweed industry will scale up, the more limited the re-use opportunities will be.

Besides upscaling, the project has identified new harvesting methods that enable maximum yield and reduced OPEX. Yet there is a need to reduce OPEX even further and additional technological development to upscale the operation is needed.

The upscaling in seeding material for the 80 km of new grow lines was made without further investments in hatchery equipment, thus keeping a low cost of production. The seeding of ropes still needs to be automated and yield quantities should be improved by selective breeding. This is a challenging part of future upscaling.

(Continued on next page)

Figure 1 *The newly deployed MACR seeded with 40 km Saccharina latissima in the Faroe Islands at a site with >50 meters water depth (Ocean Rainforest Sp/f 2020).*

The yield is the main income driver. Today a vertical line of 10-meters yields 25 kg ww per harvest, being harvested twice a year, it yields 50 kg ww/grow line which occupies a sea surface area of one square meter. The aim is to make a crossbreed that can produce 30% more within the coming 2-3 years.

The company has discovered that sugar kelp (*Saccharina latissima)* can regrow after being harvested. The use of multiple partial harvesting of *S. latissima* (up to 6 harvests without re-seeding) has allowed making the highest known harvesting yield per seeded meter growth line and has reduced the production cost by 75% (Bak et al. 2018). A better understanding of the growth pattern and effect of partial harvesting will enable maximum yield and reduced OPEX.

The next step in the AquaVitae project will be to establish criteria for site selection and find suitable sites for large-scale production (>500 ha) in open-ocean environments in the Atlantic Ocean. Thus, the Faroese seaweed production adds crucial results for the future expansion of this underexploited aquaculture industry.

Introduction

Brown algae comprise a considerable number of the secondary bioactive metabolites, including sterols which are reported to be unique in terms of their structural and functional diversity (Hannan et al., 2020) and numerous health benefits (Plaza et al., 2008). Nowadays, in order to provide effective, reproducible and rapid extraction of lipophilic compounds, a supercritical CO_2 extraction emerges as an alternative technique with many benefits over conventionally used organic solvents (Patel et al., 2020). The current study aimed to explore the potential of supercritical CO_2 for the extraction of sterols from the Mediterranean brown alga *Cystoseira barbata*, whose lipophilic fraction is described as a rich source of sterols, mainly fucosterol (Cvitković et al., 2021).

Materials and methods

Cystoseira barbata, harvested from the Croatian coast in 2020, was lyophilised and extracted with supercritical CO_2 for 120 min at 400 bar, 40 °C and a flow rate of 20 mL/min. In addition, experiments with 10 and 20% (v/w) of ethanol (96%) added to extraction chamber as modifier were performed under the same conditions. A standard method (ISO 12228-1:2014) was used for the determination of sterols. Sterols were isolated by thin layer chromatography, silylated and analysed by gas chromatography. The antioxidant properties of algal extracts were determined as DPPH radical-scavenging activity by electron spin resonance (ESR) spectroscopy (Koprivnjak et al., 2008).

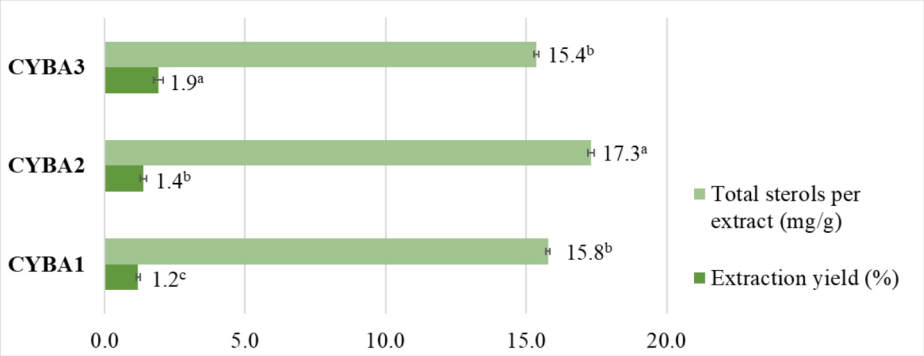

Fig. 1. Extraction yield and total sterols (means, n=3) in *Cystoseira barbata* supercritical CO_2 extracts (CYBA1 – no modifier; CYBA2 – 10% ethanol; CYBA3 – 20% ethanol). Values with different letters are statistically different at $p \leq 0.05$.

Sterols (%)	Cholesterol	Brassicasterol	Campesterol	24-Methylene-cholesterol	Campestanol	Stigmasterol	Sitosterol	Fucosterol	Isofucosterol	DPPH scavenging (%)
CYBA1	1.0^b	11.4^a	1.2^a	0.8^a	13.0^a	2.2^a	10.0^a	54.0^c	6.2^c	53.3^c
CYBA2	0.9^b	9.3^c	0.9^a	0.9^a	10.7^c	2.0^b	9.1^b	57.4^b	8.7^a	74.2^a
CYBA3	1.8^a	10.1^b	1.0^a	0.9^a	11.9^b	2.0^b	6.9^c	58.9^a	6.5^b	61.8^b

Table 1. Individual sterols (%) and DPPH radical-scavenging activity determined by ESR of *Cystoseira barbata* supercritical CO_2 extracts (CYBA1 – no modifier; CYBA2 – 10% ethanol; CYBA3 – 20% ethanol). Results are presented as means (n=3). Values with different letters are statistically different at $p \leq 0.05$.

(Continued on next page)

Results

Supercritical CO_2 extraction with 20% ethanol gave the highest yields of lipophilic *Cystoseira barbata* extracts, while significantly higher values were obtained by the addition of 10% ethanol when considering the results of total sterol per extract (Figure 1).

Considering individual sterols, fucosterol was dominant, followed by campestanol and brassicasterol, although their contents differed significantly between extracts. DPPH radical-scavenging activity was highest in extracts obtained by 10% ethanol (Table 1).

Discussion

Although the highest yields were obtained with the addition of 20% ethanol, the extracts obtained with 10% ethanol contained the highest levels of sterols. Due to its higher polarity, the addition of ethanol caused the greater extraction of other polar compounds such as chlorophylls and carotenoids (Cvitković et al., 2021), which therefore decreased the relative content of sterols in the extract. Nevertheless, considering the overall efficiency of sterol extraction results observed as total sterol content per algal dry weight, supercritical CO_2 extraction with the addition of 20% ethanol proved to be the most efficient, resulting in 0.29 mg/g algal dry weight. While fucosterol was dominant in all extracts, as expected (Hannan et al., 2020), its relative content was increased with ethanol addition. On the other hand, the levels of brassicasterol, campesterol and sitosterol were higher in the extracts without the addition of modifier. The antioxidant activity was highest in the 10% ethanol extract and correlated with the total sterol content (r=0.836).

Apocyclops panamensis AS LIVE FEED FOR *Sander lucioperca* LARVICULTURE

Laura Ballesteros-Redondo*, Harry W. Palm, Lukas Reiche and Adrian A. Bischoff

University of Rostock, Faculty of Agricultural and Environmental Sciences, Department of Aquaculture and Sea-Ranching, Justus-von-Liebig-Weg 6, 18059 Rostock, Germany
*Correspondence: laura.redondo@uni-rostock.de

Introduction

Larviculture is one of the most important bottlenecks for rearing fish in aquaculture. Often high mortality rates and variability in larval quality and quantity result in unstable production, requiring larviculture improvement. Live feed use in larviculture has increased in recent years, demonstrating higher survival and better growth rates as seen in *Sander lucioperca* larviculture, with *Artemia* sp. and rotifers from the genus *Brachionus* most commonly in use (Policar et al. 2019). Rotifers seem to fulfil the nutritional requirements for pikeperch larvae better than *Artemia* sp. (Yanes-Roca et al. 2018, Imentai et al. 2019, Imentai et al. 2020) although other organisms like copepods, as live feed, are gaining attention (Ajiboye et al. 2010). More studies are needed in order to understand the early life cycles stages when the larvae start to feed and what they can ingest during the first days of exogenous feeding.

Material and methods

The experiment took place in June 2021 in order to investigate the stomach contents of pikeperch larvae after feeding them with *Brachionus plicatilis* (Bra) or *Apocyclops panamensis* (Apo) from dph 3 until dph 7. Both diets were divided in 2 further groups with different larval stocking densities, 50 (Bra-17 and Apo-17) and 100 larvae*l^{-1} (Bra-34 and Apo-34), each one with 3 replicates, resulting in 340 feed organisms per fish per day. From each replicate, 3 larvae were taken each day after 30 minutes from the first feeding (feeding regime was 3 times a day at 09:00, 12:00 and 15:00) for subsequent stomach content analyses. In addition, water parameters, survival (dead larvae), growth (length), and yolk sac consumption were monitored daily.

Results

At dph 1 larvae were very small and tiny, while complete yolk sac consumption occurred at dph 5. At day 7 post hatch, the highest survival rates were 56% in diet Bra-17 and Bra-34 and lower in Apo-17 (32%) and Apo-34 (50%) (Figure 1) although, there were no significant differences (ANOVA, p=0.07). The total body length did not show any significant difference between the diets (ANOVA, p=0.411), with the mean total body length for all measured larvae less than 4mm. From dph 7, we observed feed inside the stomach of the fish although we could not determine its amount.

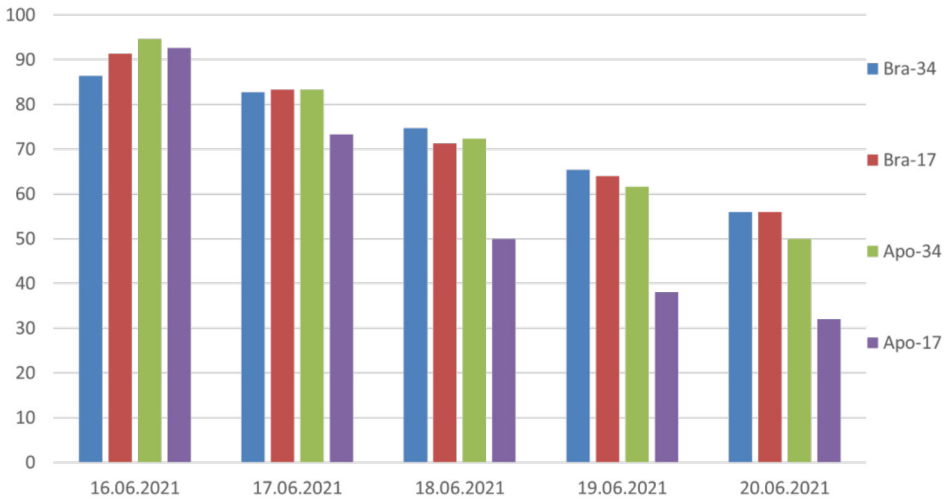

Figure 1. Survival rates from dph 3 until dph 7 for the 4 diets

(Continued on next page)

Discussion

Our study demonstrates for the first time that pikeperch larvae can ingest *A. panamensis* at dph 7 but that they are not able to digest them. The difficulty to count feed items inside the stomach of pikeperch larvae fed with *B. plicatilis* might indicate that the digestion was taking place, connected to the observed higher survival rates (even no significant differences) and confirming previous studies (Yanes-Roca et al. 2018, Imentai et al. 2019, Imentai et al. 2020). Our experiment also showed the importance of the larval quality for a successful pikeperch rearing (Policar et al. 2019) and the lack of an effect of the stocking density under application of the same amount of feed items per fish per day (Ballesteros-Redondo et al. in preparation).

Introduction

Common carp (*Cyprinus carpio*) is a dominant fish species worldwide and in Hungary it is produced in the highest volume in aquaculture. The need for a comparable genetic analysis of different common carp stocks is increasingly important nowadays due to the high demand for genetic breeding. Multiplex PCR technique offers a cost-effective way for rapid screening of genetic markers, for instance microsatellites, which are versatile markers for numerous applications including population genetics, parental analysis or marker assisted selection for breeding programs. The aim of this study was to develop a novel multiplex set for tetranucleotide microsatellites that is suitable for a comparable genetic analysis of different common carp stocks. Subsequently, the genetic investigation of Hungarian strains was performed with this newly designed set.

Materials and methods

24 novel polymorphic tetranuceotid microsatellite markers were obtained by *in silico* analysis from the previously published common carp genome (Xu et al.,2014) and optimized individually on 8 samples originating from 5 different Hunagrian landraces (Tisza, Duna, Tata, Ráckeve, Velence). These markers were ordered in multiplex reactions and optimized on 15 samples, until three different multiplex sets were assembled from the most congruous markers designed with universal tailing (Glenn et al., 2005) and three different fluorescent primers (multiplex one: triplex PCR with PET, multiplex two: tetraplex PCR with FAM, multiplex three: triplex PCR with VIC) suitable for simultaneous fragment analysis. Subsequently, this set was utilized for population genetic analysis of nine Hungarian common carp strains (n=351): seven officially recognised landraces containing five native wild carp populations (*Cyprinus carpio carpio morpha hungaricus*) considered to be vulnerable to extinction by the International Union for Conservation of Nature (IUCN): Danube, Tisza, Velence, Ráckeve and Balaton, two mirror carp landraces (*Cyprinus carpio carpio morpha nobilis*) of the fish ponds Szeged and Nagyatád, the population of the gene bank in the National Centre for Biodivertsity and Gene Conservation and one endemic wild carp population from the thermal lake of Hévíz. Genotyping was performed on 3100 Genetic Analyzer (Applied Biosystems), alleles were identified by GeneMapper 4.0 software, and population genetic analysis was performed with MSToolkit and Genalex Microsoft Excel Add-ons, Micro-Checker, R ver 3.5.3, HP-Rare and Structure software.

Strains	n	MLG	Ar	pAr	H_{exp}	H_{obs}	F_{is}	dHW
Velence	36	28	2.26	0.25	0.36	0.17	0.53	7
Ráckeve	48	38	1.71	0.12	0.25	0.15	0.41	2
Gene bank	33	23	1.87	0.16	0.16	0.15	0.07	1
Danube	25	24	1.62	0.07	0.27	0.23	0.17	3
Tisza	23	20	2.15	0.30	0.20	0.17	0.19	3
Balaton	69	62	1.77	0.19	0.35	0.22	0.37	5
Szeged	30	21	2.21	0.25	0.17	0.13	0.23	5
Nagyatád	32	22	1.68	0.14	0.15	0.16	-0.07	0
Hévíz	43	28	1.58	0.07	0.22	0.10	0.54	5

Table 1: Measures of genetic variations within 9 Hungarian common carp strain using 9 tetranucleotide microsatellite loci (n: number of samples, MLG: multi-locus genotypes, Ar: average allelic richness, pAr: average private allelic richness, H_{exp}: expected heterozygosity, H_{obs}: observed heterozygosity, F_{is}: within strain inbreeding coefficient, dHW: number of loci deviating from Hardy-Weinberg equilibrium)

(Continued on next page)

Results

24 novel polymorphic markers were isolated with an average allele number of 5.2. The average PIC value (Polymorphic Information Content) was 0.59 and 15 of the isolated markers were highly polymorphic (PIC value > 0.5). The assembled multiplex set of 10 markers had an average allele number of 7 and an average PIC value of 0.5. One marker showed evidence of null alleles in 7 populations, therefore it was excluded from further analysis. All populations (except the one from Nagyatád) showed significant deviation from the Hardy-Weinberg Equilibrium with at least one marker (Table 1.). The mean expected heterozygosity (H_e) was 0.24 and the average observed heterozygosity (H_o) was 0.17. The DAPC-PCA analysis showed that most populations have very similar genetic background except the populations of Hévíz, Velence and Balaton. The pairwise F_{st} values and the Structure analysis supported the results of the DAPC-PCA.

Discussion and conclusion

A novel multiplex tetranucleotide microsatellite set was developed for common carp and utilized for population genetic analysis of 9 Hungarian strains. Based on our results, we can conclude that this multiplex set is sufficiently informative, therefore it could be a powerful tool for rapid and cost-effective analysis of this species. Most of the investigated Hungarian strains possess low expected heterozygosity values, suggesting low genetic variability. The observed heterozygosity values were slightly lower than the expected values. The within strain inbreeding coefficient shows that most of the strains are characterized by heterozygote deficiency, only the Nagyatád population showed a limited level of heterozygote surplus. All strains except the one of Nagyatád showed deviation from the Hardy-Weinberg Equilibrium (HWE) with at least one marker. The strains of Velence, Hévíz, Balaton and Szeged showed deviation with most of the markers, which can be the result of isolation. The STRUCTURE based analysis showed the highest delta K value with K=7. Among them, 3 clusters deviated markedly from the others on the dendrogram. The DAPC-PCA analysis and the pairwise F_{st} values indicated that the strains from the lakes of Hévíz, Velence and Balaton differed significantly from the others. Based on our results, the improvement of the genetic variability of the Hungarian wild carp populations is suggested with special emphasis on the strains of Hévíz, Velence and Balaton.

DO CONSUMERS WANT TO EAT ALTERNATIVE PROTEINS FROM FISH WASTE? RAISING EUROPEAN CONSUMER AWARENESS THROUGH COMMUNICATION

Marija Banovic[1,a]

[1]MAPP Centre, Department of Management, Aarhus University, Aarhus, Denmark

[a]e-mail: maba@mgmt.au.dk

Acknowledgements
This study has received funding from EIT Food (https://www.eitfood.eu/) through the project "EcoD: Bringing new life to cod waste by turning it into food" (Grant number ID: 20432, EIT Food Business Plan 2020).

Introduction
The increased processing in fish production results in massive production of waste (20–80% of landed weight is wasted depending on the processing type) (Ghaly, Ramakrishnan, Brooks, Budge, & Dave, 2013). There are many efforts of using this waste in feed, food packaging, biofuels (Arvanitoyannis & Kassaveti, 2008; Jayasinghe & Hawboldt, 2012) and to recover more for use as human food, where this by-products can be transformed into high quality fish protein, which can be added to a wide range of food products and thereby contribute to both health and the circular economy (Alfio, Manzo, & Micillo, 2021). Thus, valorization and upcycling of by-products, such as those coming from fish waste, can have many potential applications through product development in the fish and food industry (Nawaz et al., 2020).

The next important step for European seafood industry is raising consumer awareness on the above issues, as well as on environmental and health potential of alternative proteins coming from fish waste. This is vital for managers and policy makers in order to be able to design and employ appropriate strategies around new alternative proteins coming from fish waste. Consequently, in this study, and in a cross-cultural context, it is examined how European consumers respond to new products with alternative proteins coming from fish waste while accounting for the different communication messages related to the health and environmental benefits.

Materials and methods
An online cross-cultural study has been conducted in three European countries, namely Denmark, France and Germany with a total sample of 2700 participants. Three experimental conditions have been considered: control and two message framing conditions (health vs. sustainability) to assess whether the consumers acceptance of alternative proteins coming from fish waste would be improved due to the health or sustainability messages or just plain preference (control condition) when focusing on possible food products. After reading and signing the informed consent, participants were randomly assigned to one of three above mentioned experimental conditions, where they answered questions regarding their attitudes towards fish protein, health and environmental consciousness, purchase behavior, and socio demographics, among others.

Results
The results show that the European consumers are open towards having alternative proteins from fish waste. They associate these new proteins with health benefits, and believe that they could add to a more diverse diet and more choice. Some differences have been found across European countries where French and German consumers seem to be more positive towards and more likely to buy food products containing fish protein than the Danish consumers. On the contrary, Danish consumers were found to be more reluctant towards these proteins and products containing them. In terms of communication, it seems that when health benefits are emphasized, consumers had more positive attitudes and more likely to buy food products with new fish protein, see Figure 1.

Conclusions
The valorization and upcycling of fish waste adds-value to the fish production and provides more choice for the consumers. This is significant as the European demand for fish products significantly surpasses the supply that fish sector can provide. In this context, fish industry and policy makers need to become more efficient in valorizing the fish waste and raising consumer awareness which is especially important now in the light of the green deal and farm-to-fork call for a fair, healthy and environmentally-friendly food system.

CONSUME IT, YET UNAWARE? THE INFLUENCE OF A HEALTH GOAL ON CHOICE OF AQUACULTURE PRODUCTS AMONG BRAZILIAN CONSUMERS

Marija Banovic[1,a], Jessica Aschemann-Witzel[1], Rosires Deliza[2]

[1]MAPP Centre, Department of Management, Aarhus University, Aarhus, Denmark

[a]e-mail: maba@mgmt.au.dk

Introduction

Brazil is one of the world's largest fish producer with an extensive maritime coast on the Atlantic Ocean and a great quantity of rivers, lakes and barrages. Fishing represents an important source of income for Brazil and the socio-economic characteristics of the fisheries are very much diverse, due to the coast geographic dimension as well as due to the different culture in the different geographical regions in terms of fishing and fish farming (FAO, 2020). Even though Brazil has a great potential in terms of seafood, Brazilians consume very little fish in general, accounting for only 9.02 kg/per capita/year where only 2.45 g/per capita/day of protein supply comes from fish and seafood (year 2018; FAOSTAT, 2021). This consumption differs depending on the region with northern states consuming more and southern ones consuming less fish. Underlying reasons of the low fish consumption mentioned are awareness, price, taste, and health issues (Baptista, Rodrigues, & Sant'Ana, 2020; Maciel et al., 2013; Mitterer-Daltoé, Carrillo, Queiroz, Fiszman, & Varela, 2013). To be able to develop suitable strategies to increase consumers' consumption of fish, a better understanding of consumers' fish choices across different Brazilian regions is of key importance. Therefore, in this study we account for the role of a health goal and awareness on the aquaculture product choice, and its relationship with taste and price in the congruent non-conflicting versus incongruent conflicting choice context.

Materials and methods

An experimental study was designed to examine the role of the health goal and consumer aquaculture product awareness, as well as its relationship with taste and price, in the context where all available choice-set options do not conflict with the health goal versus when all the options in the choice-set conflict with the health goal, taking into account different Brazilian geographical regions. The congruent actions were assumed (i.e., healthy - expensive) when the choice-set options do not conflict with the active health goal (i.e., congruent, healthy choice-set), and vice-versa when conflicting-choice set present. It is further assumed that this effect is moderated by consumers' aquaculture product awareness that increases (or decreases) the influence of the health goal contingent on the choice context (non-conflicting vs. conflicting). One thousand three hundred and three participants were randomly assigned to one of the four experimental conditions: 2 goals (health goal vs. control) x 2 choice-sets (non-conflicting vs. conflicting). The sample was representative of the Brazilian population.

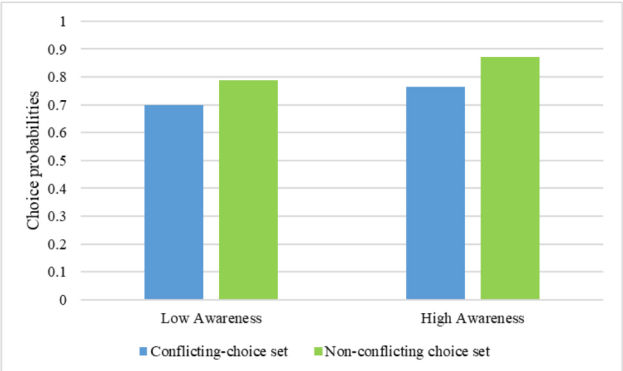

Figure 1. Impact of consumer awareness on choice of aquaculture products with health goal present.

(Continued on next page)

Results

The results from the binary logistic regression showed significant interaction effect between choice-set and consumer aquaculture product awareness when health goal present ($\beta = -0.867$, Wald = 6.416, $p = 0.011$), while region as a covariate was not significant ($p = 0.732$). This indicated that when health goal present with non-conflicting choice more congruent actions occurred (healthy - expensive) among those individuals who were high in awareness regarding Brazilian aquaculture then those individuals that were low in awareness, opting to choose more often higher-priced product options, see Figure 1.

Conclusions

The impact of health information on consumers' choice of aquaculture product should be carefully deliberated in both healthy and unhealthy choice contexts. This is particularly important as health information can be efficiently reinforced through taste establishing healthier food choices, and this is particularly true among consumers who possess higher levels of product awareness. On contrary, this can fail in the unhealthy choice contexts where this information could still increase consumers' product choice.

THE EFFECT OF BETANODAVIRUS (RGNNV GENOTYPE) ON IMMUNE AND OXIDATIVE STRESS PARAMETERS IN SEA BASS (*Dicentrarchus labrax*)

B. Carmo[1], R. Passos[1], D. Pires[1], M. Vaz[1], P. Santos[2] and T. Baptista[1*]

E-mail: teresa.baptista@ipleiria.pt

Introduction

Betanodavirus is the aetiological agente of viral nervous necrosis (VNN), also known as viral encephalopathy and retinopathy (VER). This virus is of significant importance in aquaculture since betanodavirus infections are associated with high mortalities, that can be as high as 100% in some cases. Out of the four major genotypes, the red-spotted grouper nervous necrosis virus (RGNNV) is the most prevailing in warm-water fish species in the Mediterranean. This study aims to observe the effect of RGNNV on the immune and oxidative stress parameters of sea bass (*Dicentrarchus labrax*).

Materials and Methods

This time course study was conducted at the CETEMARES facilities (Leiria Polytechnic), in which sea bass individuals (33.99 ± 32.85 g) were infected with 10^6 $TCID_{50}$/fish with NNV (RGNNV genotype) through intramuscular injection (IM). For immune response analysis, blood was drawn with heparinized syringes from random fish (N = 6) before infection (0h), after infection (6h, 9h, 24h, 48h, 120h and 144h) and from moribund fish, and the blood was centrifuged for plasma. For oxidative stress, livers were collected at the same times, being stored at -80°C until further analysis. Lysozyme was determined according to Costas et al. (2011). Oxidative stress parameters, such as lipid peroxidation (LPO), catalase activity (CAT), superoxide dismutase (SOD), glutathione S-transferase (GST) and total glutationse (tGSH) were determined by the methods described by Bird and Draper (1984), Clairborne (1985), McCord & Fridovich (1969), Habig et al. (1974) (adapted to microplate by (Frasco & Guilhermino, 2002)), and Baker et al. (1990), respectively.

Results and Discussion

Regarding lysozyme, values decreased over time since infection. Lysozyme is a defense molecule from the innate immune system with high importance in the response of the host to infections, mediating microbial invasions (Saurabh & Sahoo, 2008), which does not match the expected results, which would be an increase in the values after infection as it activated the complement system and phagocytes as a strategy of counteracting the infection (Magnadóttir, 2006).

For oxidative stress parameters, a significant increase in tGSH was observed at 48 hours, and in SOD values at 9h and 120h. CAT values decreased between 0h and 6h hours, and other sampling moments. Increased LPO values were observed at 120h, 144h and moribund fish and decreased GST values were observed at 144h compared to other sampling moments. It has been demonstrated that NNV induces ROS production (Krishnan & Kurcheti, 2021), which coincides with the increase and SOD values, which could be an attempt from the immune system of fish of trying to mantain the redox balance.

The excessive production of O^{2-} by SOD could inhibit the production of CAT (Bagnyukova et al., 2006), which could explain the decreased CAT levels observed after the first increase of SOD. GST participates in the removal and detoxification of aldehyde products from lipid peroxidation (Bagnyukova et al., 2006; Hermes Lima, 2004), and the lower values obtained point to a lack of action in the disposal of said products, which was observed in the high levels of LPO observed in the later sampling times. The increase of tGSH values is due to the damages induced on the organism by oxidative stress.

Conclusion

Oxidative stress is one of the many ways of assessing the response of aquatic organisms to infections with pathogens, and the consequent damages to the organism. In this study, *D. labrax* infected with red-spotted grouper nervous necrosis virus demonstrated a response to the infection through the production of various antioxidant compounds.

Introduction

A seafood-based diet has been widely recognized as beneficial to human health. Yet, most European consumers do not meet the dietary recommendations of eating at least two portions of fish (equivalent to 300 g) per week to ensure the provision of essential nutrients (EFSA, 2015). One third of global population has severe nutritional deficiencies, particularly iodine (I), selenium (Se) and iron (Fe), which results in impaired endocrine, neurophysiological and immunological functions (Pinkaew and Karrila, 2015). The development of eco-innovative farmed fish with adequate levels of essential nutrients through fortification with sustainable natural marine resources (e.g. iodine-rich macroalgae and Se-rich yeast) represents a potential strategy to overcome worldwide nutritional deficiencies, but also to increase consumer confidence in farmed seafood products (Tocher, 2015). The present study aimed to evaluate the potential nutritional benefits associated with the consumption of tailor-made farmed gilthead seabream (*Sparus aurata*) and common carp (*Cyprinus carpio*), fortified with macroalgae and Se-yeast enriched diets.

Material and methods

Three diets (1 control and 2 supplemented with different blends of I-rich macroalgae and Se-yeast) were tested for 3 months in each fish species, simulating a finishing diet period. At the end of the trial, fish were slaughtered following the typical commercial practices and fillets were collected without skin: one fillet was immediately stored ("raw sample") and the second fillet was steamed at 105 ºC for 15 minutes prior to storage ("cooked sample"). Iodine, Se and arsenic (As) contents were determined by inductively coupled plasma mass spectrometer, whereas macro and trace elements were quantified by micro-Energy Dispersive X-Ray Fluorescence (Barbosa et al., 2020).

Results and Conclusions

Results showed that biofortification strategies through the incorporation of I-rich seaweed and Se-yeast in seabream and carp diets can improve the nutritional quality, enhancing I, Se and Fe levels. Yet, whereas fortified carp fillets presented higher content of I (over 100% increase), fortified seabream fillets presented higher content of Se (over 90% increase) compared to non-fortified ones. Steaming increased I and Se contents in fortified seabream fish fillets and decreased Cl, Fe and Ca contents. Elements True Retention (TR) values ranged from 60% (Ca) to 134% (I) and from 65% (Ca) to 125% (I) in fortified and non-fortified seabream fillets, respectively. On the other hand, steaming increased Fe and Zn contents in fortified carp fillets but decreased K, Ca and As contents. TRs values ranged from 59% (As) to 128% (Fe) and from 64% (Ca) to 117% (Fe) in fortified and non-fortified carp fillets, respectively. Interestingly, higher TR was observed for As in non-fortified fillets (91% in seabream and 72% in carp), compared to fortified fillets (87-88% in seabream and 59-62% in carp). In terms of nutritional benefits, the consumption of 150 g of steamed fortified seabream provided higher

(Continued on next page)

contributions to the daily Adequate Intakes (AI) set for I (12%, 9% and 20% for adults, pregnant woman and children, respectively), Se (85%, 70% and over 100% for adults, pregnant woman and children, respectively) and Fe (over 100% for all groups). Similarly, steamed fortified carp provided increased contributions to the daily AI set for I (21%, 16% and 35% for adults, pregnant woman and children, respectively), Se (30%, 24% and over 100% for adults, pregnant woman and children, respectively), Fe (over 100% for all groups) and Zn (38%, 28% and 66% for adults, pregnant woman and children, respectively). It is worth mentioning that the consumption of fortified fillets still yielded Se and Fe intakes below the Tolerable Upper Intakes (Se: up to 99% UL in seabream and up to 34% UL in carp; Fe: up to 12% UL in seabream and 18% UL in carp). These findings highlight the benefits of developing eco-innovative fortified farmed fish, through sustainable, safe, and cost-effective feeds, as well as the benefits of steaming as a suitable cooking procedure for fish healthy human consumption.

Multi-use platforms (MUP) combine offshore clean energy such as wind, wave, and solar energy conversion. It combines different activities within a specific marine area.

The MUSICA project demonstrates the viability of an MUP enabling infrastructure for multiple renewable energy, desalination, and Blue Growth aquaculture services for small islands, that can share the same space and work synergistically together, sharing supply chains. It reduces operating and maintenance costs and solves increasing demand for space.

Using part of the energy on-site, the MUP will provide green support services for the island's aquaculture production, provide up to 61% renewable energy power to Oinousses Island (Greece), and provide 1000m^3 desalinated water.

AquaBioTech is the consultancy partner in the project supporting design, installation, and testing of the aquaculture component of the MUP. Performance trials will be carried out to measure and evaluate structural performance of the cage and interactions with the MUP. The project will assess environmental data along with data gathered of the quantity and quality of the fish produced. This information will allow for the assessment of the economic benefit of the structure to the local aquaculture production potential and inform the development of offshore farming that can be integrated in to future MUPs.

The overall Aim of MUSICA is to accelerate the roadmap to commercialization of its Multi-Use Platform (MUP) and Multi-Use of Space (MUS) combination for the small island market, and de-risk for future operators and investors, by validation to TRL7 and providing real plans to move to mass market commercialization. The MUSICA solution will be a decarbonizing one-stop shop for small islands, including their marine initiatives and ecosystems.

Aquaculture is the fastest growing food production sector and China has led this growth, accounting for 57.9 percent of the global share (FAO, 2020). European production, while smaller, is developing rapidly in areas of sustainability and automation innovation. There are significant skills and knowledge to be shared between the two markets, particularly in the growing sector of land-based recirculating aquaculture systems (RAS), which provide significant benefits including total control of the growth environment, low water requirement, mitigation of disease and parasite risk, and reduced distance to market, but which also pose unique technological challenges.

Water in RAS is continually reused and fish are entirely dependent on producer management for high water quality. Identifying the most important water quality indicators, their complex interactions, how to monitor them and mitigate dangerous conditions, is the priority of the AquaDetector China-Malta collaborative project. Optimising water quality for juvenile fish, which are sensitive to variations, will ensure the optimal survival, growth, and welfare of juvenile trout and grouper in RAS via visualisation of water quality distribution using validated CFD modelling.

The project is developing precise detection technologies to classify fish stress behaviours including hunger and cannibalism through video image detection and monitoring to ensure fish quality, productivity, and animal welfare in the RAS environment. Automation and precision observation will promote a shift in aquaculture production from highly labour dependent to highly technically oriented through enabling technologies including high-precision sensors and automated detection systems. These innovations will further progress aquaculture in both China and in Malta and promote collaboration between experts in the two countries for the improvement of smart and sustainable land-based fish cultivation.

Based on the circular economy model, Horizon2020 SEA2LAND project promotes the production of large-scale fertilisers in the EU through value added raw materials derived from aquaculture and fish processing waste streams. This solution is expected to reduce the soil nutrient imbalance in Europe and reduce dependency on imported fertiliser products. The basis of the project is the regional production of biobased fertilisers, developing demonstration pilots that can be replicated throughout Europe, boosting local growth. Technologies ranging from well-known processes (bokashi, composting, etc.) to more sophisticated such as thermo-mechanical fractionation and enzymatic hydrolysis are being used to process challenging marine waste streams in to customized and locally specific fertilizer products. For the Mediterranean Case Study, Freeze Concentration (FC), the concentration of materials using freezing of water rather than evaporation and BioDrying, using metabolic heat to remove water from the waste matrix at the lowest possible residence time and minimal carbon biodegradation, are the main experimental methodologies to be tested.

Recirculating Aquaculture System (RAS) production, as an intensive and enclosed land-based method, provides a unique opportunity to collect and concentrate fish waste 'sludge- faeces and uneaten feed- for use in creating these new agricultural products, but high solids concentrations are required. For producers, technological adaptations to ease collection, processing, and concentration of these wastes are needed to facilitate their use as a value added product are the most important areas of research. Local waste valorisation networks will remove the burden on producers to dispose of their wastes and harness an underutilized source of nutrients.

Introduction

Nervous Necrosis Virus (NNV) is one of the major viral pathogens in aquaculture, affecting a wide range of fish species and causing high mortality rates. The European sea bass (*Dicentrarchus labrax*) aquaculture production has long been affected, with significant economic losses, especially in the Mediterranean region. Selective breeding for increased resistance to NNV might help, together with other approaches (e.g. vaccination), to prevent such devastating disease. One of the major goals of the EU-funded project AQUAFAANG is the functional genomic characterization of important traits, which in turn might improve the accuracy of breeding value prediction. Here we present a detailed time-course RNA analysis on five time points and two tissues in juvenile sea bass, which is part of an integrated study to understand the genetic basis of response to NNV in this species.

Materials and methods

The experimental fish were generated at a commercial hatchery Valle Ca' Zuliani. Unselected juvenile fish (weight 6-20gr) were transferred to the IZSVe facility. After acclimation and quarantine, half of the animals were infected by intramuscular inoculum of 0,1ml RGNNV strain 283.2009 batch 5/19 at titre $10^{6.30}$ TCiD50/ml. The remaining fish were injected with DMEM. All fish were anesthetised before injection with MS222. Four fish per time point per group (NNV-infected, mock-infected) were sampled, euthanized, and brain and head kidney samples were dissected and stored for RNA analysis. Tissue sampling was carried out at 6h, 12h, 24h, 48h, and 72h post-inoculum. Total RNA was extracted from all samples, quality assess using Agilent 2100 Bioanalyzer, and only RNAs with RIN>7 were processed. cDNA libraries were constructed using QuantSeq 3' mRNA-Seq Library Prep Kit FWD for Illumina and sequenced on a HighSeq 4000 with a single 1 x 100 bp setup. High-quality trimmed reads were mapped on the European sea bass genome, (seabass_V1.0 GCA_000689215.1 in Ensembl). Normalisation was performed using the function RUVs (within the package RUVSeq/v1.18. Normalised counts were imported in edgeR/v3.26.8 to perform differential expression analysis in pairwise comparisons (time-matched mock-infected vs NNV-infected). Genes with an FDR adjusted p-value < 0.05 and FC>±1.5 were considered as differentially expressed (DEGs). Putative zebrafish orthologues to sea bass genes were obtained from Ensembl. Annotations from zebrafish orthologues were used for functional enrichment analysis in DAVID.

Results

Transcriptomic response to NNV in both tissues was significant already at 6h post-inoculum and became massive at 48h and 72h. The number of up- and down-regulated genes in each tissue is reported in Table 1.

While the transcriptome response to NNV was quite complex, functional enrichment analysis showed a few general trends. Gene Ontology (GO) terms and KEGG pathways related to immune response (e.g. GO:0051607~defense response to virus, dre04622:RIG-I-like receptor signaling pathway) and proteolysis/proteasome (e.g. GO:0006508~proteolysis, dre03050:Proteasome) were significantly enriched (FDR<0.05) in up-regulated genes at 24h, 48h, 72h in both tissues. Down-regulated genes in the brain were enriched in GO terms and KEGG pathways related to vision (e.g. GO:0007601~visual perception, dre04744:Phototransduction) as early as 12h after infection. In the head kidney, genes involved in glycolysis were significantly under-expressed in infected fish at 6h, while protein translation related genes (e.g. ribosomal genes) later on. The most relevant result was the significant involvement of different families of heat shock proteins (HSP40, HSP70, HSP90) in the host response to virus with up to 22 HSPs being differentially expressed. Of particular interest are HSP90ab1, HSP90b1, and HSP90aa1, which showed a complex, tissue-specific pattern being up- and down-regulated at different time-points.

(Continued on next page)

Table 1 DEGs in brain and head kidney (FC>±1.5, FDR<0.05)

	6h post-challenge	12h	24h	48h	72h
Brain up-regulated	99	37	19	773	1310
Brain down	2	25	32	479	1088
Head kidney up	29	26	64	228	401
Head kidney down	24	10	17	55	386

Discussion

Detailed time-course analysis of the brain and head kidney transcriptome revealed a vast, complex response, providing a large set of functionally relevant genes to inform genomic prediction of NNV-resistance in the European sea bass. Of particular interest are HSP90s as HSPs are known to have a key role in host-virus interactions (Wan et al. 2020) and HSP90ab1 has been reported to be essential for RGNNV entry into target cells in marine medaka (Zhang et al. 2020).

Introduction

The production of halophyte plants for human consumption, such as *Salicornia ramosissima,* is increasing as they have the ability to grow in saline soils or be irrigated with seawater allowing the utilization of unexploited cultivation areas. Additionally, these are known for their ability to synthetize high concentrations of bioactive secondary metabolites which can have health promoting effects for the consumer. However, the green tips of Salicornia are the only part sold as food, while the remaining the plant is considered a residue, making the valorization of the latter crucial for a more sustainable and profitable production cycle. The principles of circular economy, where waste is recovered and utilized to create added value, are increasingly more important and being applied to economical relevant areas, including the aquaculture industry. The whiteleg shrimp (*Penaeus vannamei*) is the most produced crustacean species worldwide, making it a highly valued commercial product whose demand has substantially increased in recent years. However, feed associated costs are significant, making the creation of more economical and sustainable formulations essential for the success of shrimp farming. Therefore, the current study aimed at evaluating the potential of incorporating *S. ramosissima* biomass in diets for juvenile *P. vannamei.* For this purpose, shrimp growth performance, survival and nutrient digestibility were assessed.

Methods

Five experimental diets were tested in quintuplicates: a commercial like diet (Control), two experimental diets containing *S. ramosissima* stems at 5% and 10% inclusion levels (SL5 and SL10, respectively) and two containing *S. ramosissima* leaves and seeds at 5% and 10% inclusion levels (SS5 and SS10, respectively). Whiteleg shrimp juveniles (mean wet weight 6 g) were kept at around 28 ºC and fed *ad libitum* for 55 days. At the end of the trial, shrimp were weighted and counted for growth performance and survival determination. Additionally, shrimp feces samples were collected after the feeding period and analyzed to determine the apparent digestibility coefficients of the experimental diets.

Table 1. Initial and final weight, relative growth rate (RGR), feed conversation ratio (FCR), feed intake and survival of whiteleg shrimp juveniles fed the experimental diets for 55 days.

	Control	SS5	SS10	SL5	SL10
Initial weight (g)			6.1 ± 0.0		
Final weight (g)	17.6 ± 0.4	18.1 ± 0.5	18.1 ± 0.4	18.1 ± 0.4	18.3 ± 0.3
RGR (% day^{-1})	2.0 ± 0.0	2.0 ± 0.1	2.0 ± 0.1	2.0 ± 0.0	2.0 ± 0.0
FCR	3.1 ± 0.2 ^{a}	3.6 ± 0.2 ^{b}	3.7 ± 0.1 ^{b}	3.6 ± 0.2 ^{b}	4.0 ± 0.1 ^{c}
Feed intake (% ABW day^{-1})	5.3 ± 0.3 ^{a}	6.2 ± 0.2 ^{b}	6.4 ± 0.2 ^{b}	6.3 ± 0.2 ^{b}	7.1 ± 0.2 ^{c}
Survival (%)	96.7 ± 1.5	97.1 ± 2.4	98.2 ± 2.6	96.0 ± 2.7	97.8 ± 1.5

Results expressed as mean ± standard deviation (n = 5 experimental units). Different superscript letters indicate statistical differences (P<0.05) between treatments in a One-way ANOVA.

Table 2. Apparent digestibility coefficients (ADC) of the experimental diets.

	Control	SS5	SS10	SL5	SL10
Dry matter[1]	58.2 ^{bc}	51.8 ^{b}	65.3 ^{bc}	51.0 ^{ab}	40.4 ^{a}
Protein[2]	81.5 ^{a}	81.3 ^{a}	87.0 ^{b}	81.5 ^{a}	82.6 ^{a}
Lipids[2]	83.6 ^{bc}	82.8 ^{bc}	86.2 ^{c}	81.1 ^{b}	74.9 ^{a}
Energy[2]	77.4 ^{bc}	73.5 ^{bc}	80.0 ^{c}	71.8 ^{b}	62.7 ^{a}

(Continued on next page)

Results and discussion

No statistically significant differences in growth performance and survival were observed among treatments (Table 1), suggesting that the inclusion of *S. ramosissima* biomass, at least in the forms and levels tested, did not compromise the adequacy of the diets. Nevertheless, shrimp fed diets containing Salicornia ate significantly more to achieve the same weight as those fed the Control, with this effect being more prominent in the SL10 diet which produced significantly higher FCR and feed intake values than the remaining diets (Table 1). These results can be explained by the significantly lower apparent digestibility coefficients of dry matter, lipids and energy observed for SL10 when compared to the remaining diets (Table 2).

Conclusion

Data from this study indicate that *S. ramosissima* biomass can be included in diets for juvenile *P. vannamei* with no detrimental effects on growth performance or survival. The inclusion of Salicornia steams in whiteleg shrimp diets seems to be preferable over leaves and seeds, which is the ideal scenario for adding value to halophyte production and potentially reduce shrimp feed formulation costs. Additionally, the valorization of a residue contributes to the principles of circular economy.

Introduction

Shrimp aquaculture is considered one of the most profitable aquaculture industries. The increase in *Penaeus vannamei* production contributed to make this product available and accessible to a large number of consumers on a global scale. In order to respond to this increase in production, hatcheries need to intensify and improve post-larvae (PL) rearing. In the early stages of development, the use of diets with high protein levels are preferred and fishmeal and soybean have been used as the main source of this nutrient (Xie et al., 2016). However, these stages of production are often associated with non-optimal growth and low survival rates, which may be at least partially related to problems in nutrition. This indicates that there is room for improvement in this field and that new inert diets may play an important role in improving this production phase. In this context, innovative microdiets for *P. vannamei* PL were tested and their effects in shrimp survival and growth performance assessed.

Methods

Six experimental microdiets (52P, FISH, SQUID, KRILL, FISHHF and NBIND), using different marine ingredients as the main constituent, were tested in triplicates. The 52P, a commercial like diet with 52% protein was used as a control; FISH, SQUID and KRILL were formulated with fish, squid and krill meal as their main ingredients, respectively; FISHHF was formulated with fish meal as their main ingredient but with higher lipid levels; and NBIND differed from the commercial control by the type of binders used. White-leg shrimp PL (mean wet weight 13 mg) were kept at around 28 ºC and fed *ad libitum* for 21 days. At the end of the trial, shrimp PL growth performance, feed conversion ratio and survival were assessed.

Results and discussion

No significant differences between treatments were observed regarding final body weight (FBW) (Figure 1). The overall FCR values were low (≤ 1). The exception was FISHHF, which had significantly higher values than KRILL (FISHHF: 1.2 ± 0.4; KRILL: 0.6 ± 0.0). Survival was significantly higher in the 52P and KRILL treatments than in FISHHF, with no significant differences between the remaining treatments (Figure 2).

Clear benefits in shrimp PL growth performance and survival were observed when utilizing specific marine ingredients in the formulation of microdiets, namely, squid and krill proved to be good sources of protein for the development of shrimp. Increasing lipid levels did not benefit shrimp development (FISH vs FISHHF). Amongst all diets tested, the 52P, KRILL and SQUID seem to be the most adequate for this stage of shrimp development.

(Continued on next page)

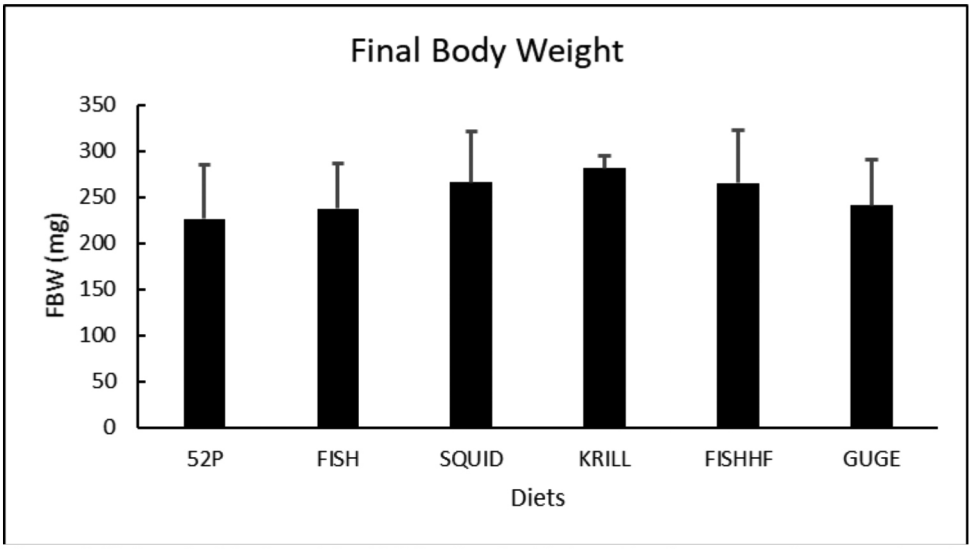

Figure 1 Shrimp final body weight (FBW) after the 21 days. Results expressed as mean (n = 3 experimental units).

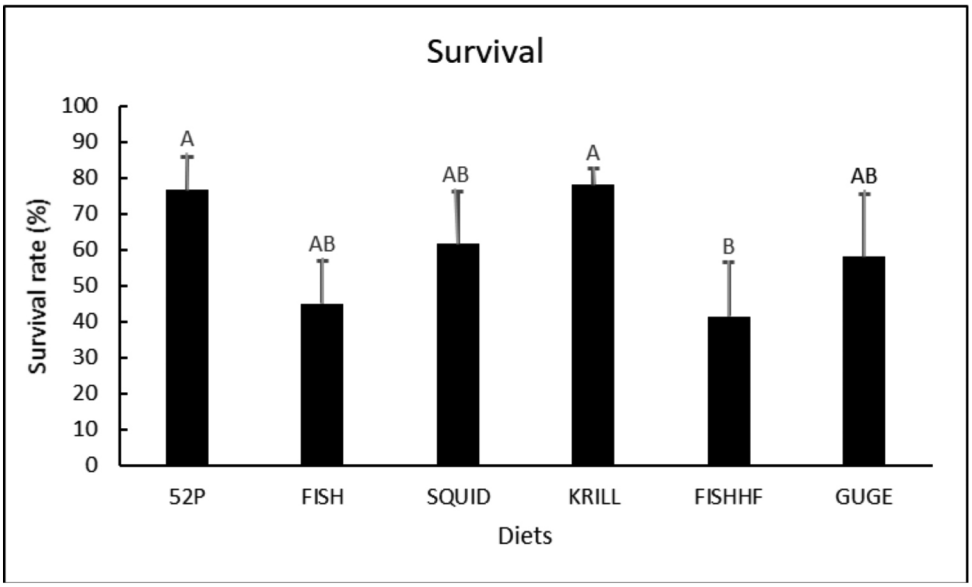

Figure 2 Shrimp survival after the 21 days. Results expressed as mean (n = 3 experimental units). Different letters indicate statistically significant differences between groups ($p < 0.05$).

QUANTIFICATION OF FEED INTAKE IN ATLANTIC SALMON (*Salmo salar*) JUVENILES WITH THE INRA'S AUTOMATED FECES COLLECTION SYSTEM

F. Barros*[1]; A. Santos[2], J. Couto[2], J. Dias[2], P. Rema[1]

Introduction

Fish feeding behavior is a complex topic, since it is affected by several sensory systems comprising the detection of a feed item (vision, olfaction, acoustic, lateral line organ, and electroreception) up to its swallowing (taste, mechanoreception). Palatability and taste are terms often used interchangeably which are determined mostly by the chemical characteristics of the feed, although criteria such as the physical pellet properties can also affect the acceptability and final ingestion.

Over the last decades, the aquafeed industry has achieved a significant reduction on the incorporation levels of traditional marine-harvested resources (fishmeal and fish oil) and a concomitant increase on the use of oilseed-derived raw materials. In a scenario of low incorporation levels of fishmeal, marine protein hydrolysates or other phagostimulants have been shown to improve the palatability and feed intake, that often result in an enhancement of growth performance and overall status of fish and shrimp. Therefore, a reliable estimation of feed intake is a relevant criterion in fish nutrition.

Various methods are used to quantify the voluntary feed intake in fish. These are generally based on direct observation, the recording of feeding activity using on-demand feeders, the quantitative determination of gastrointestinal content using a non-invasive labelled feeds with isotopes or x-ray opaque particles and the measurement of waste feed. This last approach is relatively easy to implement provided that feed pellets present good physical stability after immersion. A study was undertaken to assess the use of INRA'S automated feces collection system, originally developed for digestibility studies as an experimental tool to quantify feed intake in Atlantic salmon (*Salmo salar*) juveniles.

Methods

The trial comprised 3 dietary treatments. To guarantee a high feed intake, a formulation containing high levels (30%) of fishmeal and krill meal, moderate levels of plant protein sources (wheat gluten, pea protein concentrate, soy protein concentrate) and wheat was used as positive control (diet PC). On the opposite, to attain a low feed intake scenario, a diet with moderate levels of fishmeal (5%), devoid of krill meal and with a very high level (41.5%) of soy protein concentrate, while maintaining the other ingredients constant served as the negative control (diet NC). The additional diet was based on the NC basal formula, but contained 5% of a marine protein hydrolysate (diet HYDRO). Diets were extruded and were isonitrogenous (45% CP), isolipidic (19.5% CF) and isoenergetic (21.6 MJ/kg).

Six homogenous groups of 20 fish with a mean body weight (BW) of 29 ± 3 g were randomly allotted to cylindroconical tanks (volume: 60 L). The tanks were equipped with the automated INRA feces collection system (Figure 1). In this open-flow system, the tank outlet water is sieved by moving grids, and all suspended residues (e.g. feces, pellets) are separated from the water and projected into a metallic tray. Although originally developed for feces collection, the system allows a full recovery of any uneaten pellets (Figure 1).

Experimental tanks were located outdoors, supplied with flow-through freshwater (flow rate: 4.2 L/min; temperature 10.6 ± 0.5°C, dissolved oxygen above 9.0 mg/L). Fish were fed, twice a day (10.00 and 15.00h) and the amount of feed distributed quantified on a daily basis. For approximately 20 minutes after each meal, the uneaten feed pellets were recovered with the automated INRA feces collection system. Every day, uneaten pellets from each tank were dried overnight in a convention oven and afterwards quantified in a dry basis. This procedure was repeated for a period of 15 consecutive days.

$$\text{Feed intake, \% biomass} = 100 \times \frac{\text{Distributed dry feed - Uneaten dry feed}}{\text{Fish biomass}}$$

(Continued on next page)

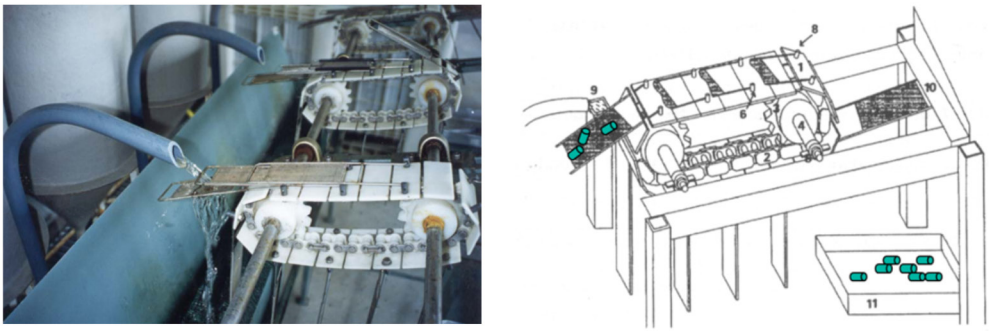

Figure 1. INRA feces collection system used for collection of uneaten pellets.

Fish fed the PC diet showed a significantly higher feed intake than those fed the NC and HYDRO diets ($P<0.05$). Moreover, fish fed the HYDRO diet showed a significantly higher feed intake than those fed the NC diet ($P<0.05$).

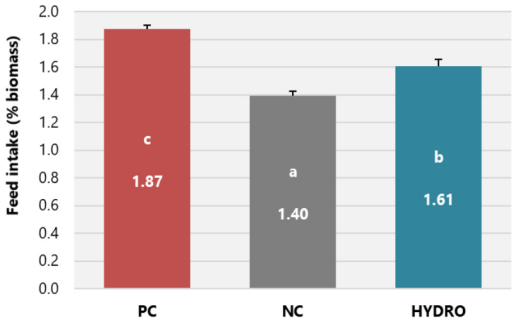

Figure 2. Feed intake (% biomass)

Results and discussion

The average feed intake measured throughout the experimental period varied between 1.40 and 1.87 % of biomass, with statistical differences among the various treatments (Figure 2).

Conclusions

Data from this study indicates that the INRA's automated feces collection system is a suitable methodological tool to recover excess feed and allows a precise measurement of feed intake in juvenile fish. The low intra-treatment variability allows the discrimination of small changes on feed intake between treatments. This methodology has also been successfully used to screen and identify various feed additives with a phagostimulatory potential.

Introduction

Reducing the use of antibiotics in aquaculture is one of the biggest challenges of this sector. Antimicrobial peptides (AMPs) are considered promising alternatives to these drugs, but studies evaluating the potential use of AMPs in the production of sea bass are still missing, with only one report addressing the effects of synthetic hepcidins in infected sea bass (Álvarez et al, 2016). Most mammals present a single hepcidin gene, with limited antimicrobial activity and a major function in the regulation of iron metabolism, by inhibiting the iron exporter ferroportin (Nemeth et al, 2004). However, many fish, including the European sea bass (*Dicentrarchus labrax*), present two hepcidin types that have subfunctionalized, with the single type 1 hepcidin regulating systemic body iron, and the various type 2 hepcidins having an almost exclusively antimicrobial role (Neves et al, 2015). As such, in this study we evaluated the potential of bass derived hepcidins to treat or prevent iron disorders and infectious diseases, by administering them to animals subjected to various experimental models of infection or iron modulation.

Material and Methods

Several experimental models were performed to test if sea bass hepcidins can be effectively used to treat/prevent iron disorders or bacterial infections: 1) peptide administration - intraperitoneally (i.p) administered 100 µl of a 50 µM solution of hamp1 (QSHLSLCRWCCNCCRGNKGCGFCCKF) or hamp2 (HSSPGGCRFCCNCCPN-MSGCGVCCRF) to healthy sea bass; 2) iron overload – i.p. administered 100 µl (5 mg) of iron dextran; 3) iron overload+peptide – iron overload followed 24 hours later by peptide administration, as before; 4) infection – i.p. infected with 10^5 CFU of *Photobacterium damselae* spp *damselae* PP3; 5) infection+peptide – infection followed 24 hours later by peptide administration, as before; 6) peptide+infection – peptide administration followed 24 hours later by infection, as before. At pre-determined time points, animals were terminally sampled, and blood, serum and tissues collected, for determination of haematological and serological parameters, tissue iron content, CFU counts and gene expression analysis.

Results

We observed that administration of hamp1 can have a significant impact on several iron related parameters, when administered to healthy animals. This leads to a condition of anemia, which might be connected to the slight increase in mortality observed when hamp1 is also administered to infected animals, making them more susceptible. However, when administered to iron overloaded animals, it seems to limit the severity of its effects. Hamp2 on the other hand has shown no significant impact on iron metabolism, and had no discernible effects during iron overload. But when administered to infected animals, either before or after infection, reduced mortality very significantly (from around 55% to between 6-17%), decreased bacterial loads and reduced the impact on several iron related parameters, in particular limiting the development of anemia of inflammation.

(Continued on next page)

Discussion and conclusions

Our findings show that when hamp1 is administered to healthy animals interferes with the iron metabolism, leading to significant anemia. Administration during infection leads to an even more severe anemia of inflammation, likely contributing to the increased mortality. However, hamp1 seems to attenuate the effects of iron overload, and as such might have applications in the treatment of iron disorders. Hamp2 on the other hand presents itself as a viable alternative to the use of other prophylactic or therapeutic substances, in particular antibiotics, since it is a bioactive molecule that does not interfere with iron metabolism and is very effective in controlling bacterial infections. Additionally, the effects of hamp2 are likely not limited to a direct antimicrobial effect, but also by stimulation of the overall inflammatory response, but further studies are needed to address this. Nevertheless, costs of production of antimicrobial peptides still represent a significant barrier to their more generalized use.

Introduction
Antimicrobial peptides (AMPs) are considered as promising alternatives to the use of antibiotics in aquaculture, due to their antimicrobial and immunomodulatory properties. In the European sea bass (*Dicentrarchus labrax*), a fish species with a high commercial value, only hepcidins and piscidins have been studied (Neves et al, 2015; Barroso et al, 2020). However, the characterization of other AMPs in sea bass is still missing. In this study, we identify two different beta-defensins in the European sea bass (Barroso et al, 2021). Defensin sequences were isolated from sea bass tissues and characterized, using phylogenetic and syntenic studies. The putative amino acid sequences were determined, as well as the tertiary structure of each defensin. Further studies are necessary to understand the functions of sea bass beta-defensins during infection.

Material and Methods
Healthy sea bass (*D. labrax*) with an average weight of 30 g, were kept at optimal conditions and used to collect samples for gene isolation and basal expression. Primers were designed according to conserved regions of beta-defensin mRNA sequences of other fish species and from sea bass expressed sequence tags (ESTs) and whole genome shotgun sequences (WGSS) available in the National Center for Biotechnology Information (NCBI) and Ensembl databases. The coding and genomic DNA products were sequenced and the putative amino acid sequences were determined. The tertiary structure of each sea bass beta-defensin was determined, using models available in the SWISS-MODEL server (https://swissmodel.expasy.org/). A phylogenetic and syntenic analysis of fish defensins was performed, as well as a comparison between sea bass defensins and other vertebrate peptides. The basal expression of each defensin was also evaluated, using several tissues collected from fish.

Results
We isolated in sea bass two different beta-defensins. Both genes consist in a three exon/two intron structure, similar to what is observed for other fish defensins. The tertiary structure consists in three antiparallel beta-sheets, with beta-defensin 1 presenting an extra alpha-helix at the N-terminal. Phylogenetic and syntenic analysis place sea bass defensins in the subfamilies 1 and 2, with other fish species, particularly Cyprinids and Salmonids, presenting additional defensins, separated in different branches. Both defensins are highly expressed in tissues including the spleen, head kidney or gill, with the lowest basal expression in the liver and brain.

Discussion and conclusions
Defensins are the most studied group of AMPs, with several fish and non-fish peptides being already characterized. However, an in depth study addressing the beta-defensin family in sea bass is still missing. Both sea bass defensins present similarities with other fish defensins, including their amino acid sequences and tertiary structure, and are included in the subfamilies 1 and 2. Other fishes, particularly Salmonid and Cyprinids, present several defensins, suggesting a diversification of this group, while in sea bass, hepcidins and piscidins become much more diversified. Further studies are necessary to understand their antimicrobial and immunomodulatory functions, particularly the chemotactic activity towards different cells. These peptides might be helpful in the development of novel prophylactic or therapeutic substances to be used in the production of sea bass.

Introduction

Since the use of insect protein in aquafeeds was approved by European Union in 2017, its use as fishmeal (FM) alternative has been increasingly explored in several fish species. Despite several studies addressed the impact of insect meal-based diets in food intake of fish, there is no knowledge about their impact in mechanisms of food intake regulation. Understanding the underlying mechanisms responsible for feeding behavior in fish, namely stimulation (orexigenic) or inhibition (anorexigenic) of appetite, is pivotal for ensure the most adequate dietary formulations for aquaculture and consequently, the best growth performance of fish. There are evidences that in fish, as in mammals, the key neuropeptides involved in orexigenic action are neuropeptide Y (NPY) and agouti-related protein (AgRP), while those involved in anorexigenic action are cocaine-amphetamine related transcript (CART), and pro-opiomelanocortin (POMC) (Soengas et al., 2018). In this context, this study aimed to evaluate the impact of partial replacement of FM by defatted TM (*d*TM) on the expression of these neuropeptides in brain regions of European sea bass juveniles.

Material and methods

A FM-based diet with 48% crude protein on a dry matter basis was formulated and used as control (CTRL). Two other isonitrogenous and isoenergetic diets were formulated to replace 40 and 80% of FM by *d*TM (TM40 and TM80, respectively). Each diet was assigned to triplicate homogeneous groups of 25 fish (initial average body weight 55 ± 2 g) fed until apparent satiation for 10 weeks. Fish were subjected to a 12-hour light/12-hour dark photoperiod regime and kept in a recirculating saltwater system (35‰, 24 ± 1 °C). Feed consumption was monitored during entire trial. At the end the trial, samples of plasma and different brain areas (hypothalamus and telencephalon) were collected at different post-prandial times (2, 6 and 24 hours after feeding) to evaluate circulating metabolites and mRNA relative abundance of neuropeptides involved in the regulation of food intake.

Results

All diets were equally accepted by fish, resulting in similar food intake and weight gain. Plasma cholesterol levels decreased 24 hours after feeding in fish fed TM40; fish fed *d*TM diets had higher cholesterol levels, 2 and 6 hours after feeding, than those fed CTRL diet. Increased non-esterified fatty acids (NEFA) levels occurred in plasma of fish fed TM80, regardless of the sampling time. At central level, no changes occurred in the mRNA abundance of neuropeptide Y (*npy*), agouti-related protein 2 (*agrp2*), pro-opio melanocortin a (*pomca*) or cocaine- and amphetamine-related transcript 2 (*cartpt2*).

Discussion and conclusion

The results obtained suggest that dietary replacement of FM by 50-80% of *d*TM for 10 weeks does not affect food intake and its homeostatic regulation in European sea bass at central level. Considering that the same experimental diets did not induce detrimental effects on nutrient digestibility, growth performance, and fillet nutritional value for human consumption (Basto et al., 2021), these results certainly will help to improve sustainability of diet formulation for this species using *d*TM meal in replacement of an important amount of FM. However, a short-term study is needed to fully characterize the response of mechanisms involved in food intake regulation immediately after exposure to diets rich in *d*TM.

Introduction
Tenebrio molitor (TM) is one of the recently authorized species for use in aquafeeds. When defatted (*d*-) is particularly rich in highly digestible protein (up to 93% on a dry matter basis) and have a well-balanced amino acid profile able to meet European sea bass (*Dicentrarchus labrax*) requirements (Basto et al., 2020). However, *d*TM has limited long-chain polyunsaturated fatty acids (LC-PUFA), like eicosapentaenoic (EPA; 20:5n-3) and docosahexaenoic (DHA; 22:6n-3), with health benefits for consumers. When a new ingredient is tested in aquafeeds, the flesh nutritional value, sensorial properties and acceptance by consumers are important factors to consider. In this study, we have evaluated the impact of replacing fish meal (FM) with *d*TM in European sea bass growth performance, nutrient utilization, skin and muscle quality traits.

Material and methods
A FM-based diet with 47% of protein and 20% of fat was formulated and used as control (CTRL). Two other isoproteic and isolipidic diets were formulated to replace 50 and 100% of FM by *d*TM (TM50 and TM100, respectively). Each diet was assigned to quadruplicate homogeneous groups of 15 fish (69 ± 5 g) fed until apparent satiation for 16 weeks. Fish were subjected to a 12-hour light/12-hour dark photoperiod regime and kept in a recirculating saltwater system (35‰, 22 ± 1 °C). By the end of the trial, feed consumption was determined and all fish were weighed and measured. Ten fish from the initial fish stock, and 4 fish per tank, by the end of the experiment were sampled for whole body (WB) composition, total lipid and FA profile analysis. Muscle from other 4 fish per tank were also collected for nutritional evaluation (lipid content and FA profile analysis), color analysis and textural properties (TPA and histology). Twenty fish per treatment were collected for sensory evaluation using a panel of 60 untrained panelists. After the growth trial, the apparent digestibility coefficients of the experimental diets were determined according to Cho & Slinger (1979), after including 1% Cr_2O_3, as inert marker, to the experimental diets.

Results
Fish fed TM50 had a significantly lower voluntary feed intake (VFI) and feed conversion ratio (FCR) compared to the CTRL, resulting in similar final body weight and condition factor among treatments. TM50 had the highest N and E retention efficiency values and reduced N and E overall losses. Total phosphorus (P) losses decreased with dietary *d*TM inclusion. The whole body lipids increased with dietary inclusion of *d*TM, mainly due to oleic acid (OA; 18:1n-9) gain and retention. Muscle total lipids levels remained similar among dietary treatments. The sum of saturated FA (SFA) increased in muscle of fish fed *d*TM, whereas monounsaturated FA (MUFA) didn't change. The dietary inclusion of *d*TM resulted in a concomitant increase of muscle LA level. Despite the relative percentage (% total FA) of muscle EPA and DHA decreased in fish fed *d*TM, when expressed in wet weight muscle EPA + DHA final contents were similar among all fish (0.30 g 100 g^{-1}).

Muscle cohesiveness and resilience were higher in fish fed TM50; this fish also had the largest-sized and lowest number of muscle fibers. Fish fed TM100 had a significantly lower number of smaller-sized muscle fibers (<25 µm) than those fed the CTRL. Skin and muscle lightness (L*), redness (a*), yellowness (b*) and Chroma (C*) values were similar among groups. The hue angle (Hº) was significantly lower in skin of fish fed TM100 compared to CTRL, but in muscle remained similar among all dietary treatments.

The panelist could not detect any significant differences in fish overall liking and acceptance that remained high for all fish, but *d*TM samples were strongly associated with a "pleasant taste" and "juicy texture".

(Continued on next page)

Discussion and conclusions

The results of the present study demonstrate that the substitution of 50% FM by *d*TM significantly improves FCR. Diets with *d*TM didn't impair European sea bass growth and still resulted in fair levels of EPA and DHA in muscle (0.30 g 100 g^{-1} of wet weight), which are above the recommended level for human consumption to decrease the risk of cardiovascular diseases (0.25 g 100 g^{-1} portion of fish; EFSA, 2010). Despite some differences observed in the muscle histomorphometric and instrumental texture measurements, all samples were characterized by their soft and pleasant texture. Altogether, these results evidence a great potential of *d*TM to fully replace FM in diets for European sea bass. However, the long term impact of feeding *d*TM diets still needs to be addressed.

Introduction
Since the insect protein from seven insect species was authorized by the European Union for use in aquafeeds, the interest in such ingredient has clearly emerged to both the scientific community and the aquaculture industry. In just a few years, the insect's production industry has risen in Europe, and the *Hermetia illucens* (HI) and *Tenebrio molitor* (TM) are the main insect species produced. Consequently, they have been the most studied insect species as fishmeal (FM) substitute in diets for both freshwater and marine fish. Between both insect species, defatted (*d*-) TM seems more adequate to replace FM in European sea bass (*Dicentrarchus labrax*) (Basto et al., 2020), one of the most important fish species in Mediterranean aquaculture. However, long-term studies under farm-scale conditions are still not available. Thus, the main objective of this work was to predict the long-term effect of *d*TM as main protein source in diets for European sea bass reared under a farm-scale scenario, using the FEEDNETICS™ dynamic nutrient-based model smart-software.

Material and methods
A formulation with 40% (as feed basis) of FM was used as control (CTRL), and two other isoproteic, isolipidic and isoenergetic dietary formulations (47% protein, 20% fat and 24% energy), with 50% and 100% FM replacement by *d*TM (TM50 and TM100, respectively) were evaluated *in silico*. The FEEDNETICS™ was used to run predictions of a long-term trial with 300 000 European sea bass juveniles, stocked at 1/3/2021, with initial body weight of 5 g, considering a monthly mortality rate of 1% and a harvest weight of 500 g. Predictions were run considering the annual water temperature profile of Alvor (Portugal), obtained from www.seatemperature.org, which ranges between 13 °C and 24 °C. Feeding tables used were generated for each feed using FiT feeding tables™ (www.fitfeedingtables.com).

Results
The FEEDNETICS™ simulations indicate that feed efficiency should be slightly higher if fish were fed with *d*TM formulations (Figure 1). Consequently, those fish could reach the harvest weight of 500 g in approximately 12 months, while fish fed with CTRL would require 13 months. For the considered environmental conditions, the model suggests that formulations with *d*TM may result in slightly lower amounts of nitrogen and solids being released into the water. It is also expected that the increase of dietary inclusion of *d*TM may result in a concomitant decrease of total phosphorus wastes. Despite the model does not indicate differences in whole-body crude protein and crude fat among dietary formulations, it does in fact indicate some changes in amino acids and fatty acids (FA) profile. The formulations with *d*TM seem to increase total saturated FA, due to increased levels of palmitic acid; have no impact on total monounsaturated FA; reduce total polyunsaturated FA (LC-PUFA), due to decreased levels of some essential FA such as arachidonic, eicosapentaenoic and docosahexaenoic acids. The predictions also demonstrated that *d*TM may be responsible for a marked increment of whole-body linoleic acid. Despite simulations for TM50 and TM100 indicate a LC-PUFA reduction, a fair level of n-3/n-6 ratio (1.2) was still predicted for TM50 (Figure 2.).

Discussion and conclusions
In the long-term, TM50 seems to be the most promising dietary formulation for European sea bass reared under a practical farm-scale scenario. Overall, results of predictions based on this feed reflect a good balance between feed efficiency, growth performance, body composition and environmental outputs. The use of FEEDNETICS™ proved to be a useful tool to predict the outcome of nutritional trials. However, simulations still need to validated simulations through pilot scale trials.

A STUDY OF THE DYNAMICS OF THE PROKARYOTIC COMMUNITY IN A RECIRCULATING AQUACULTURE SYSTEM (RAS) FROM A SOLE *Solea senegalensis* HATCHERY

Recirculating aquaculture systems (RAS) allow water reuse by managing waste and nutrient recycling, consequently making intensive fish production compatible with environmental sustainability, and improving fish welfare. A key aspect of these systems is the beneficial bacterial community of the biofilter[1]. In this study we aim to investigate the dynamics of this community in a sole (*Solea senegalensis*) hatchery RAS and its interactions with physical-chemical parameters.

Samples from different matrices (water, biofilter and tank wall biofilm) were collected from several compartments (Figure 1A) of a commercial hatchery (including the Pre-Ongrowing and Weaning working in RAS regime). Total DNA was isolated from the different matrices and the V4-V5 region of the 16S rRNA gene was sequenced using Illumina MiSeq® platform and analysed in the DADA2 pipeline using the SILVAngs database.

It was found that biofilm samples (both biofilter carriers and tank biofilm) were richer in terms of prokaryotic diversity than water samples. At beta diversity level, the Bray-Curtis dissimilarity index visualized through NMDS (Figure 1B) revealed high prokaryotic community dissimilarity between samples from the Pre-Ongrowing and the Weaning system. Overall, the prokaryotic communities were dominated by Proteobacteria (12-89%) and Bacteroidetes (8-86%) and a total of 58 genera contributed with more than 3% of the relative abundance across the different samples. The most abundant genera were *Tenacibaculum, Sulfitobacter, Leucothrix, Novosphingobium, Marinicella, Pseudoalteromonas, Polaribacter_2, Schleiferia* and *Algibacter*. Genera commonly associated with biofiltration activity in RAS[2], such as *Nitrospira* (nitrificaton), *Nitrosomonas* (nitrification) and *Thiothrix* (sulfide-dependent autotrophic denitrification) were found in the Pre-Ongrowing and Weaning biofilter, even though they were not the utmost representative genus found in these matrices. With the Adonis test, using the Bray-Curtis dissimilarity index for the distance matrix, it was found that prokaryotic community shifts were modelled by water parameters such as salinity and pH.

Our results demonstrated that the studied RAS sole hatchery was dominated by a highly dynamic prokaryotic community, sensitive to the physical-chemical changes within the different compartments of the same aquaculture unit, developing different community profiles. These are relevant findings for fine tuning when designing modulation protocols, without compromising fish welfare, since the community appears to be sensible to small variations. Future studies are fundamental to identify how the key players in maintaining a healthy RAS system can be used to achieve a healthy prokaryotic community when imbalances or fish disease outbreaks occur.

Aquaculture has been rapidly growing as the increasing exponential population has imposed a higher demand for seafood supply. Recirculating aquaculture systems (RAS) can be used in intensive fish production, being considered a more sustainable and eco-friendly technology. In fact, with the RAS systems, it is possible to reuse water by managing the waste and nutrient recycling, and, at the same time, improve the fish welfare. One of the main advantages of RAS is the bacterial community that inhabits the biofilter [1]. They can improve the water quality of RAS systems as they can be involved in nitrification processes or prevent pathogen resistance. However, these communities are very sensitive to physical chemical fluctuations, which can result in pathogen outbreaks or inefficient removal of nutrients.

This work aimed for the modulation of the culturable bacterial community from a RAS system, in order to develop bacterial solutions for the maintenance of water quality and fish welfare. More specifically, this work was divided into main objectives: 1) isolate the nitrifying bacteria from the RAS system, to develop a formulation ready to use for application in case of unexpected fluctuation on nutrient levels or to reactivate the nitrifying bacteria in a new facility; 2) prevent diseases outbreaks caused by the pathogenic bacteria *Tenacibaculum maritimum*. Experiments using water and biofilter carriers were conducted aiming to isolate the culturable bacteria present in each matrix.

For the isolation of the nitrifying bacteria, different approaches were performed: a) direct isolation of nitrifying bacteria from the water and biofilter carriers, using selective AOB (ammonia oxidizing bacteria) and NOB (nitrite oxidizing bacteria) culture media and b) enrichment of nitrifying bacteria, using water and biofilter carriers from RAS system, and afterwards, isolate the culturable enriched community. For the direct isolation, samples of water and biofilter carriers were spread in ten-fold dilutions into 6 different culture media, rich in the respective nutrient (ammonia or nitrites). All the bacterial strains with different morphological features were selected and purified.

For the enrichment process, a set of microcosms were assembled: half only with water and the other half with water and biofilter carriers from the RAS system. The microcosms were supplemented with 335 μM of ammonium sulphate and 35 μM of sodium nitrite. The experiment was conducted in cycles of 14 days. After each cycle, part of the culture was diluted into a renewed media. Ammonium supplementation was performed in the beginning of each cycle (14 days) and supplementation of nitrites was performed at the beginning of each cycle and after 7 days. Each week, the cultures were transferred to new sterile flasks to avoid the oxygen depletion. The enriched cultures were incubated at room temperature, in dark and static conditions. After each cycle, a portion of the culture was spread in ten-fold dilutions, into 4 different selective culture media.

From the direct isolation, 20 bacterial strains were recovered and purified. All the strains will be cryopreserved at -80°C for further experiments. In addition, DNA extraction will be performed, and the extracted DNA will be used for the screening of nitrifying genes using qPCR and for further taxonomic identification of each bacterial isolate. Regarding the enrichment process, the enriched culture supplemented with sodium nitrite displayed removals higher than 95% of nitrite from the media. On the other hand, the enriched culture supplemented with ammonium displayed low removal of ammonia in all cycles. The isolation of the culturable bacteria of each enriched culture is still an ongoing work.

(Continued on next page)

For the second objective, related with prevention of outbreaks of *T. maritimum*, a direct isolation of the bacterial community present in the water and biofilter carriers was performed, using nonselective culture media, rich in different carbon sources and micronutrients. Previously, next generation sequencing data from the RAS system, more specifically, correlation and network analysis, was performed to assess the potential bacterial genera that can be negatively related with *T. maritimum*. After this analysis, different culture media were selected aiming the isolation of these particular bacterial genera. For that, samples of water and biofilter carriers were spread in ten-fold dilutions into 4 different culture media. Again, all the bacteria with different morphological aspects were isolated, purified and cryopreserved at -80°C, for further biotechnological applications. From this experiment, 256 bacterial isolates were retrieved and cryopreserved. For all isolates, a sample was collected for further DNA extraction and taxonomic identification. Assays targeting the inhibition of *T.maritimum* are being conducted. Two screening assays were developed, one based on streaking method and the other based on the disc diffusion method. Until now, 39 bacterial isolates were tested, in which 6 bacterial isolates presented potential inhibition capacity against *T.maritimum*. The bacterial isolates with the capacity to inhibit *T.maritimum* will be tested and validated in microcosms experiment, and effects driven by the addition of this bacterial isolates on the natural community as well as the impacts on the water quality will be assessed.

This work can contribute for the improvement and maintenance of water quality and fish welfare in aquaculture RAS systems, by developing new formulations for improvement and maintenance of the RAS systems.

Introduction

The efficient management of intensive fish rearing requires the close monitoring of fish performance. The knowledge of fish sizes and biomass within sea cages is of utmost importance for the rational evaluation of the production process (e.g. growth, feed efficiency, drug administration, size variation, harvest). The estimation of fish biomass in the sea cage environment during intensive rearing has long been a research and technological challenge. Various equipment (mainly applied to salmon rearing) is available but none has yet been widely used for gilthead seabream and European seabass rearing for reasons of accuracy, complexity of use, time and cost efficiency.

Objectives

The main objective of the project is the design and manufacture of a fish size/biomass estimator adapted to the two major Mediterranean aquaculture species, gilthead seabream and European seabass. The ambition is to produce an underwater device that a) will not require time-consuming and invasive measurement procedures, b) will use high level automatization and minimize the need for expertise personnel, c) will be cost efficient.

Materials and Methods

The biomass estimator will be based on the reconstruction of the 3D scene where the fish live, using the coded structured light technology. This method requires a projector which projects a pattern onto a part of the area where the fish swim and a camera which records this area. The projected pattern contains coded information in order to find corresponding points between the pattern and the image which is acquired by the camera, in a similar manner to the one realized in stereoscopic vision and the way which the human eye operates. Finally, a method called triangulation can be used to extract the coordinates of the 3D points of the scene, exploiting the previously mentioned corresponding points. After the 3D reconstruction of the area where the fish live, it is feasible to isolate the fish whose bodies are entirely recorded by the camera. Using the resulting 3D representation of these fish, the extraction of geometric features related to their body is also feasible.

The estimator will be equipped with the necessary software which will be based on gilthead seabream and European seabass morphometrics and relationships with body weight. To achieve the latter a series of body measurements will take place in a large number of fish covering a body weight range from around 100 g up to commercial size. The equipment will be tested on the field and re-calibrated if necessary.

Expected outcomes

The successful completion of the project will provide a practical, economical, and reliable solution for estimating the size and biomass of farmed fish. In the short term it may lead to the development of a commercial product that will be affordable, even for small and medium-sized enterprises of intensive aquaculture. Overall, the project hopes to provide a vital tool to support an efficient fish farm management that will further promote the Greek aquaculture sector.

Aknowledgements

The project is co-funded by the European Maritime and Fisheries Fund and the Greek government.

EVALUATION OF ANTARCTIC KRILL (*Euphasia superba*) MEAL SUPPLEMENTATION IN DIETS FOR OLIVE FLOUNDER (*Paralichthys olivaceus*)

Tibiabin Benitez-Santana*, Kasun Tharaka, Buddhi E. Gunathilaka, Min-Gi Kim, Chorong Lee, Jaehyeong Shin and Kyeong-Jun Lee

Aker BioMarine Antartic AS
Oksenøyvn 10. PO Box 496NO-1327 Lysaker, Norway
tibiabin.benitez-santana@akerbiomarine.com

The supplemental effect of Antarctic krill meal (KM) into a low fish meal (FM) diet was evaluated for olive flounder (*Paralichthys olivaceus*). A 56% FM-based diet was regarded as a high FM inclusion diet (HFM), and a low-FM diet (LFM) was prepared by replacing 50% FM from the HFM. Four other diets were prepared by supplementing 3%, 6%, 9% and 12% KM into the LFM diet gradually replacing soy protein concentrate and tankage meal (designated as KM3, KM6, KM9 and KM12 respectively). Quadruplicate groups of fish were fed one of the diets for 12 weeks. The growth performance and feed utilization efficiency were improved by the dietary KM supplementation. Digestibility of dietary protein and dry matter was increased by the KM3-9 diets. Haematocrit and haemoglobin were increased by KM supplementation. The innate immunity and antioxidant capacity assessed by Ig, antiprotease, lysozyme, GPx and SOD and the condition factor of fish were significantly increased by KM3-9 diets. Moreover, goblet cell counts, villi length and fillet yield of fish were significantly improved by all the KM-containing diets (KM3-12). A 25-day-long challenge test with the *Edwardsiella tarda* pathogen showed that the cumulative mortality was higher in fish fed the LFM diet than in fish fed the HFM or KM-supplemented diets. The results indicate that dietary KM supplementation in a LFM diet can increase growth performance and feed utilization efficiency, diet digestibility, intestinal development and functions, innate immunity and disease resistance of olive flounder. The recommended level of KM inclusion in a LFM diet seems to be 6.6% according to quadratic regression analysis.

ETHOLOGICAL STUDIES ON AFRICAN CATFISH (*Clarias gariepinus* BURCHELL, 1822) UNDER DIATARY SUPPLEMENTATION OF THE CLAY MINERAL MONTMORILLONITE-ILLITE/MUSCOVITE (1G557) IN A COMMERCIAL RECIRCULATING SYSTEM

E. Berchtold, H. W. Palm, & B. Baßmann

University of Rostock, Faculty of Agricultural and Environmental Sciences, Professorship of Aquaculture and Sea-Ranching, Justus-von-Liebig-Weg 6, D-18059 Rostock, Germany

Clay minerals are considered to have positive effects on health and welfare of fish in aquaculture. These effects are caused by their molecular structure, which is able to adsorb harmful substances, thereby improving water quality. The clay mineral „Friedland Ton“ mined in Mecklenburg-Western Pomerania, NE Germany, contains montmorillonite-illite/muscovite and was approved as feed additive by the European Union under the abbreviation 1g557. Palm et al. (2015) described an increased survival rate, higher final weights, more efficient feed conversion and reduced size variance of White Leg Shrimp postlarvae (*Litopenaeus vannamei*) under application of feeds containing 2% 1g557, or a mixture of 2% 1g557 and 2% of the microalgae *Chlorella vulgaris*.

To analyse the behaviour of African catfish *in situ*, an infrared camera system was used for the first time. This allowed fish observation under the common low-light conditions in a commercial recirculation system for African catfish. During a 125-day trial, three groups of juvenile African catfish were fed a standard catfish diet containing 0.0%, 0.5%, and 2.0% 1g557. For ethological studies, video recordings (30 min per fish tank) were made at four times during the experiment. One day prior each video recording, welfare (skin lesions, plasma cortisol, blood glucose) and growth parameters were measured.

Using 1g557 as feed additive in a commercial recirculating system with African catfish (*Clarias gariepinus*, Burchell 1822) has shown that groups fed with 1g557 had significantly fewer bite wounds compared to an unsupplemented control group. This was supported by the video recordings which also indicated that treated fish showed less aggressive behaviour towards their conspecifics improving fish health and welfare.

RELEVANCE OF SUSTAINABILITY DIMENSIONS AND ANIMAL WELFARE FOR CONSUMERS WHEN BUYING INNOVATIVE AQUACULTURE FISH PRODUCTS

A. Bermúdez*, L. López-Mas, L. Guerrero.

IRTA, Food Technology Program, Finca Camps i Armet, E-17121 Monells (Spain)
*E-mail: alejandra.bermudez@irta.cat

Introduction

A strategy of differentiation when launching new products is to incorporate added-value attributes that impact on consumers' choices. Previous research identified sustainability as a key factor in buying intention. Consumers are increasingly reflective in their food decisions and have broadened their understanding of sustainability (Mintel Food & Drink Industry Trend, 2020). Animal welfare has also been identified as a relevant driver of fish consumption in some circumstances. Therefore, it becomes necessary to undercover the concept of 'sustainability', but also animal welfare, into smaller parts (dimensions) and to investigate the role they play in innovative aquaculture fish products choice.

Self-reported measures, those given explicitly by consumers, are the most common way to grasp their opinion. Even so, in recent years has gained attention the advantages of combining explicit and implicit methods (i.e. physiological and emotional measures gathered by non-invasive sensors). This study, carried out within MedAID project (European Commission, Horizon 2020, No. 727315), aims to gain understanding on consumer's decision making process for new aquaculture fish products.

Material and methods

A combination of explicit and implicit methods was used during a choice experiment (i.e. ranking-based conjoint analysis) of a 'Meagre aquaculture fish burger with mushrooms', developed by AZTI (Spain). Explicit measures included a ranking task for six versions of the product with different factors and levels (Table1). Additionally, a questionnaire assessing willingness to try and buy the product, as well as product familiarity, healthiness, and convenience, the Single-item Food Choice Questionnaire (FCQ) (Onwezen et al., 2019), Spanish versions of Prosocialness Scale for Adults (Martínez-Pampliega et al., 2018) and New Environmental Paradigm Scale (Vozmediano et al., 2005) was used. Implicit methods consisted in Eye tracking (ET) to measure visual attention. Areas of interest (AOI) for all statements presented in the ranking task were assigned. Fixation count was used to identify relevant areas and duration of fixations to assess degree of involvement (Van Loo et al., 2015).

The study included 30 Spanish participants, divided in experimental and control group. Manipulation consisted in the viewing, previous to the ranking task, different versions of a video, differing in the information contained: general facts about aquaculture (control) and positive outcomes of aquaculture emphasising its sustainability (experimental).

Results

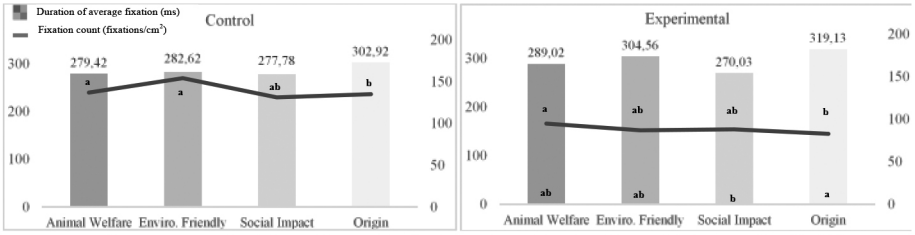
Low scores for familiarity confirmed the innovativeness of the 'Meagre fish burger with mushrooms'. Sensory, health, and natural were the most important attributes when choosing fish products, followed by items connected to sustainability as environmental issues, animal welfare, and social justice over price, convenience, familiarity, mood, or weight control. Participants revealed prominence of environmental and prosocial values. The results of the conjoint analysis showed that animal welfare was the most relevant factor, both in control and experimental conditions. In all cases, respondents preferred having information about positive outcomes on the different sustainability dimensions (environmental and social) and animal welfare. Besides, Spanish origin was chosen.

When comparing visual attention between factors (Figure 1), fixation count was higher for statements about environmental impact and animal welfare for the control group, and animal welfare for the experimental group. On the other hand, origin was the factor with longer fixation duration for both groups. In relation to the factor levels, social impact presented significant differences in attention between the level of information displayed, both in control and experimental conditions. Fixation count was higher when the statement referred had no information about social impact, whereas fixation duration was higher for the statement with information about positive outcomes. In addition, significant differences were found in the fixation count between groups for those statements that had no information about social impact or animal welfare, with lower counts for the informed condition

(Continued on next page)

Table 1. Factors and levels in the conjoint analysis design.

Factor	Levels
Environmental Impact	Fish farmed respecting the environment /No information
Animal Welfare	Fish farmed respecting the fish welfare /No information
Social Impact	Positive impact on local communities /No information
Origin	Spain / EU / Non-EU



Superscript a–b: different letters indicate statistically significant differences ($p < 0.05$).

Figure 1. Visual attention to factors control vs. experimental conditions.

Conclusions

For fish products perceived as innovative, animal welfare had greater importance in consumers' choices than origin, which traditionally has been one of the most important attributes for fish. When relevant information about positive outcomes of aquaculture (i.e., sustainability and animal welfare) was given, origin importance decreases. In line with respondents' choices, visual fixation to animal welfare statements was significantly higher than origin, highlighting its greater importance. On the other hand, higher fixation duration for origin indicated that participants noticed the attribute and they took longer time in the deliberation process. Considering visual attention between factor levels, social impact is perceived as a complex attribute. When relevant information about the positive outcomes was given, both fixation counts and fixation duration decreased, suggesting less complexity of the deliberation process.

Animal welfare and social impact concerns are gaining consumers' attention over environmental impact and origin. It is highly recommended to incorporate these added-value giving attributes when developing new aquaculture fish products. Communication that includes information about the outcomes of aquaculture and its sustainability could help consumers to select fish products aligned with their values and beliefs.

Introduction

The Venice Lagoon represents a vulnerable ecosystem prone to significant variations of biotic and abiotic factors based on the spatiotemporal conditions as well as extensive anthropogenic interventions (Deheyn and Shaffer., 2007). These stressors can have consequences on the biology and ecology of sessile and highly sedentary organisms, such as bivalve mollusks, that cover, in turn, important ecological and economical roles. Shellfish, like the Manila clam (*Ruditapes philippinarum*), are extensively farmed in several areas of the Venice Lagoon, mostly due to their high tolerance and adaptability to di□erent conditions and to strong variations in environmental parameters (Boscolo Brusà et al., 2013). Recent studies have demonstrated that clam health depends also on the microbiota, or associated microbial community, which plays key roles in nutrient assimilation, homeostasis, immunological regulation (Aceves et al., 2018) and the protection against pathogens and environmental stressors (Milan et al., 2018). However, seasonal variations, adverse climatic conditions, chemical-physical features of different farming sites, and anthropogenic activities can influence the fitness of farmed clams as well as their associated microbial communities, with potential negative consequences on the clam farming aquaculture industry. In addition, the inauguration of the new Experimental Electromechanical Module (MoSE), system of flood barriers, designed to safeguard Venice and the lagoon from high tides, may lead to further modifications of the delicate Venice lagoon ecosystem. In this study, a long-term monitoring campaign was carried out on clams from four farming sites in the south of the Venice Lagoon characterized by different environmental conditions. The aim of this study was to investigate the correlations between seasonal trends of microbiota and gene expression profiles in the digestive gland and gills of clams, and the biometric characteristics, condition index, and site-specific environmental chemical-physical parameters. Overall, this study reports key information for predicting and identifying the potential impacts of the MoSE system on Manila clam farming activities.

Material and Methods

Twenty thousand individuals of Manila clam spat (*Ruditapes philippinarum*), supplied by the Satmar Company (France) in August 2018, were partitioned in 4 groups and placed at gradual distances from the Chioggia inlet, from the outmost to the innermost site. Clam sampling was performed at five intervals throughout a one-year period, representative of the seasonal variations (May 2019, July 2019, October 2019, February 2020 and May 2020). After each sampling, biometric parameters and condition index of clams were recorded. Digestive glands and gills were collected for transcriptomic analyses (RNA-sequencing) and microbiota characterization (16S rRNA Amplicon Sequencing). Raw data elaboration from molecular analyses is still ongoing. To link potential alterations in clam health with changes in environmental conditions, the sediments of each sampling area were collected to measure levels of dibenzo-p-dioxins/furan (PCDD/F), polychlorinated biphenylenes (PCB), hexachlorobenzene (HCB) and heavy metals at each sampling time. Moreover, two multiparametric probes located at different distances from the inlet continuously measured water temperature, turbidity, pH, chlorophyll-*a*, salinity, dissolved oxygen, and saturation throughout the year.

(Continued on next page)

Results

Results regarding biometric parameters showed no relevant differences between clams harvested in different sites at any single sampling time during the monitoring year. The highest growth rate was detected between May and July 2019, in all sites. The lowest condition index was recorded in October 2019 in all study areas, while the highest value was detected in the outermost site in May 2019 and February and May 2020. Detectable levels of the investigated pollutants were not different between investigated areas. Regarding environmental parameters, probes in both sites recorded a similar seasonal trend of each environmental parameter. Generally, the average temperatures, dissolved oxygen, and turbidity are always higher in the southern part (innermost probe), with the exception of the winter period in which a higher average temperature was observed near the inlet. Finally, the ongoing analyses on gene expression profiles and microbiota characterization performed in the two investigated tissues of clams will allow to evaluate seasonal alterations in clams farmed in different areas of the lagoon; their potential link to biometric analyses and environmental parameters will be also presented and discussed in this presentation.

Conclusion

By merging results obtained through the multidisciplinary approach applied in this study, important information regarding the influence of several environmental factors on the health status of farmed clams may be underlined. Furthermore, results of 16S rRNA sequencing and RNA-seq will make it possible to describe the host-microbiota interactions in the Venice lagoon farming areas, which may be associated with different environmental conditions. Overall, results obtained by this study will represent the "baseline" information which to evaluate the potential consequences of the MoSE system on Manila clam farming areas in the future from.

E-mail: Bernath.Gergely@uni-mate.hu

Introduction

Tench (*Tinca tinca*) and crucian carp (*Carassius carassius*) are endemic ecologically important fish species in Hungary. The angling interest and demand was increased for the two fish in the last decades. The size of their natural populations shows a drastic decreasing tendency in Hungary and in other European countries as well. Sperm cryopreservation is an efficient tool to support the reintroduction of the vulnerable natural populations using spermbanks (Horváth et al.2012; Martínez-Páramo et al. 2017).

Materials and methods

The aim of the study was to improve sperm cryopreservation methods in the two endemic species for conservational purposes. In our experiments, two different extenders (E1: 200 mM glucose, 40 mM KCl, 30 mM Tris, pH: 8.0±0.2; E2: 150 mM glucose, 75 mM NaCl, 30 mM KCl, 1 mM Na_2HPO_4 * $12H_2O$, 1 mM $MgCl^2$ * $6H_2O$, 1 mM $CaCl^2$ * $2H_2O$, 20 mM Tris, and 0.5% BSA, pH: 8.0 ± 0.2) and two different cryopreservation methods (Styrofoam box and controlled-rate freezer-CRF) were compared according to the experimental design. Sperm was frozen using the conventional 0.5 mL straw and 10 % methanol as cryoprotectant. Sperm motility (progressive motility) and other kinetic parameters (distance curved line, distance straight line, curvilinear velocity, straight line velocity, linearity) was investigated using a Computer-assisted Sperm Analysis (CASA) system.

Results

A significantly higher post-thaw progressive motility was recorded using E1 (34±4%) than in E2 (22±4%) in crucian carp. Contrary, no significant difference in progressive motility was observed between E1 (36±9%) and E2 (45±20%) in tench following thawing. However, motility reduced significantly in E1 in comparison with the fresh samples (Fig.1.). No significant difference was measured between the Styrofoam box (10±2%) and the controlled-rate freezer (6±1%) in thawed tench sperm. Furthermore, no significant difference was recorded in the other kinetic parameters between the different treated groups in tench and crucian carp as well.

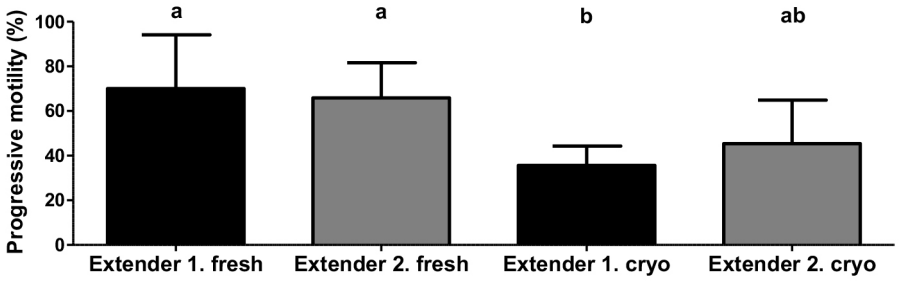

Fig.1. The progressive motility measured in tench sperm using two different extenders prior to cryopreservation and following thawing (*N*=6). The columns represent mean and SD. The different letters indicate significant difference between the columns at p>0.05.

(Continued on next page)

Discussion and conclusion

According to our results, different extenders can be efficient in the two cyprinid species. The reduced motility in tench sperm observed following thawing (cryopreserved in S. box and CRF) was caused probably by urine contamination (Król et al. 2018). Urine activated spermatozoa prior to the freezing process. Future improvement and standardization of the sampling method can prevent the mentioned undesirable phenomenon. The results can contribute to the establishment of future spermbanks in the case of the two endemic species.

Introduction

Sparicotyle chrysophrii represents one of the main parasitic threats for gilthead seabream (*Sparus Aurata*) cultures in the Mediterranean basin (see e.g. Alvarez-Pellitero, 2004), causing mortality and poor fish quality. A data set has been collected by the fish farm Cromaris, including ectoparasite counts and environmental hydrographic variables. In this study, a logistic regression model is fitted to identify factors that are connected to Sparicotyle outbreaks.

Data

The proposed analysis focuses on a single Cromaris farm, located in Bisage. In particular, seven cages have been monitored on eight examination days in the first year of life of the 2017 generation. For each of the resulting 56 observations, Sparicotyle presence has been checked on the left gill arches of 12 or 13 randomly drawn fishes. To understand the factors that may influence parasite presence, the dataset is integrated with some concomitant information about fishes (and the environment where they are bred) on the day of examination, such as actual water temperature (°C), average fish weight (g), actual fish density (kg/m^3) and average haematocrit value (%).

Model specification

Let Y_i be a random variable describing the observed number of Sparicotyle-infected fishes out of n_i (12 or 13) sampled from a single cage on a specific date. For each observed sub-sample $i = 1, ..., k = 56$, denote with $x_{i1}, ..., x_{iP}$ the values taken by P concomitant variables on the n_i sampled fishes (or the cage they are drawn from). Conditional on $x_i = (1, x_{i1}, ..., x_{iP})$, each Y_i is assumed to be independent and to follow a Binomial distribution with parameters n_i and π_i, where the latter represents the probability to observe the presence of *Sparicotyle chrysophrii* in one of the four left gill arches of a single fish. This probability is assumed to depend on the concomitant covariates x_i through a logistic function, as

$$\pi_i = \frac{\exp(\boldsymbol{x}_i\boldsymbol{\beta})}{1 + \exp(\boldsymbol{x}_i\boldsymbol{\beta})} \in [0,1], \qquad i = 1, \dots, n,$$

where $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_P)$ is a $(P+1)$-dimensional vector of unknown coefficients.

Results

All the covariates introduced in the Data Section have been included in the logistic regression model, together with the degree days (i.e. the sum of daily temperatures), which take into account the amount of time that passed between stocking fish on farm to the day of examination. Nevertheless, the latter has been removed from the model, as well as the average haematocrit value, during the variable selection phase, carried out via backward approach. The resulting model is adequate according to the X^2 goodness-of-fit test (p-value = 0.258).

	$\hat{\beta}$	exp ($\hat{\beta}$)	s. e. ($\hat{\beta}$)	p-value
intercept	-1.534	0.014	0.804	0.056
temperature (°C)	0.099	1.104	0.030	0.001
weight (g)	0.039	1.040	0.016	0.014
density (kg/m^3)	-1.053	0.349	0.447	0.018

Table 1: Maximum likelihood estimates of the regression coefficients $\widehat{\boldsymbol{\beta}}$ (numerically approximated via Fisher scoring algorithm), together with their exponential (for interpretation purpose), standard error and p-value of the corresponding Wald test.

(Continued on next page)

According to Table 1, the odds of a fish being sparicotyle-infected increase by about a 10.4% with each additional degree Celsius of temperature, and about a 4% with each additional gram of weight, keeping constant the values of the two remaining covariates. On the contrary, fish density seems to be negatively related with the parasite presence. However, it is worth noting that the latter coefficient estimate presents a sensibly higher standard error with respect to the two other variables.

Conclusions and further developments

The logistic regression model, fitted on the Cromaris data, highlights some statistically significant potential determinants of the *Sparicotyle chrysophrii* outbreaks in the gilthead seabream Mediterranean aquaculture. Nevertheless, the results presented are referred to a preliminary analysis which will be extended by integrating additional variables and observations. Moreover, some further work can be done to better fit the logistic regression model to the Cromaris data. For instance, random effects for each cage could be included in the analysis, as in the mixed paradigm (see e.g. McCulloch & Neuhaus, 2005). Furthermore, although a portion of the effect of time is already being caught by the variables considered (temperature and weight, in particular), the within-cage time dependence could be made explicit, e.g. by specifying an autocorrelation structure based on autoregressive-moving-average (ARMA) models (see e.g. Diggle et al., 2002).

Introduction
Mycotoxins and their effects have been examined in different animal species; however, more information about their impact on the fish immune response is still required. Fumonisins, produced by several Fusarium species, represent the most common mycotoxins in plant meals, which have been more frequently used in fish feed production in recent years. These toxins can cause major health problems in fish (Oliveira & Vasconcelos 2020), including both immunostimulation and immunosuppression (Riley et al. 1996; Pestka et al. 2004). Their effects need to be investigated more, especially in the main aquaculture species.

Materials and Methods
Physical and chemical changes occurring in the fish during storage were explored by using a non-destructive tool based on the dielectric property analysis. Specifically, dielectric constant (and loss factor () of trout eyes were acquired by using an open-ended coaxial probe (DAKS-3.5 probe, Speag). The probe was connected to a VNA (Vector Network Analyzer, Copper Mountains) and interfaced by USB with PC (DAK Software Installer 2.6.1.7). The calibration of the instrumental chain was conducted through the customized calibration kit (Speag DAK-3.5/1.2 Shorting Block, Metallic Strip Sets, and 0.6 l of Tissue Simulating Liquid). Acquisitions were carried out at 23 °C (± 1°C) on 7 fish in the GHz frequency range during 5 days of storage at 0°C (± 0.5°C).

Results
Non-specific stimulation showed a significant increase in proliferative activity after vaccination against Y. ruckeri in the fish from both fumonisin groups (vaccinated and non-vaccinated), indicating a pro-inflammatory immune reaction. Similar results were obtained in the non-vaccinated control. The vaccinated compared to the non-vaccinated fish from the control group showed significantly lower proliferation levels. With specific stimulation, significantly higher values were detected in the vaccinated fish from the fumonisin group compared to the vaccinated control.

Levels of specific antibodies were significantly increased in the vaccinated fumonisin group compared to the non-vaccinated fish at week 9. However, at week 10, the control fish showed similar results with even higher values. The enhanced immune reaction, which occurred very quickly in the vaccinated fish from the fumonisin group, may be indicative of pro-inflammatory changes (Ellis 1999).

Conclusion
Dielectric constant and loss factor of trout eyes appeared to describe the main changes occurring in the fish during storage. Further steps may include the validation of the techniques with other fish species and different rearing conditions. The setting up of a non-destructive and rapid tool will represent an important step in the project development.

Introduction

Improvement of feed efficiency is an important factor in sustainability of the finfish aquaculture industry. Improving feed efficiency via selective breeding requires an ability to identify the most efficient individuals among selection candidates. A method recently developed for the European sea bass (*Dicentrarchus labrax*) is based on individual rearing of fish in aquariums under restricted feeding (Besson et al., 2019). In Besson et al., (2019), we showed that individual feed efficiency in the aquariums had a significant genetic basis (genomic $h^2 = 0.47$). There is a need, however, for greater understanding of physiological mechanisms underlying individual variation in feed efficiency in fishesdespite its potential. This paper reviews past work to improve FE in fish using selective breeding and assess future directions. Direct selection on FE traits requires methods to measure individual feed consumption and estimate FE efficiently and accurately. This is particularly difficult to do in fish because of the environment in which they live. Many of the published studies on FE were found to be inaccurate because of methodological problems. The relatively low heritability estimates of FE traits in fish published to date are probably partly as a result of inaccurate measurements of feed intake. Improving ways to measure the individual feed intake with high accuracy will be critical to the successful application of genetics to improving FE. Indirect selection criteria that could be used to improve FE (including growth after starvation/refeeding, body composition, neuropeptides or hormone levels. It is generally assumed that growth and, more specifically, lean growth are major contributing factors to individual feed efficiency (Knap and Kause, 2018). However, growth and body composition are only expected to explain 60-87 % of individual variation in feed efficiency in fishes; the remaining variation may be caused by individual basal metabolic rate, immune response functions, physical activity, and responses to social factorsinflammatory challenges or lactation have been studied. After nine generations of selection, the divergent selection for RFI led to highly significant ($P<0.001$. Our aim was therefore to explore the phenotypic and genomic correlations between individual feed efficiency and metabolic traits in European sea bass.

Material and Methods

First, 458 sea bass were phenotyped in aquariums to estimate their feed efficiency following the procedure of Besson et al., (2019). Briefly, the fish stayed 3 periods of 2 weeks in 10L individual aquariums. Fish were individually fed a restricted daily ration based on their body weight and corresponding to 50% of the optimal ration given by the feed manufacturer (Le Gouessant – NEO MARIN). Because feed was restricted, individual feed efficiency was estimated as the residual of the final body weight on initial body weight at the start of the experiment (rFBW).

Second, 934 sea bass (336 previously phenotyped in aquariums and 598 of their sibs) were placed, in consecutive batches, in 32 individual respirometry chambers. Measurements of oxygen uptake (MO_2) were made by intermittent stopped-flow respirometry as described in McKenzie et al. (2014). The procedure was based on 15-minutes cycles comprising 8 minutes stopped-flow and 7 minutes flushing with aerated water. Water oxygen levels in the chambers were measured every ten seconds. During stopped-flow, oxygen uptake by the fish was calculated as the slope of the decrease in oxygen quantity over the 8 minutes (MO_2 in mg O2 h^{-1}). Measurements were done for 36h following 12h of acclimation allowing us to potentially estimate 144 MO_2 values per fish. With all the values of MO_2 obtained, we estimated the standard metabolic rate (SMR in mg O_2 h^{-1}) of the fish by averaging the lowest 10% of the MO_2 measurements. After the 48h, fish were weighed to correct the SMR for the effect of metabolic body weight ($BW^{0.8}$) and generate residual SMR (rSMR).

All fish were genotyped on the 57k SNP array DlabChip (Griot et al., 2021). Genomic links between fish enabled the estimation of genetic parameters of rFBW and SMR and genetic correlations between those traits using AIREMLF90 software.

(Continued on next page)

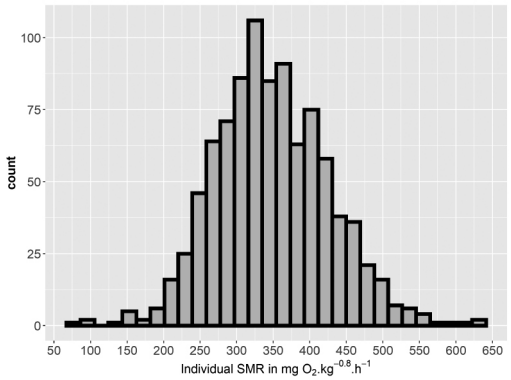

Figure 1. Histogram of SMR for the 934 sea bass phenotyped in the metabolic chambers.

Table 1. Genomic heritability (on the diagonal) of residual body weight gain in aquarium (rFBW) and residual standard metabolic rate (rSMR). Above the diagonal is the genomic correlation between the two traits.

	rFBW	rSMR
rFBW	0.23 (0.08)	-0.77 (0.41)
SMR		0.10 (0.04)

Results

We found large phenotypic variation in SMR (Figure 1). The mean SMR was 354 mg O2.kg-0.8.h-1 with a CV of 27%. Additionally, despite being weak, the phenotypic correlation between rFBW and rSMR was significant (r = -0.15, $F_{1,335}$ = 7.45, p-value = 0.0066). This correlation suggests that the most efficient individuals were also those with low standard metabolic rate, as expected.

Both rFBW and rSMR were heritable (Table 1) and the genomic correlation between them was strong and negative (-0.77 ± 0.41). This result supports the phenotypic correlation found between the two traits and indicates that SMR plays a role in the genetic basis of feed efficiency in sea bass.

Discussion

This study confirms that the individual efficiency under restricted feeding in aquariums is heritable. Furthermore, to our knowledge, this is the first study to phenotype several hundreds of fish for their individual oxygen consumption, allowing reliable estimation of genomic parameters for rSMR. We found that rSMR had a genetic basis and that individual feed efficiency of sea bass was partly explained by their metabolic rate. This finding is valuable for sustainable fish farming, in understanding how the physiology of fishes may relate to their robustness and efficiency.

GENETIC CORRELATIONS BETWEEN PROCESSING TRAITS AND INDIVIDUAL FEED EFFICIENCY IN A GILTHEAD SEA BREAM (*Sparus aurata*) COMMERCIAL LINE

A. Bestin*[a], M. Besson[a], A. Vergnet[d], F. Allal[d], F. Clota[c,d], S. Cariou[b], J.-S. Bruant[b], P. Haffray[a], M. Vandeputte[c,d]

Introduction

In fish farming, costs of feed range from 30 to 70% of the total production cost (Doupé and Lymbery, 2004; Kolstad et al., 2004). The gilthead sea bream (*Sparus aurata*) is the most important species of Mediterranean aquaculture, with 228,000 tons produced in 2018 (FAO, 2020). Feed efficiency is a key driver of profitability in this species, and its improvement would contribute to reduce environmental impacts of farming. Selective breeding could be used to improve this trait, provided individual phenotypes of feed efficiency are available. An experimental setting was implemented for this purpose at Ifremer (Palavas-les-Flots, France) and tested in a sea bream population of the FMDS line as described in Besson et al. (2019) for sea bass. We estimated then the heritability of individual feed efficiency, production traits and their genetic correlations.

Material and Methods

The cohort was derived from the FMDS breeding program in September 2018, using 61 sires and 28 dams mated in a partial full factorial design. The fertilized spawn of each dam was incubated separately. Larvae were transferred and reared in a single tank to minimize environmental variance. About 800 fish (~2.7g, at random) were individually tagged at 91 days post hatching (dph) and sent to Ifremer to undergo the individual feed efficiency trial, starting at 161 dph. About 1530 of their sibs were tagged and sent in a sea-cage for growing from 128 to 432 dph. All progeny and their parents were tissue-sampled for DNA parentage assignment (cage-reared fish) or for genotyping with the DlabChip 57K SNP chip for fish tested for individual feed efficiency.

From the feed efficiency trial we obtained the individual residual body weight gain (rBWG) as a proxy of individual feed efficiency according to this formula:

$$\mathrm{rBWG} = \mathrm{BWG} - (\beta_0 + \beta_1 \times \mathrm{MBW} + \beta_2 \times \mathrm{IFI})$$

MBW is the initial metabolic body weight of the fish ($BW^{0.8}$). β_0 is the regression intercept, β_1 is the partial regression coefficient of an animal's BWG on its metabolic weight and β_2 is the partial regression coefficient of an animal's BWG on IFI, its cumulated feed intake during the trial period.

From the slaughtering after sea-cage rearing we obtained Harvest Body Weight (HBW), Fat content (Distell® FatMeter, Scotland), gutted carcass weight and headless and gutted carcass weights, which were regressed on HBW to obtain phenotypic and genetic parameters for residual headless and gutted carcass weight (rHC_W) and residual carcass weight (rC_W) as surrogates for the yield of those body parts relative to HBW.

Heritabilities and genetic correlations for all traits were computed based on multivariate linear mixed animal models fitted by restricted maximum likelihood in AIREMLF90 using a single-step approach, using genomic information for fish with individual feed efficiency phenotypes and pedigree information for cage-reared fish (Misztal et al., 2002).

Results and Discussion

As shown in Table 1, individual feed efficiency is a heritable trait in sea bream (0.23 ± 0.09). None of the processing traits measured at slaughtering in the sea cage was significantly genetically correlated with feed efficiency. Nonetheless, there might be a tendency where leaner fish have a higher feed efficiency (genetic correlations of -0.20 with Fat and +0.55 with rHC_W). Efficient fish may also be the fastest growers (genetic correlation of +0.22 between harvest body weight and feed efficiency).

(Continued on next page)

Table 1: Heritabilites and genomic correlations of processing traits on cage-reared sibs with individual residual body weight gain. Heritabilites are on the diagonal and genomic correlations are above.

rBWG	HBW	Fat	rC_W	rHC_W
0.23 (0.09)	0.22 (0.56)	-0.20 (0.35)	0.24 (0.30)	0.55 (0.44)
	0.23 (0.08)	0.59 (0.24)	0.68 (0.18)	0.98 (0.12)
		0.25 (0.08)	0.02 (0.25)	0.16 (0.48)
			0.40 (0.09)	0.79 (0.31)
				0.16 (0.07)

Conclusion

Individual feed efficiency measured in a commercial line of sea bream is a heritable trait, which can thus be improved by selective breeding. This first result in sea bream supports the study by Besson et al. (2019) on sea bass in which individual feed efficiency traits measured in aquaria were also heritable. This trait is positively genetically correlated with growth and processing traits, which would enable selection on feed efficiency without impairing other production traits of interest.

Introduction
Mercury (Hg), especially the organic, methylated form (MeHg), is a toxic heavy metal that can accumulate in large amounts in fish through time in various organs, like liver and brain. Brain, with neurons, is the principal target of MeHg toxicity (Ni et al. 2012). MeHg induces its toxicity through induction of oxidative stress and inflammation (Morcillo et al. 2017). Selenium (Se), an essential micronutrient mainly involved in antioxidant protection, has been shown to reduce MeHg toxicity. However, Se and MeHg interactions are far to be totally understood. As relatively high levels of these two elements can be found in marine ingredients, a better understanding of their interactions is important to improve aquafeed formulations.

Material and Methods
Six plant protein-rich diets were formulated to contain two different MeHg levels (0 and 2.5 mg Hg/kg in HgC and HgH diets) combined with 3 different Se levels and forms (0.3 mg Se/kg in SeC diets and 2.6 mg Se/kg supplied either as sodium selenite in SeI diets or as L-selenomethionine from Orffa in SeO diets). Each diet was distributed to 3 replicate tanks of 50 fish (initial mean body weight: 26±1 g) to apparent satiation over a 3-week feeding trial at a water temperature of 17.5°C. Fish growth performance (n=3 tanks/diet) was analysed as well as total Hg and Se contents (n=3 individuals/diet) and relative gene expression levels (RT-PCR, n=9 individuals/diet) in liver and brain.

Results
Reduced growth performance of fish fed MeHg was recorded only within the non-Se supplemented SeC-group (Table 1). Feeding MeHg significantly increased total Hg concentrations in both liver and brain but to a significant smaller extent in liver when fish were supplemented with Se. Along with the hepatic increase of total Hg, dietary MeHg supplementation decreased total Se content in liver. Dietary inorganic Se supplementation increased total Se concentrations in liver to a larger extent than dietary organic Se supplementation but inorganic Se intake did not increase significantly Se content in brain contrary to organic Se intake.

In liver, MeHg intake increased transcript levels of enzymes involved in cellular stress response and antioxidant defences such as GSTπ and MsrB3 (Table 1). Both dietary organic and inorganic Se supplementation increased hepatic transcript levels of the selenoprotein GPX1a and also SelPa1 but only in HgC groups. In brain, dietary MeHg supplementation decreased transcript levels of RBFOX3, a neural marker, and up-regulated expression of IL-1β, a pro-inflammatory cytokine.

Discussion and conclusion
The growth inhibition by MeHg after only 21 days of feeding could be due to the prooxidant and proinflammatory properties highlighted by gene expression analysis in brain and liver. Fighting against MeHg-induced oxidative stress and inflammation consumes energy that is thus less available for growth (Morcillo et al. 2017). The mitigation by dietary Se supplementation that promoted antioxidant genes lends further support to this hypothesis.

Indeed, at the transcript level we found that MeHg induced inflammation in brain and antioxidant defences in liver to fight against oxidative stress. The antioxidant support by dietary Se supplementation in plant-based diets at the transcript level, in agreement with previous studies (Fontagné-Dicharry et al., 2020), could provide better protection against xenobiotics like MeHg in rainbow trout juveniles, even if the controlled genes by dietary MeHg and Se are not systematically similar and deserved further investigation for a better understanding.

(Continued on next page)

Table 1. Effects of dietary MeHg and Se supplementation and their interaction on growth performance, total Hg, total Se and gene expression (normalised with luciferase and EF1α to the control group HgC-SeC) in liver and brain of rainbow trout juveniles fed for 3 weeks using two-way ANOVA. GSTπ, glutathione S-transferase; MsrB3, methionine sulfoxide reductase B3; GPX1a, glutathione peroxidase 1a; SelPa1, selenoprotein Pa1; IL-1β, interleukin 1β; RBOX3, RNA binding fox-1 homolog 3.

	Dietary MeHg group		Dietary Se group			Interaction
	HgC	HgH	SeC	SeI	SeO	
Final mean body weight (g)	42.7	41.9	41.7	42.6	42.6	**0.025**
Liver total Hg content (µg/g)	0.3^{b}	5.9^{a}	4.1^{y}	2.5^{z}	2.6^{z}	**0.008**
Liver total Se content (µg/g)	18.8^{a}	16.0^{b}	2.6^{z}	33.4^{x}	16.1^{y}	**0.002**
Brain total Hg content (µg/g)	0.4^{b}	3.6^{a}	1.9	1.8	2.2	0.624
Brain total Se content (µg/g)	1.2	1.1	0.8^{y}	1.0^{y}	1.7^{z}	0.920
Liver GSTπ transcript level	1.4^{b}	2.1^{a}	1.4	2.1	1.8	0.858
Liver MsrB3 transcript level	1.9^{b}	2.4^{a}	1.8	2.3	2.3	**0.040**
Liver GPX1a transcript level	1.3	1.3	1.1^{y}	1.4^{z}	1.4^{z}	0.230
Liver SelPa1 transcript level	1.5	1.6	1.5	1.6	1.7	**0.002**
Brain IL-1β transcript level	1.6^{b}	2.5^{a}	1.7	2.2	2.3	0.190
Brain RBFOX3 transcript level	1.1^{a}	1.0^{b}	1.0	1.1	1.0	0.740

The present results provide evidence of interactions between dietary MeHg and Se on tissue Hg and Se concentrations, especially in liver. The difference of Hg and Se storage between the two tissues suggest post-absorptive interacting effects between Hg and Se maybe at the depuration level due to their strong affinity for each other as suggested by Amlund et al. (2015) in zebrafish but do not exclude interactive effects at the digestive or absorption level that deserve further investigation. As muscle, the edible part, has been shown to readily accumulate MeHg (Berntssen et al. 2004), this tissue should be included in the study to ascertain this finding with different dietary Se levels and forms.

Our data showed that the dietary level of 2 mg Hg/kg diet supplied as organic mercury induced adverse effects as early as 21 days of feeding, especially in Se-deficient diets, in agreement with the threshold levels of dietary MeHg set as 5 mg Hg/kg by Berntssen et al. (2004) for salmonid diets. In brain, our RBFOX3 results confirm the high sensitivity of neurons to MeHg toxicity (Ni et al. 2014). Longer exposure, for example up to 6 months, should be assessed in rainbow trout juveniles for a better understanding on the adverse effects of MeHg and the interacting effects with dietary Se.

Introduction

The European eel (*Anguilla anguilla*) is a high commercial valued species for aquaculture. Nowadays, the control of the reproduction and the ability to produce eels seems to be the unique sustainable solution to reduce the pressure on eel natural populations (Kagawa et al., 2009; 2013). Traditionally, the European eel has been induced to sexual maturation by hormonal injections (Asturiano, 2020), but the weekly injections require repetitive handling, which causes stress to the fish. In this sense, the study of new methods must be a powerful tool to optimize the sexual maturation protocols in this species. The goals of this study were *i)* to validate osmotic pumps as a system to induce the sexual maturation in both sexes and *ii*) to evaluate the production and quality of gametes both from males and females.

Material and methods

Eels were moved to our facilities in the Universitat Politècnica de València, Spain. Regarding males, the eels were divided in Control, OP-100 and OP-200 groups (n=10 per group). The control group received weekly injections of hormonal treatment (hCG_{rec}, 1.5 IU/g fish) for 15 weeks. The induction of sexual maturation of osmotic pumps (OP) groups was carried out by implanted hCG_{rec}-loaded osmotic pumps (ALZET 1004 and ALZET 2006, respectively). Sperm samples were collected weekly by stripping and several sperm parameters were assessed using software CASA. Biometric parameters such as fin color and gonadosomatic index were evaluated

Concerning females, the eels were divided in Control (n=11) and OP-2ML4 group (n=10). The control group received weekly injections carp pituitary extract (CPE; 20 mg/kg fish) for 15-20 weeks. The induction of sexual maturation of OP-2ML4 was carried out by CPE-loaded osmotic pump ALZET 2ML4. The females were weekly monitoring and samples of oocytes were collected using a cannula. The ripe females were carried out to spawning using DHP injections. The eggs were collected by stripping and some fertilization trials were done. Biometric parameters such as gonadosomatic index were also evaluated.

Results and discussion

Concerning males, outcomes from study showed that the implantation of osmotic pumps ALZET 1004 and ALZET 2006 were able to induce the sexual maturation and gamete production in European eel males (Fig. 1A). In that sense, OP groups reached gonadosomatic index values of 2.23 ± 0.81 (OP-100) and 3.06 ± 1.43 (OP-200), also showing a fin colour darker throughout the maturation treatment.

Regarding gamete production, while the Control group generated 90% of spermiating males from 8th week, and sperm samples from this group showed high quality (>70% of motility) during the peak of the spermiation period (12-15th week), the Osmotic Pumps groups (OP-100 and OP-200) did not show enough values of volume (Fig. 1B), density (Fig. 1C), and motility (Fig. 1D).

Concerning females, the use of osmotic pumps also became as an effective method to induce the sexual maturation. The 80% of females of OP-2ML4 group reached the sexual maturation and the 50% showed an unusual early maturation between 4th and 10th week (Fig. 2). Several females were successfully induced to spawning, reaching embryos stage.

Therefore, this study showed that the use of osmotic pumps was able to induce sexual maturation, spermiation and ovulation on European eel. In the case of males, results showed that osmotic-controlled release delivery system have not still enough potential to produce acceptable values of sperm quality parameters for aquaculture purposes. However, in European eel females the osmotic pumps were able to generate spawning females so this method could become and viable alternative for eel hatchery procedures.

[b]Centro de Conservación de Especies Dulceacuícolas de la Comunitat Valenciana (CCEDCV). Plaza 04, El Palmar, Valencia, Spain.

Introduction

The sensitive state of conservation of several endemic fish species such as Iberian toothcarp (*A.iberus*) and Valencia toothcarp (*V. hispanica*) has led local government to consider the implementation of conservation measures to preserve their populations (GVA, 2015). In fact, they are included in the IUCN Red List of Threatened Species, classified as "Endangered" (*A. iberus*) and "Critically endangered" (*V. hispanica*).

The *in-situ* measurements carried out during the last few decades have been successfully supplemented with the *ex-situ* conservation action (captive breeding programs and periodic repopulations) carried out at the Center for the Conservation of Freshwater Species of the Valencian Community (CCEDCV, El Palmar, Valencia). However, the limited knowledge about the reproductive biology of these species makes necessary to investigate different aspects of their reproductive cycle, to improve their population management. Besides, to complement the conservation tasks, one strategy currently applied in fish management is the creation of genetic resources banks (GRBs) by cryobiology techniques (Martínez-Páramo et al., 2017). In this sense, the main objectives of this work were *i*) to improve the knowledge on the breeding biology of both species, and *ii*) to develop protocols for the conservation of gametes for the future management and conservation.

Material and methods

Temporal series of samplings were carried out in different places in the Comunitat. Valenciana (Spain) for catching the fish. Sperm samples were collected by stripping. Sperm motion (motility and velocity) and sperm morphometric parameters were assessed by using CASA and ASMA software, respectively (see Gallego & Asturiano; 2018). A protocol based on PBS medium and 10% (v/v) of methanol as cryoprotectant was applied for cryobanking the sperm of these threatened species, where high quality sperm samples (>60% motility) were used at the beginning of the trial.

Results and discussion

Sperm kinetic patterns were similar in both species, which showed high motility values until 30 s post-activation, reaching maximum motility values of 71.2 and 74.8% (*A. iberus,* Fig. 1A; *V. hispanica*, Fig. 1C). Both species displayed high curvilinear velocity values at the beginning of the activation process, reaching the highest values of 169.5 and 198.3 μm/s (*A. iberus,* Fig. 1B; *V. hispanica*, Fig. 1D). Spermatozoa from both species showed similar features to other external fertilizers belonging to Cyprinodontiformes, with spherical heads, uniflagellated and without acrosomes (Table 1).

Cryopreserved samples showed lower motility than fresh samples but reaching acceptable percentages of motile cells after thawing of around 20 and 25% (*A. iberus* and *V. hispanica*, respectively). Several authors have reported in other fish species with similar technical limitations (hard management, tiny sperm volume, *etc*), similar motility results in cryopreservation trials (Diogo et al., 2018; Fernandes et al., 2019).

This study improves our knowledge on the reproductive biology of *A. iberus* and *V. hispanica* by reporting sperm motion parameters and spermatozoa morphometric features. In addition, this study is the first of its kind to achieve gamete cryopreservation of these two endemic and endangered fish species. These are all new tools which can be used to complement the management and conservation programs that are being developed.

Introduction

Marine organisms are subjected to various extreme environmental conditions (temperature, salinity, light, pH, nutrients availability) which affect their chemical composition and lead to the production of diverse metabolites that can be used as ingredients in industrial food production (Kim, 2015). It is important to find the appropriate extraction method of marine metabolites to preserve their biological potency as they give a nutritional value and health benefits when applied in the food products. Many marine-based food ingredients belong to the category of nutraceuticals, which are defined as bioactive substances that have physiological benefits or can provide protection against chronic diseases (Rasmussen and Morrissey, 2007).

Encapsulation

Rapid development of technology and increased consumer awareness of the close relationship between diet and health has forced food researchers to develop and create new products with functional properties (Waterhouse and Sun-Waterhouse, 2018). Among many ways of incorporating the beneficial compounds into the food, encapsulation is one of the most emerging. It is defined as a physicochemical or mechanical process of entrapping active agents within a carrier material (Kostov et al. 2016). This protective barrier is "temporarily isolating" the substances from the surrounding environment (e.g. light, temperature, moisture or oxygen) and enables its controlled release at a target site (Oliver and Augustin, 2009). Carrier materials, known as encapsulants, can be made of various carbohydrates, proteins and lipids.

Application in cheese

Encapsulation process finds its application in cheese production where extracted compounds from marine organisms can enhance functional properties of cheese. Various types of fish, microalgae, sponges, marine microorganisms, like bacteria and fungi, are capable of synthesizing polyphenols, polysaccharides, pigments, vitamins, minerals and other compounds that can be entraped and secured in microcapsules and then added in cheese during its production (Parte et al., 2017). For example, derived marine enzymes are extremely resistant to temperature and pH oscillations. Hence, they can provide numerous advantages over traditional enzymes used in cheese production. Proteinase can be used in protein coagulation of various cheese types or they can help removing the milk oxidized flavour (Rossano et al., 2011). Furthermore, marine polysaccharides, can improve cheese quality acting as stabilizers (Rasmussen and Morrissey, 2007), enhancing its texture, creaminess and controlling syneresis. Also, sulfated polysaccharides and polyphenol extracts exhibit good antioxidant and antimicrobial activities (Fleita et al., 2015) that contribute to the longer shelf-life of cheese. Various bioactives have antifungal properties against *Aspergillus* spp. that can cause spoilage and contamination of cheese by producing mycotoxins, such as aflatoxins that are known for their potential to cause liver damage and acute poisoning (Bhosale et al., 2000). Compounds isolated from the algae are known for their health benefits, for instance vitamins A and B, fatty acids and pigments are known for their body weight, blood pressure and blood sugar regulations (Krishna Koyande et al., 2019). The addition of calcium-rich algae in cheese can help in absorption of that element and prevent hypocalcemia (Ścieszka and Klewicka, 2018).

Conclusion

Incorporation of marine-based bioactive compounds into cheese would greatly contribute, not only to the technological and sensory properties of cheese, but also to the improvement of the consumers health, thus making it a possible new trend in cheese production.

Introduction:
In Europe, as well as in many other western countries, jellyfish (JF) are not a traditional food, they are not usually consumed and the JF market is probably limited to Asiatic communities. The use and marketing of JF in Europe is still hindered by the regulation on novel food (Commission Regulation EU 2283/2015) and mainly by the absence of standard methods for the treatment and processing of the raw material according to the EU safety standards. JF is considered a traditional food in Asian countries, such as China, Japan, Korea, Thailand which host the majority of consumers and producers. Although JF did not make its way to European consumers, some JF species originating from the EU were exported to East Asia for consumption.

Traditionally JF are soaked in a mixture of NaCl and aluminum salts. This procedure reduces the water content and changes the JF gelatinous tissue into the consistency expected for the final edible product. This product is generally characterized by a crispy and firm texture highly appreciated by the Eastern market. However, aluminium, that is so extensively used in this procedure, is supposed to cause memory impairment and cognitive dysfunctions, which would lead to neurodegenerative diseases such as Alzheimer's and Parkinson's disease. Then, a reduction of dietary intake of aluminium is highly recommended. In Europe a Tolerable Weekly Intake (TWI) was established of 1 mg aluminium /kg body weight/week; however, the limits could even be more restrictive for overexposed populations.

Then, new processes have to be designed to obtain final products observing safety and quality standards, maintaining nutritional traits, having sensory properties suitable for Western consumers. This is particularly true for raw material that has no history as food in western Countries and specifically in the European area (Torri et al., 2019). In within the GoJelly H2020 project, a new process and jellyfish-based products were developed.

Material & Methods:
An accurate search of possible already existing methods for JF processing/treatment for food uses was performed. Then, the laws in force in terms of food safety and process hygiene criteria were considered to establish the most important quality and safety parameters, in compliance with European Union laws, to be applied to JF-based foods.

Rhizostoma pulmo was used as a model of edible JF for the setting-up of the processing procedure. Among all already available food additives and information on their possible use in EU, U.S.A., Australia and New Zealand, some of them were chosen for treating JF tissue, in order to reduce the development of enzymatic activities and undesired microorganisms and to improve the texture and nutraceutical traits of the semi-finished product.

Safety assays (microbiological, biogenic amines), physico-chemical (texture, pH, salinity), nutritional (fatty acids, protein content, antioxidant activity, elemental content, aminoacids, etc.) analyses were performed on JF treated samples. Accredited standard parameters established by the law in force regarding food safety and process hygiene criteria were also applied.

A completely new jellyfish processing chain for the design of human foods in a "western style" was developed at CNR-ISPA, Italy, on Mediterranean species, and treated JF were used to design and preparation of different new jellyfish-based food prototypes. They were tested for safety, quality, sensory traits, as well as for their shelf-life. The procedure was also tested on JF species sent to Italy from the other GoJelly partners.

(Continued on next page)

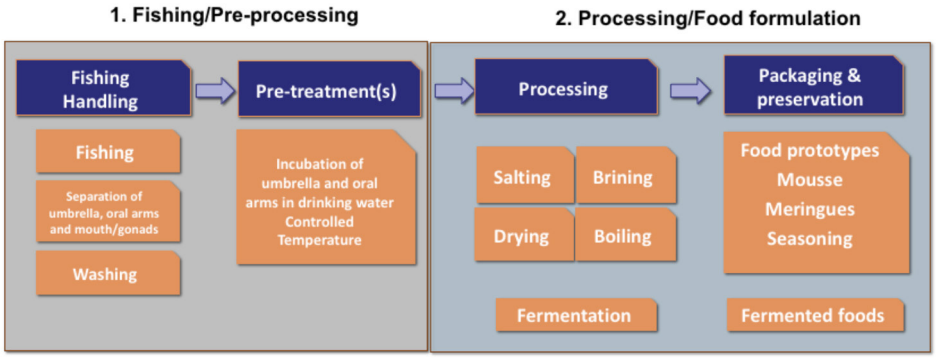

Figure 1. Flow chart of the new food chain for JF treatment for food uses developed at CNR-ISPA.

***Results**:*
In the absence of specific indications, a set of market safety standards in force in Europe for food products comparable to JF, together with diverse essential hygienic criteria valid for fish and fish-derived foods in some European Member States, were considered and successfully applied to the barrel JF, *Rhizostoma pulmo*, from the Ionian Sea Italian coasts, that was assessed as a model for human food.

A protocol for the stabilization and processing of *R. pulmo* JF into a semi-finished food product without using alum was developed at CNR-ISPA, Italy. Safety and quality parameters, together with a series of technological and nutritional traits were used to monitor and characterize the JF obtained products (Bleve et al., 2019). Some food thickening/stabilizing agents allowed in the EU were able to control possible microbial pathogens and spoilage species to increase the texture and nutritional traits.

Different new food prototypes obtained by treated JF were studied at laboratory scale: a) drying; b) cooking under vacuum; c) formulation of new JF-based foods. Laboratory-scale prepared food prototypes were tested for main quality and sensory traits and preliminary data on the final product shelf-life were produced. Finally in collaboration with professional chefs JF-based recipes were proposed.

Discussion & Conclusion:
A new flow chain for JF preparations, from the starting material to semi-finished food products, was developed (Figure 1).

The obtained products are very different from the traditional Asiatic ones. Still the possible production of JF as human food by replacing alum with salts allowed by the EU regulations as stabilizing and thickening agents, was demonstrated. This new procedure can offer new food chain opportunities based on JF and JF-derived foods to be considered novel food acceptable in the EU. A European Patent describing the developed procedure was deposited by CNR-ISPA, Italy, on July 2020.

The proposed method can also be applied for the stabilization/treatment of other abundant and putatively edible JF species in Mediterranean Basin and in other Seas. New JF based food prototypes following a "Western Style" have been designed.

NEW GRADING DEVICE WITH NOVEL STRUCTURES INCREASES SELF- GRADING SUCCESS OF WHITELEG SHRIMPS *L. vannamei* IN AQUACULTURE CULTIVATION SYSTEMS

Mirko Bögner*, Amirhossein Karamyar, Christian W.G. Detsch, Matthew J. Slater

Alfred Wegener Institute Helmholtz Center for Polar- and Marine Research, Am Handelshafen 12, 27570 Bremerhaven, Germany

Introduction

Uneven growth of aquacultured shrimp leads to an increase in cannibalism, untargeted feeding and uneven product size. Size grading can prevent these effects. However, current sorting methods are highly invasive and cause high stress levels and flight responses. The animals can injure themselves and may even jump out of the tank.

In this study, a size grading device was developed that allows the animals to sort themselves voluntarily according to size in the cultivation tank. For this purpose, innovative structures were developed that are specifically adapted to the body shape and behaviour of the animals. These structures are conceptualised to either encourage or discourage passing of the grading device. Results demonstrate strong grading effects (75 %) on the distribution of shrimps between different tank compartments and the ability to separate shrimps of different size voluntarily (up to 85%). Small animals can be separated from the cohort without stress or any personnel effort and a uniform size distribution of the shrimps can be guaranteed.

This voluntary grading system is expected to increase animal welfare and growth performance in shrimp farms while it reduces labour.

Material and Methods

In the first experiments sorting elements (through which shrimp could pass) with different structures (tubes, wedges, bars, V- shaped) were installed in the middle of the experimental tanks (2.5 x 0.7 x 0.7 m) (N=3). The control group had a perforated sorting element plate as a subdivision (N=3). Twenty-five shrimp (18.4 g ± 2.9) were placed on each side of the tank and shrimp were of a size theoretically capable of passing the structures and perforated plates in both directions. The structures facilitate or make it harder to pass the device in one direction and thus divide the tank into a “sorting” and “non sorting” area. For each structure the distribution of the shrimps was documented hourly for 36 h. The most effective structure was used in subsequent experiment. In this experiment, twenty-five small (2.6 g ± 0.6) and twenty-five large shrimp (14.6 g ± 2.9) were placed in the “unsorted” area of the tank. The structures were narrowed so that only the small animals could cross it into the “sorting” area. Shrimps in both tank areas were counted hourly for 72 h.

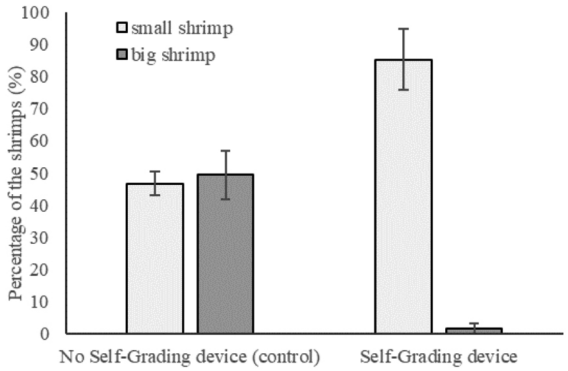

Fig.1: Proportion of large and small shrimp in the “sorting” area after 72 h using grading structure and without.

(Continued on next page)

Results and Conclusion

In the first experiments, tubular structures resulted in 73% of animals moved into the sorting area. The use of wedges (59%) and bars (57%) had little supporting effect. The combination of wedges and tubes caused 75% movement to the sorting area as did the V-shaped structure. In the second experiment with mixed size groups, the V-shaped structure caused about 85% of the small individuals to migrate into the sorting area (Fig. 1).

Tested devices with novel structures are effective and achieve high levels of self grading in shrimp.

UP-SCALLING THE APPLICATION OF HYDROGEN PEROXIDE AS DESINFECTION METHOD IN A COMMERCIAL RAS REARING ATLANTIC SALMON (*Salmo salar*): A CASE STUDY

Introduction

Disinfection is a very important part of recirculation aquaculture systems (RAS). RAS allows for controllable environments in which main variables relevant to animal welfare and a successful production can be manipulated as required to improve efficiency and profitability. Common disinfection methods include chemical disinfectants, antibiotics, biocides, UV radiation and ozone. They can be used to treat disease outbreaks, or to reduce the bacterial load of the system which otherwise could lead to the overgrowth of potential pathogens or opportunistic bacterial groups competing with biofilter bacteria for space and resources. Ozone is the most used disinfection method requiring expensive technology and trained stuff. Hydrogen peroxide (H_2O_2) has been on focus as a "green" alternative. High H_2O_2 doses are associated with acute toxicity symptoms for some species. Low doses are harmless, offer additional system oxygenation and contribute to water quality improvement. After testing the use of low doses in a small research RAS, the present study aims to describe the first case study up-scaling a continuous hydrogen peroxide application to commercial fish production in RAS with focus on the determination of required concentrations, application monitoring and variations on microbiome composition.

Material and Methods

The present study was performed at RAS facilities of Danish Salmon A/S in Hirtshals, Denmark, one of the European pioneers in rearing salmon in land based aquaculture facilities and producing about 1.200 metric tons/year of Atlantic salmon (*Salmo salar*). Two identical Grow-out RAS with own water treatment elements and eight pre-grow tanks were used as treatment and control systems to compare the effects of continuous H_2O_2 application in combination with ozone to common operational practice. Oxygen Cones and additional aeration stones ensured the basic Oxygen supply in the tanks. Defined H_2O_2 quantities were applied with a dosing lance connected to a peristaltic pump and an International Bulk Container with PERSYNT® 50, (EVONIK Industries) into the distribution pipe feeding a collection tank from where the water was evenly distributed to all tanks. Based on previous experiments, a final dosing of about 20 l/h was projected. Water samples were collected at the start (REF) and after slowly enhancing the dosage over time (24h and 30d), for the determination of the total microbial count (certified chromogenic Compact Dry TC plates from R-Biopharm), microbial viability (BacLight Viability Kit) and bacterial community composition (FISH). Water parameters (Ammonia, Nitrite, Nitrate, Phosphate, COD, Turbidity and H_2O_2 concentration) and production related information (feeding rate, fish biomass, oxygen consumption, ozone production) were also regularly evaluated.

Results and Discussion

H_2O_2 application started on August 06, 2020 with 1 l/h (0.51mg/L) and was increased over time up to 14 l/h (7.09 mg/L) (Fig1). On September 30, 2020 the application was stopped due to detected changes on feeding behavior of the fish as well as incorrect redox measurements in the treatment system which could probably be attributed to accumulation of oxidative species not having enough organic material to react. The test and control systems had similar biomass during the experimental period (test: 34.9-52.5 tones and control 36.4-51.4 tones) and the feed intake was accordingly adjusted (mean feed intake test: 496 kg/day; control 450 kg/day). The oxygen demand registered on the treated system (82 l/min - 90 l/min) was lower than the control (104 l/min - 115 l/min). In general, there was a reduction of turbidity and decreased nitrogen species and phosphate in the treated system. System maintenance (biofilter cleaning and backwashing) might had influenced the COD and total microbial counts measurements. Total microbial counts reflected a steady increase in the number of CFU/ml in both systems (Fig.2) and evidenced microbial accommodation. There was an increased rate of microbial mortality according to the viability results with higher values in the treated system reflecting the longer exposure of this system to oxidative stress (Fig 3). The community composition varied according to the treatment (Fig.4) and changes in the abundance of the different bacterial groups analyzed could be attributed to variable vulnerability of members of these groups to the disinfection potential of H_2O_2 or its combination with ozone.

Introduction

Further development of recirculating aquaculture systems (RAS) towards zero-exchange depends mostly on the improvement of water treatment technologies. Ozone and UV radiation are leading technologies requiring high energy demand and educated staff able to manage the hurdles of their application. Moreover, there are some constrains for systems with poor mechanical filtration or where accumulation of particles higher than 50 μm significantly reduce the penetration potential of UV application. An alternative method commonly used in wastewater treatment to eliminate particulate aggregates is sonication. This method is based on cavitation effects which contribute to disrupt bacterial bioflocs and to break microbial cell walls leading to reduced viability. The present study aims to evaluate the disinfection capacity of a prototype created to treat process water in a RAS rearing aquaculture relevant freshwater and saltwater species with three sonication frequencies. The potential impact on the microbiome of the system in different compartments beside the reactor as well as bacterial viability was evaluated.

Material and Methods

An ultrasound prototype composed of 12 inducers connected to control devices was created in the frame of this project and adapted to a 5 m^3 research RAS composed of three rearing tanks, a drum filter, 2 biofiltration units (nitrification-denitrification), a sump and a protein skimmer with ozone disinfection. For the experiments the system was initially prepared for rearing European Seabass (*Dicentrarchus labrax*) and in a second experiment for rearing tilapia (*Oreochromis niloticus*). Process water coming from the sump was conducted into the prototype at a flow rate of 10 l/min and treated with 575 kHz, 862 kHz and 1142 kHz without further disinfection. For the saltwater experiments we tested 50% and 75% frequencies amplitude while only 75% amplitude was used for freshwater experiments. Each frequency was applied for 96 h and daily sampling was conducted to determine variations on microbial viability (BacLight Viability Kit) and bacterial community composition (FISH) with respect to reference samples collected before treatment. For FISH analysis (Fig. 1) generic FAM labelled DNA probes for Eubacteria (EUB) and Archaea (ARCH) as well as more specific probes for α-, β-, γ-, δ-Proteobacteria (ALF, BET, GAM, DELTA) and Actinobacteria (HGC) were included. When available, also non-labelled competitor DNA probes in equimolar concentration as the respective labelled probe were used. All samples were counterstained with DAPI.

Results and Discussion

Marine RAS:
The sterilizing effect was impacted by the amplitude used. Frequencies 575 kHz and 1142 kHz showed higher disinfection potential by 75% amplitude than 50%. The proportion of dead cells increased with the frequency. At 1142 kHz, a decrease in the total number of most of the selected bacterial groups was detected (Fig. 2) while the total numbers of bacteria at the end of application did not significantly change when using 575 kHz and 860 kHz. Sonication with all tested frequencies lead to changes in the bacterial community. Especially at 1142 kHz, a strong decrease in ALF, BET, GAM and ARC and an increase in DEL was observed (Table 1). This suggests a selective effect of US treatment on microbial community.

Freshwater RAS:
The sonication treatment of the system while rearing freshwater species did not show a defined impact with respect to changes in bacterial composition over time. At a frequency of 860 kHz, there was an increase in the number of counted bacteria over time (Fig. 3) while a slightly drop was observed by 575 and 1142 kHz. No marked changes in the composition of the bacterial community were detected for the latter frequencies. For all frequencies tested there was no conspicuous change in the percentage of dead cells.

VIRAL INFECTION DRIVES THE REGULATION OF FEEDING BEHAVIOUR RELATED GENES IN *Salmo salar*

David Muñoz, Andrea Aguilar and Senastian Boltaña*

Departamento de Oceanografía, Centro de Biotecnología, Universidad de Concepción, 4030000 Concepción, Chile
*sboltana@udec.cl

The feeding behaviour in fish is a complex activity that relies on the ability of the brain to integrate multiple signals to produce appropriate responses in terms of food intake, energy expenditure, and metabolic activity. Upon cues stresses, like infection by virus or activating mediators such as proinflammatory cytokines, Prostaglandins and Cortisol, both POMPC and NPY/AgRP neurons from the hypothalamus are stimulated, thus triggering a response that controls both energy storage and expenditure. However, how appetite modulators or neuro-immune cues link pathogenesis and energy homeostasis in fishes remains poorly understood. Here, we provide the first evidence of a molecular linkage between inflammation and food intake in *Salmon salar*. We show that in vivo viral challenge with IPNV impacts food consumption by activating anorexic genes as *mc4r, crf* and *pomcb-1*, and 5-HT in the brain of *Salmon salar*. At the molecular level, viral infection induces an overall reduction of lipid content in the liver, favouring the production of AA and EPA associated with the increment of *elovl2* gene. In addition, infection upregulates leptin signalling and inhibits insulin signalling. These changes are accompanied by a robust inflammatory response represented by the increment of IL-1β, IL-6, TNFα, and PGE2; also, an increased cortisol levels *in vivo*. Thus, we propose a model in which hypothalamic neurons respond to inflammatory cytokines and stress-related molecules and interact with appetite induction/inhibition. These findings provide evidence of crosstalk between pathogenesis-driven inflammation and

NEW INSIGHTS INTO CLOCK GENES AND THE CIRCADIAN SYSTEM IN SALMONIDS

Introduction

Circadian rhythms or 'clocks' are the visual expression of endogenous oscillatory expression of genes and proteins lasting approximately 24-hours, which synchronises biochemical, physiological, and behavioural responses enabling organisms to respond to diel environmental changes (Cox and Takahashi, 2019). They can be directly linked to altered metabolic, physiological and behavioural traits and influence most biological processes (Wulund and Reddy, 2015). The circadian mechanism is highly conserved across organisms however, our understanding of core clock mechanisms and circadian control of fish physiology remains limited (Frøland Steindal and Whitmore, 2019). There is an unusually large complement of clock genes in salmonids as a direct result of the two rounds of whole genome duplication (WGD) events (Ts3R, teleost specific and SSr4, salmonid specific) resulting in an abundance of circadian related genes (Lien *et al.*, 2016). As such deciphering the circadian clock mechanism in salmonids is complex and the functional divergence remains largely unknown (West *et al.*, 2020).

The aims of this study were to describe the effects of the salmonid specific WGD on clock gene diversity in Atlantic salmon. Through phylogenetic analysis, core clock gene ohnologs were classified and renamed. This was confirmed by transcriptomic analyses during early freshwater development of salmon reared under controlled lighting regimes including photoperiodic manipulations and narrow bandwidth lights. New findings provide a tool for further circadian clock research in salmon.

Materials and Methods

The genomes of five species of salmonids (*Salmo salar, Salvelinus alpinus, Oncorhynchus mykiss, Oncorhynchus kisutch, and Oncorhynchus tshawytscha*) were interrogated using *Danio rerio* clock genes [*clock, arntl, period, cryptochrome, nr1d, ror and csnk1e/d*] and *Esox lucius* [the ancestor of all salmonids – a pre-SSr4 duplication outgroup] to further explore the effect of the salmonid specific WGD SSr4 on the clock genes in salmonids. The transcriptomic isoforms with the highest percentage identity to the reference were selected and aligned. Maximum Likelihood (ML) trees were inferred to identify the relationship between identified clock genes and those of the latest common ancestors. Identified putative clock genes were re-classified based on the zebrafish nomenclature and were renamed from their predicted names after zebrafish orthologues.

Two separate cohorts of *S. salar* at different life stages [early development (UiB) and pre-smolt juveniles (UoS)] were kept under controlled lighting regimes and sampled over 24-hours at 4 hrs intervals. A range of lighting conditions were tested during egg incubation including photoperiod (14L:10D-LD, continuous darkness DD, and continuous light-LL), intensity (0.01 W/m^2, 0.1 W/m^2 and 1.0 W/m^2), and spectra (blue, green, red, and white) and at the juvenile/parr stage (12:12 LD vs. LL). RNA was extracted from dissected embryos or tissues (brain and liver) and sent away for RNA sequencing. RNA sequences were aligned to the published genome and gene expression patterns were statistically analysed.

Results

Most clock genes identified in salmonids are duplicated as a direct result of the salmonid specific WGD event SSr4. There are individual gene families in which some members display reciprocal gene loss and gene retention from the latest common ancestors (*E. lucius* and *D. rerio*). RNA sequencing identified that all *S. salar* putative core clock genes identified and classified *in silico* were expressed at both life stages sampled. Expression varied throughout early development from eye pigmentation through to first feeding (255dd – 690dd). Despite noise caused by individual variance two clock genes displayed significantly rhythmic expression patterns over a 24-hour sampling period pre-first feeding (690dd). Exposure to DD appeared to significantly down regulate some clock genes, whereas exposure to LL appeared to significantly up regulate clock gene expression of several clock genes when compared to those on the LD treatment. Spectral composition appeared to significantly influence the regulation of several clock genes. With red and green light treatments appearing to significantly down regulate a few of the identified genes when compared to white light during the midpoint of the light and dark periods. In late fresh water developmental stages (UoS) 262 genes were significantly rhythmically expressed in *S. salar* parr amongst which 13 of the putative core clock genes were identified.

Discussion/ Conclusion

Clock genes are expressed from early development in *S. salar*. Whilst there appears to be variance between individuals relating to the time at which clock genes peak and trough, it appears that as the salmon develop there is an increase in the number of putative core clock genes which are significantly rhythmically expressed. This is indicating maturation of the 'biological clock' or circadian mechanism in *S. salar* throughout freshwater developmental stages. There was a greater influence of the LL photoperiod on the significant regulation of clock genes than DD when compared to the LD group, indicating that the presence of light signals has a greater influence over clock gene regulation than the absence of lighting cues. Spectral composition to a lesser extent than photoperiod also influences the regulation of clock gene expression. However, the effect of intensity at early developmental stages was negligible. The role of feeding from first feeding in entraining the circadian system can be hypothesised. Additional work is required to further elucidate the complexity the circadian mechanism in salmonids and how the complement of clock genes identified function as components of this mechanism.

Introduction

Several land-based abalone (*Haliotis midae*) farms in South Africa have practiced commercial integrated multitrophic aquaculture (IMTA) for many years, using the green seaweed *Ulva rigida* to enable partial water recirculation of bioremediated effluent and to re-use waste nitrogen as feed (Bolton et al. 2009, 2016; Nobre et al. 2010). Buffeljags Abalone Farm (Viking Aquaculture) (34.7550° S, 19.6154° E) produce over 500t of *Ulva* yr^{-1} in abalone effluent in raceway ponds, principally to remove ammonia enabling 50% water recirculation, thus saving ca. 40% of pumping costs. The aim of this study was to measure water parameters to assess the functioning of the system, and to conduct a preliminary trial to assess the effects of increasing the recirculation rate. The latter was carried out on a particularly warm day in summer and included 100% recirculation, which was tested in case of the need for the farm to be isolated from the inbound water stream in the occurrence of a Harmful Algal Bloom (HAB).

Methods

Experiments were conducted on fully commercial abalone systems containing ca. 10 000kg of abalone per module. Two experimental data collections were carried out. Environmental parameters were measured where water enters and leaves the abalone tanks, and where it exits the *Ulva* paddle raceway, in three replicate commercial modules running at the customary 50% recirculation rate, over the course of 24 hours. In addition, over a 3-day period in the summer, single commercial modules were adjusted to compare the 50% recirculation rate with 75% and 100% recirculation, with parameters measured at the sump which directly supplies the abalone tanks. Parameters presented are temperature, pH, Total Ammonia Nitrogen (TAN) and Free Ammonia Nitrogen (FAN), as well as the % removal of TAN and FAN in the *Ulva* paddle raceways at 50% recirculation.

Results and Discussion

Over a 24-hour period at 50% recirculation, temperature varied minimally between sampling points during the experiment, with slight daytime increases throughout. The pH was higher in abalone inbound and *Ulva* effluent water compared to the abalone effluent water. Total ammonia nitrogen percentage removal across the seaweed biofilters ranged from 65%-85% (mean 73%). Free ammonia nitrogen removal across the seaweed biofilters ranged from 41%-80% (mean 63%). A regression analysis demonstrates a strong positive linear relationship between TAN removal and TAN load to the seaweed biofilter (r^2= 0.90). Principal component analysis revealed a strong negative correlation between FAN removal and pH, as pH increased across the seaweed biofilters the proportion of FAN removal decreased.

There were no statistically significant differences (Mood's Median Test, $p>0.05$) between the 50% and 75% recirculation cluster for temperature, pH, TAN or FAN. Statistically significant differences occurred between 100% and 50% recirculation, 100% and 75% recirculation and 100% recirculation and ambient conditions for pH, TAN and FAN, whilst no statistically significant differences occurred for temperature. At 100% recirculation, TAN and FAN increased rapidly, though the commensurate rapid and considerable decrease in pH meant the FAN increase was not as high as it would be at a normal seawater pH of ca. 8.2. Abalone suffered no mortalities at 100% recirculation for three days and later reports from the farmers suggested no effects on growth rate in the months following the experiment. TAN levels breached WWF guideline maximum effluent concentrations for abalone aquaculture (0.6mg/L = 35.23 μM/L) only in the 100% recirculation cluster, and only then during three of the thirteen sampling runs. The TAN concentrations in 50% and 75% recirculation treatments were far below the WWF guideline maximum effluent concentration with maximum concentrations of 7.15 µM/L in 50% and 13.46 μM/L at 75%.

Some increase, up to 75%, in recirculation rate seems feasible for maintenance of normal farm functioning, and these results suggest that short-term 100% recirculation to reduce or prevent HAB impact can be a practical solution.

Introduction

Plant-based protein (mainly soybean meal) is one the major protein source for fish feed, however since EU has a 70-80% protein deficit, it massively imports soybean from third countries. On the other hand, in order to produce enough plant-based proteins to satisfy the needs of the whole animal and aquaculture sector, about 20-30% of EU arable land should be dedicated to this purpose (Martin, 2014). Furthermore, soy and other plant-based ingredients, naturally contains anti-nutritional factors (ANFs) such as trypsin inhibitors and oligosaccharides that can hinder digestibility. Therefore, alternatives to plant-based protein sources are needed. The introduction of low-cost microalgae meal from biorefinery would improve sustainability of the entire aquaculture chain by: i) promoting the recovery and reuse of resources, ii) providing an alternative to conventional fish and soy protein and lipid sources and iii) maintaining a high nutritional quality. Previously results about inclusion in aquafeed of microalgae from biorefinery, as partial substitution of fishmeal, suggest that this biomass is a valuable nutrient source able to ensure an adequate growth performance, especially when the microalgae biomass was previously subjected to the hydrolysis treatment (Bongiorno *et al*., 2020). In fact, the release of low molecular weight bioactive peptides and free amino acids induces positive effects on the health *status* of GUT of fish (Galafat *et al*., 2020). No data are yet available regarding the potential replacement of plant-based ingredients with microalgae deriving from biorefineries. This study aims to evaluate the effects of partial replacement of dietary plant-based nutrient sources with different microalgae meals based on *N. gaditana* on growth performance of gilthead seabream (*S. aurata*) juveniles. The replacement included crude and hydrolyzed microalgae biomasses, coming from both biorefinery and conventional cultivation system.

Materials and methods

N. gaditana microalgae, grown on conventional Synthetic Medium (SM) and diluted Pig Manure (PM), were included in aquafeeds as hydrolyzed (Galafat *et al*., 2020) or crude biomasses. In particular, five complete experimental diets were formulated to be grossly iso-proteic and iso-lipidic. Control diet (C) was prepared using a blend of conventional animal and vegetal protein sources while experimental diets were prepared replacing the 5% of plant-based protein and lipid by *N. gaditana* grown on Synthetic Medium (crude (SM-C) or hydrolyzed (SM-H)) and grown on Pig Manure (crude (PM-C) or hydrolyzed (PM-H)). Each diet was randomly assigned to tanks and tested in triplicate according to a mono-factorial design. Microalgae dried biomass and diets were analyzed microbiologically and verified for nutritional quality. To carried out the feeding trials at pilot-scale, 900 *S. aurata* juveniles (average 36.1±0.02g each) were randomly allocated among 15 square-shaped 500-L-fiberglass tanks, (60 fish/tank) in a RAS under controlled rearing conditions (temperature, 23.1°C, dissolved oxygen 8.3 mg/L, artificial day-length, 12h, 300 lux). Diets were offered in two daily meals with a feed ratio between 2-3% body weight, over 12 weeks and each group were weighted every month under moderate anesthesia. At the end of the trial, Survival Rate (SR), Final Body Weight (FBW), Specific Growth Rate (SGR), Feed Conversion Ratio (FCR) and Feed Intake (FI) were evaluated, and fifteen fish per group were subjected to individual biometry and dissected to determine biometric, somatic indices and slaughter yield. All the data were evaluated for normality distribution and differences among treatments were analyzed by one-way analysis of variance (ANOVA) and, if adequate, means were compared using the Duncan's test, set for $P < 0.05$, using SPSS-PC release 17.0 (SPSS Inc., Chicago, IL, USA).

Results and discussion

All the experimental diets resulted similar for their proximate and fatty acid composition as well as for their microbiological quality (data not reported). Growth performance, nutrient utilization, biometric and somatic indices of *S. aurata* juveniles fed the test diets over 12 weeks are shown in Table 1. No significative differences were observed in IBW, FI, SR and biometric and somatic indices ($P>0.05$) except MFI ($P<0.05$). Dietary treatments significantly affected growth parameters, FBW SGR, FCR ($P<0.05$). To date, no data are available on the potential inclusion of microalgae obtained from a biorefinery as plant-based ingredients substitution in aquafeeds. The results obtained in this study suggest that a dietary inclusion of 5% of *N. gaditana,* as partial replacement of some vegetable origin ingredients (mainly soy protein concentrate), improves the growth performance in seabream juveniles after 90 days of feeding, independently of the biomass treatment and the growth medium used. Further studies are underway to verify both the quality of the fillets and the health *status* of the GUT in those seabream specimens.

Introduction

Conventional land-based crops like grains, pulses and their derivatives are commonly used as feasible alternative for partial replacement of fishmeal and fish oil in aquafeed production. However, these ingredients usually have imbalanced nutrient profiles as well as anti-nutritive factors that may negatively affect nutrient digestibility and bioavailability, and hinder their use in aquafeeds, especially at high inclusion level. In this regard, microalgae can be considered as a potential alternative to plant-based protein sources. Microalgae has been successfully evaluated as dietary ingredients in different fish species, although their high production costs and the existence of a cellulosic-rich cell wall, that could limit the bioavailability of nutrients, are two of the main bottlenecks for their generalized use in commercial feed formulation. Because of this, growing microalgae in agro-industrial waste could be of interest in the context of a circular economy, not only for recycling valuable nutrients but also for reducing the microalgae production cost. In addition, the use of enzymatic hydrolysis treatment of microalgal biomass before inclusion to aquafeeds could be a valuable tool for improving its performance as dietary ingredient. Given these considerations, this study aims to assess the effect of the dietary inclusion of crude and hydrolyzed *Nannochloropsis gaditana* biomasses produced in a sustainable bio-refinery on the activity of digestive enzymes in gilthead seabream (*Sparus aurata*) juveniles.

Materials and methods

Nannochloropsis gaditana biomasses produced on synthetic medium (SM) and on 1:10 (v/v) diluted pig manure (PM) were obtained from the SABANA facilities (Universidad de Almería, Spain). Enzymatic hydrolysis of microalgae biomasses was carried out using the procedure described by Galafat *et al*. (2020). A pilot scale feeding trial was carried out at the Istituto Sperimentale Italiano L. Spallanzani (Italy). After the acclimatation period, 900 gilthead seabream (*S. aurata*) juveniles (36.1 g) were randomly distributed in fifteen 500-L fiberglass tanks (60 fish/tank) and fed (2-3% fish biomass) with five experimental diets; i) a microalgae-free diet (Control, CT), and ii) four diets replacing 5% of plant-based protein and lipid ingredients by *N. gaditana* grown on synthetic medium [crude (SM-C) or hydrolyzed (SM-H)] and grown on pig manure [crude (PM-C) or hydrolyzed (PM-H)]. All the diets were tested in triplicate over 12 weeks. At the end of the feeding trial, fish were euthanized and sacrificed by spine severing and the whole digestive system were obtained from four specimens per tank. The proximal and distal intestinal segments were separated for analysis. Tissue samples were randomly pooled to obtain twelve different enzyme extracts per dietary treatment, and total alkaline protease, trypsin, chymotrypsin, leucine aminopeptidase and alkaline phosphatase activities were measured according to Vizcaíno *et al*. (2014). In addition, the effect of dietary treatments was evaluated considering three different factors: i) use of microalgae (with or without dietary inclusion), ii) type of fertilizer used for producing microalgae biomasses (SM vs PM), and iii) enzymatic hydrolysis of microalgae biomasses (crude biomasses vs hydrolyzed biomasses).

Results and discussion

The results of the analysis of digestive enzyme activities are summarized in Table 1. Overall, the use of microalgae biomass did not negatively affect none of the digestive enzymes studied. All the enzymes, except for alkaline phosphatase, showed significantly higher activity levels in the distal region of the intestine compared to the proximal region ($p<0.05$). Trypsin, chymotrypsin, and total alkaline protease activity levels were higher in fish fed on *Nannochloropsis*-supplemented diets ($p<0.05$), which might increase the availability of small peptides favouring the digestion process. Leucine aminopeptidase and alkaline phosphatase remained unaffected. A significant effect of the type of fertilizer used for growing microalgae was observed. Chymotrypsin and total alkaline protease activities were significantly higher in fish fed on diets supplemented with microalgae grown on SM in both proximal and distal intestinal regions ($p<0.05$). Similarly, feeding fish on diets

Data are mean ± SD (n=12). Codes: LEU (leucine aminopeptidase); AKP (alkaline phosphatase); TRY (trypsin); CHY (chymotrypsin); TAP (total alkaline protease). Different small letters in the same row denote significant differences among dietary treatments (ANOVA, $p<0.05$). Factors are: i) Microalgae (with or without microalgae inclusion), ii) Fertilizer (synthetic medium vs diluted pig manure), and iii) Treatment (crude biomass vs hydrolyzed biomass). For the different factors, significant differences were stablished by a comparison of means (Student's t-test).

supplemented with microalgae hydrolysate induced an increase in the activity level of these last enzymes, but only in the proximal intestine. As a conclusion, the positive effect observed in this study confirmed the usefulness of *N. gaditana* produced in a sustainable bio-refinery for feeding gilthead seabream juveniles. Additional research is needed to evaluate the effect on different aspects of the physiological status of fish as well as to determine whether these biomasses meet the nutrient standard required to be used as dietary ingredients for feeding this fish species.

GROWTH, SEAWATER ADAPTATION AND STRESS RESPONSE OF DIPLOID AND TRIPLOID ATLANTIC SALMON (*Salmo salar*) FED TWO DIFFERENT DIETS DURING SMOLTIFICATION

Introduction

Recently, the use of artificially induced triploid fish has received great attention in the Atlantic salmon (*Salmo salar*) farming industry. Triploidy is generally induced in fish to produce sterile individuals for reproductive control and genetic containment. Moreover, triploidy induction represents one of the easiest and suitable methods to avoid adverse effects of pre-harvest sexual maturation, such as reduced growth and flesh quality deterioration (Piferrer et al., 2009). Nevertheless, triploidy may display some critical issues related to smoltification, a delicate process of physiological changes controlled by the GH/IGF axis that enables young salmonids transition from freshwater to seawater. Moreover, it may lead to growth impairments. In fact, previous studies have reported a higher incidence of vertebral deformities in triploid than diploid salmons due to the different dietary requirements for phosphorus and amino acids compared with their diploid counterparts (Smedley et al., 2016). Hydrolyzed fish proteins have high concentrations of free amino acids that may be absorbed more efficiently, enhancing nutrient utilization and fish growth (Olsen and Toppe, 2017; Peruzzi et al., 2018). On this basis, the inclusion of these two elements in aquafeeds for triploid fish may guarantee an adequate growth performance and improved fish health. Hence, the present study evaluated growth, seawater adaptation and stress status in diploid and triploid salmon fed high-protein phosphorus-rich fishmeal-based diets to better understand if the physiological changes associated with triploidy and a different feeding regime may influence these aspects during smoltification.

Materials and methods

A total of 60 fish (30 fish per ploidy) were allocated to twelve 200L circular indoor tanks. Triplicate tanks per ploidy were fed either a standard fish meal (STD) diet or a modified diet in which 45% of the fish meal fraction was replaced with hydrolyzed fish proteins (HFM) (15 fish per diet) (Skretting AS, Stavanger, Norway). Phosphorus inclusion in STD and HFM diets (MasterLab, Boxmeer, Netherlands) was equal to 19 g kg^{-1} and 18 g kg^{-1}, respectively, which is considerably higher than the reported requirement of Atlantic salmon (8 g phosphorus kg^{-1} diet). Fish were reared under 12h of light (12L:12D) and at low temperature (10.0±0.5°C) to simulate winter conditions and to induce parr-smolt transformation. Samplings took place every month from October to December and fish muscle and liver were collected. Radioimmunoassay (RIA) and Real Time PCR were used, respectively, to evaluate muscle cortisol levels and to assess growth hormone (GH) and its receptor (GHrec), insulin-like growth factor I (IGF-I), Myostatin (MSTN) and heat shock protein (HSP70) muscle gene expression. An in-situ hybridization was performed on liver's sections using a novel and highly sensitive multiplex nucleic acid technology called RNAscope®, which allows to detect and localize at the cellular level IGF-I mRNA in formalin-fixed paraffin-embedded organs. Data of gene expression and IGF-I mRNA were expressed as mean ± standard error. Prior to statistical analysis, all the data were evaluated for normality distribution. Differences between treatments were analysed using a mixed model and, if adequate, means were compared using the Satterthwaite's method, set for $p < 0.05$, using R software.

Results and discussion

Cortisol levels showed significant differences according to both ploidy and sampling time, with higher levels in triploids and in November, suggesting this month as crucial for salmon smoltification. No significant changes were found in GH, GHrec and IGF-I expression according to diet or ploidy, whereas variations were found according to sampling time, where gene expression increased from October to November. The in-situ hybridization of liver sections mirrored this trend, as the parenchyma of the November samples was evidently more positive to IGF-I probe than that of the October ones. Indeed, during salmon smoltification, GH by mean of IGF-I along with cortisol can improve salinity tolerance, as they are key molecules involved in fish osmoregulation and saltwater adaptation, and the observed increase in their levels underlines once again how they act in synergy. As for MSTN expression, it did not show significant changes, indicating that myogenesis was not affected by any of the three factors studied. The same result was obtained for HSP70, given the optimal conditions and low temperatures in which the animals were reared.

(Continued on next page)

Conclusions

The obtained results confirmed that smoltification period was successfully induced, given the significant changes in cortisol levels and in GH, GHrec and IGF-I expression over time. Given that ploidy and diet seemed to have little or no effect on growth, seawater adaptation and stress response, we can conclude that no significant physiological changes associated with triploidy and feeding regime have negatively impacted these aspects. Besides, the use of artificially induced triploid salmons is a proper solution to contain the drawbacks resulting from farmed escapes and pre-harvest sexual maturation cases, which are two main concerns for the Atlantic salmon farming industry.

BIOFLOC-BASED PHENOTYPE SWITCHING IN *Vibrio parahaemolyticus* PROTECTS AGAINST AHPND IN SHRIMP

P. Bossier, V. Kumar, M. Wille, T. Margarida Lourenço

Lab of Aquaculture & Artemia Reference Center, Department of Animal Sciences and Aquatic Ecology, Faculty of Bioscience Engineering, Ghent University, Ghent, Belgium
Peter.Bossier@ugent.be

This study aimed to describe the underlying mechanism behind the AHPND protective effect of a biofloc system in *Litopenaeus vannamei*. First, the results confirmed that a biofloc system maintained at a C/N ratio of 15, improves the water quality and contributes to the nutrition of cultured animals as bioflocs might serve as an additional protein source. Secondly, the study demonstrated that the biofloc system enhances the survival of *L. vannamei* upon challenge with a *V. parahaemolyticus* AHPND strain. Remarkably, the results highlight that in the biofloc system, AHPND-causing *V. parahaemolyticus* possibly switch from virulent planktonic phenotype, producing AHPND toxins, to a non-virulent biofilm phenotype (not producing APHND toxins), as demonstrated by a decreased transcription of flagella-related motility genes (*flaA*, *CheR*, and *fliS*), Pir toxin ($PirB^{VP}$), and AHPND plasmid genes (*ORF14*). In contrast an increased expression of the phenotype switching marker *AlkPhoX* gene was observed in both *in vitro* (in the biofloc) and *in vivo* (in the stomach of biofloc-based shrimp) conditions. Taken together, results suggest that bioflocs steer phenotype switching, contributing to the decreased virulence of *V. parahaemolyticus* AHPND strain towards shrimp postlarvae. This information opens the possibility to combat AHPND not only by trying to eliminate the AHPND-causing *V. parahaemolyticus* from the system but rather to steer the system allowing for a phenotypic switch of *V. parahaemolyticus*.

Introduction

Nanoplastics, nanometric-sized plastic particles formed from the breakdown of larger plastic objects (<1,000 nm, NPs) (Hartmann et al., 2019), are considered emerging pollutants of global importance, as they have the potential to enter the environment and cause adverse ecological effects (Geissen et al., 2015). Nevertheless, the scientific community's understanding of their effects on biota and ecological impact is still limited. The gilthead seabream (*Sparus aurata*) is a top predator and one of the most relevant fish species for human consumption in the Mediterranean region, with a joint aquaculture and capture fisheries production of over 195 thousand tons in 2016. These circumstances, taken together with the fact that more than 8 million tons of plastic end up in the ocean each year (Jambeck et al., 2015), highlight the need to investigate the effect that NPs may have on commercially cultured fish such as gilthead seabream. In the present study, we aimed to investigate the effects that a short-term exposure (24 and 96 h) to polymethylmethacrylate (PMMA) NPs might have on the gilthead seabream, using biomarkers of different levels: gene expression endpoints in liver, biochemical markers in liver and plasma and erythrocyte nuclear anomalies (ENAs) in blood.

Material and methods

S. aurata juveniles weighing (8.7 ± 0.4 g) were obtained from an aquaculture facility in Spain and acclimatized in 1,000 L aquaria with aerated ASW (salinity: 30) at 19 ± 1 ◦C and natural photoperiod (14 h light: 10 h darkness) for 2 months. Fish were then randomly distributed in six different experimental groups: 0, 0.001, 0.01, 0.1, 1 and 10 mg L^{-1} of PMMA-NPs. Each experimental condition consisted of replicate 3 tanks with 15 L of experimental media each and 6 fish in the tank. The animals were exposed to NPs generally following OECD Guideline 203 regarding acute toxicity tests (OECD, 1992) and sampled at two different time points, 24 and 96 h. For each time-point, 3 animals per replicate tank were sampled (n = 9) and blood and liver samples were collected, for the determination of cellular, biochemical, and molecular markers.

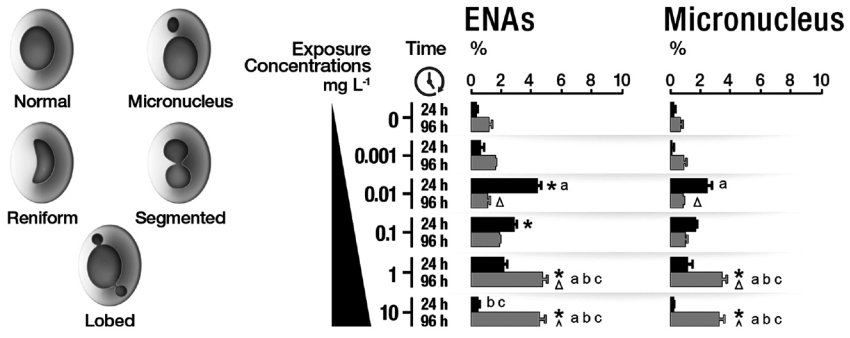

Fig. 1. Erythrocytic nuclear anomalies (ENAs) and micronuclei in the blood of gilthead seabream after 24 and 96 h exposure to polymethylmethacrylate nanoplastics (PMMA-NPs). Significant differences are marked as follows: Asterisk (*) vs. control, a versus 0.001 mg L^{-1} PMMA-NPs, b versus 0.01 mg L^{-1} PMMA-NPs and c versus 0.1 mg L^{-1} PMMA-NPs, within the same exposure time. Significant differences between sampling time points are marked at 96 h with a triangle (Δ) versus 24 h, $p < 0.05$.

(Continued on next page)

Results and discussion

In the present study, we sought to assess response of two hepatic key functions, lipid metabolism and antioxidant response. All the tested PMMA-NPs' concentrations induced a significant overexpression of hepatic *ppar**β**, rxr* and *apoa1* levels at 24 h, whereas *ppar**α*** and *pparγ* levels remained unaltered at this time point. After 96 h of exposure, expression levels of *ppar**α*** (0.001, 1 and 10 mg L-1), *pparγ* (10 mg L-1) and *rxr* were up-regulated, while *ppar**β*** and *apoa1* returned to control levels. Additionally, increased cholesterol levels were found in liver and plasma at 96 of exposure to PMMA-NPs, while triglycerides were also altered in plasma. This changes in values of both lipid compounds, together with the alterations in the expression of genes responsible for regulating lipid metabolism (*ppar**α**, pparγ, rxr, apoa1*) could suggest that PMMA-NPs are somehow preventing fish from properly using their fat stores and that fish could be exploiting alternative pathways in lipid metabolism. Regarding the genes encoding antioxidant enzymes evaluated in the liver of the gilthead seabream, we observed an overall increase in gpx1, sod2 and gr expression levels at an early time-point, which returned to control levels at 96 h. Moreover, we observed an increase of total antioxidant capacity (TAC) levels at both 24 and 96 h, and an increase in total oxidative status (TOS) at 96 h. Oxidative stress can cause damage to biological molecules such as DNA, therefore potentially inducing the formation of ENAs. An increase in the total number of ENAs at both exposure times was found, with micronuclei being the most frequently recorded ENAs. The observed increase in ENAs found in our study could derive from the direct interaction of NPs with the nuclei of erythrocytes or from increased oxidative stress after exposure to PMMA-NPs. Comparing results obtained at the different sampling times, it is possible that at 24 h the observed ENAs come from the action of NPs on cells, while at 96 h the effects of oxidative species might be added.

Conclusions

Increased transcriptional levels of key genes related with lipid metabolism and changes in plasmatic levels of cholesterol and triglycerides suggest an alteration of lipid pathways after a short exposure to PMMA-NPs. An early up-regulation of genes related with the antioxidant status indicates that fish were able to activate antioxidant defences, however increased TOS levels at 96 h suggests that antioxidant defences might not be able to completely counteract the exposure's effects. The increased frequency of ENAs suggests that PMMA-NPs can induce clastogenic/aneugenic damage in fish erythrocytes. Taken as a whole, the results of this study show that the gilthead seabream is affected by the exposure to PMMA-NPs in the short-term, as reflected by the alteration of parameters at different levels of biological organization.

MICROBIOME INCEPTION: AN INTESTINAL CESTODE CAUSES A HIERARCHICAL LANDSCAPE OF DISTINCT MICROBIAL COMMUNITIES NESTED WITHIN FARMED ATLANTIC SALMON (*Salmo salar*)

Jaelle C. Brealey*

Department of Natural History, NTNU University Museum, Norwegian University of Science and Technology (NTNU), Trondheim, Norway
Email: jaelle.brealey@ntnu.no

Introduction
Cestodes represent a major health concern for both human and animal populations. The cestode *Eubothrium*, which parasitises Atlantic salmon (*Salmo salar*), impacts salmon health and is of significant economic burden to the salmon aquaculture industry. As intestinal parasites, cestodes share the space with the host gut microbiome. Studies suggest that parasitism perturbs the gut microbiome, potentially disrupting the important role that the microbiome plays in maintaining host health. Cestodes may also carry their own internal microbiome, despite lacking a digestive tract, and the extent to which this endomicrobiome resembles the surrounding host gut environment is currently unclear.

Methods
In one of the first such studies performed in a cestode, we investigated the microbiome of *Eubothrium*. We sampled the host gut mucosa, the surface of the cestode (the tegument) and the cestode endomicrobiome in 30 sea-farmed, harvest-aged Atlantic salmon and profiled the microbiota with 16S amplicon sequencing (Figure 1). We also used shotgun metagenomics sequencing of eight cestode endomicrobiome samples to further characterise putative functional differences among strains detected by the 16S data.

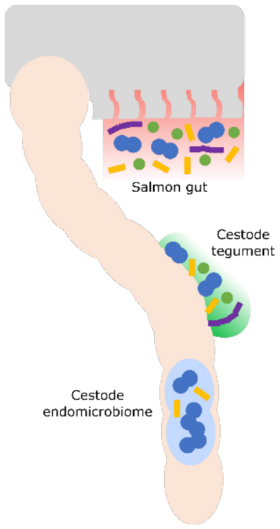

Figure 1. Schematic of the three sampling sites (salmon gut mucosa, cestode tegument surface and cestode endomicrobiome) profiled with 16S amplicon sequencing.

Results
We determined that cestode presence altered the salmon gut microbial community, with an increase in pathobionts and a decrease in the dominating commensal *Mycoplasma* phylotypes. We also established that despite lacking a gut, the cestode carried a distinct endomicrobiome, while the tegument harboured an intermediate microbial community including bacteria from both the cestode and the salmon microbiomes. Shotgun metagenomics revealed distinct *Mycoplasma* phylotypes in the cestode endomicrobiome with functional potential that differed from the *Mycoplasma* phylotypes abundant in the salmon gut.

Conclusions
Our results indicate that cestode infection is associated with gut dysbiosis in the salmon host by simultaneously serving as a potential source of novel bacterial species as well as a selective force benefiting putative pathogens. Our results highlight the importance of taking a hologenomic approach to understanding parasite infections, where the parasite and its associated microorganisms are considered as a holobiont with combined effects on the host microbiome and overall host health.

AQUACULTURE AND MARITIME SPATIAL PLANNING: LONGLINE FARMS AS ELEMENTS OF DESIGN FOR THE COASTAL SEASCAPE

D. Brigolin[1], E.M.D. Porporato[2], R. Pastres[3]

Introduction
In EU, the Maritime Spatial Planning Directive (Directive 2014/89/EU) provides the basis for an integrated management approach of maritime activities, and most of the states are currently finalizing their national plans of the sea. A sound site selection and zoning of aquaculture, carried out in the framework of MSP implementation, represent a priority for a sustainable expansion of the sector (Sanchez-Jerez et al., 2016).

Here we present an attempt to consider shellfish farm as an element for designing the costal seascape, by exploring the potential of different layouts of areas allocated to shellfish aquaculture. Our analysis was carried out in two contiguous regions of the Northern Adriatic Sea, and considered both the suitability for aquaculture expansion in the area, and the interplay between shellfish aquaculture and other coastal uses, namely: nature conservation, maritime traffic, and trawling fishery.

Methods
In the first step of the analysis, the work presented by Brigolin et al. (2017), based on a spatial multi-criteria optimization technique was expanded, in order to cover the coastal area of Veneto and Emilia Romagna regions, representing one of the most productive spots along the Norther Adriatic coast. Within this region, Intermediate Level Criteria (ILC) (Radiarta et al., 2011) were considered according to: i) optimal growth conditions; ii) environmental interactions and iii) socio economic evaluation. Based on the suitability maps obtained, we identified potential areas of interest for aquaculture expansion. We took into consideration the uncertainty in the weights assigned to different criteria, by identifying high-suitability stable areas, i.e. areas in which the different weights assigned a-priori in the analysis produced similar results.

As a second step, we explored different solutions for areas of shellfish aquaculture expansion, by considering the following factors:

- Creating continuity between existing conservation areas, in which trawling activities are prevented;
- Imposing a physical constraint to limit traffic outside navigation corridors in the area.

The second step of the analysis was carried out by using a goal function to compare different solutions and considering existing data on sea traffic intensity derived by Emodnet, the locations of existing Natura 2000 sites, and the maps of sea currents obtained from CMEMS Copernicus Marine Service data portal.

Results and discussion
Based on the output of growth and deposition models, and on the multi-criteria analysis, it was possible to map areas characterized by high (0.75-0.90) and very high >0.90 suitability, with a spatial resolution of 1 km (Fig.1). Existing mussel cultivation areas, and perimeters of the Natura 2000 sites present in the area were also mapped, and superimposed to the layer representing traffic intensity in this maritime region. Two scenarios of increase of the surface covered by mussel leases were considered, namely +50% and doubling the surface within the region, and allocation distributed between three maritime areas selected within the portion of sea characterized by high and very high suitability, and marked with A1, A2 and A3 in Figure 1. Results of this exercise highlighted that the optimal allocation of the increase in mussel farms among A1, A2 and A3, and different shapes of the farms within these areas, can drive to different results when considering aquaculture suitability alone, and considering the effects produced by the farms on conservation and maritime traffic. Results are discussed with respect to the influence of weighting factors on the outcomes of the analysis and the perspectives for including additional regulation services, such as eutrophication control and carbon sequestration in the analysis.

Introduction

The INTERREG project AdriAquaNet (https://www.italy-croatia.eu/web/adriaquanet), coordinated by Udine University, aims at enhancing the sustainable development of Adriatic mariculture and fostering cooperation between Italian and Croatian operators. In order to achieve these goals, the project is developing innovations concerning the whole seabass and seabream supply chain. In particular, the project focuses on: 1) farm management, fish nutrition and waste disposal; 2) fish health and welfare; 3) new added value products. The project also tests a comprehensive monitoring system, which integrates the real time monitoring of relevant environmental parameters, i.e. water temperature and dissolved oxygen, footage captured with high resolution video camera, which allows monitoring fish behaviour and simulation models. In this paper, preliminary results of fish growth performance using a novel feed formulation including insects and poultry PAP at lab scale and in at operational level, are also presented.

Methods

Feeding innovations have been tested on the basis of a comprehensive approach assessing both the zootechnical performance and local environmental impact. The systematic approach included: 1) designing novel aquafeed low in fish meal, including insect and poultry by product meals; 2) comparing new feeds to standard formulations at a laboratory scale (TRL 4-5) under controlled environmental conditions, in order to determine Key Performance Indicators, e.g. Specific Growth Rate, FCR; 3) validation of lab results in a trial at an actual farm (TRL 8) in order to estimate the above KPIs at an operational level; 4) assessment of the potential local environmental impact due to faeces and uneaten feed pellets using FiCIM, Fish Cage Integrated model, (Brigolin et al. 2014). This dynamic model, available for demonstration at https://www.bluefarmenvironment.com/, includes four modules. The "individual" module allows fish growth estimation, oxygen demands and ammonia excretion rate in relation to feed composition and water temperature. This module can also be used as a stand-alone model for quickly simulation of site-specific growth trajectories, based on water temperature climatology. The user-friendly interface was developed and presented to AdriAquaNet end-users as part of the project training activities. The second module, "population" upscales the output of the individual model at a population level, in order to simulate the change of the total biomass in a fish cage, as well as the total oxygen consumption, total ammonia and organic particulate (uneaten feed + faeces) emissions. Time-dependent emissions are taken as input by the "dispersion" module, which allows one to estimate the potential effects on the water column and the deposition of organic carbon particle on surface sediment underneath a fish cage. The fourth module cumulates daily flows of organic carbon and convert them into an increase in the concentration of organic carbon above the background level in surface sediment, considering the dynamics of early diagenesis processes. As a result, FiCIM can provide maps of organic carbon enrichment in a form on which potential damage to the benthic community can be assessed. FiCIM as the main inputs requires feed composition and time series of feed quantities provided to the fish, water temperature, and current. The two latter parameters were collected by deploying a buoy equipped with dissolved oxygen, water temperature sensors and a current meter. Data, collected every 15 minutes, were sent to a cloud and available in real time.

Results & Discussion

The AAN approach was applied to a new feed formulation for gilthead seabream. The new feed was tested on 100g sea bream over a 25 weeks long trial at laboratory scale: the results were very encouraging, showing improved FCR (1.37 vs. 1.50, $p<0.05$) when compared to conventional FM or Veg-protein rich feeds. Based on these findings, a 7-month trial started in cooperation with the project partner – Friskina at the inshore fish farm located in the middle Adriatic area (Hr), with seabream kept in cages and comparing the test feed with a commercial one in duplicate. The test feed resulted in improved weight (447 vs. 417g, $p<0.08$), SGR (0.57 vs. 0.53% d^{-1}) and FCR (1.7 vs. 1.9). Measured fish weights in cages (n=50) throughout the trial are compared with the output of FiCIM individual module (Fig. 1). As presented, the model correctly predicts the final weight, as well as the stagnation of the weight in cage 2, towards the end of the trial when fish was not fed.

(Continued on next page)

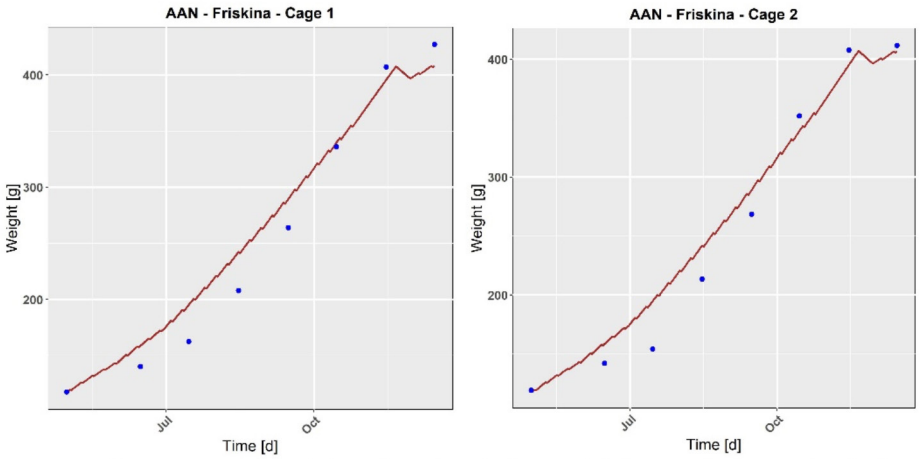

Figure 1 Comparison of model predicted and observed fish growth during the feeding trial at Friskina farm.

Concluding remark

The results presented here indicates that novel feed formulations with limited reliance on fish meal and conventional feed proteins are effective and sustainable under operational conditions. In addition, the FiCIM model can effectively simulate the growth of seabream in relation to the environmental forcings and feed features. As a next step, FiCIM will be applied for mapping the organic carbon enrichment of surface sediment at both AdriAquaNet pilot sites, located at Friskina and Orada farms, in order to complete the integrated assessment of the novel feeding protocol.

DIETARY EFFECTS ON THE REPRODUCTIVE PERFORMANCE OF THE SEA URCHIN *Tripneustes gratilla*

Introduction

Tripneustes gratilla has been identified as a commercially viable species for aquaculture production in South Africa, with the potential for inclusion in integrated multi-trophic aquaculture (IMTA) systems. However, these broadcast spawning animals often display differential parental contributions within aquaculture environments. This reproductive strategy can reduce genetic variation through a bottleneck effect, subsequently resulting in a poor response to artificial selection and poor production output in cultured populations (Grant *et al*., 2017). Additionally, feed-type and quality, as well as the feeding regimes used for broodstock conditioning, will impact feed intake, digestion and eventual nutrient availability, affecting gametogenesis and reproductive performance of these animals (Azad *et al*., 2011). This study assessed various biological and genetic factors for *T. gratilla*, as well as different feeding regimes that could affect reproductive competition, larval growth and juvenile performance after implementing a factorial breeding design.

Materials and Methods

First-generation (F1) broodstock animals (n = 32) were conditioned on 4 diets [formulated feed (20% *Ulva* inclusion (Cyrus *et al*., 2014)), kelp (*Ecklonia maxima)*, green seaweed (*Ulva rigida*) and mixture of the three diets] for approximately four months. Spawning was induced by injecting 0.5M KCl. Sperm or eggs were collected for quantification and subsequent morphological assessments, as well as for the quantification of egg lipids, proteins, carbohydrates and fatty acid profile assessments using gas chromatography flame ionisation detection (GC-FID). Remaining gametes were used in a factorial breeding design, where a standardised number of sperm and eggs of each individual were combined with that of other individuals fed the same broodstock conditioning diet. After spawning, broodstock animals were dissected, gonad weight and colour assessed and gonads processed for routine paraffin histology to evaluate gonad maturity.

Larvae were reared in 130L conical tanks. Larval morphology and survival were assessed for 20 days. Larvae from the kelp and mixed diet fed broodstock survived for the full duration of larval rearing and were transferred to 87L settlement containers, pre-coated with *Ulvella lens*. Approximately 3 months post-settlement, DNA was extracted and 10 species-specific microsatellite markers (Carlton and Lippé 2007; Wainwright *et al*., 2012) were amplified across 16 F1 broodstock (8 fed kelp and 8 fed mixed diet) and a total of 364 second-generation (F2) offspring. Genetic diversity of F1 broodstock relative to the F2 offspring, parental contribution through parentage assignment and heritability (h^2) estimates for growth were evaluated.

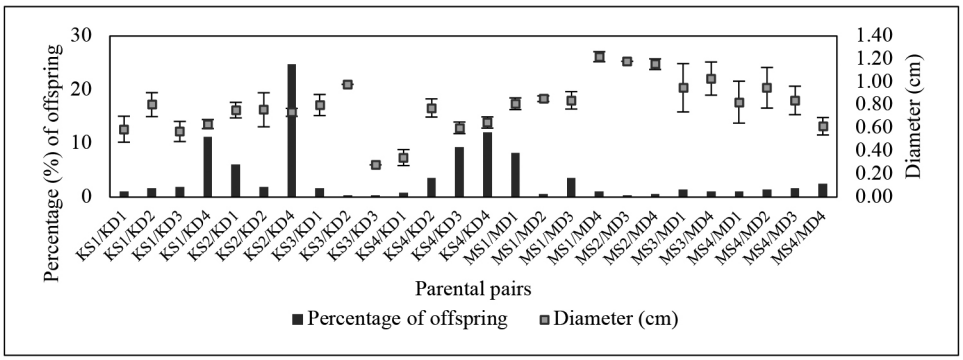

Figure 1 Percentage of *Tripneustes gratilla* offspring assigned to parental pairs in F2 cultured cohort, where 26 full-sib families were identified and mean family body diameters (cm) are indicated (K: Kelp, M: Mixed, S: Sire, D: Dam).

(Continued on next page)

Results and Discussion

Across broodstock, significant differences ($P < 0.05$; ANOVA) in gonad and egg colour suggest a formulated feed (20U) should not be fed in isolation for reproductive purposes. Dietary carotenoids (red, orange and yellow pigments) incorporated in sea urchin gonads and eggs could have downstream effects on urchin health and reproduction; via pro-vitamin A, photoprotective, and immunity-related roles, resulting in improved hatching and larval survival. Excess linoleic acid (C18:2n6) was observed in samples from animals fed a formulated feed. Although these fatty acids may elicit inflammatory response in urchins, there are potential benefits to including a formulated feed in conjunction with natural feeds in a mixed feeding regime. The egg fatty acid profile associated with the mixed diet clustered separately (principal component analysis) from the singular feeds, possibly as a result of the interactions between the combination of compounds obtained from the individual diets.

Larvae from broodstock fed kelp and the mixed diet displayed similar growth rates, with larvae from broodstock fed a mixed diet displaying a greater extent of phenotypic plasticity. Genetic diversity analyses showed no statistically significant ($P > 0.05$) differences between F1 broodstock animals and their F2 offspring, with an average allelic richness (A_R) of 5.31 ± 0.52 and 5.18 ± 0.42, respectively. A total of 26 out of 32 possible parent pairs contributed to the F2 generation (Fig. 1) and juveniles assigning to broodstock fed a mixed diet were significantly ($P < 0.05$) larger (average offspring size of 0.94 ± 0.10 cm) than broodstock fed kelp (average offspring size of 0.66 ± 0.07 cm). However, a larger number of offspring (79.65%) were assigned to kelp fed broodstock (Fig. 1). An assessment of offspring phenotypic performance showed low heritability estimates ($h^2 = 0.050 \pm 0.058$) for body diameter, suggesting that additive genetic effects play limited roles in this trait.

Conclusion

Aquaculture establishments could take advantage of the maternal provisioning strategy of sea urchins to benefit future commercial production. Animals fed the mixed feeding regime outperformed the other feeds across various measurements, with relatively equal parental contributions to offspring. The varied nutrient content of the included feeds, carotenoid content, diverse array of essential amino acids and fatty acids supplied by the respective singular feeds, as well as improved digestibility through the enzymatic activity of the bacterial communities of the natural feeds, could have contributed to the reproductive success of the mixed diet fed broodstock. This study also showed that the implementation of a factorial breeding design maximises genetic diversity in subsequent generations by negating unequal parental contributions to some extent.

THE SIGNIFICANCE OF INTRODUCING A DESIGN CODE TO THE AQUACULTURE INDUSTRY IN NORWAY AND THE EFFECT ON FISH ESCAPE

Joachim Buarø

STIM Knowledge Services, Kjøpmannsgata 37, N-7011 Trondheim (Norway)

Introduction

From the initiation in the 70s to the end of the 90s there was an accelerating development in the growth of the aquaculture industry in Norway. It was observed that the increase in activity led to an increased number of incidents of structural failures leading to fish escape. This led to the development of regulations to make the aquaculture systems more reliable.

Regulations and design code

In 2003 the first revision of the NYTEK-regulations and the relating standard NS9415 was ready to be implemented. Further with the introduction of the aquaculture act in 2005 the authorities got tools that helped improve the robustness of the aquaculture plants and decrease the risk for fish escape. The NYTEK-regulation and NS9415 has been through revisions and is currently being revised.

Effects on fish escape

The regulations design code has proven to be effective as the number of fish escapes have plummeted in a period when the production volume has nearly tripled. The number of escapes due to system collapses are close to none and the few fish escape that happen is related to operations and human error.

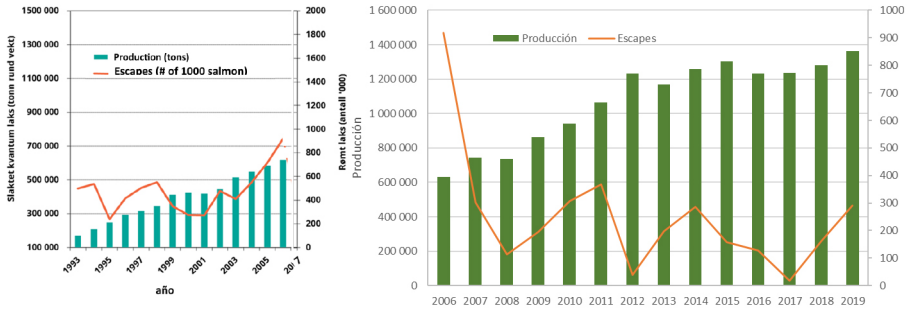

Figure 1: Historical relation between production and fish escape

GENOME EDITING TO PRODUCE MONOSEX AND STERILE FISH FOR AQUACULTURE

John Buchanan, Spencer Herbert, Takeshi Umazume, and Xavier Lauth

Center for Aquaculture Technologies, 8395 Camino Santa Fe Suite E, San Diego, California, USA
jbuchanan@aquatechcenter.com

Introduction

The ability to produce sterile progeny from broodstock for aquaculture has significant benefits to culture productivity and environmental sustainability. We describe the development of strategies to generate, breed and mass-produce infertile fish. Our solutions rely on precise genetic modifications to create broodstock lines that can be incorporated into breeding programs. These approaches were validated in tilapia but are transferrable to multiple species of fish. We expect that adoption of these technologies will result in broad economic and environmental benefits for aquaculture.

Methods and Results

One strategy for mass producing sterile fish is designed to produce monosex, sterile populations in culture. In addition to the benefit of sterile fish, this allows the benefit of sexually dimorphic performance traits in culture. We first investigated gene mutations in two evolutionarily conserved pathways, one governing sex differentiation and the other sex competency. We created edits in genes necessary for spermiogenesis and steroid hormone synthesis causing male sterility and masculinization, respectively. Double gene edit combinations for these genes produced all-male sterile populations. Likewise, we created variants in genes whose inactivation caused females to develop atrophic ovaries arrested at a previtellogenic stage or string-like ovaries lacking oocytes. We further disrupted genes causing genetic males to sex reverse into females. Double gene edit combinations for these genes produced all-female, sterile populations.

Propagation of the double KO broodstock lines was achieved via germ cell transplantation from a juvenile mutant donor into a germ cell free wild-type recipient embryo. In the resulting recipients, the induced edits had no effect as the genes targeted are not expressed in germ cells. With this approach, we generated fertile broodstock that successfully mas- produced sterile, monosex populations.

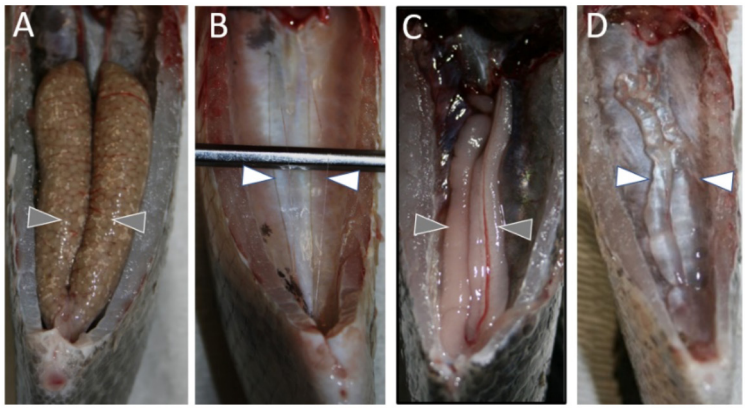

Fig 1 A-D. Dissected gonads of fertile and sterile Nile tilapia. Female (B) and male (D) with genome edited changes show string-like ovaries and translucid testes devoid of oocytes and spermatozoa, respectively. Age matched control female (A) and male (C) display mature gonads. Gray arrow heads point to gonads from fertile fish and white arrow heads point to the gonad from sterile fish.

budino@cetga.org

Introduction

At present, and for over a decade, the superpopulation of starfish has been wreaking damages on the bivalve populations along the Galician coast, reducing productivity and forcing the fishermen's associations to carry out costly cleaning work for their removal. The valorization of this marine resource, currently treated as a non-usable waste, would open a new business opportunity for the shellfish sector, helping its revitalization and job creation, as well as contributing to the implementation of sustainable aquaculture. The objective of this work is to analyze the viability of using starfish as raw material for the production of organic feed for aquaculture, with the purpose of reducing the dependence on fishmeal, opening new opportunities in the fish nutrition market.

Material and Methods

Starfish sampling: Starfish (*A. rubens*), obtained from 3 predator cleanings on the west coast of Galicia (NW Spain), were sacrificed by thermal shock and frozen at -20ºC.

Starfish microbiological and biochemical analysis: The presence of *E.coli* and *Salmonella spp*. was determined by qPCR with specific primers. Metal determination was performed by total digestion with hydrogen peroxide and nitric acid in microwave and subsequent analysis with ICP-MS for trace metals and with ICP-OES for major metals. Quantification of saponins was performed by UPLC-MS on the samples previously extracted with acetonitrile. Lipophilic toxins were determined by HPLC-MS/MS, amnesic toxins were quantified by HPLC-UV and paralytic toxins were analyzed by UPLC-FLV.

Manufacture of starfish meal and experimental diets: Two diets, control diet (CD) and experimental diet (ED), were formulated and manufactured (Acuinuga, Spain), with the only difference that ED substituted 15% of fish meal for the obtained starfish meal.

Determination of the fatty acid profile and proximal composition: Samples were lyophilized (Virtis; 24 h, 25 mtorr, -50 ºC) and. fatty acid methyl esters obtained (Bligh&Dyer,1959). The fatty acid profile was determined using a gas chromatograph with flame ionization detector (Agilent 8860 GC), with a DB-FastFAME column (Agilent, 30 m length, 0.25 mm internal diameter, 0.25 µm phase thickVirtness), using FAMEs standard of 10 mg ml^{-1}. The percentages of crude protein (volumetry), ash, fiber, fat and humidity (gravimetry), and total sugars (Luff-Schoorl method) were determined in the elaborated starfish meal and diets.

Feeding trials: The trial with rainbow trout (*Oncorhynchus mykiss*) was conducted at the facilities of Aiguanatura dels Ports, and the trials with turbot (*Psetta maxima*) and sea bream (*Sparus aurata*) at the facilities of CETGA. The diets (CD and ED) were fed to groups of 75 trouts in 2000L tanks, and to groups of 50 turbots and sea breams in 400L tanks, supplied with circulating filtered sea water or spring water, with dissolved oxygen >8 mg l^{-1}, temperature ranging 15-20ºC and natural photoperiod. Fish were fed at a feed rate of 1.5% weight, and weighed every 30 days. Results were compared by ANOVA and Fisher LSD test (BioStat, AnalystSoft).

(Continued on next page)

Results and Discussion

According to our results, major metals in starfish were Ca (86,6-203,58 g Kg^{-1}) and Na (17,77-27,63 g Kg^{-1}), and none of the legislated trace metals (As, Cd, Hg and Pb) were above the maximum admissible values. Paralytic, amnesic or lipophilic toxins above the permitted limits for animal feed (Regulation (EC) No. 853/2004) were not detected.

The most common saponins in the analyzed *A. rubens* were the ruberosides A-F.The highest ones were ruberoside A and ruberoside F, with no biological activity reported for them (Singh & Ort, 2020). Forbeside A, which possesses anti-inflammatory and antiviral activity (Findlay *et al.,* 1987), was detected in 2 of the 3 samples.

Starfish meal shows a lower content of protein, fat and fiber, and a higher ash content than fish meals. Regarding metal content, Ca predominates in starfish meal (8-20%), with Na and Mg values slightly higher than those of fish meal, and slightly lower values of P, K, Fe and Mn. In addition, the presence of Cr, As, Cu and Pb stands out, although the maximum limits allowed by legislation for raw materials are not reached.

The two diets tested (CD and ED) show a protein content of 41.2-42.7%, a fat content ranging 11-13%, with an ash content exceeding any of the commercial fish feeds (12-17% *vs.* 8-12). The inclusion of 15% starfish meal in the CD results in a small decrease in protein content (from 41.2 to 42.7%), an increase in fat content (from 11 to 13%) and a significant increase in ash content (from 11.7 to 16.9%), also lowering the fiber content (from 9.5 to 5.7%). Fatty acid profile of the CD is not significantly altered by replacing 15% fish meal with starfish meal.

The diet efficiency was assessed in rainbow trout (103 day trial) and in turbot and sea bream (30 day trial, still in progress). In trout and turbot trials, weight gain was significantly higher in the group fed the CD compared to the group fed ED ($p<0.001$ in both cases). In the sea bream trial, however, no significant differences were observed in the weight gain of both groups ($p=0.732$). Specific growth rate (SGR) in trout was 0.05% for the ED and 0.85% for the CD, and in turbot was -0.15% for the ED, since turbot even lost weight, compared to 0.6% for the CD. For sea bream, SGR was 0.29% for both diets.

The high ash content of starfish meal and its high hygroscopic capacity make it difficult to use it as a raw material in fish feeds. It would be possible to reduce the ash content through a hydrolyzing process of the meal, which would lead to an increase in the percentages of the remaining components, also eliminating the moisture problem. The solution to the palatability problem (detected in turbot and trout, but not in sea bream) lies in the inclusion of aromas and flavorings in the diets. According to our preliminary data, the efficiency of starfish meal *A. rubens* as a raw material for aquaculture feeds depends on the target species.

Introduction

Engineered Nanoparticles (ENPs) are an emerging technology widely used, currently applied in several fields as electronics or pharmaceutics. The rising of ENPs used in modern technologies leads to their release into aquatic environment. Potential effects in marine products is a current object of study and consequences are presently being tested by different by *in vivo* and *in vitro* model approaches (Torrealba *et al.,* 2019).

Innate immunity has been described as a biomarker to environmental pollutants. Leukocytes are one of the main components of the innate immune defences in the cellular response and have a relevant role in clearing of foreign elements. In fish species, kidney is the main immune and detoxification related organ, as well as an important source of leukocytes. Taking this into account, kidney leukocytes were obtained to expose them to the different types of NPs to assess cell viability. In this study, sea bream and sea bass were chosen as models for *in vitro* tests for being species of wide interest in aquaculture field for which the offshore culture is used, being directly exposed to marine pollutants.

Material and Methods

Animal research and ethical considerations: Sea bream (*Dicentrarchus labrax)* and sea bass (*Sparus aurata*) individuals were obtained from CETGA culture facilities. Fish were sacrificed following European regulations by using MS-222 anaesthetic overdose.

Cell extraction and leukocyte purification: anterior kidney was split off, rinsed and maintained in Leivobitz-15 (L-15) medium containing heparin (10 units/mL) and foetal bovine serum (FBS, 2%). To separate de cells, kidney pieces were passed through a 100uM mesh and stored on ice. For cell type separation, a Percoll gradient was performed and the band of interest was collected (band enriched in leukocytes). Finally, cells were re suspended at the desired concentration in L-15 without phenol red, containing 10% of FBS and antibiotics (penicillin/streptomycin), dispensed into 6-well plates and cultured for 24h to let macrophages to adhere. Non-adherent cells (mostly leukocytes) were collected.

Nanoparticles: Titanium dioxide NPs [TiO_2-5nm (TiO_2 13.3g/L, 1:1.5 TiO_2:citrate ratio), TiO_2-45nm (TiO_2 15.5g/L, 1:1.5 TiO_2:citrate ratio) and TiO_2-P25 (21nm aprox, TiO_2 13.3g/L, 1:0.8 TiO_2:citrate ratio)]; Silver NPs [PVP-Ag 15nm (Ag 6.2g/L, 1:3 Ag:PVP ratio) and PVP-Ag 100nm (Ag 4.83g/L, 1:3 Ag:PVP ratio)] as well their respective stabilizers, sodium citrate (20g/L) and PVP (30g/L) were provided from INL, that carried out the characterisation in seawater (DLS, UVvis, TEM/SEM).

Cell viability tests: Cell viability was assessed by using MTT (2-(4,5-dimethyl-2-thiazolyl)-3,5-diphe-nyl-2H-tetrazolium bromide) assay (modified from Tada *et al*., 1989). For such purpose, kidney cell suspension (10^7 cells/mL) were seed into a 96 well plate (100uL per well). NPs and stabilizer stocks, were diluted 1/10, 1/100, 1/500, 1/1000 and 1/10000 and each dilution (100uL) was added to the cells (n=3). Controls of the NPs alone, to check photo degradation were included as well as cell controls without NPs. Moreover, cells with different dilutions of the NPs stabilizer (citrate and PVP) were also tested. Cell culture media was supplemented with 4g/L of glucose in order to activate cellular metabolism and cells were incubated for 24h. Following, MTT tetrazolium salt solution at a 5mg/mL concentration in PBS, pH 7.4 and sterilize it by filtration (0.2um) was prepared. 40uL of MTT solution was added into each well and cells were cultured at 20ºC for 5h. Immediately after, 150uL of the supernatant were carefully removed and 100uL of a 10% Sodium dodecyl sulphate (SDS) solution were added to dissolve formazan crystals. Plates were incubated overnight at 20ºC. Finally, absorbance at 570 and 690 nm was read in a Multisky Scanner Spectrophotometer (ThermoFisher).

(Continued on next page)

Data calculation and statistical analysis: data was analysed after subtracting the background absorbance at 690nm and the absorbance of the nanoparticles alone for each case. Results were represented as viability percentage respect to the control group without NPs, including calculations for the average and the standard error. Statistical analysis was performed by t-test of each concentration respect to the previous one to infer the concentration at which NPs became toxic for the cell, by using Graph Pad Prism software. LD_{50} was calculated by using Quest Graph™ LD50 Calculator tool.

Results and Discussion

Effect of NPs depends on their properties as size, shape, material, surface, aspect-ratio, dispersion and stability among others. NPs of 2 different materials (Ag and TiO_2) and different sizes were tested. Regarding TiO_2 NPs, the loss in cell viability at 24h was higher in the bigger NPs (45nm). Nevertheless, this effect is not correlated to size as the medium size NPs (P25) didn´t have any effect on cell viability while the smallest ones (5nm) presented a similar effect to 45nm ones. Citrate, the TiO_2 nanoparticles stabilizer didn´t cause any interference in cell viability. TiO2 NPs were described to cause effects from the surface of the cells (Picchietti *et al.,* 2017). A potential explanation may be related to the NPs aggregation, avoiding being internalised by the cell but this hypothesis needs to be further studied.

Concerning Ag NPs, a decrease in cell viability was observed for both types, being as well an independent effect from NP size. Nevertheless, the stabilizer of Ag NPs (PVP) showed a slight negative effect at the higher doses in sea bream. Moreover, a higher background signal was observed in Ag NPs by naked eye, under the microscope and by spectrophotometric results in comparison to TiO_2 NPs. NPs effects were very similar in both fish species. Nevertheless, some interspecific differences can be appreciated, as for the case of 5nm TiO_2 NPs, which affects sea bream cells viability in a more pronounced way.

Ag NPs caused a reduction in cell viability at lower concentrations than TiO_2 NPs. All the effects observed for the 2 NP types showed significant differences to the control at the higher dosages (g/L range), which are far from their predicted environmental concentrations (µg/L – ng/L).

The results of this study served as the basis for designing more comprehensive toxicity studies deepen in other aspects as microscopy, spectrometry or molecular biology.

MULTIDIMENSIONAL AQUACULTURE INVESTOR INDEX: BLACK SEA RIPARIAN COUNTRIES

Yuliia Buhlak[1,2], Patrice Guillotreau[1], Thomas Vallee[1], Veronique le Bihan[1], J.A. Theodorou[2]

[1]Institut d'Economie et de Management de Nantes, LEMNA, Université de Nantes, Chemin de la Censive du Tertre, 44322 Nantes, Cedex 3, France
[2]Department of Animal Production, Fisheries & Aquaculture, University of Patras, Nea Ktiria Gr 30200, Mesolonghi, Greece
E-mail: buglak@aq-ua.info

Introduction

The demand for fish products in Black Sea riparian countries has been intensively growing annually by 4% since 2000. This demand was predominantly covered by importation and/or capture fisheries. To reduce pressure on the wild fish stocks of the shared sea basin, regional and national development plans are aiming to stimulate aquaculture production. However, there is a scarcity of instruments that allow assessment of the situation on the regional level to capture the multidimensional nature of such activity. A Composite Indicator or so-called Index has been recognized as one of the best ways to investigate the complex system statement and reveal areas of concern. This study was aiming to investigate whether some indicators have greater impact on industry development. Furthermore, the index can be used by investors as a quick guide to fish farming bottlenecks and strengths of each country in the Black Sea region and facilitate investments to the industry.

Materials and Methods

The Index was constructed on the basis of best practices carefully selected by the joint collaboration of Organisation for Economic Co-operation and Development and Joint Research Centre (OECD, 2008). The conceptual foundation of the current research was drawn from the Horizon 2020 Aquaspace project deliverable D2.4: Smartphone 'Investor Appeal' application (Ferreira, et al., 2017; Ferreira, et al., 2020) with region-specific adjustments and improvements suggested by the authors. All indicators and analytical methods were selected considering the nature of the data in the given region. Moreover, 20 experts were invited to participate to the selection and validation of indicators. In addition to that, they were asked to assign weights to each indicator. Principle Component Analysis were also used for weights allocation as a counterweight for comparison of two methods. Finally, with the help of innovative approach all final indicators were tested for correlation with the main output variable such as aquaculture production per capita. This approach helped to equalize all countries in terms of production capacity and to see if some indicators have greater correlation with higher production performance among countries.

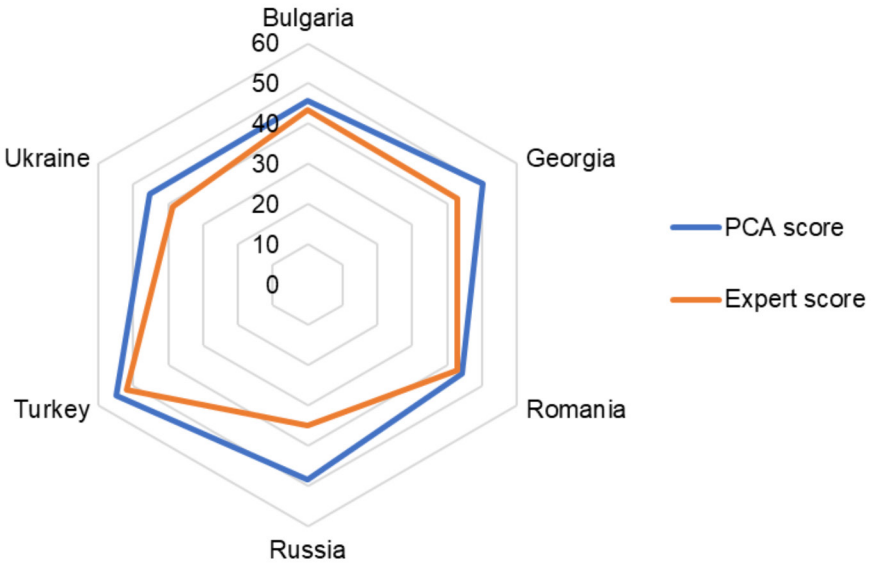

Figure 2. Comparison of final scores obtained with two weighting methods: PCA-based and Expert-based

(Continued on next page)

Results

Final scores with expert-based weighting were not largely different from PCA weighting. The main difference was observed only for Russian scores due to the low involvement level of aquaculture experts (Fig.1). It is also interesting to notice in some disparities of scores, that all experts were more concerned by the governance factors, while unbiased PCA method assigned higher scores to some market indicators which were largely underestimated by the experts. It was concluded, that further research should include experts from the market sector.

Overall market-related factors appeared to be more influencing in aquaculture development for all countries in the region (Fig.2). Environmental and Production sectors were less influencing than Market dimension; Governance and Social dimensions had the smallest impact on fish farming development in the Black Sea region.

Discussion

Multidimensional aquaculture investor index has demonstrated to be an effective method to capture the level of importance of aquaculture-relevant indicators to build successful governance strategy and to assist investors. Due to the time restrictions of the project, some indicators data couldn't be collected on time. Though, indicative results were obtained even with the reduced list of indicators. Further research with complete list of indicators will provide greater insight to the aquaculture landscape in the region and give more additional highly-influencing factors for policymakers.

Introduction
Global aquaculture production more than tripled in live-weight volume in the past two decades, reaching 112 million tonnes. To ensure efficient production fish health monitoring is essential to minimise pathogen outbreaks in a continuously growing industry. Our team has developed an AI framework "EpitopePredikt" to predict B-cell immunodominant epitopes. The immunodominance is an immunological phenomenon in which immune responses are dominated by only a few peptides of the antigenic nature. The identification of antigenic peptides will facilitate the development of accurate serodiagnostic tests, more effective vaccine and adjuvants as well as improve efficiency of antibody production. The second innovative platform is a non-reactive bioengineered scaffolds "EpitoGen" whereby epitope/s can be assembled to create chimeric antigens suitable for serology-testing, vaccine delivery and efficacy testing, and immunoassay validation. Combined, the two technologies will revolutionize the health-related tools for the aquaculture sector. We currently have generated ~50 antibodies to key markers, and >100 recombinant proteins including flagellins, potent immunostimulants. Employing AI precision-based platform with innovative bioengineered scaffold will offer ground-breaking solutions to persistent problems in the sector.

Aims
1) Develop a panel of antibodies for research in fish.
2) Develop sensitive and affordable high throughput antibody and peptide-based serology assays to monitor fish health in aquaculture, i.e., enzyme linked immunosorbent assays (ELISAs).
3) Develop the next generation of bio-active immunomodulators to boost fish robustness.

Materials and Methods
We performed fish biomarker search using published based on published literature in combination with gene expression and sequence data. We identified a panel of key health markers in need of immunoassay to chart their levels. We predicted 3D structures of candidate biomarkers to identify optimal accessible and surface exposed regions suitable for antibody production. EpitopePredikt was utilised to identify "hot spots" suitable for antibody design. Short peptides were used as immunogens to generate mono and polyclonal antibodies against the fish candidates in mice and rabbits respectively. We are also developing bio-active molecules to potential immunostimulants such as interferons, antimicrobial peptides to enhance ongoing research.

Results
We have generated a range of fish antibodies and bio-active recombinants that can be used as tools for academic research, as well as prospective immunoassays to monitor fish health in aquaculture. We are currently finalising our study and validating specificity for a panel of generated antibodies and to test bioactivity. Our products will be produced to support the unmet demands of the aquaculture sector for affordable, accurate and high throughput platforms.

OXYGENATION EFFECTS ON TEMPERATURE AND OXYGEN AT A COMMERCIAL ATLANTIC SALMON (*SALMO SALAR*) FARM

Introduction

Climate change has threatened coastal ecosystems through elevated sea temperatures while contending with increased nutrients through expanding development. Both warmer waters and higher nutrient loads have resulted in intensification of coastal oxygen deficits (Breitburg et al. 2018). Adequate dissolved oxygen (DO) concentrations through finfish farms are paramount as low oxygen can directly impact the health and growth of fish. In the short-term, low oxygen can impact feed intake and feed conversion rates, and if prolonged, can result in fish stress, vulnerability to diseases, and mortality (Oldham et al. 2019). Open net-pen farms that contain high stocking densities or exhibit low oxygen during warmer months, may use oxygenation devices to increase DO (Berillis et al. 2016). However, the transport and distribution of oxygen can be costly in ocean environments thus it is only occasionally used and the viability of these systems have yet to be adequately examined. This study explores the effectiveness of oxygenation in an Atlantic salmon net-pen farm to inform farm managers on its use as climate change threatens the industry.

Materials and methods

This study was conducted at a Cooke Aquaculture Atlantic salmon farm consisting of 6 circular cages (48 m in diameter, 10 m deep), located within a bay in southwest Nova Scotia. The study period was between June 1 and November 30 2019, with the deployment of oxygenation within each of the cages between August 4 and November 6. The oxygen system was the NetOx Net (OxyVision AS, Norway), which releases micro-bubbles of oxygen as a curtain at 8m depth. The cage analyzed in this study contained 2 DO and temperature sensors (AquaMeasure, InnovaSea Systems, Inc., Bedford, Nova Scotia), one at 2m and one at 7m. Additionally, there was a reference sensor located ~75 m outside the cage. Satellite sea surface temperature (SST; 4km AVHRR Pathfinder Version 5.3) produced by NOAA National Centers for Environmental Information, was also used as a far field reference for cage temperature. Physical (e.g. tide, wind stress) and biological factors (e.g. theoretical fish consumption), which typically affect oxygen dynamics within a farm, were examined to determine how oxygenation may interact with those processes.

Results

Through June 1 – August 26, there was a strong stratification between 2m and 7m for both temperature and oxygen. The activation of oxygenation (Aug. 4) coincided with a sharp drop in temperature at both depths. There was a significant difference in temperature when comparing 3 weeks before/after the onset of oxygenation, with average values dropping from 16.7 to 15.4°C and from 14.3 to 13.2°C for 2m ($p<0.001$) and 7m ($p<0.001$), respectively (Fig. 1A). However, this drop was not observed in the satellite SST. On August 26th, autumn mixing began and stratification broke down resulting in a negligible difference between depths. While the temperatures declined at the onset of oxygenation, there was a concurrent increase in oxygen from an average value of 7.3 to 7.8 mg L^{-1} and from 8.3 to 8.9 mg L^{-1} at 2m and 7m, respectively. This resulted in an overall significant increase in oxygen on average 3 weeks after oxygenation compared to 3 weeks before ($p<0.001$; Fig. 1B).

Discussion

The results of this study suggest that although SST was similar before and after oxygenation, the system may have caused an upwelling of cooler waters which decreased temperatures throughout the cage. Similar findings were described in studies by Endo et al. (2018) and Bergheim et al. (2006). This decrease in temperature increased solubility while decreasing fish metabolism, furthering an increase in oxygen concentrations. Overall, the results imply that the oxygenation system increased upwelling and DO at the cage level until autumn mixing became the dominant source of re-aeration. This suggests that the system was effective promoting an increase in DO, but it does not need to run for the entire duration of the warm season, it may only be useful until de-stratification, which would save the farm associated economic costs.

(Continued on next page)

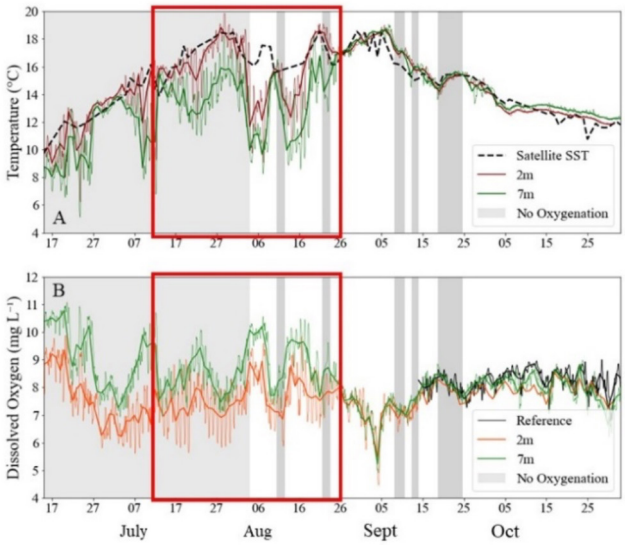

Figure 1. (A) Hourly (lighter lines) and daily (darker lines) average temperature (A) and DO (B) within cage 5 at 2m (maroon/red) and 7m (green) in 2019, along with the sea surface temperature (SST) derived from satellite data (dashed line) and at the reference (black). The grey bars indicate approximate times when the oxygenation system was off, and the red box indicates the period of analysis.

Introduction
The increasing global need to find alternative and sustainable protein sources has promoted research in the field for non-conventional feed ingredients, such as insects. There are many positive aspects of insect use as sustainable aquafeed ingredient especially for their high nutritional value and being a source of macronutrients and bioactive compounds[1]. Most studies have explored the effect of insect meal as fishmeal (FM) replacement on growth and health of Mediterranean fish species, while less attention has been paid on the evaluation of nutritional value as well as technological and sensorial properties of the final fish product. Thus, this study was performed in order to assess the effects of different inclusion levels of *Hermetia illucens* (HI) larvae meal on growth performances, plasma biochemistry, as well as gilthead sea breams' nutritional, technological and sensorial quality.

Materials and methods
One trial with gilthead sea bream was conducted in a closed recirculation aquaculture system (RAS). Fish (initial weight: 98.6 ± 0.6g), were fed over 113 days with four experimental diets containing different inclusion levels of HI meal (0% CTRL, 5% HI5, 10% HI10, and 15% HI15) in substitution to FM. At the end of the trial, growth, and feed efficiency parameters (Specific Growth Rate, SGR, Feed Intake, FI, Feed Conversion Rate, FCR and survival), and somatometric indexes (Viscerosomatic Index, VSI, Hepatosomatic Index, HSI, Condition Factor, CF, Fat Index, FaI), were assessed. Blood was collected from the caudal vein of five fish per tank to perform plasma biochemistry analysis. Also, a total of sixteen fish per tank were sacrificed and the dorsal-left skinned fillets collected to carry out nutritional composition analysis, to assess the main technological properties of meat, with a special reference to its ability to absorb a marinade solution and to investigate if a sensory (panel test) difference could be detected between the control diet and each one of the three experimental diets. Data were analysed by a one-way ANOVA followed by a Tukey's multiple comparison test.

Results
At the end of the trial, no significant differences ($p > 0.05$) ascribable to the different diets were observed in terms of final body weight, SGR, FI, and FCR and survival for all treatments (Figure 1). Also, no significant differences ($p > 0.05$) were found in somatometric indexes (i.e., VSI, HIS, CF, FaI).

Discussion and Conclusion
The results showed equivalent growth performances regardless of the different diets showing that HI larvae meal could replace 5%, 10% and 15% of FM without compromising the growth and feed utilization. This is in line with previous studies on sparids in which IM was tested, stating that a replacement of FM up to 25% do not negatively affect fish performances[2]. The investigation on the technological and sensorial aspects of the fillets will boost the current knowledge on insect meal properties as valid alternative protein source to FM for aquafeed in Mediterranean fish species.

(Continued on next page)

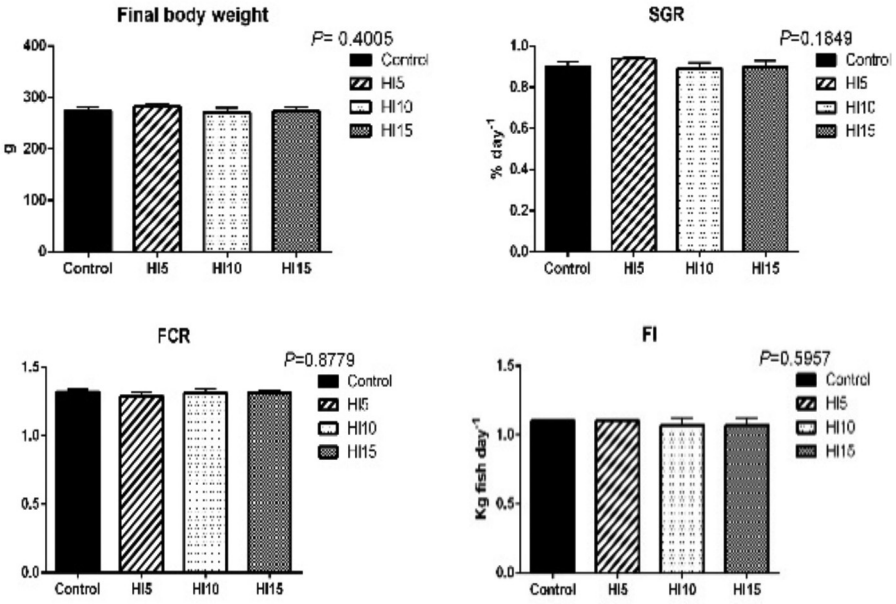

Fig. 1 Final body weight, SGR, FI and FCR obtained at the end of the trial under different treatments. No significant differences ($p > 0.05$) were observed.

AQUACULTURE BUSINESSES DURING COVID-19: A UK CASE STUDY

S.C. Franco *[1], S.L. Billing[1], G. Charalambides[1]

* corresponding author: sofia.franco@sams.ac.uk
[1] Scottish Association for Marine Science, Oban, Scotland PA37 1QA, UK

Introduction

The seafood industry has been under unprecedented pressure to deliver on national food security during COVID-19/ SARS-CoV-2 pandemic, while adapting to remain viable. However, limited literature exists on the systemic impacts to the seafood industry in European countries, adaptation actions employed by businesses or its associated environmental and socio-economic consequences. This hinders both the timely adoption of measures that address ongoing challenges, and the implementation of strategic actions aimed at increasing the industry and food system resilience to future disruptive events.

This study, part of the RiseUp project (www.sams.ac.uk/science/projects/riseup/), collected evidence on the early impacts of COVID-19 disruption across the UK seafood industry, how these have been managed by businesses and how impacts propagated trough the supply network. We focus herein only on the impacts and responses as experienced by aquaculture businesses in the UK, placing these in context of the wider systemic effects across the supply network and in consideration of concurrent changes, notably the change in trade and cooperation with the EU (shown in the e-poster only).

Material and Methods

This study adopted a constructivist qualitative approach which enabled in-depth exploration of the research questions with the study participants, through 40 interviews across the UK seafood supply chain. Semi-structured interviews (av. 42 min/interview) were conducted virtually or by phone between October 2020 and February 2021 (of which 17.5% were done in 2021). Participants comprised aquaculture, fisheries, processing, wholesale, retail, food service, other supply chain, government and regulators, including associations and trade bodies; which enabled a cross-cutting representation of seafood system actors. The interview guide (see Franco et al.) explored (i) COVID-19 impacts and context of business responses, (ii) representation and interaction with government responses, (iii) pathways forward and the 'new normal'.

Interviews were transcribed and qualitatively coded using an inductive approach within a flexible thematic framework, from high-level themes based on literature and grey reports on COVID-19 impacts. This considered Seafish reporting areas (market volatility, supply-chain disruption, labour pressures, fish production, food safety and health, global business climate, sector support), the thematic areas in the interview guide and the timeline of COVID-19. Coding was conducted using a thematic approach, following from open, to focused coding and final consolidation of codes, continually referring to the interview transcripts to ensure that the final coding and emergent themes (i.e., 'communication', 'BREXIT') were representative of the raw data. We herein present the results relevant to aquaculture respondents, mostly addressing the research questions on (i) 'How were businesses in the UK seafood industry impacted by COVID-19 pandemic?'; (ii)' Which actions did businesses take in response?', and to a lesser extent on (iii) 'What helped businesses respond to change?'.

Results and Discussion

The main early challenges of the COVID-19 pandemic to UK shellfish and finfish aquaculture producers related to the added costs and operational constraints in maintaining ongoing production and keeping animal welfare standards, whilst coping with significant disruptions to trade, from the collapse of export markets and food service closures (e.g., from lockdowns) to transportation disruption (e.g., decline in passenger flights, challenges to road haulage, temporary border closure). With a high volume of UK production intended for export, respondents reported a depression in trade volume from market volatility and supply chain disruptions. Though businesses sought to identify alternatives export routes, these proved challenging (e.g., using air freight was deemed an uneconomical alternative to passenger flights), with attempts made to raise awareness and address logistical efficiency challenges (e.g., delays to product transportation; lack of chilled warehousing infrastructure). Some businesses further responded to market volatility and supply chain disruptions by shifting markets/outlets (e.g., in between export countries, from hospitality to farmers markets) and working with their supply chain to change the product offering to fit new market demands (e.g., change in range or format), with varying degrees of success. Some noted the challenge of contesting the market share with international competitors or across-segments.

(Continued on next page)

Finfish and shellfish producers continued operating with the introduction of COVID-secure measures (e.g., social distancing, etc.), despite reporting impacts from reduced staff levels at times and pressure on the workforce. The benefits of being designated as 'key workers' and support mechanisms such as the furlough scheme or various support grants were noted across the sector, despite reported differences between developed nation differences and suitability, across sub-sectors or company size. Improved communication was generally considered a key positive change. Performance across businesses/sub-sectors varied, with some recovery noted by respondents in the second half of 2020, upon the re-opening of hospitality/food service and various export markets. Various businesses reported experiencing very high losses in the first half of 2020, from the impacts to export markets and closures in hospitality, which were partially mitigated in some cases by gains in the UK market, derived from higher sales in UK retail or direct-to-consumer sales. Shellfish farmers further mentioned a shift to direct-to-consumer sales during market closures, though this was noted by businesses as not being economically viable in the long term. Some shellfish businesses reported developing seafood box schemes, diversifying product lines or increasing online presence and marketing. Others reported halting expansion plans and using up contingency funds (i.e, planned for disease outbreaks). Further specific responses from fish farmers included consulting more regularly with regulators and government on animal welfare matters (e.g., stocking biomass, medication). Seaweed producers also increased efforts in business-to-business relations to presell stock, with impacts felt to specific product lines (e.g., grab & go), further highlighting issues of lack of representation as a relatively new sector, with one mentioning the difficulty of start-ups to access government support.

The impacts of market volatility and supply chain disruptions to 'business-as-usual' were reflected in a number of adaptations by aquaculture businesses, which focused in one hand on ensuring continuity of operations and avoid market oversupply, and in the other in re-establishing routes to market and build new income streams. Whilst impacts-to-responses varied by sub-sector, vulnerabilities such as the high reliance on given export markets, hospitality sector, locked-in transportation routes, limitations from price-benefit positioning, importance of the chilled segment and of short time to costumers, were exacerbated by structural limitations such as poor chilled infrastructure or export pathways, limitations in seafood uptake and price-competitiveness in the domestic market, and the lack of recognition of sub-sector-specific challenges in some of relevant government departments. Major strengths related to focus on business-to-business relations, benefits of sector representation in engaging with policy-makers, flexibility within the regulatory system, as well as individual financial contingency mechanisms or eligibility for funding, and internal capacity to diversify and/or evolve business models.

Introduction

In fish culture setting grounds, exogenous steroids input is a matter of concern. Recently, we unveiled that in the gilthead seabream (*Sparus aurata*), the G-protein-coupled estrogen receptor agonist G-1 (G1) and the endocrine disruptor 17α-ethinylestradiol (EE_2) are potent modulators in polyreactive natural antibodies production. However, the integral role of the microbiota upon antibody production under the effect of EE_2 remains largely unexplored.

Material and Methods

Here, 240 juvenile seabreams continuously exposed for 84 days to oral G1 or EE_2 at a fixed dose (5 μg/g food) were i.p. vaccinated on day 42 with the model antigen keyhole lymphet hemocyanin (KLH). A critical panel of systemic and mucosal immune markers, serum vitellogenin, humoral enzymatic, and bacteriolytic activities were recorded and correlated with the gut bacterial microbiome 16S rRNA status one day post priming (dpp). Besides, 15 dpp animals received a boost to explore the systemic- and mucosal-specific anti-KLH titers production by the end of the trial.

Results and Conclusion

EE_2 but not G1 induced a significant shift in the serum vitellogenin level one dpp. Simultaneously, in the serum and gut mucus of the EE_2 treated group, we recorded significant changes in some immune enzymatic activities. While we only inferred an attenuated profile in the immunized groups. The gut genes qPCR analysis exhibited a related pattern only emphasized by the significant shift on the EE_2 group *il1b* expression. The gut bacterial microbiome undergoes dynamic changes in alpha diversity indices, but only with exposure to dietary G1, supporting functional alterations on cellular processes, signaling, and lipid metabolism. By the same token, the immunization in both treated groups decreased the relative abundance of Fusobacteria and remarkably promoted changes in the estrogen-associated bacterial genera. Besides, systemic and mucosal KLH-specific IgM/T titers observed significant changes after 84 days of estrogenic oral administration.

In summary, these are the first results highlighting the intrinsic relationship between estrogens and their associated receptors in the ubiquitous fish immune regulation and the subtle but significant crosstalk with the gut endobolome.

DEPLOYMENT OF MICROBIOMES FOR SUSTAINABLE FISH FARMING IN THE SIMBA PROJECT

J. Cabello*, I. Folgueira, I. Iglesias, E.-j. Malta

Centro Tecnológico de Acuicultura de Andalucía (CTAQUA), Muelle Comercial S/N, 11500, El Puerto de Santa María, Spain
Presenter: j.cabello@ctaqua.es

Introduction
SIMBA is a €10.5 million European Union Horizon 2020-funded Innovation Action project that has the vision to create a better EU Agro-Aqua-Food system using microbiomes that is resource efficient, climate resilient, sustainable and consumer centred. To do this, over the four-year project, SIMBA will explore and utilise microbiomes from the land and sea to develop numerous innovative solutions to address key challenges identified.

Work Package 3 of the project I dedicated to marine microbiomes. In this WP, one of the tasks is the optimisation of fish feed for sustainable fish farming. On the one hand, this included the optimisation of fermentation mixes to produce high protein fermented vegetal products that can (in part) substitute less sustainable protein sources in fish food, such as fish meal, work carried out by the Danish partner Fermentation Experts. On the other hand, the role of the microbiome in the production of phytoplankton species that can serve as feed additives is evaluated by the Portuguese partners NECTON and ALLMICROALGAE. Potential new feed mixes made with these ingredients are evaluated for sea bream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*) at CTAQUA (Spain) and for freshwater and seawater grown Atlantic salmon (*Salmo salar*) at LUKE (Finland) and NIVA (Norway) respectively.

Material and Methods
Effects of dietary administration (2% inclusion) of microalgae (*Chlorella vulgaris*, *Nannochloropsis* spp, *Tisochrysis lutea*), rapeseed meal-seaweed fermented with lactic acid bacteria (EP199, 15% addition substituting 50% of fish meal) and soybean meal-seaweed fermented with lactic acid bacteria (EP299, 30% addition substituting 50% of fish meal) were evaluated on fish performance parameters, biometric and somatic indices, variation of gut microbiota profiles (to be analysed by SIMBA partner MATIS, Iceland), water quality, main non-specific immune indicators and final fillet quality in gilthead seabream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*). A total of 720 gilt head bream and European seabass juveniles of 10.73 ± 0.02 and 9.13 ± 0.01 mean body weight respectively, were grouped into 6 treatment diets and fed for 12 weeks.

Results and Discussion
Fish performance as measured by growth rate and feed conversion was significantly 10 to 15% lower for the EP199 diet compared to the control diet for sea bream. In sea bass, the other diet containing fermented compounds (EP299) also showed a slight but significant reduction in performance compared to the control. Diets containing phytoplankton did not differ significantly from the control (Figs. 1A and B).

Analyses of most relevant non-specific immune indicators are currently in progress. First results of the non-specific immune indicator lysozyme activity, showed higher values for the diets containing fermented compounds and the microalga *Chlorella* in both fish species, however the differences were not significant compared to the control diet. A consistent significant decrease of lysozyme activity compared to the control diet was observed in diets containing *Nannochloropsis* sp. and *Tisochrysis lutea* (Fig. 2).

Additional analyses of non-specific immune indicators, fillet composition and composition of the intestinal flora are currently being carried out. Current results indicate that addition of phytoplankton to fish feeds does not impact nor improve general performance, whereas effects on immune indicators might be species specific. Partial substitution (50%) of fish meal protein by fermented compounds, in particular compound EP299 had no negative impact in the case of sea bream and a slight reduction in performance in the more exclusively carnivorous sea bass, suggesting that perhaps at lower substitution percentages this might be a sustainable alternative for fish meal protein.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 818431 (SIMBA). This output reflects only the author's view and the Research Executive Agency (REA) cannot be held responsible for any use that may be made of the information contained therein.

(Continued on next page)

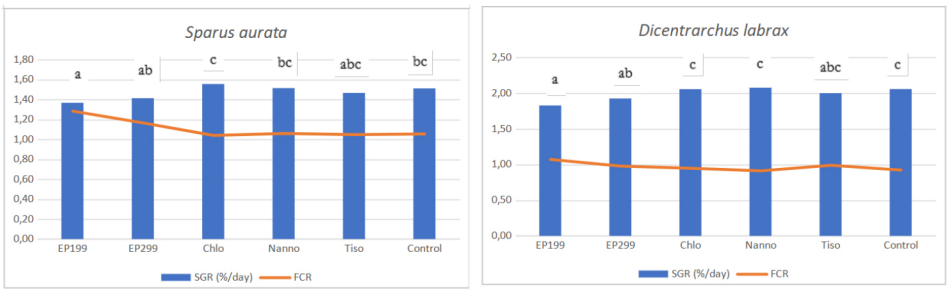

Fig. 1 A and B: Fish performance (growth rate and feed conversion rate) in five experimental diets containing fermented compounds or phytoplankton compared to a standard control diet in *Sparus aurata* (A) and *Dicentrarchus labrax* (B).

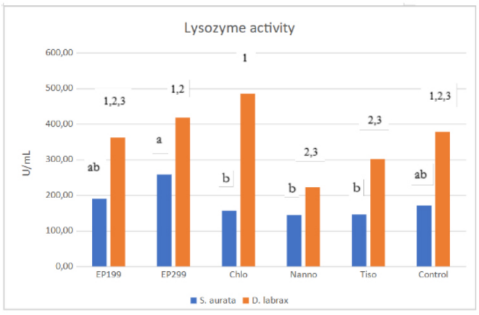

Fig. 2: Lysozyme activity in *Sparus aurata* (blue bars) and *Dicentrarchus labrax* (orange bars) fed five experimental diets containing fermented compounds or phytoplankton compared to a standard control diet.

FUNCTIONAL GENOMIC ANALYSIS OF LANDLOCKED ATLANTIC SALMON (*Salmo salar*) POPULATIONS

Ross Cairnduff [1] *, Erik Kjærner-Semb[1], Rolf B. Edvardsen[1], Per Gunnar Fjelldal[1], Tom Hansen[1], Tom Ole Nilsen[2], Anna Wargelius[1]

Introduction

Given both the economic and societal impact of the Atlantic Salmon *(Salmo salar*) farming industry in Norway, increased knowledge around heritable traits, which may translate into welfare gains in both wild and farmed salmon, is of high demand. This may include traits associated with disease resistance, growth and sea-water adaption. Genetic potential may reside in landlocked populations which have undergone different selection pressures compared to their anadromous counterparts for the last 10,000 years, due to their lack of sea water transfer, lack of marine pathogen pressures and different feed availability. We have in previous studies identified genes and genomic regions diverging between anadromous and landlocked Atlantic salmon populations from a widespread geographical distribution. However, we do not yet understand the biological significance of these diverged genomic regions, spanning about 250 genes distributed on several chromosomes. Hence, the objective of this study was to increase the biological understanding of the genetic differences between anadromous and landlocked populations. From the 250 genes present in diverging regions, we picked 22 candidate genes previously associated with either disease resistance, growth and sea-water adaption in other species. Gene expression was assayed in several tissues before and after the predicted smoltification season in a common garden smoltification experiment including one-year old anadromous farmed salmon (Mowi) and landlocked salmon (Gullspång).

Results

From the 22 genes we identified differential expression in 4 genes; *ncor1*, encoding a thyroid hormone mediator in the gill was shown to be down-regulated in Gullspång post smoltification, while remaining fixed in the Mowi counterpart. *spcs3* encodes a protein involved in microsomal peptide signalling in the head kidney and was shown to be up-regulated in Mowi, while remaining fixed in Gullspång. *csf2rb2* encodes an activator in the JAK-STAT pathway and was down-regulated in Gullspång while being fixed in Mowi. *bcl2l13,* linked to adipocyte biogenesis, was significantly higher Gullspång than it was in Mowi. To further investigate whether the identified genomic regions contain genetic variation relevant for understanding and improving traits in farmed salmon, we are currently screening farmed salmon strains for potential landlocked alleles using a genotype-by-sequencing (GT-seq) approach. The plan is to perform genotyping of 28 regions in the salmon genome in a vast material of farmed fish in which traits of interest have been quantified, such as growth and sea-water adaption. This study provides a basis for further functional studies of candidate genes through the creation of knockout models and subsequent functional studies including growth, disease and feeding trials.

TRACEABILITY TOOLS TO VERIFY THE GEOGRAPHIC ORIGIN OF AQUACULTURE PRODUCTS: FOSTERING ORIGIN CERTIFICATION AND FIGHTING FRAUDULENT PRACTICES

R. Calado*, R. Mamede, A. Santos, D. Gonçalves, M.R. Domingues, A.I. Lillebø, P. Domingues, S. Cruz, F. Rey, P. Cartaxana, E. da Costa, B. Marques, C. Patinha, E. Ferreira da Silva and F. Ricardo

E-mail: rjcalado@ua.pt

Seafood trade has been steadily growing worldwide over the last decade, with aquaculture production playing a key role. Food safety is increasingly important to consumers that want to know the origin and mode of production of their seafood. Traceability in seafood supply chains is increasingly becoming a requirement in importing countries to safeguard public health and ensure good practices. The concept of traceability has been defined by the EU as the ability to trace and follow a food, feed, food-producing animal or substance intended to be, or expected to be incorporated into a food or feed, through all stages of production, processing and distribution. Implementation of seafood traceability regulations is especially challenging on origin certification, although EU legislation has specific requirements targeting seafood origin. It is worth emphasizing article 58 of EC 1224/2009 that states the need of "all lots of fisheries and aquaculture products shall be traceable at all stages of production, processing and distribution, from catching or harvesting to retail stage".

DNA barcoding tools are commonly employed to reveal species mislabeling and adulteration but fail to resolve issues on the geographic origin of aquaculture products. These constraints can be overcome using elemental fingerprints of mineralized structures and biochemical approaches surveying the fatty acid profile and the lipidome of specific tissues. Both approaches are cost-effective, relatively fast and rely on well-established techniques. Both hold the potential to accurately discriminate cultured specimens originating from production sites less than 1 Km apart, with biochemical fingerprints also allowing to infer the time elapsed post-after harvesting.

Elemental and lipidomic tools coupled with feature selection methods allow speeding-up biogeochemical and biochemical analysis (respectively) by determining which chemical elements and/or lipids best predict geographic origin. These approaches have already been successfully employed to discriminate the geographic origin of multiple farmed fish, shellfish and seaweed species, thus confirming their potential for origin certification and prevention of fraudulent practices.

Overall, these traceability tools can contribute to add-value to aquaculture products by safeguarding that trade chains are increasingly more transparent, by maximizing food safety and enhancing the trust of consumers on aquaculture products.

This work was financially supported by project TraSeafood (Tracing the geographic origin of seafood as a pathway towards the smart valorization of endogenous marine resources) (PTDC/BIA-BMA/29491/2017), funded by FEDER, PT2020 Partnership Agreement and Compete 2020 and by national funds (OE), through FCT/MEC. We also acknowledge FCT/MEC for the financial support to CESAM (UIDP/50017/2020+UIDB/50017/2020) through national funds and co-funding by FEDER, within the PT2020 Partnership Agreement and Compete 2020.

ADVANCE SENSING OF OCEANIC AQUACULTURE SYSTEMS

Rui Caldeira*[1], João Monteiro[2], Carlos Lucas[1], Jesus Reis[1], Patrício Ramalhosa[2], Sílvia Almeida[2], Sahar Chebaene[2], Pedro Diniz[3], Natacha Nogueira[4], João Canning-Clode[2], Carlos Andrade[1,4]

The growing global demand for seafood has prompted an increase in offshore aquaculture facilities and farms worldwide. However, despite the crucial role that aquaculture plays in reducing marine natural food resources exploration, concerns on the potential impact of offshore activities warrant close monitoring of cages, infrastructures, and surrounding areas. As such, industry standards and good practices require offshore systems to regularly monitor how their activity may affect surrounding fish communities, benthos, water quality, and sediments. Comprehensive monitoring of offshore aquaculture infrastructures, cages, moorings, and surrounding areas can contribute to the early detection of potential negative impacts on surrounding habitats and marine diversity and provide valuable information for operational optimization, infrastructure maintenance, and damage prevention. In this context, remote sensing, remotely operated vehicles, and autonomous monitoring technologies can provide significant operational advantages to aquaculture activities. While remote sensing, autonomous apparatus, robotic systems, and automation technology require a relevant initial investment, over time, it can effectively contribute to optimizing operations, maximizing yields, reduce maintenance costs and prevent critical damage. Additionally, the operational flexibility and range of available sensors of these systems and technology make them suitable for various applications and scenarios. In this context, we developed a case study in Madeira Island (NE Atlantic) to explore how open source and commercially off-the-shelf unmanned and autonomous technologies can be combined to monitor multiple variables in offshore aquaculture infrastructures.

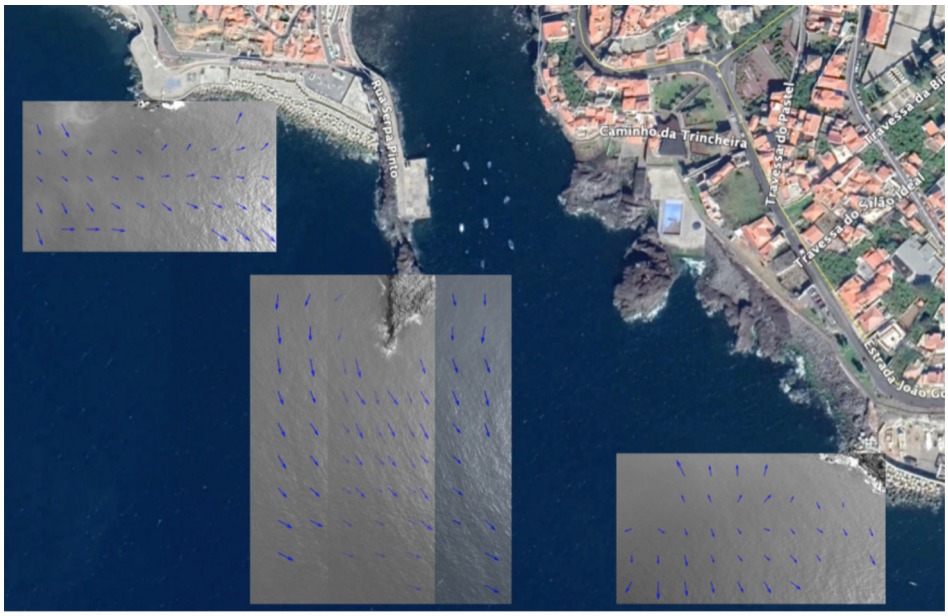

Figure 1 – Sea surface currents calculated from sequential quadcopter images

Unmanned Aerial Systems (UAS) remote sensing were used to measure temperature and currents at the sea surface. Aerial imagery and Structure from Motion photogrammetry were used to assess cages' response to tidal flow and deformation in floating structures. The evolution of a plume of food and/or detritus can also be monitored with UAS videos. Acoustic Doppler Current Profiles (ADCP) and temperature sensors provided a time series of ocean currents through the water column. Ocean circulation impacts the surface dispersion of food and sedimentation of residues on the seafloor. Moreover, timing the feeding window with the ocean circulation is of utmost importance for optimizing the operation. Aerial systems were used to monitor temperature and currents, Remotely Operated Vehicles equipped with multiple cameras and sensors to provide valuable information on the sea bottom and benthos, assess sedimentation, and enable visual inspection anchoring and mooring systems. Finally, the use of Baited Remote Underwater Video Systems was tested to monitor pelagic and benthic fish diversity and communities in surrounding areas, replacing the need for the underwater visual census. Video annotation, automated image analysis, and artificial intelligence-assisted image classification streamline aerial and underwater image processing and data compilation.

SUSTAINABLE AQUACULTURE: FROM NUTRIENT RECYCLING TO IMPROVED HATCHERY DIETS TECHNOLOGY

*presenting author: camilla.campanati@gmail.com

Introduction

As aquaculture intensifies, there is increasing pressure to find more sustainable practices that save resources and reduce waste. Combined with increases in resource use efficiency across the aquaculture sector, from feeding methodologies to product storage, nutrient recycling can enable aquaculture to contribute sustainably towards the nutritional requirements of billions of people over the next century. The marine aquaculture sector is expanding towards lower trophic level cultures such as macroalgae and bivalve molluscs, which offer numerous sustainability and human health benefits, with a low environmental footprint and a rich source of essential fatty acids and micronutrient. Despite these clear benefits, the growth of bivalve industry has failed to keep pace with fish aquaculture due to a number of challenges including suboptimal and unreliable diets, yield loss due to disease, and unpredictable quality of product. Indeed, conventional hatchery systems rely on the cultivation of lipid-rich algal diets, which are highly vulnerable to contamination and can occupy half the hatchery footprint. In this project we selected and encapsulated algae as alternative more cost-effective substitutes to conventional microalgal diet. Nutritional requirements of mussel *Mytilus galloprovincialis* spat and conditioning broodstock were researched and growth, gametes development and tissue fatty acid contents were assessed. The aim of this study was to determine the substitution level of microalgae by microencapsulated feeds (BioBullets) in hatchery feeds which could uplift mussel production through a reduction of costs.

Material and method

Optimal nutrients for encapsulation were identified from a wide range of aquaculture side streams, with the marine algae *Undaria pinnatifida* and *Schizochytrium* offering complementary nutritional profiles with collectively high EPA and DHA levels. Diets were produced commercially and characterised in the laboratory, showing a spherical shape, a 40-50% loading of nutrients by mass, near-neutral buoyancy and a size of 20-140 μm. Various nutritional feeding studies were designed to identify the optimum level of commercial microalgal substitution (partial or complete) with microencapsulated feeds to support high growth and fast gamete development of *M. galloprovincialis* at commercial scale. In particular, we firstly conducted feeding trials using blended BioBullets (BB), containing *U. pinnatifida* and *Schizochytrium* sp., for mussel spats and compared hatchery performances with spat fed commercial algal diets (A), the combination of conventional diets and BioBullets (ABB) and unsupplemented spat in the laboratory (NC) and in natural conditions (Mutriku). We further conducted experiments on *M. galloprovincialis* spat and broodstock using BioBullets containing *Schizochytrium sp*. at different level of commercial microalgal diet substitution (0 % (A); 60 % (ABL); 80 % (ABM); 100 % (B)).

Results

A circular economy, which allows side streams and by-products to be recycled within the aquaculture sector, will certainly play a key role in increasing production output (Fig. 1A). BioBullets containing *Schizochytrium* sp. and *Undaria pinnatifida* supplied to mussel spat at 100 % substitution of commercial microalgae, provided a balanced nutritional diet which supported survival and growth rates similar to mussels fed conventional diets (Fig. 1B). BioBullets containing only *Schizochytrium* sp. were able to sustain mussel spat growth at 60 % inclusion in the diet (Fig. 1C). At the end of the 6 weeks conditioning, adult mussels fed algae + BioBullets at low and medium inclusion (ABL and ABM) presented 40-60 % of individuals already in resting stages, similarly to A-fed mussels. (Fig.1 C).

Discussion and conclusion

Hatchery diets with microencapsulated feeds can provide dependable, contaminant-free diets that reduce costs of seed production and, thus, can sustainably support mussel farming. Additionally, by sourcing the encapsulated algae from side streams of the aquaculture industry, microencapsulated feeds can promote more sustainable practices and circular economies within the sector. Further tailoring of the nutritional composition of microcapsules to specific bivalve species or growth stages could allow microcapsules to replace a greater proportion of or even completely replace algal diets. Inclusion into microcapsules of therapeutics or even flavourings open up additional potential benefits to this important and growing industry.

(Continued on next page)

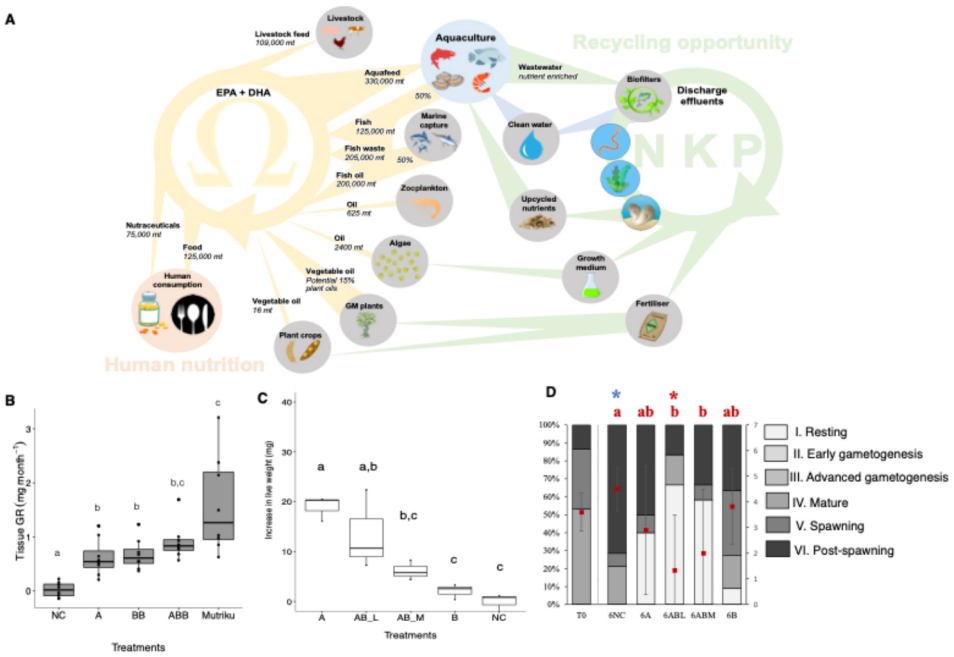

Fig. 1. A) Supplies and demands of omega-3 fatty acids (EPA and DHA). Major demand for omega-3 is from aquaculture, which can then substantially contribute to the market supply, through recycling of nutrients from farm wastewaters. Nutrients can be upcycled into biomass through the food web and/or to fertilize omega-3 producing crops. The use of biofilters in the recycling of nutrients from farm effluents not only provides potential for increased biomass yield that can be used as aquafeeds, but also clears water that can then be reused for farmed species, promoting a circular economy within aquaculture. The vertex of each triangle represents the direction of the arrows and the size is proportional to the volume (in MT). B) Spat tissue growth in the first feeding trial being fed for 6 weeks with different diets; C) Spat increase in live weight in the second feeding trial being fed for 8 weeks with different diets; D) Percentages of gamete developmental stages (I-VI) in adult mussels before (t0) and after 6 weeks of experiment being fed with different diets. NC=No food; A=conventional microalgae; BB=blended Biobullets containing *U. pinnatifida* and *Schizochytrium* sp.; ABB= conventional microalgae + blended BioBullets; Mutriku=natural field condition; ABL= 40 % microalgae + 60 % BioBullets containing *Schizochytrium* sp.; ABM= 20 % microalgae + 80 % BioBullets containing *Schizochytrium* sp.; B=100 % BioBullets containing *Schizochytrium* sp.; Different letters represent significant differences among treatment groups.

@AQUAGIS: A G.I.S. WEB APPLICATION FOR MARINE SPATIAL PLANNING AND AQUACULTURE IN ITALY

M.P. Campolunghi*, S. De Corso, C. Cipolloni, F. Cardia, T. Petochi, A. Bruschi, G. Calise, G. Marino

ISPRA - Italian Institute for Environmental Protection and Research, Rome, Italy
Email: mariapaola.campolunghi@isprambiente.it

Introduction

The key feature of EU Directive for Maritime Spatial Planning (2014/89/EU) is the integration of various sectors and societal needs to achieve a sustainable development of blue economies. In this framework marine aquaculture moves from traditional single sector planning to a more integrated approach, where Geographic Information Systems (G.I.S.) are essential analytical tools (Gimpel et al., 2018).

The INSPIRE Directive (2007/2/EC) established the access to spatial data sets and services between public authorities of EU Member States and the Open Data Directive (2019/1024/EU) encouraged public sector bodies to make data available and recognizing geospatial, earth observations and environmental data as high-value dataset.

@AquaGIS is a WebApp, published on the ISPRA's Portal, which provides services and tools to visualize, query and analyse heterogeneous data for marine spatial planning and aquaculture supporting the identification of AZAs (*Allocated Zones for Aquaculture*) in coastal and offshore marine areas and performing site suitability assessment (Marino et al. 2020).

Materials and Methods

The '@AquaGIS' WebApp is an application tool that is part of an Integrate Information System for cartographic services and web applications that provides aquaculture data. The Aquaculture Information System is integrated into the ISPRA's Spatial Data Infrastructure SINACloud, a complete system for the acquisition, validation, management and publication of data, metadata and network services, working according to INSPIRE Technical guidelines. It consists of two main frontend components: i) an application server for publishing the data and delivering them as cartographic API and OGC/INSPIRE web services (WMS, WFS, WCS) and ii) a geoportal for cartographic content management. The platform is supported by an SDI architecture composed farmhouse of ArcGIS and GeoServer web servers that allow the publication of network services. The data is incorporated in an Enterprise-type multi-user Geodatase integrated as part of SDI and managed by the GIS Client applications.

The '@AquaGIS' WebApp is the consultation application of the aforementioned cartographic network services. In addition to the visualization component, @AquaGIS provides users with a system performing complex queries using standard and customized widgets.

Results

@AquaGIS currently stores 111 layers that can be displayed and queried, including feature classes, tables and raster data, most of them with a national geographic extension (Fig.1). The table of contents allows the navigation trough different groups of layers related to administrative boundaries, aquaculture constraints, environmental conditions and site suitability, including:

- National and regional waters boundaries within 12 NM
- Marine uses (e.g. aquaculture licenses, ports, marine traffic, fishing effort, tourism, industries, military area, pipelines and cables, wind farms)
- Environmental constraints (e.g. MPAs, protected species/habitats, contaminated sites, river mouths, wastewater treatment plants)
- Other constraints (e.g. wrecks, dumping sites, unexploded ordnances)
- Physic and biogeochemical marine data (e.g. bathymetry, currents, waves, SST, Chl-a) from satellite and numerical models
- National marine monitoring network (e.g. MSFD, WFD)
- Maps of non-compatible or restricted areas for aquaculture activities
- National, regional and local maps of suitability for fish and shellfish farming

(Continued on next page)

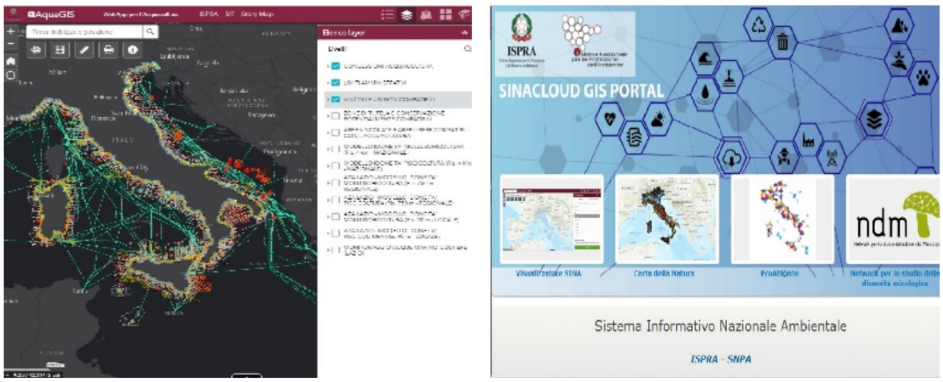

Fig.1 – @AcquaGIS WebApp and the SINACloud GIS Portal

For the process of AZA identification, the data analysis is carried out on a national scale with a resolution of 4 km. In some marine areas, analysis are provided with a regional resolution of 750 m. Site suitability for new fish and shellfish aquaculture installations is performed with a local resolution of 90 m in some key case studies. A section of @AquaGIS is dedicated to the national environmental monitoring network (MSFD, WFD), making available *in situ* marine data collected and processed by the National System for Environmental Protection (ISPRA-SNPA).

Discussion and conclusion

@AquaGIS is a multifunctional decision-making tool that, through an iterative and interactive process, permits the visualization and interrogation of the factors contributing to the aquaculture planning and suitability assessment. It can also be a node for exchanging information from different institutional sources as a "*mirror station"* of their services. @AcquaGIS also provided information on aquaculture and the planning process for AZAs through a "*Story Map*". @ AquaGIS is a key tool for national, regional and local authorities, aquaculture stakeholders and other marine users involved in the maritime spatial planning in Italy.

Acknowledgments

This project has been developed also using data from CMEMS, EMODnet, the Italian Navy Hydrographic Office and the Ministry of Ecological Transition website.

Introduction

The bivalve mariculture sector is an important food-producing sector since is one of the five sectors listed in the EU's Blue Growth Agenda. Careful management practices need to be implemented to ensure its sustainable development. Major challenges include the competition for space, production and ecological carrying capacity and food safety (e.g., harmful algal blooms). Management and development of this sector is highly dependent on the information on the physical conditions: current speeds, temperature, and wave conditions.

The H2020 FORCOAST project (https://forcoast.eu) aims to offer information services co-designed with stakeholders, which provide high-resolution data of water quality and metocean variables at coastal zone and nearshore that are used to give focused answers to specific questions from the targeted wild fisheries, bivalve mariculture, and oysterground restoration sectors.

These services allow improving operation, planning, and management of different marine activities in these sectors. Their value depends on the efficiency and effectiveness in the operations and productivity while decreasing the pressures on the marine and coastal environment. The increasing availability of data and technological advancements will contribute to a better and deeper understanding of the surrounding environment. The demand for such services is increasing as the marine related business has been observed to be growing in economic value.

The Ytide service

Despite the proliferation of means to extract and utilise environmental data (observed and modelled), various potential users are still not using them to optimise their daily outdoor activities. In other words, many ocean-related businesses can further improve their efficiency, reduce costs, and maximise profits should they start using data science tools. At the same time, the users' contribution to the development of data interface/delivery systems is paramount to tailor data services to their specific needs.

The Ytide service aims to provide easy access to tailored information for the aquaculture sector through existing mobile messaging applications. It has been co-designed by the +ATLANTIC CoLAB and the ExporSado company to meet the requirements of professional bivalve producers in intertidal areas and to reduce their operational environmental constraints, considering that:

- Producers need to reach the production areas in time, following local tides,
- Bivalve producers can only work during low tide conditions,
- Production sites are frequently located distant from tidal gauges,
- Local meteorology and hydrography that influence water levels are often disregarded in existing solutions, and
- The location-specific information is needed with a few days in advance for planning.

The current version of Ytide provides access to various environmental parameters that are key for the oyster production activity: daylight period, high and low tide heights and times, and optimum operation time window. Other environmental limiting factors, such as wind and rain, are also included (Figure 1).

The main innovation of the Ytide service is that the information is formatted and distributed automatically through existing messaging smartphone apps, such as Telegram. The main advantages of this approach include:

- Ease of access: faster and easier to access a smartphone app than a website,
- Interaction with colleagues: sharing information and interacting is quick and easy, and
- Productivity: enables better performance, time optimisation and more efficient work

To configure a new service, the end-user must provide geographic coordinates of the aquaculture production areas, optimal water hight for their activities, thresholds of environmental limiting factors and a list of contacts that will receive the information. After that, the end-users simply need to install the Telegram application to start receiving the information.

(Continued on next page)

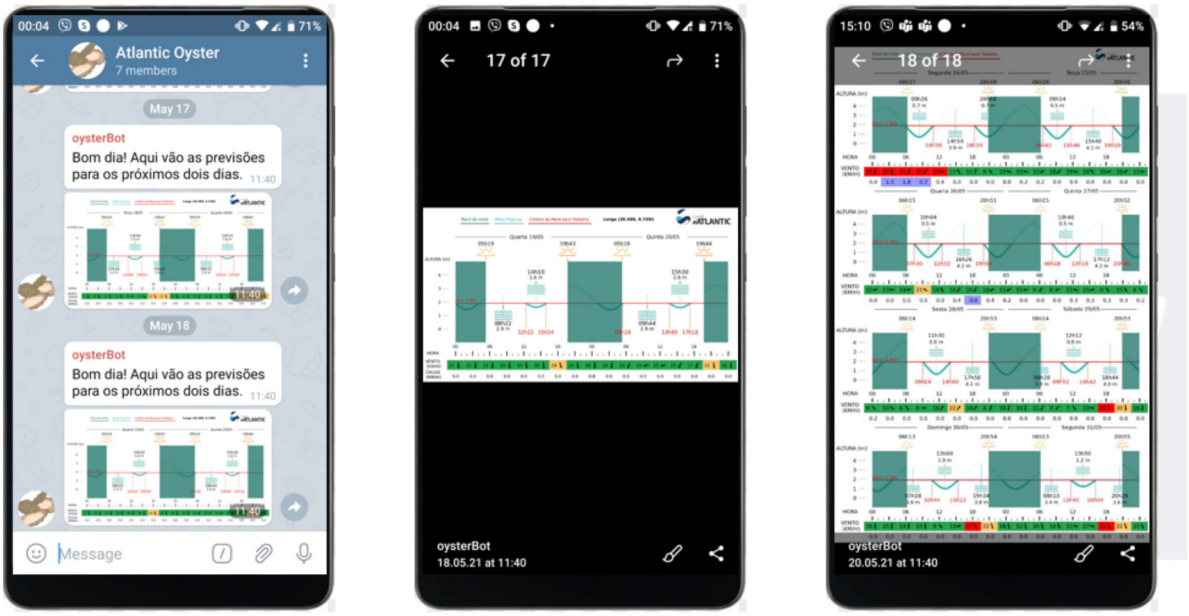

Figure 1: Notification messages shared through Telegram for the ExporSado production area

The Sado estuary pilot service

Based on the identified needs of local oyster producers, the Sado estuary aquaculture community is being used as a pilot application. The service is being executed automatically in two formats:

- Daily: information for the two following days with the best operational forecast, and
- Weekly: every Thursday, with information on the conditions for the next week.

Conclusions

The FORCOAST project aims to improve the quality, reliability, and customization of the currently offered operational marine products. By making these products more accessible and usable to the European wild fisheries, oystergrounds restoration, and bivalve mariculture, it benefits these industries' know-how, expertise, and competitiveness, increasing their potential to seize market opportunities.

The Ytide service is based on the harmonisation of different types of data, resulting in a location-specific and user-customisable tool that adds value to the end-users. Their involvement in the customisation and testing phases is key for the quality of the provided forecasts. The Ytide service can be easily customised to other geographical areas and to various other ocean-based economic activities and communities.

Acknowledgments

The FORCOAST project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 870465.

Introduction

Traditionally the nets used in sea cage farming are made of nylon, a synthetic thermoplastic polymer widely used in fabrics production. As a robust polymer, nylon is not easily degraded (Lewis et al., 2004), but it can be broken into small sized particles as a result of aging and UV exposure. In the particular case of fishing nets and sea cage nets, biofouling establishment is likely to further potentiate the aging and breakability of nylon.

Net biting is a gilthead seabream specific behavior long reported by farmers and suggested to be related with feeding ratio and the presence of micro-fouling (Glaropoulos et al., 2012; 2013). Whether seabream actually ingests net pen debris has not been documented. But if it does, it can be hypothesized whether net pen debris may induce intestinal alterations, directly or indirectly as possible vehicles of toxic chemicals (Oliveira et al., 2013; Peda et al., 2016).

As an alternative to the traditional netting, a copper-alloy mesh conceived for sea-cages has been recently introduced in the market. Being made of copper, its exposure to micro-fouling (including pathogens) and its susceptibility to predators' attack is said to be minimized. Although it seems to be promising as an alternative to nylon, it remains to be known whether the mesh aging could lead to copper leaching and whether that could affect fish health.

This study aimed to evaluate the risks coming from the interaction of gilthead seabream with net pens of different materials and aging status by studying: 1) the bacterial community established on the nets with an emphasis on potentially pathogenic genera; 2) the biting behaviour and net erosion in relation to biofouling establishment and 3) the impact of net exposure on fish health status.

Materials and methods

Fish were grown out from 100 to 270g (up to 6Kg/m^3, with 12 fish/tank) in a flow-through system, where 12 fiber glass indoor tanks were supplied with unfiltered and untreated seawater withdrawn at 130m from the coastline. The control group was grown in clear tanks, with no net; the NNy group was exposed to a <1-year-old nylon net; the ONy group was exposed to a >5-year-old nylon net; the Cu group was exposed to a new copper net. Nets were placed in the tanks as panels (40x20cm) immersed within the first 35 cm of the water column. Fish were fed once a day, at 12.00, except for Mondays. In each tank, the area surrounding the net panel was videotaped on Mondays (starving day), Tuesdays and Thursdays, in the morning, during the meal-time and in the afternoon, for 10 min, to evaluate the fish-net interaction behavior.

After 125 days, each net panel was hanged up off the water and two pieces of each net were sampled/swabbed for further microbiome analysis. The net panel was then removed off the tank and photographed for damage evaluation and a 10x10cm square was cut off for mobile epifauna counting e identification. Five fish per tank were sampled for blood collection for hematological profile characterization, the plasma was snap-frozen in liquid nitrogen and stored for further analysis of immune status parameters. The liver was excised for further analysis on oxidative status markers. The skin and distal gut were sampled for microbiome analysis. Distal gut sections were sampled also for histopathological qualitative analysis and for the quantification of transcript levels of inflammation-related genes by RT-PCR.

(Continued on next page)

Results and Discussion

The bacterial communities associated with copper and nylon nets used in sea cages were compared using a metataxonomic approach through the high-throughput sequencing of the 16S rRNA V4 hypervariable region. Most differences were found between both nylon nets and copper nets, with less bacterial diversity in copper nets, which confirms its bactericidal effect. However, Tenacibaculum known to harbor potentially pathogenic species, was more abundant in copper nets than in nylon nets. These results bring up the need for monitoring the bacterial communities established on aquaculture gear, particularly on nets and including copper nets, to evaluate whether they may serve as reservoirs for pathogenic bacterial strains.

No mobile epifauna was observed on copper nets. Mobile epifauna communities were different between old and new nylon nets, being more abundant in the new nylon. Although the behaviour analysis does not suggest clear differences between the 3 net types, the new nylon nets were clearly more damaged at the end of 4 months than the old nylon nets, which is probably related to epifauna abundance that should attract seabream towards the nets.

Concerning possible effects on fish health, although no signs of inflammation were found in gut histological analysis and no differences were found in gut microbiota, NNy fish displayed a higher expression of the anti-inflammatory cytokine IL-10 in the distal gut and increased bactericidal activity in plasma when compared to the control fish, as if exposed to a foreign agent. On the other hand, the distal gut of ONy fish displayed higher expression of CD8 which regulates cytotoxic T-cells activity. This group also displayed increased activities of catalase and glutathione S-transferase in their livers, when compared to the control group, while the NNy and Cu groups displayed intermediate levels. Further analysis are being conducted to check for nylon debris detection on fish gills and gut.

Overall, these results highlight the importance of sea-cage net material and aging status on the fish-net interactions and associated welfare risks, either due to the biofouling communities that could harbor fish pathogens, but also possibly due to toxicological effects of the net material.

Introduction

The research on aquaculture perceptions has been mainly focused on the attitudes of consumers towards aquaculture products, opinions of the general public on the aquaculture industry and the perceptions of aquaculture key stakeholder groups (Bacher, 2015). A great part of these studies have used Likert scales to measure the level of importance/agreement for certain characteristics or statements for aquaculture's image and its products. From these, some investigations have mixed negatively and positively worded survey items (e.g. López-Mas et al. (2021); Murray and D'Anna (2015)making aquaculture the most suitable alternative to support increase in fish consumption. However, farmed fish have a less positive image among consumers than their respective wild-caught equivalents. Food product images can be affected by consumers' beliefs, which are useful to infer the quality of the food product and the consumers' food choices. This paper investigates European consumers' beliefs regarding farmed versus wild fish. The goal is to understand not only what hinders farmed fish consumption but also provide guidelines for producers and governments to improve the image of farmed fish. An online questionnaire reaching 2511 consumers in five European Union (EU), looking to decrease the potential acquiescence bias (to agree with questionnaire statements irrespective of the content). However, Chyung et al. (2018) found that this option can be problematic, as the negatively worded items, which are usually reverse recoded, might not measure exactly the same as the positively worded statement counterparts. In addition, negatively worded items may appear as separate factors (method effect) or might be misunderstood by unwise respondents, causing erroneous data. To our knowledge, the effects of using a mix of positively and negatively worded statements have not been evaluated in the context of aquaculture perceptions. Following this, the objectives of this investigation are twofold: (1) to understand the influence of positive and negative wording on the public image of aquaculture and its products and (2) to identify whether the public image of aquaculture differs amongst segments in Gran Canaria (Spain).

Materials and methods

The study is based on a subset of a larger online survey analysing the preferences of consumers in Gran Canaria, Spain, which was conducted between April and June of 2020. In this section, respondents were asked to rate their level of agreement for 16 statements related to the image of aquaculture and its products on a scale from 1 (completely disagree) to 5 (completely agree). These statements included information about consumers' opinions about aspects such as pesticides and fish illnesses, pollution, crowded conditions of fish, cleanliness and healthiness of the environment, the naturalness of the fish farming process, comparisons with other types of farming and fisheries, the affordability of farmed fish, sustainability, the diet of the fish and the social and economic benefits.

Moreover, to understand the influence of positive and negative wording, two different survey blocks were distributed: one with the statements written in a positive way towards aquaculture, and the other one with the same statements but written in a negative perspective towards aquaculture. For example, a statement was written like this in each survey: (1) aquaculture farming is a natural process and (2) aquaculture farming is not a natural process. In the end, 167 respondents answered the negatively worded survey block and 184 the positively worded survey block.

For the analysis of the data, we used a methodology using a hybrid approach based on Fuzzy Set Theory (FST) and TOPSIS (Techniques for order preference by similarity of the ideal solution). TOPSIS is particularly useful when respondents make choices with multiple attributes, as these techniques prioritize and rank the items for easy managerial interpretation, which leads to the appropriate policy and strategy implementation. We established synthetic indicators to measure the public acceptance of aquaculture and its products, considering three different treatments (mixing positive and negative statements, just positive statements and just negative statements) and with respect to different segments, in which the sample was divided. In addition, fuzzy methods can capture the essence of human ambiguity judgement when respondents deal with multidimensional attributes. Also, we used fuzzy clustering techniques with a three-cluster solution to segment the consumers with a more realistic multidimensional description.

(Continued on next page)

Results and discussion

Results show that it is not a good idea to include negative statements on Likert-scale instruments assessing the acceptance of aquaculture and its products, as when the information of these statements is reversed for statistical analysis, the reliability and validity of the data are compromised, and the variability in the responses increases. The data with positive statements, on the other hand, retained their validity and reliability even when reversed, so it is recommended that all instruments are worded in this manner. This might be due to consumers understanding better positively worded statements, while those negatively worded might be confusing. This also indicates that it is not the same to ask questions in a positively worded manner than to ask them in a negatively worded manner.

Moreover, we obtained the findings of the perceptions of aquaculture image in Gran Canaria (Spain), based on the results of treatment 2 (positively worded items), which is the most reliable based on what was previously discussed. According to the crisp values, the three most valued items are as follows: the fish that come from aquaculture are a healthy food option (52.83), the fish that come from aquaculture are consistent and affordable (54.99), and the fish that come from aquaculture contribute to fish mass sustainability (55.37). Meanwhile, on the other hand, the three least valued items for aquaculture image are related to: fish farming is a natural process (38.41), the crowded conditions of fish farms are adequate for fish (40.01) and the captured fish have a natural diet, and this is not better for them in comparison with farmed fish (40.38). Interestingly, the three least valued items are related to fish conditions and this result can be considered strategically in order to improve the aquaculture image.

The results indicate that there is a better acceptance of aquaculture and its products for the respondents belonging to the following segments: consider salmon as one of their favourite species, prefer farmed fish over wild fish, prefer products of EU origin, live in a big household, earn lower than the national average, and are part of the youngest (below 25 years) and oldest generation (above 66 years). On the contrary, there is a lower acceptance of aquaculture and its products for respondents belonging to the following segments: consider seabream as one of their favourite species, prefer wild fish over farmed fish, prefer local products, do not read the information accompanying the seafood products, have a very low educational level, live in a small household, earn greater than the national average, and are part of the generation between 26 and 35 years of age.

According to the fuzzy clusters, it can be said that the profile of an extreme Pro-Aquaculture consumer is characterized by a consumer who perceives all of the attributes at the maximum or second-maximum values. Meanwhile, extreme Anti-Aquaculture consumers are characterized for perceiving all statements on the scale as having the lowest value. The intermediate cluster is characterized by (1) seven low valued attributes with a value of 2, (2) three intermediate valued attributes with a value of 3, and (3) six high valued attributes showing values of 4. In summary, the average probability of belonging to the “Pro-Aquaculture” consumer segment is 37.26%, to the “Anti-Aquaculture” consumer segment is 35.88%, and to the “intermediates” consumer segment is 41.63%.

Introduction

The lack of suitable sites for aquaculture is one of the main limiting factors for the expansion of the Mediterranean marine fish farming sector (COM 2021/236 final). In the framework of the EU Directive for Maritime Spatial Planning (2014/89/EU), Italy is planning the use of marine space units for different blue economy sectors, including aquaculture. This study presents a new suitability model based on Earth Observation (EO), numerical models and in situ data for 12 criteria, to identify Allocated Zones for Aquaculture (AZAs) and suitable farming sites in coastal and offshore marine areas in the Tyrrhenian Sea.

Materials and Methods

A Spatial Multi-Criteria Evaluation (SMCE) analysis (Dapueto et al., 2015) has been applied to assess the suitability for fish and shellfish aquaculture of around 9300 Km^2 of marine waters in the Lazio Region (from the coastline to 12 NM). The SMCE was divided into two phases: i) mapping of administrative, infrastructural and environmental constraints, including buffer zones, to identify areas not available for aquaculture (Boolean overlay); ii) identification of criteria (Tab.1) to map the most suitable sites for fish and shellfish farming. EO data and numerical models from different sources were compiled in the SMCE. Each layer was remapped on a regular grid with a horizontal resolution of 750 m, while each criterion was reclassified on a suitability scale from 1 (low) to 10 (high), according to the suitability criteria classification available in Marino et al. (2020). A Weighted Linear Combination (WLC) analysis was then applied following the attribution of a relative weight to each criterion (weighted overlay).

Results

The resulting outputs calculated with the WLC are the suitability maps for shellfish and fish aquaculture along the marine waters of the Lazio Region (Fig. 1, top). The marine areas with constraints were then subtracted from the two maps. The bathymetric ranges considered suitable for shellfish (8-40 m) and fish (25-80 m) farming were also applied to further refine the suitability maps (Fig. 1, bottom).

An additional query was carried out for selecting those areas characterized by suitability indices higher than 8. The analytical process finally resulted in the identification of areas with high suitability along the Lazio coasts, for a total of about 80 km^2 for shellfish aquaculture and about 190 km^2 for fish farming (Fig. 2).

Discussion and conclusion

The use of WLC, which entails the attribution of different weights for each criterion, is a very powerful tool in the decision-making process and it allows the definition of different scenarios depending on the relative importance assigned to each layer. The results obtained have been successfully used within the activities of the funded EMFF project AZA-Lazio: the maps of highly suitable areas for shellfish and fish aquaculture where used to support the consultation process with relevant stakeholders and coastal municipalities, in order to identify, among these areas, those to be allocated as zones for aquaculture (AZAs). The outputs of the process for the identification of suitable areas as well as all the spatial information used to implement the study have been integrated in a GIS WebApp specific for aquaculture spatial planning (@AquaGIS), available on the ISPRA website.

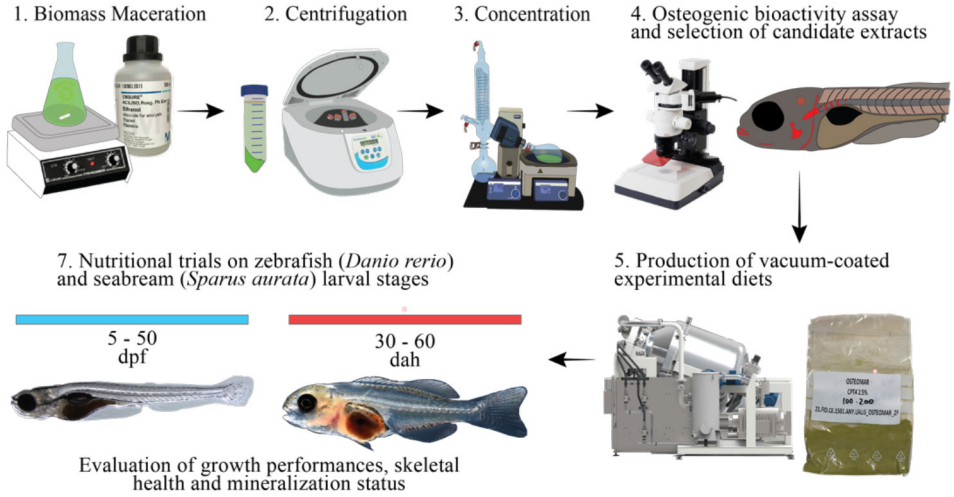
Graphical abstract



Introduction

Skeletal anomalies are omnipresent in most farmed fishes worldwide, raising concerns for animal welfare and causing economic losses for the aquaculture industry [1, 2]. Larval nutrition has been recognized as one of the main factors leading to skeletal anomalies [3, 4], thus the development of feeds supplemented with osteo-active compounds is seen as an important strategy to improve the skeletal status of farmed fish. In this context, extracts from marine organisms, a well-established and valuable source of nutrients, have recently been found to contain bioactive compounds with osteogenic and mineralogenic activities that could be highly relevant to improve skeletal health in larvae of commercial species. Here, we produced inert diets enriched with different concentrations of the ethanolic extracts from Skeletonema sp. and Tetraselmis sp. and tested them on larvae of the model species zebrafish (Danio rerio) and the commercial species gilthead seabream (Sparus aurata), evaluating their effect on growth, survival and development of skeletal anomalies.

Materials and Methods

Extracts were prepared through the maceration of freeze-dried biomass of *Skeletonema* sp. and *Tetraselmis* sp. (Necton S.A.) with 96% ethanol. Ethanol extracts were coated on a commercial zebrafish diet (Sparos Lda) at 0.5% and 2.5% and a commercial seabream diet at 0.5%. For zebrafish feeding trials, 5 days post-fertilization (dpf) larvae were maintained in 2.5 L tanks in static conditions at 60 larvae/L until 20 dpf, then moved to 3 L tanks in recirculating system at a density of 23 larvae/L. Experiments were conducted in triplicates for each of the 5 diets. From 5 to 16 dpf, zebrafish larvae were co-fed with the supplemented inert diet and rotifers, gradually reducing the concentration of rotifers to address the weaning from live feeds. From 17 dpf until the end of the trials, larvae were fed only supplemented inert diets. At 50 dpf, juvenile fish were given a lethal anaesthesia and final survival, total length and dry weight were assessed. Fish were sampled to asses calcium and phosphorus content and for double staining with alizarin red S and alcian blue for bony and cartilaginous structures to evaluate skeletal anomalies. The expression of marker genes of bone development, matrix mineralization and oxidative stress were assessed by qPCR.

(Continued on next page)

For the seabream trials, larvae of 30 days after hatching (dah) were fed for 30 days with control diet or diets supplemented with 0.5% of *Tetraselmis* sp. or *Skeletonema* sp. ethanolic extracts. Microdiets were formulated and processed to be isonitrogenous, and isoenergetic. Larvae were maintained in cylindroconical 100 L tanks in a semi-closed RAS with an initial density of 52 larvae/L and a photoperiod of 10h light:14h dark. Environmental parameters and mortality were monitored daily. At the end of the trial larvae were euthanized, sampled and growth parameters assessed - dry weight, length and condition factor. Samples for oxidative status, digestive capacity, total mineral content, calcium and phosphorous ratio, mRNA levels of marker genes for bone formation, matrix mineralization, and oxidative stress were collected. Some fish per condition were stained to reveal bone and cartilaginous structures and asses incidence of skeletal anomalies

Results and Discussion

In the past years, our laboratory has screened a large number of extracts from microalgae for bone anabolic activity using zebrafish in vivo tools and identified ethanolic extracts of Skeletonema sp. and Tetraselmis sp. as promising source of osteoactive compounds. Although the use of zebrafish as model organism in aquaculture is a controversial topic due to physiological differences and evolutionary distances between this small freshwater cyprinid and commercial teleost species, its use in nutritional research has been recognized as a great opportunity and results obtained in zebrafish were shown to have predictive power of the effect on stress, immunological response and dietary toxicity towards species reared in aquaculture [5, 6]we define the characteristics that a fish species should have to serve as a model for finfish aquaculture research and argue that the zebrafish fulfils essentially most of them. We first describe several aspects of the biology of the zebrafish including phylogenetic relationships, development and growth and reproduction, both in the wild and under laboratory conditions. Next, we review the work already carried out in zebrafish that is related to different aspects of aquaculture research (reproduction, stress, pathology, toxicology nutrition and growth. Aiming at providing a comparative view on the potential application of microalgae extracts in finfish nutrition, we produced inert diets enriched with different concentrations of two promising osteogenic extracts, tested them on larval stages of zebrafish and the gilthead seabream, evaluating their effect on growth, survival and the occurrence of skeletal anomalies. Regarding the feeding trials with seabream, results showed that dietary treatments had no impact on performance indicators like dry weight, length, or condition factor. For both species, the impact of the supplementation of the extracts on bone mineral content, expression of marker genes of bone growth and mineralization and incidence of skeletal anomalies revealed the advantages of microalgae extracts supplemented diets, and their potential for aquaculture applications.

Introduction

Aquaculture is one of the major sources of human food production, and its intensification, due to the increasing demand for healthy protein, can lead to environmental issues and poor fish welfare.

Farmed fish are often subjected to diverse rearing practices and environmental changes that can be stressful and affect the fish's immunity, contributing to disease outbreaks. When these occur, antibiotics are commonly used to combat the pathogens, however with the continuous use, antibiotic-resistant bacteria can develop affecting the outcome. Furthermore, the use of antibiotics can pose risks to human health and harm the environment since they can accumulate in fish and residues are often discarded in aquatic environments. Hereupon, research on antibiotic alternatives or preventive strategies is imperative.

To this end, this work proposes alternative environmentally friendly methods to boost the fish's immune system and prevent pathogenic infections. A nutritional strategy including diets supplemented with immunostimulants, and a thermal strategy to increase fish's infection coping ability, will be developed to reduce the use of antibiotics and mitigate their consequences. Overall, such alternatives will boost fish's welfare and aquaculture biosecurity, and advance the industry's and for the environment sustainability.

Material and Methods

In a first approach, gilthead seabream will be infected with the bacteria *Tenacibaculus Maritimum* to characterize the bacterial infection through Label-free shotgun proteomic (LC-MS/MS) analysis and identify possible disease biomarkers. In this experiment, the fish behavior will be observed through cameras displayed in the tanks and the optimal temperature of non-infected seabream will be assessed in thermal gradient tanks. Furthermore, hematologic, histological, and microbiological analyses will be performed.
In the second experiment, seabream will be subjected to infection and allowed to swim along a thermal gradient or being exposed to a constant temperature (obtained previously). Post-infection fish behavior and thermal preference will be evaluated through video recording.

At last, seabream will be subjected to a nutritional therapy where will be fed with two experimental diets with natural immunostimulants against a commercial diet. After this, fish will be infected with the bacteria to assess the diet's impact on fish disease behavioral phenotype and proteome. The biochemical parameters of the plasma (cortisol, lactate, and glucose) will be assessed and the liver glycogen.

THE EFFECT OF CONVENTIONAL AND NOVEL OILS ON BRAIN FATTY ACID INCORPORATION, BEHAVIOUR AND NEURAL FUNCTION OF GILTHEAD SEA BREAM (*Sparus aurata)* JUVENILES

Introduction

N-3 long-chain polyunsaturated fatty acids (LC-PUFA) are involved in several metabolic pathways, including neural development and function (Tocher, 2015). Indeed, composition of neural cells can direct influenced brain activity that, in turn, modulates fish behaviour, which is closely related with well-being and health status and of pivotal importance in fish production. Docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3) have great biological roles and are essential fatty acids (EFA) for marine species, due a limited activity of fatty acid desaturase (FADS) and elongases (ELOVL), necessary for their endogenous synthesis.

Although work has been carried out on larvae, very few studies have been conducted to understand the impact of n-3 LC-PUFA in brains and behaviour responses of fish in later stages of development. This topic deserves further attention on more species for a number of reasons: (1) With the increasing replacement of fish oil (FO) in aquafeeds, mostly with terrestrial plant or animal ingredients, n-3 LC-PUFA dietary contents could be significantly reduced. This is reflected in fish tissues and could affect fish cell responses. (2) Fish behaviour and neural function are good indicators of fish health and development, thus being of pivotal importance their study and monitorisation for an effective production of fish.

Therefore, using a long-term feeding protocol for sea bream juveniles, the aim of the present study was to investigate the effect of different conventional and novel oils with different dietary EPA and/or DHA contents on (1) brain fatty acid incorporation, (2) fish behavioural response to an external mechano-sensory stimulus and (3) expression of neurogenesis and neural activity-related markers.

Material and methods

A nutritional trial of 5 months was conducted in triplicated groups of gilthead sea bream (*Sparus aurat*a) juveniles (initial body weight of 2.50±0.01 g). Two experimental diets were formulated to present high EPA and DHA contents, one containing similar EPA and DHA levels and based on fish oil (FO diet) and the other containing 5 times more DHA than EPA using a blend of microalgae and poultry oil (DD diet). A third diet was formulated based on poultry oil (PO diet) and containing low EPA and DHA levels.

After the feeding period, 9 fish per treatment were randomly selected for testing behaviour response to an external mechano-sensory stimulus. Fish were tested in three groups per treatment, of three fish each, using a white bottom-tank of 100 L. Fish were exposed to a mechano-sensorial vibrational stimulus, which consisted in an iron pendulum of 600 g that was dropped without any additional force against the tank wall from a distance of 71 cm. Fish behaviour were monitored by video using a video-camera (Xiaomi Mijia 4k) and the following behaviour responses were analysed: responsiveness, type of escape response, basal and after stimulation activity levels, escape latency, escape distance and escape turning rate. Fish brains were collected for fatty acid composition analyses and gene expression of neurogenesis and neural activity-related markers.

Results

There was an increase in fish escape latency in response to the external stimulus with the decrease of dietary EPA and n-6 DPA, suggesting a slower reactivity to the stimulus in these fish, which might be related to a lower velocity in the translation of the neural signal to activate escape response. No significant effects were recorded for any other behavioural variable, contrary to what seen in fish larvae in previous studies (Benítez-Santa, 2012, 2014), suggesting that brains of juveniles' fish, that are fully developed, are less sensitive to dietary modification of FA composition, possibly due to the capacity of retention of n-3 LC-PUFA, mostly DHA in neural tissues for preserving vital neural functions. Indeed, DHA was highly retained in fish fed the low dietary DHA (PO diet).

Furthermore, an increase in neurogenesis and neural activity markers (*neurod1* and *bdnf*) as well as in *fads2* in fish fed PO diet was observed, suggesting a higher neurogenesis and neuroactivity as well as an activation of PUFA synthesis in those fish.

Introduction

With the aquaculture expansion, sustainability challenges have been emerging. Among them, there is great urgency in reducing the industry's dependence on finite-marine ingredients. Plant lipid sources have been commonly used to replace fish oils in feed formulations. However, vegetable oils-based diets might markedly deviate from fish natural feeding habits and negatively impact their health. In the particular case of Atlantic salmon (*Salmo salar*), this issue acquires major relevance during the seawater transfer (SWT), a stressful event and challenging production moment often associated with great losses. To improve the fish overall health, supplementing diets with immuno-modulators, such as certain amino acids, is becoming a common approach (Andersen *et al*., 2015). Among the amino acids recognized to cover functional roles that may improve fish health, histidine (His) and its derivatives (Remø *et al*., 2014) were found to behave as buffer and antioxidant and to have anti-inflammatory properties in the tissues they are present (Andersen *et al*., 2015). In this study, we have investigated whether dietary lipid source and His supplementation could influence the non-specific immune response and antioxidant system in Atlantic salmon after SWT.

Materials and methods

The fish were given four experimental diets differing in lipid source (100% fish oil or blend of vegetable oils) and His content (10 or 14 mg His/g diet) in freshwater (FW), and a cross-over was done after SWT to investigate the effect of supplying His supplementation in FW vs SW (**Figure 1**). At the end of the FW phase and 2 and 4 weeks after SWT, fish were sampled for blood plasma and liver to assess immune parameters and oxidative stress biomarkers, respectively. Gut samples were also collected for gene expression measurements.

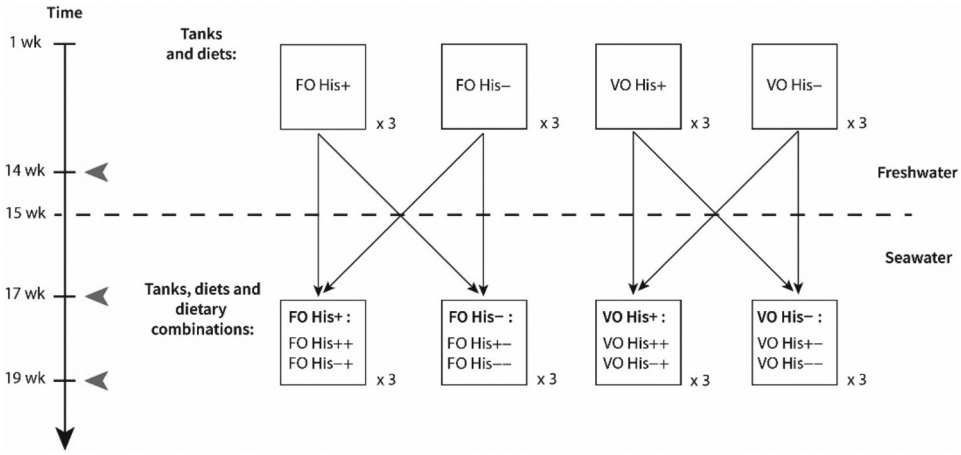

Figure 1. Schematic representation of the feeding trial design, displaying the dietary histidine (His) treatments cross-over at the seawater transfer moment (dashed line). Red arrows identify the 3 sampling points. FO His+, fish oil and high His content diet; FO His−, fish oil and low His content diet; VO His+, vegetable oil and high His content diet; VO His−, vegetable oil and low His content diet.

(Continued on next page)

Results and discussion

Regardless of dietary treatment, post-smolts appeared to be under oxidative stress two weeks after SWT, as indicated by the lower antioxidant enzymes activity. Even so, they seemed to manage to protect themselves from oxidative damage, since no increase in hepatic lipid peroxidation (LPO) levels were observed between the two times. Additionally, the increased alternative complement pathway activity in plasma found at the end of the feeding trial further suggests that all groups recover well from the transfer.

Post-smolts fed fish oil-based diets displayed higher plasma bactericidal and alternative complement activities than those fed vegetable oil feeds. Increased LPO levels were also observed in fish fed fish oil diets, possibly due to the greater susceptibility of marine lipids to oxidation. Apart from a stimulating effect of His supplementation on plasma IgM levels four weeks after SWT, it did not seem to significantly influence the post-smolt Atlantic salmon immunity and oxidative status, independently of the dietary lipid source.

Conclusion

All dietary groups seemed to recover well from the stressful SWT moment. There were, however, some minor signs of improved immunity of fish fed fish oil-based diets compared to those fed plant lipids. The small differences in both plasma innate immune parameters and liver oxidative stress biomarkers between the dietary His groups suggest that it did not significantly influence the post-smolts health status. Further analyses on gut samples are currently underway to provide more insight into the fish health condition.

Introduction

The expansion of aquaculture industry along with the limited marine resources available, including fish meals (FM), an emergent need to find alternative protein sources for use in aquaculture feeds had arisen in the last decades. A wide number of researches have been carried out studying plant alternatives, which are nowadays successfully incorporated in modern aquafeeds at elevated percentages. However, despite the potential to increase environmental and economical sustainability of aquaculture feeds, plant proteins often present insufficient protein content to meet fish requirements, unbalanced amino acid profile and reduced digestibility, particularly for carnivorous species. Consequently, without additional supplementation, diets with high contents of plant proteins could negatively affect fish productivity and/or health, and composition of fish flesh, reducing the benefits for the consumer. To solve these issues, a new era of research has been recently open with the purpose to find novel alternative protein sources for aquafeeds, reducing the dependency not only on marine ingredients (FM) but also on plant sources, for maximizing aquaculture productivity. From the novel raw materials studied, insect meal and single-cell proteins are possibly the most promising due to their high protein content and their balanced amino acid profile. Therefore, the main objective of this study was to test the potential of insect and single cell protein meals as fish meal replacers to reduce dependency on marine and plant ingredients, on gilthead sea bream growth performance, feed utilization and health parameters.

Material and methods

A nutritional trial of 112 days was conducted in triplicated groups of gilthead sea bream (*Sparus aurat*a) juveniles (initial body weight of ±65 g). A control diet was formulated with 15% FM and 63% of plant protein sources (CTRL). Insect meal (*Hermetia illucens*) was used to replace only FM at 5% (5-INS diet) or 10% (10-INS diet); and single-cell protein (a by-product generated by M*ethylococcus capsulatus'* fermentation) was used to replace only FM at 5% (5-SCP) or FM at 5% plus 5% of plant proteins (10-SCP). After the feeding period, fish were weighed for growth and feed utilization parameters estimation, and some of them were sampled for biochemical composition analysis. Additionally, health-related genes expressions were determined in posterior gut as well as plasma lysozyme.

Results

Sea bream fed 5% INS and SCP diets showed similar growth performance and feed utilization than those fed CTRL diet. However, 10% INS diet led to a reduced body weight than those fed CTRL and SCP diets, as well as a lower feed intake when compared to 5% SCP. Despite no significant differences were observed for specific growth rate and feed conversion ratio, the same tendency as body weight was observed. The dietary composition did not affect whole-body and flesh composition, neither plasma lysozyme. Similarly, no significant differences were observed in the relative gene expression of health-related parameters (*hsp90*, *hsp70*, *cox2*, *mhcII* and *tnf*α), although in general SCP-fed fish presented more similar expression values than those fed CTRL diet, whereas those fed INS presented tendentially lower expression values.

In conclusion, the results of the present study indicate the suitability of single-cell protein in replacing FM and reducing plant proteins dependency in diets for sea bream juveniles. Furthermore, insect meal showed also potential to replace FM in moderate quantities, whereas the high replacement levels affected growth performance and feed intake, possibly related to the chitin content of this meal.

TURN-UP THE SHELL: ADVANCES ON THE PATELLID LIMPETS' AQUACULTURE

Introduction

The true limpets (Patellogastropoda) are highly specialized marine gastropods commonly found colonizing rocky seashores. The limpets have been a fishery resource since the Neolithic period. Currently several limpet species are threatened by the overexploitation, which is leading to smaller and male biased populations, which individuals have less reproductive capacity and higher inbreeding ratio. Consequently, several limpets populations are endangered being taken protective measures focused on harvesting restrictions (Faria et al., 2018; Sousa et al., 2020). As alternative measure for the exploitation of the natural stocks, the limpets' aquaculture could be a sustainable effort able to develop different programs, either for human consumption or for the reproduction and reintroduction of different limpet species.

Limpets' aquaculture is a recent research field which efforts were mainly focused on the larvae production with variable success, while juvenile production has been mostly unsuccessful thus far. Recently, this state of the art changed thanks to advances done in Madeira Island and focused on the native species *Patella aspera* and *P. candei* (Castejón et al., 2021), it is now possible to obtain juveniles from an already settled larvae production.

Material and Methods

The adults were captured during the breeding period (mid autumn to mid spring in both species) and kept using an open system with high aeration, at 20 ± 1 °C and 36 ± 1 psu. The adults showed higher survival when no lesions occurred in the soft body during capture and management in captivity. Gametes were obtained dissecting adult specimens to expose the gonads. The sperm was gathered using a Pasteur's pipette and diluted in 100 ml filtered seawater. The sperm of 4 males was pooled and kept in the fridge until required. The oocytes were released breaking a female gonad placed inside a crystal beaker with filtered seawater using a Pasteur's pipette. Then, the oocytes were carefully washed using nylon meshes (200 and 55 μm). The oocytes of 4-5 females were pooled and matured artificially using NaOH alkalinized seawater baths during 3h (pH 9.0 in *P. aspera* and 9.5 in *P. candei*). The oocytes should be carefully washed after maturation since longer baths could damage the oocytes. The matured oocytes were fertilized at 100 oocytes ml^{-1} (or less) and 10^5 sperm cells ml^{-1} for a better larval production. Fecundation was realized in 500 ml crystal beakers. The sperm was kept with the oocytes during the incubation time, which lasted 24h.

Larvae were observed 24h post-fecundation as trocophora, 2/3 of the water column was siphoned using a 55 μm filter to avoid collecting debris, then the larvae were re-distributed in new beakers with clean filtered seawater at 10-20 larvae ml^{-1}, and cultured during additional 48h until pediveliger stage was reached. Then, the larvae were siphoned again using a 55 μm filter and re-distributed in culture cell plates at 5-10 larvae ml^{-1} for experimental purposes. Several substrates plus control were tested: two diatom species (*Halamphora* and *Navicula*), haptophyte *Pavlova*, and limpet shells covered by different communities of crustose coralline algae (CCA) as natural substrate. The timing for settlement was based on the observation of post-larvae, while success for settlement was based on the average ratio of juveniles in each treatment. The incubation, larval culture, and settlement assays were realized at 17 ± 1 °C.

Results and Discussion

Post-larvae were identified by the shedding of the velum and increased eye distance, while juveniles showed juvenile shell and active grazing behaviour. Earliest post-larvae occurred on CCA treatments in both species, while settlement success varied in both species: *P. aspera* juveniles were observed on CCA treatments (with rare exceptions), while *P. candei* juveniles were more frequent on *Navicula* biofilms and CCA treatments. The type of CCA community and their abundance influenced the settlement success, being *P. aspera* apparently more restrictive than *P. candei* on their settlement requirements. The larval development was completed in absence of food suggesting lecithotrophy and facilitating the larvae management. On the contrary, juvenile were active feeders. Grazing was concomitant with movement, which suggest that limpet juveniles are opportunistic consumers that needs continuous feeding. The development of a juvenile aquafeed is a mandatory step for further studies on the limpets' aquaculture. In this sense, the observation of *P. candei* juveniles grazing upon *Navicula* biofilms marks a starting point for the culture of the limpet juveniles.

*ccastro@acuinova.pt

Turbot (*Scophthalmus maximus*) is a flatfish with high-quality flesh and market value. In the European Union (EU) the vast majority of turbot production takes place in Spain (8258 tonnes in 2018, 76.9 % of total EU production) and Portugal (2350 tonnes in 2018, 21.6% of total EU production). Mass production of high-quality juveniles is still a major bottleneck in turbot aquaculture production and is due to highly variable larval survival rates (survival rates of 10-20% during the larval stage). Inadequate rearing techniques, unknown nutritional requeriments and detrimental microbiological conditions in the rearing system (e.g. the presence of pathogenic organisms) are pointed as the main causes for the losses during the early life stages.

Optimization of larviculture protocols, through the assessment of larvae nutritional needs and development of efficient rearing techniques and microbial management strategies, is essential to improve larvae and juvenile quantity and quality. Such development will contribute to enhance the profitability of turbot aquaculture production. Maximus.pt project (2021-2023) aims to create a technological basis to establish fine-tuned protocols that will allow maximum growth and survival of hatchery-reared turbot at early life stages. For this goal the project aims to 1) optimize live prey enrichment for turbot larvae; 2) improve the the weaning protocols for turbot larvae and post-larvae; 3) define optimum turbot cultivation densities and hydrodynamic conditions in rearing tanks at first feeding, weaning and pre-fattening stages; 4) characterize bacterial communities and identify taxonomic groups and/or functions that lead the community to disease or health states in turbot larvae and postlarvae.

A holistic and innovative approach will be applied in the project through the application of nutrient flux techniques and microbiome studies combined with a careful analysis and selection of nutritional strategies (algae, enrichments and microdiets). The Maximus.pt brings together a multi-disciplinary consortium of a Portuguese turbot company (ACUINOVA) and R&D institutions (CCMAR, UA) with established expertise in rearing techniques of marine flatfish larvae and juveniles (ACUINOVA and CCMAR); larvae and juvenile feeding and nutrition (CCMAR); and aquaculture microbiome diversity and function (UA).

A deep knowledge will be obtained on the interaction between rearing conditions, microbiome and feeding strategies at the larval stage, which will lead to significant improvements in the system microbial ecology and larvae performance. As a result, the Maximus.pt will leverage the supply of high volumes of premium larvae and juveniles, which will meet the current market demand. Furthermore, with project implementation, the turbot company of the consortium, ACUINOVA, will be able to expand its own robust juvenile production, which will increase the company's competitiveness.

Introduction

Fish are the most efficient farmed animals for converting feed nutrients into edible meat. The quality of such fish feed is crucial to ensure this goal. Fish feed is presented in the form of extruded pellets obtained through twin-screw extrusion. It is an agro-material whose composition, nutritional value, density, and size variations have to suit the development stages, behaviour and therefore the nutritional requirements of various fish species. For carnivorous species, their diets must have high lipid content to provide a source of easily available energy. In our case, for large Trout (i.e. weight of about 2.5 kg per specimen), the formulation has to contain up to 30 % of fat. This operation is allowed by injecting a mixture of vegetable and animal oils (*i.e.*, rapeseed oil, and fish oils) using a vacuum coating operation. When reaching these nutritional requirements, the obtained pellets may present a major defect, which is the oil leakage over time. This work describes a process approach to study this phenomenon in Trout pellets.

Materials and methods

To study the influence of the coating parameters on oil leakage rate (OLR), sixteen coating experiments were conducted with the help of an experimental design having the form of a three-variable Doelhlert's matrix. For those experiments, the coating parameters varied as follows: a stirring speed from 45 to 85 Hz, a pressure in the coater from 140 to 310 mbars, and a filling rate of the coater from 35 to 55 % in volume. For the experimental design, the time to restore the atmospheric pressure after coating was set at 120 s. Then, it was also studied at five different values (i.e. 60 s, 75 s, 90 s, 105 s, and 120 s). Pellets OLR was evaluated through the determination of the oil quantity lost and expressed in proportion to the total weight of pellets before leakage. Two temperature conditions were tested: T1 (climatic chamber, 60 % relative humidity (RH), 20 °C), and T3 (water bath, 60 °C).

Results

Coating conditions showed a real ability to influence the OLR value. The pressure in the coater was the most influential parameter on OLR. The latter contributed to a reduction of more than 50 % in the oil leakage rate at 20 °C (T1 incubation condition) (Fig. 1). This result underlines the importance of the coater pressure on OLR variation, with a progressive reduction in the oil leakage phenomenon as the coater pressure was reduced. This condition allowed deeper penetration of oil in the pellet core during coating, and thus lower oil leakage.

Lastly, the time to restore the atmospheric pressure was also influential in the reduction of the oil leakage phenomenon. **Fig. 2** shows a decreasing trend of OLR when this time is increased from 60 s to 120 s, either at 20 °C (T1 incubation condition) or at 60 °C (T3 incubation condition). In other words, better oil penetration into the core of pellets was ensured when the time to restore the atmospheric pressure was longer (i.e. 120 s). When the oil addition sequence was completed under vacuum, the latter was slowly released up to the atmospheric pressure (1.015 bars). This phenomenon created a pressure differential that forced the oil into the voids of the pellets.

To conclude, the most important finding in this work is that the control of pressure at coating is the major factor to decrease OLR, and 140 mbars pressure in the vacuum coater was identified as the optimal condition for an efficient coating and therefore for a greater reduction in OLR.

(Continued on next page)

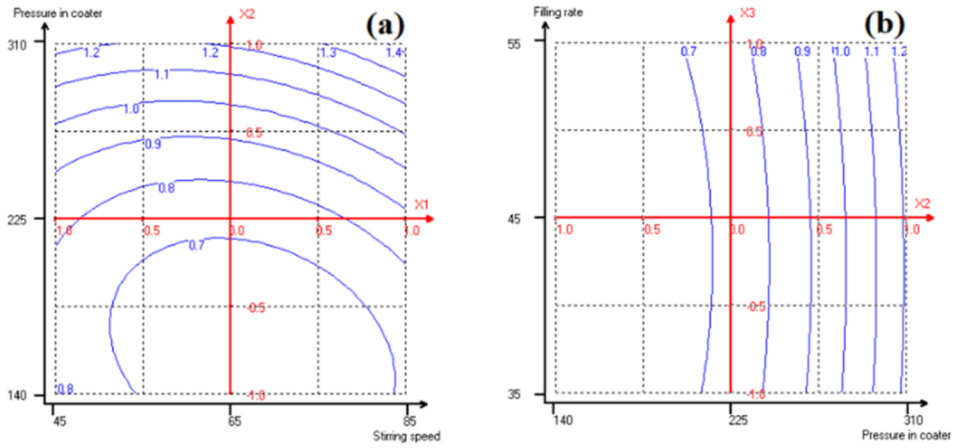

Fig. 1. Isoresponse curves for OLR at 60 % RH and 20 °C in a climatic chamber (T1 incubation condition), at a 45 % filling rate of the coater (a), at a 65 Hz stirring speed (b).

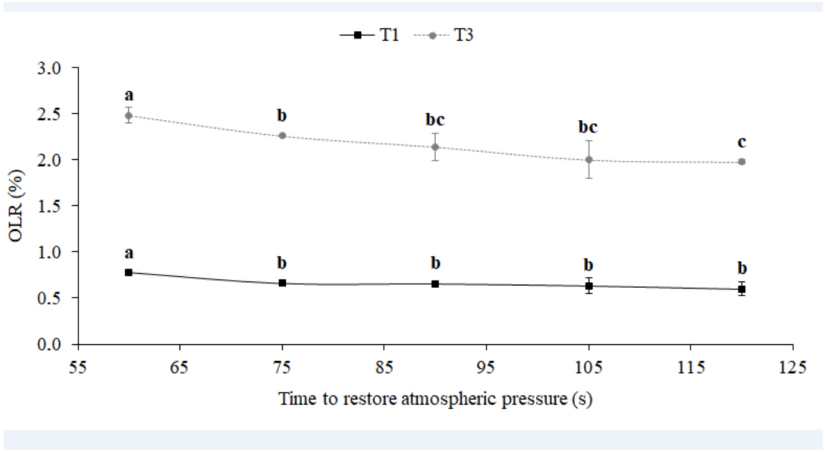

Fig. 2. Effect of time to restore the atmospheric pressure on OLR at 60 % RH and 20 °C in a climatic chamber (T1 incubation condition), and at 60 °C in a water bath (T3 incubation condition), for the next coating conditions: 65 Hz stirring speed, 140 mbars pressure in the coater, and 45 % in volume filling rate (means in the same curve with the same superscript letter (a-c) are not significantly different at $P < 0.10$).

SCREENING OF CAPTURED WILD ATLANTIC COD *Gadus morhua L.* FOR VHS VIRUS AND EVALUATE THE RISK OF TRASMITTING VHS VIRUS FROM ATLANTIC COD TO ATLANTIC SALMON *Salmo salar*

Introduction

With the expansion of mariculture industry, Atlantic cod (*Gadus morhua L.*), which is previously mainly acquired by wild fisheries, has been identified as a possible candidate for Capture Based Aquaculture (CBA). In Norway, 3 to 5 years old wild Atlantic cod, is captured, graded and transferred to sea cages. Then, after a weaning period, which consists of starvation and wet feeding, the fish are allowed to adapt to captivity. They are usually cultured for 6-8 months with feeding, before marketed as fresh cod products (Dreyer et al, 2008). However, introducing wild caught cod to aquaculture stations of Norway may lead to adverse consequences with the possibility of disease spreading specially to Atlantic salmon (*Salmo salar*), which is the main mariculture fish species farmed in Norway. Therefore, appropriate screening of wild caught cod for the prevalence of notifiable fish diseases is necessary. Viral Hemorrhagic Septicemia (VHS) is a notifiable list 2 disease according to OIE (OIE, 2019), and has led to mass mortalities in both freshwater and marine water aquaculture species causing serious economic losses. In the present study, we focused on screening wild cod population in Norwegian waters to estimate the prevalence of VHSV. Furthermore, to evaluate pathogenicity and the transmission risk of VHSV from Atlantic cod to Atlantic salmon, artificial infection trial was performed.

Materials and methods

For VHSV screening, about 2800 wild Atlantic cod from 3 main locations along the Norwegian coastline namely Vesterålen (at small community Myre), Båtsfjordand in Finnmark and Alesund were sampled to collect brain, heart and head kidney tissues, throughout the main cod fishing seasons from 2019 to 2021. RNA was extracted from 2200 brain tissues so far and screening for VHS virus was done using Taqman-based real-time PCR assay, which was previously validated and published (Jonstrup et al, 2013).

Artificial infection trial started in April in 2021 and is currently ongoing for 8 weeks, using 2 VHS virus isolates belonging to 2 main genotypes of VHSV, namely VHSV genogroup III (Storfjorden, 2007) and VHSV 1b (Baltic Sea, 2016). In individual challenge experiments, naïve Atlantic Cod and Atlantic Salmon juveniles (~80-100 g) were infected with the 2 virus strains by immersion and intra-peritoneal injection. In the cohabitation challenge experiment, infected Atlantic cod juveniles are cohabited with naïve Atlantic salmon juveniles to analyze the transmission risk of the tested virus strains from Atlantic cod to Atlantic salmon. Tissue samples will be collected at different time points and analyzed by cell culture (Ex: IFAT staining), histopathology, molecular (Ex: RT-PCR) and genetic (Ex: transcriptome) methods. Water samples from each tank will also be collected, to analyze the amount and rate of virus shedding.

Results and discussion

There was no VHSV positive sample detected, out of 2200 cod brain tissue samples which were screened so far. Therefore, according to current results, we conclude that prevalence of VHSV in the main Atlantic cod populations in Norwegian waters is very low which is consistent with previous screening studies as only two positive cases of VHSV from 8395 different species of wild marine fish have been reported (Brudeseth and Evensen, 2002).

We expect to graphically visualize mortality rates and tissue distribution of virus, and also include microscopic images of histopathological changes inflicted by VHSV in main organs of both Atlantic cod and Atlantic salmon. Furthermore, transcriptome analysis will be focused on differential gene expression to understand host specificity of VHS virus and immunological responses in two fish species, and will be analyzed statistically. Considering disease transmission, European VHSV isolates in genotype Ib, II or III which often originated from marine environment generally has shown low pathogenicity to freshwater fish (Skall et al, 2004). However, VHSV isolate from recent VHSV outbreaks in marine cultured rainbow trout in Storfjorden, Norway (Dale et al, 2009) was discovered as genetically closer to VHSV III. Therefore, we expect ongoing challenge trials which includes a co-habitation element will give us new insight to understand the transmissibility of marine originated European VHSV isolates.

Introduction

The red porgy is a benthopelagic species of high commercial value, widely traded in the Greek market. Its wild populations are located the Mediterranean Sea, but also in the Atlantic coasts of America, South Europe and Africa (Fishbase). Wild *Pagrus pagrus* from fisheries in Greece, shows similar morphological features with the corresponding imported, and closely-related species of Sparidae, as *Pagellus erythrinus,* and *Dentex gibbosus*. *Pagrus* sp. is reared in Greek fish farms, with its production conquering the third place among reared species in Greece. *Pagrus* fish farming products sold in the Greek market are found under various names, with the majority reported as *Pagrus major*. The trading of wild, reared, or imported representatives in the market, raises the question of authenticity and proper labeling of *Pagrus* products. Although fish can be classified by their morphological characteristics, molecular techniques based on genetic material (DNA), are currently being used for accurate and robust species identification. Having the ability to cross-check the sequences with databanks, the genetic authenticity and origin of each sample can be assessed, thus contributing to the detection of mislabeling and fraud. The mitochondrial DNA (mtDNA) is a useful tool for investigating molecular mechanisms and evolutionary relations between different fish species (Ceruso et al. 2019). The gene region used as DNA barcode in species identification (Ratnasingham 2007), is part of the cytochromic oxidase subunit I gene (COI). However, for the discrimination between closely related species or populations within species, data could also be drawn from other mtDNA regions (*cytb*, 16sRNA, D-loop etc.). Up to date, the complete mitochondrial genome of *P. major*, *P. auriga* and *P. caeruleostictus* have been determined. In this study, the complete mtDNA of *Pagrus pagrus*, captured in the central Aegean Sea, was sequenced. Data inferred from this sequence along with barcoding of samples collected in the Greek market (locally fished, reared, imported) were used in different molecular techniques, in order to establish a fast and reliable method for species identification within *Pagrus* genus and for estimation of population differentiation within wild *Pagrus pagrus*.

Materials and Methods

The specimens included wild *P. pagrus* (70 samples) caught in the Greek seas, FAO subareas 37.2 (Ionian Sea division 37.2.2) and 37.3 (Aegean and Cretan Seas), farmed *Pagrus* (15 samples from various Greek fish farms) and imported (labelled as *P. pagrus*), purchased from fish markets and supermarkets (10 samples). Fish species were identified according to their morphological characteristics and categorized in groups by their origin. Total DNA was extracted from the skeletal muscle or liver using NucleoSpin® Tissue Macherey-Nagel, according to the manufacturer's instructions. For the determination of total mtDNA sequence, a specimen caught at Central Aegean FAO division 37.3.1 was selected. Primers were either designed or selected from the literature (Miya and Nishida 2000), for the amplification of total mtDNA in 42 overlapping fragments ranging from 300-4.500 bp. Both mtDNA strands were completely sequenced. For barcoding, a fragment of 648 bp of COI was amplified using universal primers (Ward et al., 2005). In order to distinguish *P. pagrus* populations, Forensically Informative Nucleotide Sequencing (FINS) was carried out for *cytochrome b* gene. A 583 bp fragment was amplified using primers designed in this study. Sequences were identified with Blast search tool, compared and aligned with sequences from BOLD database and aligned with clustalW2 (Sievers et al. 2011). After in silico analysis, 3 fragments were chosen for Restriction Fragment Length Polymorphism analysis (PCR-RFLP) using a set of 10 restriction enzymes. Smaller fragments of COI and *cytb* (100-300 bp) were used in Real-time PCR (qPCR) and High-Resolution Melting (HRM) analysis.

Results

The complete mtDNA of *Pagrus pagrus* has a size of approximately 17 kb and revealed the same structure as all mtDNAs of teleosts, containing 13 protein, 22 tRNA and 2 rRNA genes and two non-coding regions (D-loop and L-origin of replication). Gene arrangement was typical of Sparidae species, with most of the genes encoded by the heavy strand, except for the NADH dehydrogenase subunit 6 (ND6) and eight tRNAs that are encoded by the light strand. The results showed that there is a clear distinction between wild specimens, imported and reared ones. According to homology in FishBol, all specimens from fisheries or imported were identified as *P. pagrus* and all specimens from Greek fish farms as *P. major*. Sequences of the same samples that were analyzed for *cytb* (FINS), confirmed these findings, being more indicative for differences between populations. Results from RFLP showed a pattern that could distinguish between *P. pagrus* and *P. major* but not between Greek and imported *P. pagrus*. Preliminary results of qPCR and HRM analyses from regions of COI, and *cytb*, are indicative and promising for fish species and population identification.

(Continued on next page)

Conclusions

Fisheries plays an important socioeconomic role in Greece, providing the market with products of high nutritional value. Due the high price of red porgies, it is important to conserve and validate the value of these products. The detection of *P. major* as a common species in Greek porgy aquaculture today raises the questions about the environmental impact from the rearing of an alien species (escapes, mixes with wild populations) in the Mediterranean and authenticity issues as described in Regulation (EU) No 1379/2013. In order to enable consumers to make informed choices, it is necessary to provide clear and comprehensive information on, inter alia, the origin and the method of production of the products. *P. pagrus*, fished in Greece, show similar morphological features with the corresponding imported, farmed fish of the same genus and closely-related species of Sparidae. Furthermore, in case the fish has been processed (exfoliated, fillet or cooked), even classification experts are unable to identify the sample. Data of this study, will ensure the identity, originality and authenticity of Greek fishery products. Moreover, extended sequence data are already being used for the development of a methodology (qPCR, HRM) that will provide a rapid tool against fish mislabeling and phenomena of fish fraud.

EFFECT OF DIETARY ELECTROLYTE BALANCE AND MOISTURE CONTENT ON THE INTERPLAY BETWEEN WATER BALANCE AND DIGESTIVE FUNCTIONING ALONG THE GASTROINTESTINAL TRACT OF FRESHWATER RAINBOW TROUT (*Oncorhynchus mykiss*)

Introduction

Feed formulation in aquaculture is undergoing a transition towards alternative ingredients (*i.e.*, plant based) due to the reduced sustainability and availability of fish meal. Yet, reduced fish meal in a diet and increased use of alternative ingredients implies reduced quality of the diet (less nutritious and digestible ingredients) together with altered mineral profile and availability. Minerals have different functions and are important for osmoregulation and acid-base balances in fish. Fish osmoregulation has been mainly studied using non-fed animals where the effects of digestion on homeostatic mechanisms in the gastrointestinal tract (GIT) were not considered. However, previous works have revealed that osmoregulation can be challenged when fish are fed (Wood *et al*., 2005; Bucking and Wood, 2006; Taylor and Grosell, 2006). During digestion, water and ion secretion disturbs fish homeostasis both in freshwater and saltwater medium. In this study, we aimed at investigate the effect of dietary moisture content and dietary electrolyte balance (dEB = $K^+ + Na^+ - Cl^-$ meq/kg) on chyme characteristics (dry matter, pH and osmolality) along the GIT of freshwater rainbow trout (*Oncorhynchus mykiss*). Moreover, the relation between chyme characteristics and digestibility in different segments of the GIT is studied.

Material and methods

This trial was performed using freshwater rainbow trout (*Oncorhynchus mykiss*) as the test animal. Four experimental diets were formulated to have contrasting dEB (- 98 and 600 meq/kg of dry matter) and moisture content (0 and 0.4 - 0.9 g water g feed). These two dietary factors were tested in a 2x2 factorial design resulting in 4 test diets. Fish performance, nutrient utilization, osmotic balance and digestive functioning along the gastrointestinal tract were measured. Chyme, blood and tissue samples were collected at 2 time points (3 and 7 h) to test the effect of time after feeding on chyme and blood characteristics according to a 2x2x2 experimental design. The diets were assigned to 24 tanks with 23 fish each, and therefore each treatment was tested with 3 replicates. Chyme was collected quantitatively from four segments of the GIT namely stomach, proximal, middle and distal intestine and was analysed for pH, osmolality and dry matter (DM) content. Blood was collected from caudal vein and heart to measure blood pH and osmolality. Faecal material was collected daily to measure apparent digestibility coefficient (ADC) of nutrients using the indicator method with yttrium oxide (Y_2O_3) as a marker.

Results and Discussion

Contrasting dEB led to differences in chyme pH and osmolality in the stomach but no significant difference was observed in the intestine. A lower ($p < 0.001$) stomach chyme pH (4.12) was measured at low dEB compared to high dEB (5.71), whereas higher ($p < 0.006$) stomach chyme osmolality (398 mOsm) was recorded at low dEB compared to high dEB (358 mOsm). Chyme DM in the proximal intestine was lower ($p < 0.004$) when fish were fed high dEB diet (13.6%) compared to those fed low dEB diet (15%). The same trend was observed in the middle intestine ($p < 0.002$) where lower chyme DM content (15%) was measured in the high dEB diet group compared to the low dEB diet (16.2%).

Dietary moisture content altered ($p < 0.034$) stomach chyme osmolality, being highest in the fish fed high moisture diet (392 vs. 363 mOsm). Dietary moisture content did not affect pH and DM in stomach and had no impact on chyme characteristics in the intestine.

A time effect on chyme DM, pH and osmolality was detected in the stomach and on chyme DM in the middle intestine. Stomach chyme DM decreased ($p < 0.032$) from 26.6% at 3 hours to 22.9% at 7 hours postprandially. In contrast, chyme DM in the middle intestine increased ($p < 0.002$) from 15.2 to 16% at 3 and 7 hours after feeding, respectively. In the stomach, both chyme pH and osmolality decreased with time (3h to 7h) from 5.34 to 4.50 ($p < 0.002$) and from 399 to 353 mOsm ($p < 0.003$) respectively.

(Continued on next page)

Blood pH altered with time postprandial, but was unaffected by the dietary treatments. The caudal blood pH decreased ($p < 0.014$) with time after feeding from 7.22 to 7.18 at 3h to 7h, respectively. Similarly, the heart blood pH was higher ($p < 0.004$) at 3h (7.20) compared to at 7h (7.16) postprandially.

Blood osmolality of the caudal vein was unaffected by differences in dietary moisture and dEB content and time after feeding. In contrast, blood osmolality sampled at the heart was affected by dietary moisture content ($p < 0.020$). It decreased from 322 to 317 mOsm when fish were fed high and low moisture diets, respectively.

ADCs, plasma electrolyte and mineral are currently being analysed and will be related to chyme characteristics.

These preliminary results suggest that most of the processes of transformation of the chyme and digestion occur in the stomach and decrease towards the intestine. One of the more significant findings to emerge from this study is that dEB has an impact on the digestive process by affecting the pH and liquefaction of the chyme in the gut and, as a consequence, on postprandial blood chemistry. Further analyses should assess whether these changes observed in chyme characteristics also have an impact on digestion.

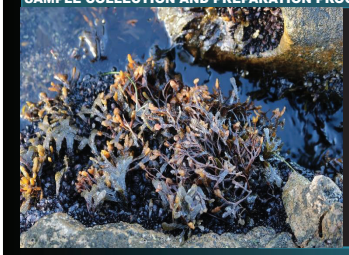
INTRODUCTION

Fucus virsoides J. Agardh (family Fucaceae, order Fucales) is known as an endemic brown macroalga distributed in the mediolittoral zones on rocky sheltered or moderately exposed shores only in the Adriatic Sea .(In the previous reports it has been stated that this alga can be a potential source of polyunsaturated fatty acids and fucoxanthin that are known compounds with certain biological activities. This study encompasses the analysis of volatilome profile of fresh samples of *F. virsoides* obtained by headspace solid-phase microextraction (HS-SPME), along with the determination of fatty acid composition and fucoxanthin content.

SAMPLE COLLECTION AND PREPARATION PROCEDURE



Fucus virsoides J. Agardh, 1868, was collected in the middle part of the Adriatic Sea coast, Novigrad sea area, in February 2021. Single point sample collection provided a representative sample. *F. virsoides* was collected from a depth of 0.5 m at the sea temperature of 12°C. The sample was collected and placed in an airtight plastic bag with surrounding seawater and was immediately transported to the laboratory.
Before HS-SPME, the sample was held at 4°C in the dark and the extraction was performed within 48 h of the sampling. The sample of *F. virsoides* was cut into small pieces, and the excess seawater was removed by the filter paper layers.
For the extraction of fatty acids and less polar non-volatiles, fresh *F. virsoides* was freeze-dried. Before the freeze-drying, the sample was washed five times in water and twice in deionized water, then it was cut in slices (5–10 mm) and frozen at -60°C for 24 h in an ultra-low freezer. Five trays of frozen samples were placed in a laboratory freeze dryer. The freeze-drying was performed under a high vacuum (0.13–0.55 hPa) for 24 h with -30°C and 20°C as the primary and secondary drying temperatures. Freeze-dried samples were further used for the analysis of fatty acids and fucoxanthin content.

Table 3. Fucoxanthin content of semi-purified fractions of *F. virosides* determined by HPLC

Fraction	Fucoxanthin (AV± SD)*
F3	79.30±10.29
F4	n.q.

* results are expressed in mg/100 g of dry mass of 3 replicates (mean values±SD; n=3); n.q. - not quantified)

CONCLUSION

The headspace composition of fresh *F. virsoides* revealed the dominance of pentadecane followed by pentadec-1-ene. The main fatty acid was oleic acid, followed by arachidonic acid and myristic acid. The significant amounts of ω3 and ω6 fatty acids were observed where eicosapentaenoic acid was the dominant ω3, while arachidonic acid was found as the major ω6 fatty acid. The fucoxanthin content determined in methanolic fraction F3 was 79.30±10.29 mg/100 g and it represented the main peak found in chromatographic analysis. Since macroalgae represent a valuable source of various bioactive compounds it is important to investigate their chemical profiles that will lead to the better understanding of marine algal biodiversity in the Adriatic Sea. The seasonal variations, differences in geographic locations and species-inherent characteristics can have an influence on the volatile compounds, fatty acids and fucoxanthin contents and further exploration is necessary.

Introduction

The FAO Committee on Fisheries stressed the increasingly key role of aquaculture in fish production for human nutrition and poverty alleviation. Its contribution to world fish production has reached 46% in 2016-2018 (FAO, 2020). Indeed, aquaculture is projected to be the prime source of seafood by 2030, as demand grows from the global middle class and wild capture fisheries approach their maximum take.

Therefore, there is a need to ensure a more sustainable aquaculture development to mitigate the environmental impacts linked to this growth. Considering that the feed production accounts for up to 60% of the total environmental impact linked to an aquaculture product (Cidad et al., 2021), efforts should be focused on reducing the impact generated on that stage. On feed production, animal feed ingredients, such as fish meal or fish oil contribute most to the impacts (up to 60%), followed by the plant-based ingredients as soybean and corn gluten (33%). Thus, more sustainable feed ingredients appear as valuable alternatives in order to reduce significantly the overall environmental impact of aquaculture products. This solution will also reduce the dependence on marine resources (Turchini et al. 2012), as 83% of fish oil and 65% of fish meal annually produced is assigned to aquafeeds (Tacon et al. 2008).

Within this framework, LIFE BREWERY project has demonstrated the environmental benefits of valorising spent grains and yeast produced by the brewery industry, as alternative ingredients for aquaculture feeds. For that purpose, a comparative Life Cycle Assessment (LCA) has been performed following the ISO 14040:2006 specifications.

Methodology

To identify, quantify and compare environmental impacts linked to different alternatives of aquaculture feeds, the LCA method appears as an internationally recognized methodology. According to the ISO 14040:2006, the method consists of 4 steps i) Goal and Scope definition; ii) Life Cycle Inventory, iii) Life Cycle Impact Assessment and iv) Interpretation. The steps are not simply sequential; LCA is an iterative technique that allows to be increased the level of detail in successive iterations.

Results and discussion

Step 1. Goal and scope definition

The goal of the study is to compare 3 different aquaculture feeds in order to assess potential environmental improvement of replacing current aquafeeds ingredients by brewers' by-products: spent grains and yeast. The functional unit of this study is 1 ton of aquafeed. The system boundary for the aquafeeds considers the collection and manufacturing of conventional and valorised feed ingredients, the transportation to the feed mill and to the final users.

Step 2. Life Cycle Inventory

The aquafeeds analysed are a conventional feed (control) and two feeds including 15% and 20% of brewers´ spent grains (BSG) and yeast (BY) meal, respectively. The data of feeds formulation and the valorisation process of brewery by-products was obtained from the demonstration trials performed during the LIFE BREWERY project (San Martin et al. 2020). The inventory data for the conventional feed ingredients has been obtained from the Ecoinvent 3.5 and Agrifootprint databases. SimaPro 9 software has been used for the assessment. It is important to highlight that the proposed aquafeed alternatives have been tested and validated with 2 aquaculture fish species: *Sparus aurata*, and *Oncorhynchus mykiss*, as models of a Mediterranean and freshwater specie, respectively (Nazzaro et al. 2021).

Step 3. Life Cycle Impact Assessment

Climate change, particulate matter, terrestrial and freshwater acidification, land use, eutrophication terrestrial and water scarcity categories are the most representative environmental impacts of the activity for the aquafeed production. In all the selected impact categories, a decrease is observed when comparing the control feed with the two alternatives. Specially, in land use (BSG:25% and BY:32%) and water scarcity (BSG:24% and BY:42%) due to the avoided animal and plant-based ingredients production. In contrast, a 6% reduction is shown in climate change in both new aquafeeds.

(Continued on next page)

Step 4. Interpretation

Environmental impact assessment determined that the proposed aquaculture feeds including brewers´ by-products appear as a sustainable alternative for reducing the impact linked to Mediterranean and freshwater aquaculture.

Conclusion

The LCA of aquafeeds have proved that replacing 15-20% of animal and plant-based ingredients with brewers´ by-products could reduce environmental impacts and obtain a more sustainable feed solution for fish aquaculture world.

Introduction

The extensive use of fishmeal and fish oil-based feeds in aquaculture contrasts strongly with the blue growth principles of sustainability and protection of biodiversity in marine ecosystems (Eikeset et al., 2018). In recent years, increasing attention has been focused on the formulation of alternative feeds produced using food waste and discards (Kang et al., 2010; Vizzini et al., 2019). The objective of this study is to test the exploitation of discarded leaves of the lettuce *Lactuca sativa* as the main ingredient of alternative and sustainable diets for *Paracentrotus lividus,* the most exploited Mediterranean sea urchin.

Material and Methods

Five diets were tested, four were made mainly of industrial discards of *L. sativa* (86%) and to a much lesser extent (10%) of one of four seafood meals (fish, krill, mussels, and anchovy industrial discards). The fifth was a control diet composed of 48% of both *Ulva lactuca* and *Laminaria laminaria*. A binder composed the remnant 4% of each diet, while a source of $CaCO_3$, *Lithothamnium calcareum*, was added. 110 adults of *P. lividus* were collected at Santa Marinella, Italy (42°03'00"N, 11°49'09"E), and transported to the LESA lab. of University of Rome "Tor Vergata". From the initial pool, 15 specimens, randomly chosen, were sacrificed to assess the gonad index (GI) baseline, while other 75 specimens were pit tagged and acclimatized in a 600 L closed circulation aquarium. After one month-starvation, sea urchins were measured (test diameter: 47.58±4.26 mm; total wet weight-TW: 48.89±15.07 g) and randomly allocated into 15 tanks (3 for each diet) of a recirculating aquaculture system. Sea urchins were fed *ad libitum* six days a week, for five months. To evaluate the effectiveness of the experimental diets, we measured: ingestion rate (IR) and absorption efficiency (AE) on a daily basis for three weeks; TW before the start of the experiment (T0), after 10 weeks, (T1) and at the end of the experiment (T2); GI before (T0) and at the end of the experiment (T2).

Results

Sea urchins showed similar IR and different AE, which peaked for the control diet (Fig. 1a). TW showed a significant increase during the experiment, without differences between diets (Fig. 1b). A significant increase of GI was also observed at the end of the experiment with respect to the initial value (3.64±2.22%) for all the experimental diets. The algal diet led to the lowest GI (12.82±8.87%) followed by the fish diet (16.56±11.15%), while krill, mussels and the anchovy discard diets gave higher and similar results (21.09±10.59, 20.69±10.34, 19.73±11.04% respectively).

Discussion and Conclusion

All the experimental diets showed low ingestion rates, suggesting appropriate nutritional quality (Boudouresque and Verlaque, 2020) and the lack of large among-diet differences indicates that all diets were qualitatively comparable despite the different origin of the ingredients. By contrast, the different composition of the sustainable diets does seem to influence absorption efficiency, since the control diet proved to be the most efficient, while the new formulated diets composed mainly of lettuce processing discards showed lower values. Although sea urchins are herbivorous, it is possible that terrestrial vegetables, rich in fibres and insoluble carbohydrates (Plazzotta et al., 2017)[fruit and vegetable waste (FVW], are less effective as a food source than macroalgae. In addition, the inclusion of *L. calcareum* as a source of inorganic carbon and other minerals may have contributed to the low efficacy of the diets containing mussels and anchovy discards that are already characterized by a higher inorganic content due to the presence of shells and bones in the seafood meal. However, the increase in somatic and gonadic growth, confirmed the suitability of all the experimental diets. Gonad index values recorded for the sustainable diets were higher than for the algae control diet, confirming the greater effectiveness of diets containing a mix of vegetables and seafood – even with only low amounts of seafood meal - over those of entirely vegetal origin (Fernandez and Boudouresque, 2000; Grosso et al., 2021). In addition, values were comparable or higher than those obtained in other studies using formulated diets based on terrestrial vegetables (Sartori et al., 2014; Vizzini et al., 2019).

(Continued on next page)

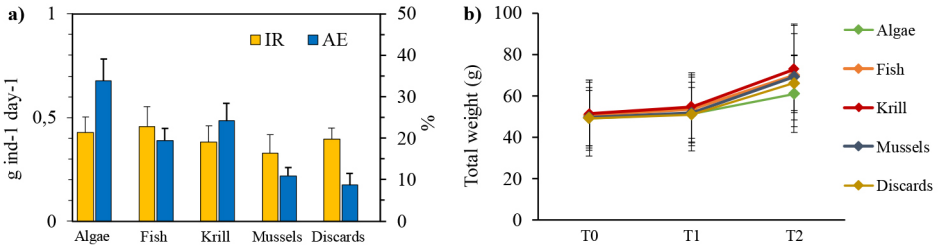

Figure1. Ingestion rate (IR), absorption efficiency (AE) **(a),** and total wet weight **(b)** of *P. lividus* for the five experimental diets, and across time (T0, T1, T2).

All the experimental diets performed well, proving to be adequate as food sources and promoting both somatic and gonadic growth. However, the krill diet provided the best performance, coupling low ingestion rate and high absorption efficiency, as well as recording the highest value for both somatic and gonadic growth.

FISH INDIVIDUAL IDENTIFICATION – CAN WE SUBSTITUTE INVASIVE TAGGING?

Petr Cisar*, Dinara Bekkozhayeva, Oleksandr Movchan

Laboratory of Signal and Image Processing, Institute of Complex Systems, Faculty of Fisheries and Protection of Waters, CENAKVA, University of South Bohemia in Ceske Budejovice, Zámek 136, Nové Hrady 373 33, Czech Republic

Introduction

The optimization of the fish production in intensive aquaculture can lead to the increase of the production with the respect to the fish welfare. The new technologies enable to develop the Precision Fish Farming (PFF) (Fore et al. 2017) concept whose aim is to apply control-engineering principles to fish production, thereby improving the farmer's ability to monitor, control and document biological processes in fish farms. Individual fish identification is one of the tasks necessary for precision fish farming.

There are many methods of individual fish identification. The widespread and popular methods of fish identification are tagging and marking (PIT, RFID or VIE tags). Most of the commonly used methods are invasive and can have adverse effects on fishes, increasing the risk of sequelae or mortality, mainly for small and sensitive fish as most of the stream fish species.

Non-invasive fish identification based on the fish appearance is cheap, less stressful for the fish and accurate. Human based identification of individual fish of the same species using the skin pattern was proved by Hirsch (Hirsch 2015). There are several different patterns which can be observed on the fish body (eye pattern, scale pattern, body texture). Even the image of the fish without any obvious pattern can be used for identification. The aim of this paper is to summarize the usability of image-based individual fish identification from the point of view of identification accuracy and pattern stability for long term identification.

Materials and methods

Five image-based individual identification studies were done for five fish species to prove the possibility of automatic computer vision fish identification.

Brook trout - 32 individuals were used for identification. Three data collections of fish out of water using the digital camera were done in 3 weeks. One image of each fish was taken for each session. The fish was automatically detected and the region of interest (ROI), containing unique dot pattern, was determined, Fig.1-A. The texture descriptor histogram of oriented gradients (HOG) was used to create the feature vector for identification. The identification was performed for all combinations of the data collection sessions.

Atlantic salmon – 328 fish individuals were used for identification. Four data collections of the fish out of water and under water were done in 6 months. Eight images per fish were taken for each individual in each session. For the first data collection all 328 individuals were used. Selected 30 fish were tagged and used for next 3 sessions. The HOG descriptor and dots position on the body were used as features for identification, Fig.1-B. The identification was done for all 328 fish for first session and for 30 fish for all sessions. Fish eye pattern was also used for the identification.

Sumatra barb – 25 fish individuals were used for identification. Two data collections were done in 2 weeks. Ten images of the fish under water were collected in each session. The fish was automatically detected in the image and the middle part of the body with two stripes was used as ROI, Fig.1-C. The identification was tested between data collections and within data collections.

Sea bass - 300 fish individuals were used for identification. Two data collections of the fish out of water were done in 2 months. Ten images per fish were taken for each individual in each session. In the first data collection all 300 individuals were used. Selected 32 fish were tagged and used for second sessions. The HOG descriptor was used to generate the features for identification, Fig.1-D. The identification was done for all 300 fish for first session and 32 fish for both sessions.

(Continued on next page)

Common carp 32 fish individuals were used for identification. Four data collections of the fish out of water were done in 4 months. Ten images per fish were taken for each individual in each session. All 32 fish were tagged and used for identification. The HOG descriptor was used to generate the features for identification, Fig.1-E.

Results

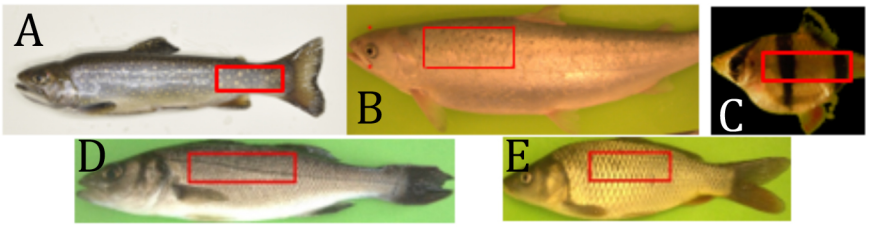

Figure 1. Region of interest used for different species identification: A – Brook trout, B – Atlantic salmon, C - Sumatra barb, D – Sea bass, E – common carp

Table 1. Identification accuracy for five species. ST – short term experiment.

	individual identification accuracy %											
	Brook trout		Atlantic salmon - eye		Atlantic Salmon - body		Sumatra barb		Sea bass		Common Carp	
	ST (32 fish)	3 weeks (32 fish)	ST (328 fish)	6 months (30 fish)	ST (328 fish)	6 months (30 fish)	ST (25 fish)	2 weeks (25 fish)	ST (330 fish)	2 months (30 fish)	ST (32 fish)	4 months (32 fish)
under water	---	---	---	---	100	100	100	100	---	---	---	---
out of water	100	100	95	40	100	100	---	---	100	100	100	90

Conclusion

Individual fish identification is one of the keystones of the emerging concept of Precision Fish Farming. The series of five studies demonstrated that the image based (fish appearance) individual identification using computer vision can be used for long-term identification. The identification was tested on three species with obvious patterns and two species with ambiguous patterns. High accuracy of the identification was reached for all species together with the long-term pattern stability. Image-based identification is non-invasive and remote approach which can substitute invasive fish identification methods.

Introduction

Among a large number of marine extracts and different isolated bioactive compounds, polysaccharides are recognized as one of the most promising sources of different biological activity (Shi et al, 2017; Gopu & Selvam, 2020). Their structure and biological activity are highly influenced by growth location and harvesting season that cause even intra-species variation, thus offering an inexhaustible source of novel bioactive compounds (Jiao et al., 2011) with unique physiological and chemical properties, including anti-inflammatory, antioxidant, antimicrobial, antiviral, anti-coagulant, and antitumor activities (Lee et al, 2017). Most recently, sulfated polysaccharides (fucoidans) extracted from the brown algae *Saccharina japonica* were able to effectively inhibit SARS-CoV-2 *in vitro* (Kwon et al, 2020). Nevertheless, marine-derived polysaccharides are still under-exploited, thus paving the way for a new trend in the discovery of compounds from a sustainable source. This study aimed to conduct comprehensive research and determine biological activities (antioxidant, antibacterial, and antifungal) of water-soluble polysaccharide extracts from 10 marine species from the Croatian coast of the Adriatic Sea: 2 green algae (*Ulva lactuca* and *Codium bursa*), 5 brown algae (*Fucus virsoides, Padina pavonica, Cystoseira barbata, Halopteris scoparia*, and *Cystoseira compressa*), 1 coral (*Eunicella cavolini*), 1 sea squirt (*Aplidium conicum*) and 1 sponge (*Chondrosia reniformis*), along with embryotoxicity and mutagenic potential to determine their safety for non-target organisms and humans.

Materials and methods

Ten marine organisms were collected from the coastal area of Croatia. Extraction of polysaccharides was conducted in acidic conditions (H_2SO_4) under high temperature (80°C). Dry residues of polysaccharide extracts were dissolved in a distilled water. Chemical characterization was performed using high-performance liquid chromatography (HPLC). Antioxidant activity was evaluated by implementing four *in vitro* assays - oxygen radical absorbance capacity (ORAC), reduction of radical cation ($ABTS^{\bullet+}$), 2,2-diphenyl-1-picryl-hydrazyl-hydrate (DPPH) assay, and ferric reducing antioxidant power assay (FRAP). The mutagenic potential was evaluated by AMES test following ISO 16240 (2005) while anti-microbial activity was analyzed by the implementation of disk diffusion and microdilution methods on 4 bacterial strains and 1 yeast strain. The toxicity of samples was determined using the zebrafish embryotoxicity test (OECD 236, 2013).

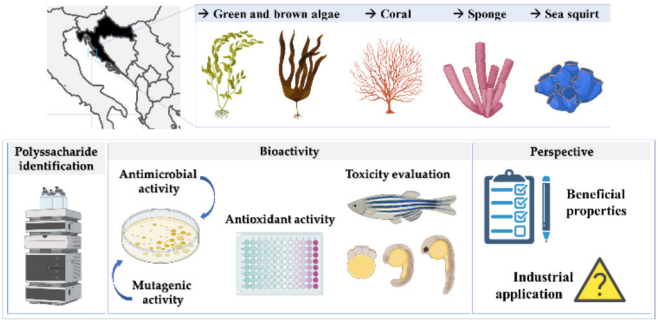

Fig. 1. Schematic overview of the experimental design used in this research.

(Continued on next page)

Results

The highest extraction yields were obtained for *A. conicum* (21.98%) and *U. lactuca* (18.89%). Chemical analysis revealed a high abundance of different polysaccharides within each sample. No clear halos were observed in the disk diffusion assay, but *C. reniformis* (42.0 ± 1.3 %), *C. barbata* (45.7 ± 12.4 %), and *F. virsoides* (37.7 ± 4.6 %) were able to inhibit the growth of *B. subtilis*, while *C. reniformis* (34.0 ± 1.2 %) and *C. barbata* (24.0 ± 3.3 %) showed antifungal activity against *C. albicans*. The highest antioxidant activity was obtained for *C. barbata* and *C. compressa* extracts using DPPH, ABTS, and FRAP assays, while ORAC assay revealed the highest activity for *C. reniformis* and *H. scoparia* extracts. Tested polysaccharide extracts showed no mutagenic or embryotoxic potential, with an exception for *C. reniformis* extract.

Discussion and conclusion

The optimization of the polysaccharide extraction is vital for obtaining high extraction yields with no interfering compounds. Pretreatment with organic solvents for the removal of polyphenols and pigments was conducted and extraction in acidic conditions followed by precipitation was performed. All samples showed a relatively high extraction yield, from 5.66 to 21.98 %. The chemical analysis supported these findings with specific chromatograms without interfering peaks. Different organisms have shown to have diverse polysaccharide compositions which contributed to various biological activities. Although antimicrobial activity was not present for most of the tested extract, some activity was obtained and was positively correlated with the increased antioxidant activity. All samples had medium to high antioxidant activity, which shows the potential usage of these compounds in different industrial applications. However, this application is limited if the extracted compounds are toxic or harmful. Combined with the AMES mutagenic test, the obtained results of embryotoxic testing have proven the safety of almost all isolated polysaccharide extracts, except for *C. reniformis* extract, thus indicating the importance of marine-derived compounds in different areas of research and applications, from food supplements to higher pharmaceutical development.

Introduction

The sea bass, *Dicentrarchus labrax* is an important species for European mariculture, mainly in Mediterranean countries. In this species, females grow faster and reach higher weight than males. However, most farmed fish batches show a highly male-skewed sex-ratio. The sea bass has a complex system of sex determination, combining both genetic (polygenic) and environmental (temperature) influences. Low initial temperatures (<17°C) favor female sex determination (Piferrer et al., 2005). In contrast, a cold treatment prolonged until the late post-larval phase has been recently shown to promote male differentiation (Vandeputte et al., 2020). In other species with environment sex determination (ESD) like *Leurestes tenuis*, both temperature and photoperiod can affect the sex-ratio (Brown et al., 2014). In this experiment, we tested the effect on the sex-ratio of *D. labrax*, of two photoperiods (12L:12D and 10L:14D), applied during the larval phase, from 9 to 90 days post hatching (dph), at a temperature of 16°C, crossed with the effect of four temperatures (19; 21; 23 and 25°C) applied from 90 dph until the fish were about 80 mm length, a time where sex can be considered definitively fixed.

Material and methods

All experiments were conducted in the Experimental Marine Aquaculture platform of Ifremer at Palavas-les-Flots, France. Fish were from a complete factorial mating of 10 males and 8 females from a West Mediterranean strain. Fertilized eggs (23,000 / tank) were directly dispatched into six 500 L tanks. Photoperiod treatments (12L: 12D and 10L:14D) were done in triplicate, from 9 to 90 dph, with water temperature kept at 16°C. Temperature was gradually increased starting at 85 dph. Fish were transferred to another room at 87, 88, 89 and 90 dph, when temperature reached 19, 21, 23 and 25°C, respectively. The other room had four independent recirculating systems with four tanks of 110L each, stabilized at 19, 21, 23 or 25°C. Two tanks in each circuit received 240 fish from the 12D:12D photoperiodic treatment and the other two 240 fish from the 10L:14D treatment. The photoperiod applied until the end of the experiment was 12L:12D for all groups. Thermal treatment was stopped when fish reached a length about 8 cm (1500 day.degrees, calculated on a 10°C basis – $DD_{10°C}$), a size at which sex is completely determined. At this time fish were individually weighed, measured and tagged with RFID glass tags, and transferred to 1.5 m^3 tanks at 22°C. All fish from the same temperature treatment were pooled in the same tank, and at 242 dph, were individually measured and transferred to a 5 m^3 tank. Fish from the 19°C and 21°C treatments were pooled in a same 5 m^3 tank, and a second tank received fish from the 23 and 25°C treatments. They were grown at 23°C until sexing at 409 dph, where 1926 fish were measured and sexed. Data were analyzed using R software. Temperature, photoperiod, interactions and tank effect on sex-ratio were tested with a logit generalized linear mixed model fitted with lme4 package in R. Sex, temperature, photoperiod, interactions and tank effect on final weight were tested with a linear mixed model. Post-hoc differences between treatments were tested by multiple comparisons of means with Tukey adjustment.

Results and discussion

Photoperiod had no significant effect on sex-ratio ($p>0.45$), while temperature effect on sex-ratio was highly significant ($p< 0.0001$). At 19°C, the proportion of females was 30.4%; it was 36.5% at 21°C, 44.0% at 23°C and 49.0% at 25°C (see fig. 1). Compared to 19°C, odds-ratios were 1.31 for 21°C, 1.78 for 23°C and 2.17 for 25°C, meaning that at high temperature (23 and 25°C), the probability to be (or become) a female was twice that observed at 19°C. No interaction between temperature and photoperiod was found ($p>0.088$). Up to now, high temperatures during the sex determination period were known to promote male development, in sea bass but also in most fish species with TSD (Ospina-Alvarez and Piferrer, 2008). Here we showed that high temperatures applied to larvae after a cold (16°C) first period, can significantly increase the percentage of females in European sea bass. Early photoperiod had no effect on the final weight of fish ($p>0.33$), while early temperature treatments showed a long-term effect on weight later on, at 409 dph. At this age, the mean weight was 101±1.92g for the 19°C treatment; 107±1.98g for 21°C; 124±1.92g for 23°C and 119±2.13g for 25°C. Sex also had an effect on weight ($p<0.001$ males: 102±1.18g, females: 123±1.39g). No effect of interaction between temperature, sex or photoperiod, on the weight at 409 dph was found ($p>005$). Since the differences between 23 and 25°C treatment are not significant neither for sex-ratio nor for body weight, we propose a treatment at 23°C during the post larval stage (90-160 dph), following an initial 90 days at 16°C, to significantly increase both female ratio and final weight, with a moderate energy cost, in a West Mediterranean strain of sea bass.

Introduction

In 2020 world population was projected to increase from 7.8 billion to 9.9 billion by 2050 (http://worldpopulationreview.com). To overcome the stagnation of wild fisheries in supplying seafood for the growing population, Aquaculture will need to address several technical challenges to secure food demand (FAO, 2020). One of the challenges is to expand the number of sustainable raw materials to increase flexibility in the formulation of highly nutritious aquafeeds.

The Galicia Region (Spain) is the main producer of farmed mussels (Mytilus galloprovincialis) in Europe (FAO, 2020). Although the main production is channelled for human consumption, processing is generating side-streams. A new solution for mussel side-streams is the production of high-quality mussel meal. To combine a new resource originated from a low trophic species side-stream with feed production will contribute to the valorisation of aquaculture value-chains and to the circular economy approach in the sector.

The aim of the present study was to evaluate the effects of fishmeal replacement by mussel meal as the main source of marine-derived protein in dietary formulations for gilthead seabream (Sparus aurata) juveniles. The dietary effects were assessed through the analysis of key performance indicators, feed utilization, and biochemical parameters.

Material and Methods

Three practical diets were formulated to be isonitrogenous (crude protein, ~48.6%), and isoenergetic (gross energy, ~ 21MJ/kg). The Commercial diet (CTRL) was formulated to be similar to a commercial feed used for gilthead seabream juveniles, with fishmeal as the main source of marine-derived proteins. The other two diets were formulated to reduce dietary fishmeal inclusion in 50% (Mussel 50) and in 100% (Mussel 100) using mussel meal as the source of marine-derived proteins. Diets were manufactured at SPAROS Lda. (Olhão, Portugal).

Gilthead seabream juveniles (initial body weight ± 5.0 g) were acquired from a commercial aquaculture and transported to the CCMAR facilities at Ramalhete Experimental Research Station (Faro, Portugal). Upon arrival, fish were adapted to new conditions for two weeks in a flow-through system with aeration, during which they were fed a commercial diet.

Triplicate groups of 90 seabream juveniles, with a mean initial body weight of 8.0 ± 0.1 g were fed one of the three diets for 8 weeks. Fish were reared in 500L tanks, supplied with flow-through seawater (temperature: 21.8 ± 1.6°C; salinity: 37.3 ± 0.4 psu, dissolved oxygen above 80% of saturation). Fish were fed to apparent satiety, by hand, three times a day. Feed intake was recorded, and utmost care was taken to avoid feed losses. Fish were individually weighed at the beginning, bulk weighed every three weeks and at the end of the trial, following one day of feed deprivation, for evaluation of several key performance indicators.

Fifteen fish from the initial stock and 18 from each replicate tank at the end of the trial, were individually weighed and measured, to calculate the condition factor. From these, three fish were stored at -20ºC until subsequent analysis of proximal composition, in other three fish liver and posterior intestine were sampled for gene expression and microbiota analysis, and from the other 12 fish, plasma, liver and whole-fillet samples were collected for analysis of immune and biochemical parameters, antioxidant status, metabolic enzymes, proximal composition and amino acid content; liver, viscera and visceral fat were weighed to calculate hepatosomatic, viscerosomatic and perivisceral fat indexes.

(Continued on next page)

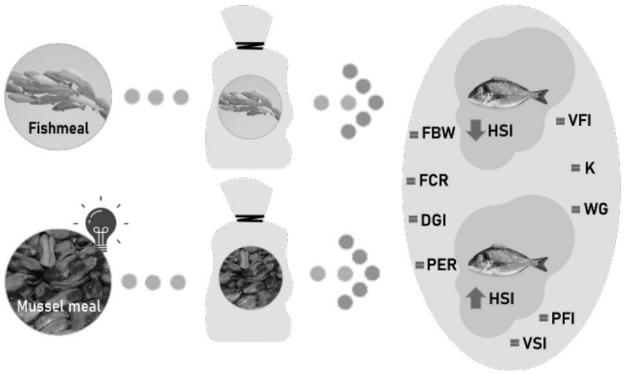

Figure 1. Growth performance and feed utilization indicators of seabream juveniles fed the experimental diets (Mussel 50 and 100) compared with fish fed the Commercial diet, at the end of the trial.

Results and Discussion

The partial or total replacement of fishmeal by mussel meal had no detrimental effect on key growth performance indicators (Figure 1). All the fish (CTRL, M50 and M100) increased the initial body weight in almost 6-fold during the feeding period. Only the hepatosomatic index (HSI) presented some changes. Fish fed the diet M50 and M100 presented a higher HSI that CTRL fish ($P<0.05$).

More parameters, such as biochemical, immune, metabolic and antioxidant responses are under analysis. Based on growth performance and feed utilization data, the replacement of fishmeal by mussel meal might be a viable strategy to tackle the identified technical challenge.

Introduction

The current drive for aquaculture sustainability has been pushing feed formulators for the design of novel aquafeeds, based on ingredients such as insect meals, by-products of fisheries and animal production, microbial biomasses, and algae-based products. All these are viable alternatives, often with inclusion levels restrictions, to those commonly used up to date, e.g. fish meal, fish oil, soy products. A challenge associated with this transition is ensuring that novel feeds provide all required nutrients, without affecting, and when possible improving farming performance. Effects on growth, health status, feed conversion, environmental impacts, and fish biochemical composition (e.g., n-3 HUFAs) from a consumer perspective, have all to be evaluated. However, these emerging ingredients have mostly been tested by researchers and on a one-by-one basis. Our approach was to test different formulation concepts using combinations of these ingredients, rather than one-by-one. Therefore, the aim was not to test individual emerging ingredients, but rather formulation scenarios that may be relevant in the near future. The GAIN project aims to promote eco-intensification of the European aquaculture, and therefore a more sustainable and efficient use of resources in aquafeeds, including circularity towards zero-waste is paramount. The GAIN aquafeed formulation concept starts in replacing cost-effectively fish meal and fish oil from feed-targeted fisheries, together with commodity ingredients from vegetables such as soy, wheat, and corn. Besides the obvious impact of fisheries, using plant protein and oil sources is an increasing concern, due to pressure on farmland resources, resulting deforestation, negative effects on global food security, EU reliance on imports of major crops, and carbon footprint of transportation of some of the raw materials across continents. The present work summarizes the GAIN project effort in testing several alternative formulation concepts in five farmed species: rainbow trout, Atlantic salmon, gilthead seabream, European seabass, and turbot.

Methods

A total of nine nutritional trials were performed using 4 main formulation concepts (see Fig. 1). These nutritional trials were performed in optimal rearing conditions for each species, at partner facilities (rainbow trout at FEM, Italy; Atlantic salmon at GIFAS, Norway; gilthead seabream at SPAROS, Portugal, and IATS-CSIC, Spain; European seabass and turbot at AWI, Germany). The feed formulations were developed for each of the target species, taking into their nutritional requirements and tolerance to different ingredients. Feeds were produced by extrusion with oils added by vacuum coating at the SPAROS pilot feed mill (Olhão, Portugal).

Results and Discussion

All feed formulations gave good growth performances and feed conversions for salmon, seabream, seabass, and turbot and very good ones for rainbow trout. GAIN formulations reached, in general, very similar values compared to the control feeds. However, some formulations performed slightly worse in terms of feed conversion: MIX and PAP in the case of seabream, and PAP in the case of salmon. Moreover, available results for the other key performance indicators assessed (e.g.: nutrient retention and digestibility; biomarker genes, enzymes, and metabolites; skin/gut histology; organoleptic evaluation) suggest that the novel formulations affect fish physiology, with fish likely driven towards a new allostatic balance, but no detrimental effects to fish health could be identified.

(Continued on next page)

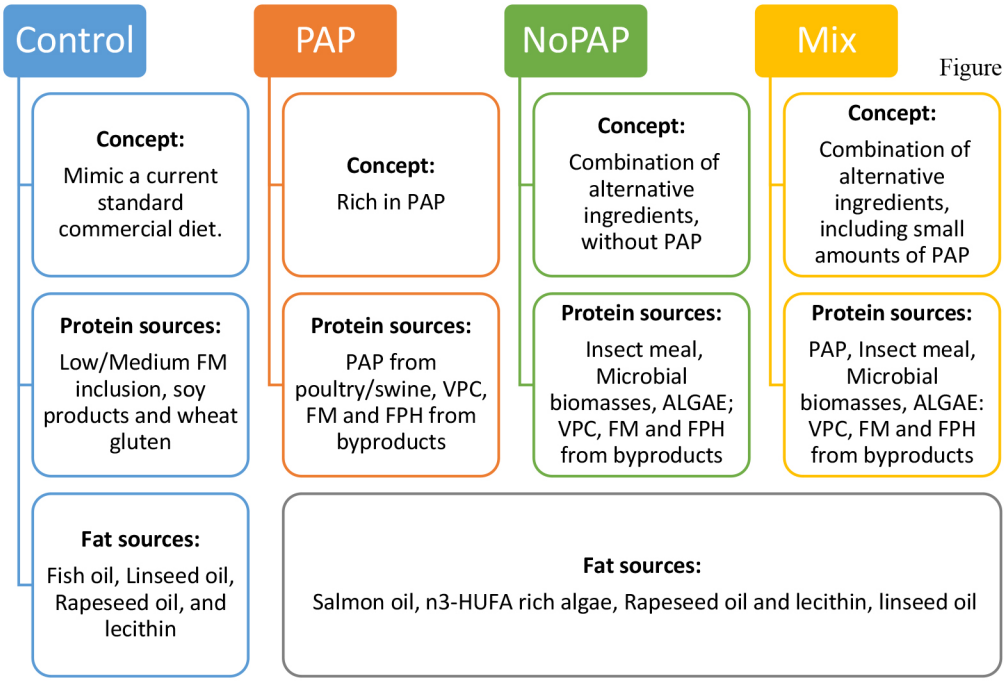

Figure 1: FM – fish meal; FO – fish oil; PAP – processed animal protein from farmed animals (e.g., poultry meal, feather meal, and blood meal); VCP – vegetable (e.g., pea, rapeseed) protein concentrates from European origin; FPH - fish protein hydrolysates from fisheries/ aquaculture byproducts (e.g., fish trimmings, heads, and frames); ALGAE: Microalgae and Macroalgae rich in Se and other minerals; Salmon oil - a by-product from the salmon farming industry.

Conclusions

Overall, these results suggest that the novel GAIN feed formulations tested are viable options shortly, if not immediately. In any case, the major farmed European species can be fed on more sustainable and resource-efficient aquafeeds, towards a zero-waste industry.

EVALUATING COST-EFFECTIVENESS OF COMMERCIAL MICRODIETS FOR WHITELEG SHRIMP (*Penaeus vannamei*) POST-LARVAE

A. Barreto[1], W. Pinto[2], R.J.M. Rocha[1], L.E.C. Conceição[2*]

[1]RIASEARCH Unipessoal Lda, Murtosa (Portugal)
[2]SPAROS Lda, Área Empresarial de Marim, Lote C, 8700-221 Olhão (Portugal)

*E-mail: luisconceicao@sparos.pt

Introduction

Whiteleg shrimp (*Penaeus vannamei*) is currently the second major species produced in aquaculture (FAO, 2020), representing in 2018 a share of 6 % of globally traded species. During the early developmental stages, shrimp larvae and post-larvae are intensively reared in hatcheries that originate around 5 million tonnes of adults per year. These are critical stages of shrimp development, with the transition from live-feeds to inert microdiets (weaning) being severely influenced by diet quality. When optimal nutritional standards are not met, sub-optimal growth, low survival, cannibalism, high size dispersion and reduced disease resistance are often verified. The latter assumes a high dependence of optimal zootechnical conditions and nutrition during weaning, as shrimp depend uniquely on their innate immune system to avoid pathogenic outbreaks and maintain a good health status. Hence, problems related to microdiet quality have a large impact on shrimp performance in the long-term, affecting the downstream production of high-quality juveniles. Although several commercial diets are currently available in the market, the room for optimizing a weaning diet for shrimp larvae/post-larvae is still large. For this purpose, this work aimed at evaluating the cost-benefit relationship of three microdiets (standard, premium and ultra-premium) for shrimp post-larval performance. Criteria such as growth, survival and economical conversion ratio were used to select the most adequate strategy to employ when selecting a microdiet for the early stages of shrimp development.

Materials and methods

Three commercial microdiets currently available in the European market for shrimp post-larvae were initially selected: A – a standard diet; B – a premium diet with a cost around 53% higher than diet A; and C – an ultra-premium diet with a cost around 144% higher than diet A. White leg shrimp post-larvae (PL13, mean wet weight 5 mg) were reared under standard procedures in triplicate tanks (0.28 m^2; density of 1076 post-larvae/m^2) at RIASEARCH Lda facilities (Portugal) and fed on these commercial microdiets *ad libitum* for 21 days. Water temperature throughout the experiment was kept at around 27 ºC. At the end of the trial, shrimp were counted and weighted to determine survival and growth performance. The amount of feed administrated to each tank was registered daily to allow the calculation of feed conversion ratio, whereas the commercial cost of each diet was taken into account to determine economical conversion ratio. These criteria were evaluated to determine the cost-benefit relationships of each diet.

Results

At the end of the experimental period, no significant differences were obtained for post-larval survival, with high results being achieved for all dietary treatments (A – 86.7 ± 6.4%; B - 74.9 ± 12.8%; C - 85.4 ± 4.5%). Shrimp post-larvae fed the ultra-premium diet achieved a significantly higher final body weight (Figure 1) and relative growth rate (C - 19.8 ± 0.1%/day) than those fed the remaining diets (A – 15.6 ± 0.5%/day; B – 17.1 ± 0.7%/day). Concomitantly, shrimp fed the standard diet achieved a significantly lower final body weight and relative growth rate than the premium diet. Nevertheless, no significant differences were found regarding ECR (Figure 1), even though diet B tended to have a higher value.

Discussion

The results obtained in this study show that the use of an ultra-premium quality diet resulted in a significant increase in post-larval weight after 21 days (+ 111 and + 62 % than the standard and premium, respectively). However, no significant differences were detected between treatments for survival and economical conversion ratio. Although the latter was not significantly different between dietary treatments, it can be inferred that higher quality diets can still be advantageous in this critical phase of production. The benefits may be related to an increase in the nutritional adequacy to shrimp dietary requirements and larval robustness/quality, which can assume a pivotal importance in shrimp production during disease outbreaks or stress periods (Racotta et al., 2003). Furthermore, it should be taken into account that higher growth may lead to savings in operational costs, as well as ultimately allowing to reduce the time shrimp take to reach commercial size and eventually allow to increase the number of yearly production cycles. Thereby, results from this study suggest that it would be advantageous to feed shrimp post-larvae with ultra-premium diets during the early developmental stages.

RECENT ADVANCES IN MARINE ANIMALS' TRANSPORT

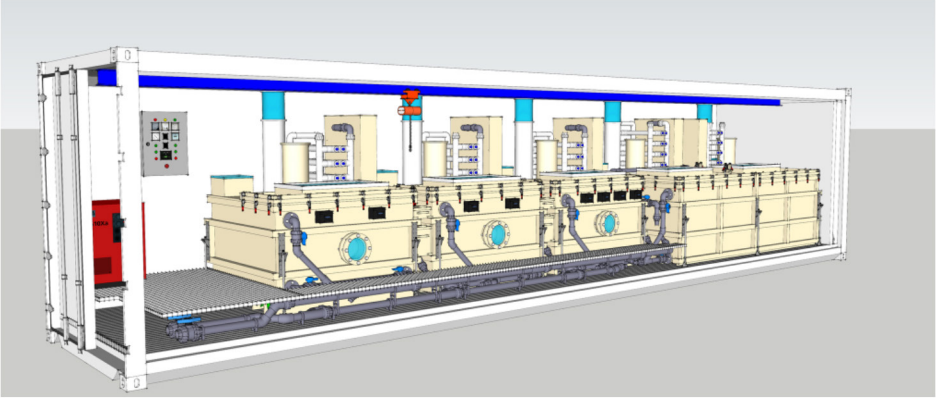
João Correia*, David Silva, Gonçalo Graça, Ivan Beltran, João Reis, Luís Silva, Pedro Marques, Rui Guedes, Telmo Morato

Flying Sharks Lda., Rua Farrobim do Sul 116, 9900-361 Horta, Portugal info@flyingsharks.eu

The opening of the Oceanário de Lisboa, where Flying Sharks' founding staff originated from, involved the collection and transport of animals from literally every corner of the planet to Lisbon, which was a monumental exercise in the development of long-term transport techniques. These techniques were then refined over two decades, allowing for the collection and transport of species once considered 'impossible', such as *Scomber* sp., *Sarda sarda*, *Mola mola*, *Naucrates ductor*, and an assortment of jellyfish, among multiple others. Such advancements include the replacement of 12 V systems for 220 V, while ammonia and pH are no longer a concern, thanks to recent developments in quenching and buffering agents. Additionally, a new paradigm in marine animal transport is presented, whereas buffering agents are used preventively and not correctively, while life support systems designed for long-term maintenance and not just transport conditions. This turned our 'transport unit' into a 'mobile holding station'.

This mobile station 's objective is to allow for long-term maintenance of live marine animals and consists of a 40 foot shipping container, which allows for movement by sea or road. Some of the more relevant technical aspects include:

- Operational volume of 17 m^3;
- Temperature controlled environment;
- Remote monitoring of water quality parameters, such as oxygen, pH, temperature and ammonia
- Remote monitoring through video of systems and animals as well;
- Multiple power inputs, such as 12V, 24V, 110V, 240V, and 380V, to allow for easy adaptation to different geographical;
- Amongst many other aspects which will be presented.



MICROALGAE AS NUTRITIONAL FEED INGREDIENTS

Joana Silva*, Inês Guerra, Nádia Correia, Pedro Quelhas, Helena Cardoso, Margarida Costa

ALLMICROALGAE Natural Products S.A., R&D department, Rua 25 de Abril s/n, 2445-413 Pataias, Portugal
Email: joana.g.silva@allmicroalgae.com

Introduction

The need to substitute classical aquafeed ingredients is becoming a continuous concern due to their sustainability issues. Higher plants face problems related to low digestibility and an unbalanced essential amino acid profile. On the other hand, the diverse group of microalgae has a biochemical profile that suits the nutritional needs of the aquatic animals. Microalgae can have several other industrial applications that include food, cosmetics, biofertilizers, among others. These organism's high digestibility, protein and lipid content, and other essential nutrients make them key ingredients for feed formulations. Besides, microalgae can also produce bioactive metabolites, such as immunostimulants, or antioxidants, which may have a role in fish health performance.

Material and methods

Different five different microalgae were cultivated during the present study, namely, *Chorella vulgaris*, *Nannochloropsis oceanica*, *Chlorococcum amblystomatis*, *Phaeodactylum tricornutum* and *Tetraselmis chui*. All microalgae were grown autotrophically in outdoor pilot photobioreactors with 2.6 m^3, at Allmicroalgae facilities. After cultivation, the cells were collected by centrifugation and further spray-dried for biochemical analysis.

CHN composition was determined using a Vario el III (Vario EL, Element Analyser System, GmbH, Hanau, Germany), according to the procedure provided by the manufacturer. The total protein was calculated by multiplying the percentage of nitrogen by the 6.25 factor (Richmond and Hu, 2004). The total ash was determined by gravimetric analysis. The total lipid content was determined following the Bligh and Dyer method (1959). The carbohydrate content was determined by subtracting the weight of proteins, lipids and ashes from the total DW of biomass.

Results

Among the studied microalgae, *C. vulgaris* was the one presenting higher productivity in 2.6m^3 tubular photobioreactors, reaching 0.261 g/L/day, followed by *T. chui*, with 0,222 g/L/day. *P. tricornutum* and *N. oceanica* grew at 0.124 and 0.104 g/L/day, respectively. *C. amblystomatis* presented the lowest productivity rate, growing at 0.090 g/L/day.

C. amblystomatis presented the higher protein content (55.7%), followed by *C. vulgaris* (54.0%). *N. oceanica* was the species presenting the lowest protein content, 29.6%. *P. tricornutum* appeared to be a protein-rich microalga (51.2%), but as well a lipid-rich microalga (29.5%). This alga was the one presenting the higher lipid content, followed by *N. oceanica*, *C. vulgaris* e *C. amblystomatis*, with 22.0%, 20.0%, and 18.3%, respectivelly. *T. chui* was the microalga with the lowest lipid content, 6.5%. Regarding carbohydrates, the concentrations ranged from 16.6%, in *C. vulgaris* to 37.8%, in *N. oceanica*.

Ash concentrations were low in all tested microalgae, being *P. tricornutum* and *T.chui* the species with the highest content, 14.0%.

Discussion and conclusions

Microalgae cultivated at Allmicroalgae facilities meet the nutritional needs for a good fish meal and fish oil substitute. Fish feed is characterized by its high protein content, which has a crucial role in fish muscle tissues (Delgado and Reyes-Jaquez, 2017). Among the studied microalgae, *C. amblystomatis*, *C. vulgaris, P. tricornutum* showed to contain protein levels above 50%, being within the range of the one found in the classical ingredient (Cho and Kim, 2010). Except for *N. oceanica*, the carbohydrate content of the studied microalgae was below 30%, representing an advantage, considering the fish's poor capacity to digest carbohydrates (Delgado and Reyes-Jaquez, 2017).

The high lipid content found in the studied microalgae, namely *P. tricornutum*, *N. oceanica* and *C. vulgaris*, reinforces the potential of these organisms to be used in the substitution of fish oils. Besides, low levels of ashes were found in all tested algae.

This study clearly shows the potential of using microalgae as fish oil and fish meal substitutes. As demonstrated, microalgae can grow at high productivities and do not need arable land, not competing with other feedstocks. Further complementary studies are needed to access the digestibility of the microalgae, their bioactivities, as well as *in vivo* feed experimentation.

Introduction

The incorporation of new species in the aquaculture industry necessitates to control the reproductive function in captivity and to produce high numbers of high-quality eggs. Greater amberjack *Seriola dumerili* (Risso, 1810) caught from the wild and reared in captivity have been shown not to develop further than early vitellogenesis or if they did complete vitellogenesis, they failed to undergo oocyte maturation and required exogenous hormonal therapies to induce ovulation and spawning (Mylonas et al., 2004).The present work represents an overview of the results obtained in a study on the oogenesis of wild and captive-reared greater amberjack carried out within the EU FP7 project Diversify (Zupa et al, 2017; Pousis et al., 2018, 2019).

Material and Methods

Twenty-one wild and twelve captive-reared greater amberjack females were sampled during 2014, 2015 and 2016 at three different phases of the reproductive cycle: early gametogenesis (EARLY), late April-early May (wild fish = 5; captive-reared fish = 4); advanced gametogenesis (ADVANCED), late May-early June (wild fish = 4; captive-reared fish = 4); spawning (SPAWNING), late June-early July (wild fish = 12; captive-reared fish = 4). Wild fish were sampled on board a professional purse-seine fishing vessel operating around the Pelagie Islands (Sicily, Italy); captive-reared individuals belonged to a broodstock captured as juveniles and moved to a sea cage of Argosaronikos Fishfarming S.A. (Salamina Island, Greece). For each fish, biometric data (fork length, FL, in cm; body mass, BM, in kg; testis mass, TM, in g) were registered and gonadosomatic index (GSI = 100 × TM/BM) was calculated. Liver samples were store at -80°C and subsequently used for the analysis of vitellogenin (*vtga*, *vtgb* and *vtgc*) expression through RT-PCR. Ovary samples were used for histological analysis and for vitellogenin receptor (*vtgr* and *lrp13*) expression analysis through RT-PCR. Blood samples were centrifuged and plasma was stored at -20°C for the analysis of testosterone, 17β-estradiol and 17,20β-dihydroxypren-4-en-3-one by ELISA assays.

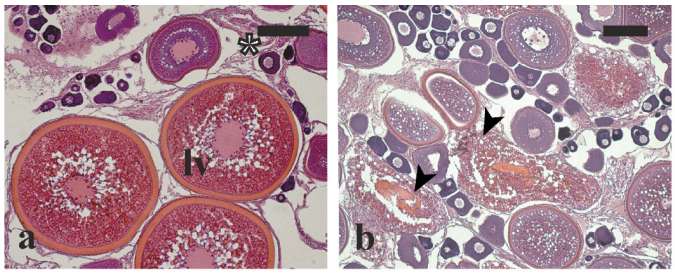

Fig. 1. Micrographs from greater amberjack ovaries sampled during the ADVANCED phase of the reproductive season. (a) Wild fish showing late vitellogenic oocytes and post-ovulatory follicles. (b) Captive-reared fish showing extensive atresia of late vitellogenenic follicles. Haematoxylin-eosin staining. Magnification bars = 150 μm. Arrowheads: atretic late vitellogenic follicles; asterisk: post-ovulatory follicle; lv: late vitellogenic follicle.

(Continued on next page)

Results and Discussion

The GSI and all the sex steroid plasma levels were lower in captive-reared fish. During the EARLY phase, wild and captive-reared fish displayed perinucleolar or early vitellogenesis as the most advanced oocyte stage. During the ADVANCED phase, when the wild greater amberjack breeders were already in spawning condition (Fig. 1a), ovaries of captive-reared breeders showed extensive atresia of late vitellogenic oocytes (Fig. 1b). During the SPAWNING period, all captive-reared fish had regressed ovaries, while wild breeders still displayed oocytes at late vitellogenesis and maturation stages as well as postovulatory follicles.

The expression levels of *vtga*, *vtgb* and *vtgc* did not differ significantly between captive-reared and wild females. Ovarian *vtgr* and *lrp13* transcription was more active during early gametogenesis, suggesting that vitellogenin receptor transcripts were synthesized by previtellogenic oocytes and remained in the cellular mRNA pool until oocytes resumed meiosis and entered vitellogenesis. A reduced *vtgr* and *lrp13* transcription was observed in captive-reared compared wild greater amberjack during the EARLY phase. The observed reproductive dysfunction, leading to oocyte atresia and reduced gonadosomatic index, arose during the early phase of oogenesis, when transcription of vitellogenin receptor genes appeared to be reduced, and did not appear to be associated to a lower liver capacity to synthesize the egg yolk precursors. Severe reproductive dysfunctions were observed also in males of the same broodstock and involved low sex steroid plasma concentrations and precocious cessation of spermatogenesis (Zupa et al., 2017). Preliminary data obtained within the H2020 project NewTechAqua indicate that hatchery-produced greater amberjack reared in sea cages in Salamina (Greece) have similar GSI compared with wild fish sampled in the same period of the reproductive cycle (early June 2021). Although further analyses are required, the available data indicate that hatchery-produced individuals might be less affected by captivity-induced stress than wild-caught breeders.

Financial grant provided by the European Union´s Programmes FP7 (GA 603121, DIVERSIFY) and H2020 (GA 862658, NewTechAqua).

EVIDENCE OF MULTIPLE GENOME DUPLICATION EVENTS IN *MYTILUS* EVOLUTION

A. Corrochano-Fraile, A. Davie, S. Carboni, M Bekaert

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, UK
E-mail: ana.corrochano-fraile@stir.ac.uk

Introduction

The marine mussel *Mytilus* is among the foremost cosmopolitan marine genera and is present in estuarine and oceanic habitats, in both the subtidal and intertidal zones (Koehn, 1991). In Scotland, mussel aquaculture is a growing industry, dominated by the production of *Mytilus edulis* (Dondero et al., 2006). To improve knowledge of distribution and genetic structure, this report presents the first draft genome assembly for *M. edulis* (Linnaeus, 1758) and the comparison with two other genomes from the same genera: *Mytilus Coruscus* (Gould, 1861) and *Mytilus Galloprovincialis (Lamarck, 1819)*. The *Mytilidae* have the capability to become a model shellfish for climate change adaptation using genome-enabled systems biology and multi-disciplinary studies of interactions between abiotic stressors, pathogen attacks, and aquaculture practises.

Material and Methods

An adult specimen of *M. edulis* was collected from a wild costal population located in St. Andrews (Scotland). Gills were dissected and genomic DNA was extracted. High-weight DNA was used for library preparation and sequencing using both Oxford Nanopore and Illumina platforms. The genome comparisons were carried with *M. coruscus* (Assembly GCA_011752425.2; Li et al., 2020) and *M. galloprovincialis* (Assembly GCA_900618805.1; Gerdol et al., 2020). The mitochondrial genome was retrieved manually from the genome assembly.

Complete annotated nuclear genomes of Bivalvia (class) were collected. Blast+/BlastP v2.10.0 (Altschul et al., 1990)was used to search for duplicated sequences in protein-coding genes between each genome. Duplicate pairs were identified as sequences that demonstrated over 70 % sequence similarity, mutual protein coverage > 80%, protein length > 30 amino-acid from an all-against-all search.

A set of core-orthologs was constructed from the three complete annotated nuclear genomes of *Mytilinae* (subfamily), *M. edulis, M. galloprovincialis and M. coruscus* and were used to identity cluster of orthologous genes with a 1:1:1 ratio.

Results

This study presents the annotated genome sequence assembly of the blue mussel, *M. edulis*. The genome was assembled into 3,339 scaffolds with a total length of 1.83 Gb and a scaffold N50 of 1.10 Mb. Annotation of the *M. edulis* genome assembly identified a total of 69,265 genes. To assess the paleo-history of the Mytilinae (subfamily), we performed a comparative genomic investigation. A total of 2,293 gene duplications younger than Ks = 5 were inferred across the total data set of 16,291 assembled unigene clusters in *Mytilinae* (*M. coruscus, M. edulis* and *M. galloprovincialis*). The functional analysis of positively selected orthologs has also allowed for the identification of gene duplications assembled unigene clusters involved in key physiological processes.

THE GILL MICROBIOTA COMPOSITION IN SEA FARMED ATLANTIC SALMON (*Salmo salar*): LOCATION MATTERS

Introduction

There is a growing interest in the gill health of economically important species such as Atlantic salmon (*Salmo salar*) as this organ is central to many physiological functions and overall fish performance. As a mucosal surface, gills can be colonised by pathogens and act as a site of pathogen entry. Numerous pathogens and environmental factors contribute to the gill inflammation, but the underlying response mechanisms to the disease are poorly understood. The terms "complex gill disorder" (CGD) and "proliferative gill disease" (PGD) reflect the complexity and multifactorial aetiology of gill inflammation. Microbiota associated with the gill mucosal surface that remain in homeostasis are believed to be an essential part of the gill immunity and health. Over the last decade, the interaction between microbiota and mucosal immunity has become an active field of research, aiming to improve understanding of gill health. The main objective of this study is to further our understanding of gill health in Sea farmed Atlantic salmon.

Materials and methods

We sampled Atlantic salmon from three different marine production sites in Scotland (A on Isle of Mull and B and C in Shetland) and examined the gills at three different levels of organization: gross morphology with the use of PGD scores (macroscopic examination), histopathology (microscopic examination) and microbial community composition (samples and other parameters fully described in Król et al. 2020). Gill mucus swabs were taken from 75 fish in total and used to extract DNA. Gill microbiota composition was evaluated by sequencing the V3/V4 variable region of the bacterial 16S using an Illumina MiSeq platform, followed by analysis of amplicon sequence variants (ASVs) with a DADA2 pipeline (Callahan et al. 2016). Functionality was inferred using Piphillin (Iwai et al. 2016).

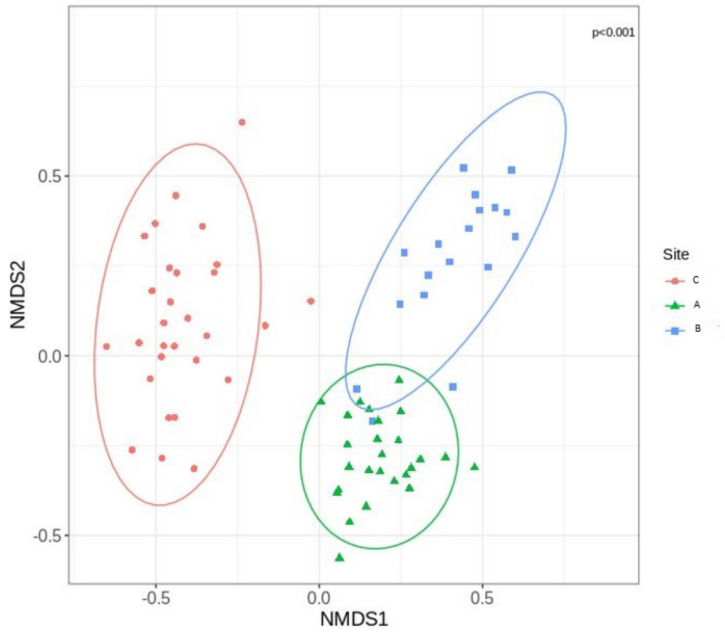

Figure 1: Beta-diversity based on Bray Curtis distances visualised in an NMDS plot. Different colours specify Atlantic Salmon separated by site (A, B and C) as described in Król et al. 2020. Data ellipses are based upon an assumed multivariate t-distribution at a level of 0.95.

(Continued on next page)

Results

Fish from the three different sites (A, B and C) had significantly different gill microbiota composition ($p < 0.001$, Fig. 1). The dominant gill microbial phyla were *Actinobacteria*, *Bacteroidetes*, *Firmicutes* and *Proteobacteria*, which is consistent with other salmonid studies (Brown et al., 2019). Site C, which had lower gill histopathology scores than sites A and B (Król et al. 2020), was characterised by significantly higher alpha diversity indices. All three sites were clearly separated by beta diversity. Despite the differences, all fish had a core gill microbiota that was shared between the sites. The functional analysis of the gill microbiota composition revealed the differences associated with the metabolic pathways.

Discussion and conclusions

The diversity of the gill microbiota composition was predominantly associated with the origin of fish (sites A, B and C), suggesting the importance of spatial and temporal drivers in shaping gill microbiota and gill health. Gill microbiota diversity was the highest in the fish with the lowest histopathology scores (site C), although the causality of this observation remains unknown. Oppositely, fish with the decreased gill microbiota diversity had higher gill histopathology scores (sites A and B). The relationship between gill microbiota composition and gill histopathology as well as their impacts on gill health require further studies.

Introduction

Soybean meal (SBM) contains several anti-nutritional compounds (ANCs) (e.g. lectins, trypsin inhibitors, soy antigens, isoflavones) that are major hindrances towards the nutritive value of SBM in fish diet [1]. Several methods including thermal treatments are being used to inactivate or eliminate many of these ANCs before SBM can be used in fish diets. The degree to which SBM must be heated may vary among fishes [2]. Isoflavones are a class of phytoestrogens with structure & function similar to synthetic estrogens having a range of estrogenic-like activities as well as antifungal, anti-oxidative and anti-inflammatory properties. The isoflavone genistein is present in soybeans in high amounts [3]. Dietary estrogenic-like effects of genistein-enriched diets may have positive but also negative effects in fish metabolism & health status [4]. There is good evidence that genistein affects the lipid metabolism in different fishes and alters plasma triglyceride and cholesterol levels as well as overall growth rates [5]. Yet, heat treatment of soybean products can affect not only the content but also the profile of isoflavones and their antioxidant activity [6]. The objectives of this study were to compare the feasibility of replacing FM protein in formulated diets with either a conventional SBM or a thermal treated SBM and evaluate the impacts on growth indexes & overall health status of gilthead seabream (*Sparus aurata*) juveniles, an important carnivorous sparid for marine cage culture, using selected growth indexes & biomarkers responses.

Materials and Methods

Three diets (isoproteinic & isolipidic) were produced in our lab: a 30% fish meal based diet (FM) & two other diets in which the FM was being replaced with a 28 % of SBM (Untreated-SBM) or with a 28% of SBM heat treated (Treated-SBM) (Table 1). Fabrication of all diets involved weight of raw materials, addition of 3% fish oil and mixing (Hobart), extrusion in pellets (Clextral) and drying at 40°C for 5 hours. The remaining amount of fish oil was added with a coater (Dinessen) under vacuum. Heat treatment involved addition of 20-30% hot water (80-90°C) in raw SBM following continuous mixing and heating at 60-65°C for 15 minutes and then drying at 50°C for 2 hours. Genistein was qualitatively & quantitatively analyzed in the methanolic extracts by UPLC-HRMS (Table 2). Juveniles of *S. aurata* (31.4 ± 0.5 g) were reared in 300 l tanks (30 fish/tank) in an open flow through seawater system (salinity 35‰, 22°C) and fed for two months. Trials were run in triplicates. At the end all fish were anesthetized counted & weighted. Blood samples were taken for immune biomarkers analysis. Liver & whole intestines were removed, snap-frozen in liquid nitrogen & stored at -80°C until analysis of enzymatic antioxidant, lipogenic & digestive biomarkers responses. Data were subjected to proper statistics analysis with the SPSS 21.

Results & Discussion

Replacement of FM with untreated SBM significantly affected the selected growth indexes and biomarkers responses. Further, heat treatment of SBM increased the content of genistein (Table 2). Most of the growth indexes were affected but only FCR, fish total body length and digestibility of lipids & carbohydrates were statistical significantly influenced compared to untreated-SBM (Table 3 & 4). Changes of lipogenic & digestive biomarkers responses were not significant after heat treatment (Table 5), whereas the most immune and enzymatic antioxidant biomarkers were significantly altered after SBM heat treatment (Table 6 & 7). Results obtained pointed out to take into consideration the possible consequences of SBM treatment and dietary isoflavone genistein on nutritional value of fish diet and *S. aurata* juveniles growth and health status.

EMBRYONIC AND EARLY LARVAL STAGES DEVELOPMENT OF THE SEA CUCUMBER HOLOTHURIA SANCTORI: A NEW POTENTIAL SPECIES FOR AQUACULTURE

G. Courtois de Viçose, M. Magdy

Instituto ECOAQUA/GIA Universidad De Las Palmas De Gran Canaria, Juan de Quesada 30, 35001 Las Palmas de Gran Canaria Spain
Email: gtricor@hotmail.com

Introduction

The continuous and increasing demand for sea cucumbers and new target species leads to certain overfishing scenario in some regions of the world requiring responsible management of catches and sustainment of market needs by other sources such as aquaculture. Therefore, several studies have investigated sea cucumber aquaculture, including hatchery production, as preliminary steps to the success of aquaculture of such species. Various species have been studied in Europe (Domínguez-Godino and González-Wangüemert, 2018; Laguerre et al., 2020 and Rakaj et al., 2019). However, no hatchery production studies have been performed on *H. sanctori* that exists naturally in the Mediterranean Sea and the eastern Atlantic Ocean. Hence, the study of its life cycle is of interest for production and environmental needs. Thus, the present study aims to test spawning induction methods, report embryonic and larval development and investigate larval rearing techniques of the sea cucumber *Holothuria sanctori*.

Materials and methods

Broodstock collection and maintenance

Adult specimens of *H. sanctori* were collected by scuba diving and were maintained in a biofilter reservoir, naturally filled with sediments, with flowing seawater at ambient temperature and under natural photoperiod until their transfer to experimental units for spawning induction and larval production experiments.

Spawning induction

Prior to the induction procedure, broodstock were washed with fresh seawater and placed in 300 L tanks at a density of 7 specimen/m^2 and then subjected to three different spawning induction treatments, that combines mechanical shock, thermal shock and algal stimulation. Each treatment was tested in triplicate.

Embryonic and larval culture

The fertilized eggs were stocked at two different densities in 200 L conical bottom larval tanks, filled with 1 **µm** filtered fresh seawater and UV sterilized, and fed at two different algal densities when the auricularia stage was reached. Three treatment were tested in triplicate: Treatment (A): 0.3 egg/ml and algal density from $5x10^3$ cells/ml to $2x10^4$ cells/ml. Treatment (B): 0.3 egg/ml and algal density from 10^4 cells/ml to $4x10^4$ cells/ml. Treatment (C): 1 egg/ml and algal density from 10^4 cells/ml to $4x10^4$ cells/ml. Tanks were maintained under natural photoperiod, constant temperature and provided with aeration and constant water flow. The algae tested as a source of feed were *Nannochloropsis* sp. and *Amphora* sp., provided in equal proportions (3 times/day) with concentrations gradually increasing until reaching a fixed algal concentration at the end of the experiment.

Embryonic and larval development

Embryonic and larval development was monitored microscopically from fertilization of the eggs up to the late auricularia stage. Embryos were observed every hour to observe cell divisions and take measurements. Daily water samples were taken from each treatment, for 26 days, to monitor larval development, and register larval size (length and width) of 10 larvae per tank.

Results

Spawning induction

Spawning was induced by mechanical shock and algal stimulation and spawning behaviour exhibited consisted in specimens clinging to the walls of the tanks close to the water surface. Male and female gametes were expulsed from a single gonopore at the top dorsal anterior surface of the body.

(Continued on next page)

Embryonic and larval development

Once fertilized the eggs were observed to go through different cleavage and gastrulation stages until reaching a fully elongated blastopore 57h30 min after fertilization. Early, mid and late doliolaria stages were observed until reaching until length and width of 1013.16 ± 151.46 **µm**, and 681.32 ± 112.6 **µm**, respectively.

Larval growth

Larve presented significantly higher lengths and widths ($P < 0.05$) al lower larval density while their length was not significantly affected ($P > 0.05$) by algal feeding density throughout auricularia larval development.

Discussion

The observed embryonic and larval development of *H. sanctori* were in line with the previous studies performed on several sea cucumber species. *H. sanctori* fertilized eggs had a medium size of 143 **µm**, lower than higher values reported for *H. polii, H. forskali, H. tubulosa*, and *H. mammata* (Domínguez-Godino and González-Wangüemert, 2018; Rakaj et al., 2018; Rakaj et al., 2019; Laguerre et al., 2020) and higher than lower values reported for *A. mauritiana* (Ramofafia et al., 2003), while the early auricularia size of 563 **µm** exceeded the ones reported for these species. The timing of the emergence of auricularia larvae in *H. sanctori* (3 days 6 hours) was close to that observed in *H. polii* and *H. tubulosa* (3 days) (Rakaj et al., 2018; Rakaj et al., 2019), bred at a similar temperature. The larval growth results corroborate the ones of previous study on *H. scabra* suggesting that the best larval density is between 0.3 – 0.7 larvae/ml (James, 1996), but are also contrary to work protocols used in hatchery production for other species where the larval stocking density is reported to be 1 larva/ml (Domínguez-Godino and González-Wangüemert, 2018; Rakaj et al.,2018). However, similarly to *H. tubulosa* (Rakaj et al., 2018) the low concentration of microalgae administered to the larvae was found to provide better growth and development than in higher concentration regimes.

Introduction

Various studies have demonstrated the interest of including deposit feeders, as an integrated element of IMTA systems devoted to the consumption of organic materials (Cubillo et al., 2016). Sea cucumbers are of interest as deposit feeder, for their environmental value, their interesting growth potential and low mortality rates (Zamora and Jeffs, 2012). Various sea cucumber species within IMTA systems have been tested for co-culture with a variety of fish (Hannah et al., 2013), molluscs (Kang et al., 2003; Zhou, 2006) and seaweed (Beltran-Gutierrez et al., 2016). The interest of Holothurians as deposit feeders was demonstrated in these studies and their mitigation ability within different IMTA systems was further tested, indicating that sea cucumbers can optimise the net use of wastes (Reid et al., 2013).

Given the existing research, the current study investigates the potential for the integrated culture of the sea cucumber *H. sanctori* with the abalone *Haliotis tuberculata coccinea* in order to develop the integrated Land Based IMTA production of these species.

Materials and methods

Experimental specimens

Young individuals of *H. sanctori* (mean weight: 31.07 ± 14.51 g) were collected at a depth of 0-10 m, by scuba diving, and maintained and acclimated in experimental installations, placing them under abalone (*H. tuberculata coccinea*) baskets (in which abalone were fed macroalgae). After their indoor acclimation, they were then respectively allocated to experimental IMTA units.

Adult abalone of *H. tuberculata coccinea* (mean weight: 37.32 ± 9.01g and mean size: 60.83 ± 5.30mm) were obtained from the abalone production unit of the ECOAQUA institute, University of Las Palmas de Gran Canaria.

IMTA experimental set up

Experimental IMTA systems were designed to provide two levels compartments; one for the fed abalone (*H. tuberculata coccinea*) of 50L capacity and the other for sea cucumber (*H. sanctori*) located below the abalone compartment. Together located in 300L tank capacity. The abalone compartment was perforated on the bottom and on the sides to allow water exchange and release of abalone wastes to reach the sea cucumber located below.

Stocking density

Tests were performed in triplicates in the IMTA experimental units at two sea cucumber densities (2.5 Specimen.m^{-2} and 3.75 Specimen.m^{-2}) that were placed under abalone baskets stocked at 50 Specimen/m^{-2} and weekly fed 0.8kg of IMTA produced macroalgae.

Growth performance and ingestion rate

Weight Gain (WG), and Specific Growth Rate (SGR) were estimated on a monthly basis while ingestion rate was estimated in mg/g/h

Biochemical analysis

Triplicate samples of sea cucumber body wall were collected from experimental and wild specimens and were analyzed for total lipids, protein, carbohydrate, and ash.

Results

Growth performance

Overall, the mean SGR and WG values differed significantly ($p < 0.05$) among high density and low-density treatments. All sea cucumber specimens within the density 3.75 sp.m^{-2}, were found to lose weights and exhibit negative SGR and WG values. On the contrary, for specimens stocked at a density of 2.5 sp.m^{-2}, their growth performance improved as all specimens could gain weight and exhibit positive SGR and WG values.

(Continued on next page)

Biochemical analysis

No significant difference ($p > 0.05$) was observed between the proximate biochemical composition of sea cucumbers produced in the tested IMTA system and the wild-caught specimens, supporting the suitability of such system for the production of this sea cucumber species.

Discussion

The loss of condition amongst sea cucumber fed abalone faeces at high density in the current experiment indicates that stocking density has a significant impact on *H. sanctori* growth. Similarly, several authors have reported an inverse proportionality between sea cucumber stocking density and their growth rates (Dong *et al*., 2010; Pei *et al*., 2012). Based on these results, a stocking density of 2.5 $sp.m^{-2}$ is suggested to sustain growth of *H. sanctori*. In terms of biochemical composition, the similarities observed between the experimental specimens and their wild counterparts suggest the ability of sea cucumbers to adjust their feed intake to satisfy their nutritional requirements and to maintain a steady nutrient composition within their body walls, this being of interest for future successful production of the species.

Introduction

Marine macroalgae represent a source of bioactive compounds capable of producing a myriad of secondary metabolites. Due to the wide range of biological activities, polysaccharides extracted from macroalgae have a wide variety of potential industrial applications including functional foods, nutraceuticals, etc (Garcia-Vaquero et al. 2016). The Adriatic Sea is a challenging habitat characterized by high salinity (35.0-38.5 ‰), large temperature oscillations (7-27°C), relatively shallow depth (~200 m depth), and increased impact of UVA and UVB radiation (Grbec et al. 2018). The ability of marine macroalgae to survive such harsh environmental conditions suggests the presence of unique protective compounds and mechanisms. Their structure and biological activity are highly influenced by growth location and harvesting season that cause even intra-species variation, thus offering an inexhaustible source of novel bioactive compounds (Jiao et al., 2011; Garcia-Vaquero et al. 2016). The present study was undertaken to evaluate the toxic potential and novel *in-vivo* antioxidant activity determination of polysaccharide fractions and to complete this research by developing a robust platform for the high-throughput screening of novel marine compounds with antioxidant properties.

Materials and methods

The 7 marine macroalgae [two green algae: *Ulva lactuca* (ULLA) and *Codium bursa* (COBU) and five brown algae: *Padina pavonica* (PAPA), *Halopteris scoparia* (HASC), *Cystoseira compressa* (CYCO), *Cystoseira barbata* (CYBA) and *Fucus virsoides* (FUVI)] were collected from the coastal area of Croatia. Extraction of polysaccharides from freeze-dried samples included the addition of acetone under constant stirring for 18h, followed by filtration and drying of residues which were afterward stirred in hot sulphuric acid and filtered. Polysaccharides were precipitated by the addition of ethanol, refrigerated, collected and dried after 24h. The extraction yield of polysaccharides, as well as the content of fucose, sulfuric groups and uronic acid was determined.

Zebrafish embryotoxicity test (ZET) was performed on 0.25, 0.50 and 1.00 mg/mL of each fraction using zebrafish *Danio rerio* embryos (WIK strain) in accordance with OECD 236 Guidlines (2013). Lethal and sub-lethal effects, as well as cardiotoxic and neurotoxic potential, were estimated at 96 h of exposure. The zebrafish embryo was further employed to confirm the protective effect of polysaccharide fractions on H_2O_2-induced ROS generation *in vivo*, following the developed protocol described in the study of Jerković et al. (2021).

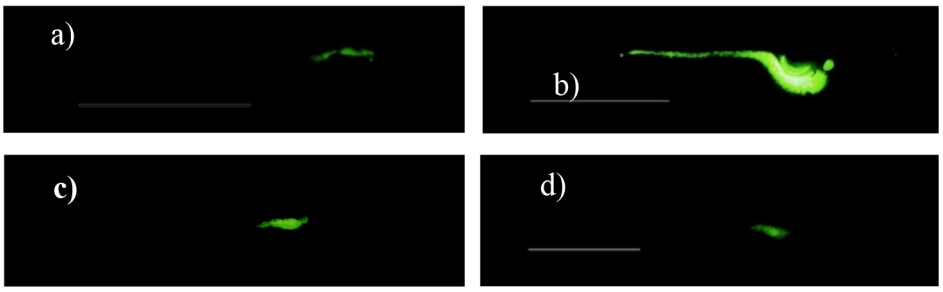

Figure 1. *In vivo* evaluation of antioxidant potential of polysaccharide fractions in DCF-DA stained larvae. a) Non-treated control, b) Hydrogen peroxide-treated specimens. Specimens pretreated with: c) 0,5 mg/mL HASC, and d) 1,00 mg/mL HASC. Scale bar=100 μm.

(Continued on next page)

Results

Fractions of brown macroalgae contained a higher amount of sulphated polysaccharides (up to 95.17%), fucosis (up to 20.51%) and uronic acid (up to 8.45%) than fractions prepared from green algae. Tested polysaccharide fractions showed no embryotoxic, cardiotoxic and/or neurotoxic potential. The only exception was COBU that increased mortality and heartbeat rate at 1 mg/mL, which was excluded for further testing of antioxidant activity. The H_2O_2 treated embryos exhibited significantly high fluorescence intensity (386.7%, $p<0.05$) compared to the non-treated group (100%). Embryos pretreated with CYCO, CYBA and HASC polysaccharide fractions exhibited a statistically significant decrease of fluorescence intensities (Figure 1), subduing the effect generated via H_2O_2. The highest antioxidant activity was noticed on HASC (fluorescence intensity decreased for 60.27% comparing to the group on H_2O_2).

Discussion

Among seven tested polysaccharide fractions, a protective effect against H_2O_2-induced oxidative stress was proven for CYBA, CYCO and HASC fractions. Concentration of CYCO and HASC fractions in 1 mg/mL showed the highest antioxidant activity, which corresponds well with the high amount of polysaccharide groups (95.17 and 70.47%, respectively). Amongst tested fractions, CYCO contained the highest amount of uronic acid, well known for its antioxidant properties (Ai et al. 2020). Moreover, synergistic action in such a complex mixture should be taken into account. Collectively, the results obtained in the study suggest that polysaccharides isolated from the Adriatic Sea macroalgae might be a potent source of natural antioxidants that could be sustainably utilized in industrial applications. Due to the high degree of genetic similarity among zebrafish and humans, our findings suggest that zebrafish is a valuable model not only in determination of biomolecule's safety for human usage but also in the prediction of their mechanism of action in the human organism.

EFFECTS OF *BMP15* KNOCKOUT ON ATLANTIC SALMON GAMETOGENESIS

D. Crespo[(1)*], E. Kjærner-Semb[(1)], K. O. Skaftnesmo[(1)], E. Andersson[(1)], P. G. Fjelldal[(2)], T. J. Hansen[(2)], R. B. Edvardsen[(1)], R. W. Schulz[(1,3)], A. Wargelius[(1)], L. Kleppe[(1)]

Inducing sterility represents an alternative strategy for sustainable Atlantic salmon (*Salmo salar*) aquaculture since that can avoid genetic introgression of farmed escapees into wild populations and unwanted precoucius male sexual maturation. One possibility is to target proteins essential for germ cell formation or survival, such as previously identified gonad-specific factors. Bone morphogenetic protein (BMP15) is a critical regulatory factor in mammalian female reproduction that plays a crucial role in ovary development and oocyte maturation, while inactivating mutations in *BMP15* result in sterility. Despite its importance in female fertility, little is known regarding the biological function(s) of BMP15/Bmp15 in male gonads in vertebrates. Previous work of our group revealed, as reported in mammalian models, a gonad- and germ cell-specific expression of *bmp15* in salmon. To further investigate the role of Bmp15 in gonadal development, we generated in this study *bmp15*-edited Atlantic salmon using CRISPR/Cas9. Gamete quality analysis showed that fertilized eggs from highly mutated F0 generation *bmp15* CRISPR-ed fish had low or no survival, suggesting an important role of Bmp15 in the production of functional gametes, and/or in embryonic development in salmon. However, surviving larvae were kept in order to stablish an F1 generation and to investigate potential phenotypes during gametogenesis. For that purpose, F1 *bmp15* knockout (KO) mutants and control fish were reared in a common garden, gonad samples were collected, body weight and length measured and gonado-somatic (GSI) indices scored at 3 different time points (18, 22 and 26 months). At 18 months of age, ~21% of the *bmp15* KO females investigated had 1 ovarian bulb only and the majority (83%) of the *bmp15* KO males showed germ cell-poor testes, which was accompanied by reduced *vasa* expression levels compared to the control group in both sexes. In addition, transcripts levels of genes involved in estrogen biosynthesis and signaling (*cyp19a1a* and *esr1*) were stimulated in *bmp15* KO females. In the following samplings (22 and 26 months of age), no significant difference was recorded for the females in none of the parameters analyzed. In contrast, the stage of spermatogenesis seemed advanced in *bmp15* KO males compared to the control group, showing significantly elevated GSI values and higher cumulative frequency of spermiating testes (~50 *vs*. 22%) but lower expression levels of steroidogenic enzymes (*cyp17a1* and *star*). However, the effect of *bmp15* loss-of-function on sperm quality and viability requires further investigation. Taken together, our results suggest that Bmp15 plays a role in the regulation of germ cell development during early stages of both oogenesis and spermatogenesis in salmon, and that genetic ablation of *bmp15* in males advances the stage of spermatogenesis but sperm production is normal. Unfortunately, due to the long generation time in female salmon, data on later stages of maturation and ovulation are not available yet and further analysis will have to clarify whether *bmp15* loss-of-function leads to obvious ovarian phenotypes as described in mammals.

A NOVEL ENVIRONMENTAL METHOD FOR CIRCULAR INNOVATIONS: EMERGY ASSESSMENT OF RAS BY-PRODUCT VALORISATION OPTIONS

Introduction

Driven by environmental concerns, resource optimisation goals, costs abatement, and market competitivity, the aquaculture sector is not exempt from seeking circular and less impacting solutions. By definition, RAS systems allow for direct recirculation of water. Here, a step forward is analysed, addressing by-products that are currently not recirculated in the plant nor in outer human economies, in turn implying safety and environmental threats in addition to disposal expenditures: namely, wastewater and fish mortality. The former yields sludge that is converted into biogas, while the recirculated water still averagely contains relevant quantities of nitrogen (N, 0.028 mg/L), ammonium (NH_4, 0.036 mg/L), Chemical Oxygen Demand (COD, 219 mg/L), and suspended solids (SS, 100 mg/L) when leaving a regular RAS. The latter is mostly treated by the technology of ensilage, with biomass treated with formic acid, thus causing a hazardous by-product to be transported and safely disposed of, while exposing humans to a liquid that is able to cause acid etching to the skin, eyes, lungs, and more; the waste liquid may also produce gases that are harmful to human health and that can be explosive. Targeting such two by-products, some eco-innovations were developed within the Horizon 2020 project GAIN – Green Aquaculture Intensification in Europe (2018–2021), aimed at abating costs and impacts for the farm, and valorising current by-product as new resources for fertiliser mixes, pet food, cement production and/or energy generation. Carried out by Norwegian industrial partners Salten Havbrukspark (SHP) and Waister AS (WAS), such proposals were independently evaluated by Italian public research partner Università Ca' Foscari Venezia through an emerging comprehensive environmental accounting method – i.e. EMergy assessment – allowing to enlarge the evaluation boundary compared to well-oiled Life-Cycle Assessment (LCA), which is anyway also used here for comparisons.

Materials and methods

This study presents the environmental assessment of several options per innovation. In both, scenarios (A) represent reference conditions depicting business-as-usual approaches. Regarding wastewater, innovative scenario SHP(B) shows the consequences of a filtered and dried sludge, i.e. more purified water to be recirculated and a resulting powder, rich in nutrients, to be recirculated and valorised in outer economies: (B1) as a fertiliser; (B2) as bio-energy in a cement factory; and (B3) as biogas substrate. Regarding fish mortalities, drying innovations differ for the cooling media of the new machinery, i.e. water in WAS(B) and a mix of water and glycol in WAS(C), and for the consequent fact that in (B) hot water is recirculated in the RAS, allowing to save electricity in the fish farm. For such innovation, end-of-life valorisation options are represented by the reuse of the dried product as a pet food ingredient, as bio-energy in a cement factory, and as biogas substrate. Both eco-innovations are referred to demonstration plants in Norway; all inputs, including transportation ones to the final valorisation sites, are computed for that geo-economic context, yet allowing for exportation and adaptation. The economic implications of savings from the avoided disposal or even by the sale of by-products are also evaluated in the present assessment. Indeed, this is possible through the thermonidamics- and systems ecology-based EMergy accounting (EMA) approach (Odum, 1996; Brown & Ulgiati, 2016): changing the perspective from the final user (receiver) to the environment (donor), material and immaterial inputs and outputs are associated with their direct and indirect requirements to the geobiosphere. LCA results from the standardised Life-Cycle Assessment (LCA) (Arvanitoyannis, 2008) are also offered and discussed. Through EMA, the reliance upon natural resources is further explored compared to LCA, focusing more on impacts. Such approaches may be seen as complementary; for this reason, they are increasingly used together for more comprehensive views on a process' sustainability.

(Continued on next page)

Results

The eco-innovations' potentials, limits, and margins for improvement are presented and discussed. The eco-innovations for fish mortality treatment seem to perform better than business-as-usual ensilage. Through LCA, environmental gains larger than –80% are obtained in most indicators, even when the product is simply disposed of, and larger environmental gains arise from the reuse of the dried product in the processing of pet food, implying avoided disposal and savings in alternate ingredients. Positive LCA results, although smaller than in the other innovation, also come from innovations addressing wastewater, with no marked preference among all end-of-life options. In both innovations, smaller, neutral, and in some cases contrasting results are reached on water consumption. Compatible trends seem to be confirmed by EMA, anyway still in progress while submitting the present proposal, allowing for further insights about the mineral and fossil fuel scarcity, and adding up novel information about flows that are instead not accounted for in LCA: among these, the most interesting ones for the assessment at hand seem to derive from free-of-charge renewable inputs, from human labour, and from the environmental significance of the monetary costs associated with the purchase and selling of inputs, waste, and valorised by-products.

Introduction

Ruditapes decussatus (grooved carpet shell) is an European native clam species with high economic and gastronomic value. In the last two decades, *R. decussatus* production has declined mainly due to over-exploration of natural clam beds, pollution, significant temperature and salinity variations and pathologies caused by bacteria, virus and protozoa. In particular, new diseases like Perkinsosis caused by the protozoan parasite *Perkinsus olseni*, associated with environmental degradation, are causing abnormal mortalities (Matias, 2013). Of the *Perkinsus* species, *P. olseni* can have a severe impact on bivalve molluscs, namely in clam species (*R. decussatus*, *R. philippinarum* and *Venerupis corrugata*) and has been associated with high mortality rates in different molluscan species worldwide, resulting in severe economic losses (Ruano et al., 2015).

It is known that heavy *P. olseni* infection provokes the accumulation of large granulocytomas invading clam's gonad, and thus reducing the reproductive area (Casas & Villalba, 2012). In addition to the physical effects of *P. olseni* on clam's organ structure, heavy infections also cause a reduction in host condition index (Casas, 2002). The energy consumed by the parasite in heavily infected clams may suppose a considerable subtraction of the energy available for growth and reproduction (Choi et al., 1989). Studies available in the literature showed contradictory results in clams. Park et al. (2006) found that spawning frequency and oocyte production were negatively affected in *R. philippinarum* females heavily-infected by *P. olseni*. Contrary, Casas & Villalba (2012) did not find a significant effect of infection on gonadal index, fecundity or spawning efficiency. However, to our knowledge no studies have investigated the effect of *P. olseni* on *R. decussatus* maturity and reserve storage during hatchery conditioning. In this work, the effect of *P. olseni in vitro* infection of *R. decussatus* on gametogenesis.

Materials and Methods

Perkinsus free adults of *R. decussatus* were divided randomly in three groups: a control group (non-infected, injected with saline solution), and two *in vitro* infected groups by injection - low infection (LI) (5000 *Perkinsus*/clam) and high infection (HI) (500.000 *Perkinsus*/clam). Clams were held in tanks in a flow-through circuit containing filtered seawater, at 19ºC and were fed daily with a mixed diet.

Sampling were done at the beginning of the experiment (T0), after 34 days (T1) and at the end of the conditioning period (58 days) (T2) for the determination of condition index, gametogenic stage, gross biochemical composition (total proteins, glycogen and total lipids) and *Perkinsus* infection level by RFTM standard method. The software SigmaPlot (version 12.5 Systat Software, Germany) was used to perform all statistical analyses.

Results and discussion

It was observed an increase of *Perkinsus* infection directly correlated with the dose injected: control (no infection); low dose -> medium infection; high dose -> high infection.

During the conditioning period, it was observed the decrease of glycogen reserves *vs* the increase of total lipids in all treatments, indicating *de novo* synthesis of total lipids to gamete formation.

The decreased of glycogen contents observed during the conditioning period, was more accentuated in the first 34 days and in the treatments with clams infected. Behind the consumption of glycogen to gametogenic process, the clams infected with *Perkinsus* seem to spend more energy for their metabolism.

The effect of *Perkinsus* infection in clam's conditioning was evident, since in HI treatment was observed a delay in the gonadal development comparatively with the two other treatments. This fact was also supported by the higher values of total lipids observed in the HI, at the end of conditioning period.

Introduction

Oceano Fresco is a private company that develops and produces bivalves varieties with superior performance, respecting environmental sustainability and ensuring consumer safety.

There are a few breeding programmes for bivalve species in the United States, Australia, New Zealand, and France. These programmes have mainly focused on oysters and their diseases. In clams, there are some studies dealing with the heritability of growth in *R. philippinarum* (Manila clam), mostly at a research level (Huo et al. (2016) and Zhao, et al. (2012)). However, presently and to our knowledge, there is not one single commercial breeding program for European native clams. Despite the clam market being larger and having a higher price per kilogram than the oyster market, the clam aquaculture sector is still very rudimentary – i.e. made up of small players with little capacity to invest in R&D or verticalize their business. Thus, a clear business opportunity exists.

The market potential of high-value clams was confirmed directly by Oceano Fresco's team during a field study conducted when the company was launched in key aquaculture geographies (Portugal, Spain, Italy, China, South Korea, US and Norway) as mentioned above. We have since then in-depth validated that there is material commercial value to have both our target species (*Rudipates decussatus* and *Venerupis corrugata*) available at the same time to create scale and productivity. This is because of technical fit reasons (ie. some producing areas or plots are more suitable to produce either submerged or partially submerged clams) and also commercial reasons driven by geo consumption patterns impact on sales and distribution coverage (ie. some areas consume both while others only one of the species).

On its State of the World's Aquatic Genetic Resource for Food and Agriculture report of 2019, FAO concluded that there is a tremendous opportunity to sustainably improve aquaculture productivity through the widespread adoption of genetic improvement "with a focus on well-managed and long-term selective breeding for continuous genetic improvement programs, into which other genetic technologies can be integrated".

Oceano Fresco and its R&D partners will conduct a selective breeding program that will allow a sharp increase in the production of high-quality and high market-value clam species – *R. decussatus* and *V. corrugata*, resulting in the sustainable improvement of aquaculture production. This will be done at EUROCLAM project, where various cutting-edge tools and methodologies will be applied.

This project started in January 2021 and has a duration of 2 years.

Materials and Methods

At EUROCLAM project the following work packages are planned: i) production optimization of elite stocks of *Ruditapes decussatus* and *Venerupis corrugata*; ii) Large-scale test model for *Perkinsus olseni* resistance; iii) Development of genomic tools for *R. decussatus*; iv) GWAS experiments and genotyping and update of breeding plan for *R. decussatus*; v) Commercialization, communication, and management.

Results and discussion

At the end of the EUROCLAM project, it is expect to have (1) applied a science-based approach, at the industrial level, for breeding and cultivation of European clams; (2) developed a large-scale test model for the clam pathogen *Perkinsus olseni*; (3) sequenced the genome of a European clam and develop several genomic tools for selection; and (4) implemented an industrial breeding plan for *Ruditapes decussatus*.

This blue growth project will increase the production of a high nutritional protein, restoring and preserving biodiversity, and contributing for non-damaged ecosystems.

Introduction

Nutrient-related water quality degradation is a global challenge to coastal waterbody health. Bivalve aquaculture can help reduce impacts of eutrophication through filtration, which removes particulate organic material (POM). Some filtered POM is assimilated into tissue and shell, and rest is expelled as faeces, pseudofaeces and ammonia. The potential contribution of bivalve aquaculture to reduction of nutrient impacts in European (EU) coastal waters was evaluated to develop a framework for nutrient credit trading in the EU that will include bivalve shellfish producers. An economic valuation of the removed nutrients was also made to show the value within the larger context of the shellfish industry and nutrient management, and to show the potential compensation that might be paid to shellfish producers for the nutrient removal service provided, if they were included in a nutrient credit trading program.

Methods

Nutrient Loads: Data for nutrient loads to Regional EU Seas were compiled, updating a previous evaluation (Ferreira and Bricker, 2016). Sources included: (i) Skarbøvik et al. (2013) for Norwegian and Barents Seas; (ii) HELCOM (2015, 2018) for the Baltic Sea; (iii) OSPAR (2017) for the Greater North Sea, Celtic Seas and Bay of Biscay; and (iv) Bouraoui et al. (2011) for Greater North, Black, and Mediterranean (Med) Seas.

Shellfish production and associated nutrient removal: Bivalve production data for blue mussel, Med mussel, Pacific oyster, European oyster, and Manila clam were sourced from META (Longline Environment Ltd, 2020) and Eurostat (Eurostat, 2020) websites. Net nutrient removal was estimated in two ways: (i) through elemental analysis of shellfish flesh and shell for each species which was then scaled to production, and (ii) by application of the Farm Aquaculture Resource Management (FARM) model. The model calculates nutrient removal and potential economic value, providing a substitution or 'avoided' cost of land-based nutrient removal that would serve as additional revenue to the farmer in a nutrient credit trading program (Cornwell et al. 2016; Ferreira and Bricker 2016; Bricker et al. 2018).

Scaling nitrogen removal to country and European scale: Nitrogen (N) removal estimates were upscaled to estimate bioextraction potential and associated economic value for the regulatory ecosystem service provided by each shellfish species at country and EU level. Total N removal by shellfish aquaculture was compared to total N load to EU Seas.

Table 1. Nitrogen loading to European seas in 2018 and N removed by shellfish harvest at each area as percentage of total loads. Percentages were calculated based on the country of production.

	Nitrogen loading ($t\ y^{-1}$)	Nitrogen removal (%)	
		Elemental analysis	FARM
Norwegian Sea	64 600	-	-
Barents Sea	11 010	-	-
Baltic Sea	601 900	-	-
Greater North Sea	1000 000	0.05%	0.06%
Celtic Seas	275 000	0.06%	0.09%
Bay of Biscay and Iberian Coast	450 000	0.54%	0.89%
Black Sea	700 000	-	-
Mediterranean Sea–Europe only	950 000	0.16%	0.37%
Total	4052 610	0.12%	0.22%

(Continued on next page)

Results and Discussion

Nutrient Loads: The total N load to EU seas was 4777 × **10**^{3} tonnes (t) y^{-1} (Table 1). The Greater North Sea (1500 × 10^3 t y^{-1}), Med Sea (950 × 10^3 t y^{-1}) and Baltic Sea (826 × **10**^{3} t y^{-1}) received the highest loads, while the Arctic region received the lowest: Norwegian Sea (65 × 10^3 t y^{-1}) and Barents Sea (11 × 10^3 t y^{-1}).

Shellfish production and associated nutrient removal: The five species selected for this study accounted for >95% of total EU farmed shellfish production and 40-45% of all farmed aquatic organisms (Eurostat, 2020). The largest EU producers were Spain and France. Spanish bivalve production was 42% of EU output, dominated by Med mussel, while France accounted for 24% of EU farmed bivalves with Pacific oysters as the main species (65% in 2018), followed by blue mussels (31%).

Scaling nitrogen removal to country and European scale: The total estimated N removed by farmed bivalves in EU Seas was 8.9 × **10**^{3} t y^{-1} and 4.9 × **10**^{3} t y^{-1} by the FARM model and elemental analysis, respectively. Comparison of removal estimates by the two approaches shows that FARM model results were higher for all species except blue mussel culture for which estimates showed good agreement. Both approaches showed the bulk of N removed was attributed to Med mussel aquaculture (between 61 and 68%). Pacific oysters were the second largest contributor to N removal, 8.0-15% of total, depending on approach. Spain was the primary contributor to N removal due to high production of Med mussels, accounting for 45-49% of total removal depending on the approach. Italy and France each account for 15-20% of total N removal. The elemental analysis approach showed Med and blue mussels had the highest capacity for N removal, reaching ~9-10 t of N removed per 1000 t harvested. Oysters and Manila clams ranged from 2.9-3.7 t of N removed per 1000 t harvested. The modelling approach showed that Manila clams have greatest removal capacity followed by flat oyster and Med mussel, which had similar removal.

Shellfish production in the EU removed between 0.12% (elemental) and 0.22% (FARM) of total 2018 N inputs to European Seas (Table). This varies by waterbody; N removal in the Greater North Sea is ~0.05% of inputs, while in the Bay of Biscay and Iberian coast it was as high as 0.89% due mostly to Med mussel production. While this seems small, the estimated avoided cost value of removed N, using the Virginia Chesapeake Bay Nutrient Credit Exchange Association value of US$8.33 (6.89€) per credit, is 34-61 million € or ~3-6% of the total production value (974 million €). This could be compensation to growers if they were included in a nutrient credit trading program. If shellfish growers are not included, this valuation could still enhance public awareness of water quality issues, and could help shift attitudes to allow increased opportunities for shellfish aquaculture that would improve water quality, especially helping reduce difficult to manage non-point sources, and stimulate local economies.

Introduction

In southwest Iberia extensive and semi-intensive fish culture in earthen ponds are traditional activities in saltmarsh. The most used commercial fish species are gilthead seabream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*). Since most of this activity takes place in protected areas, intensifying the production is out of the question, however increasing product diversification with IMTA, may provide an answer by creating a balanced system for environmental sustainability of earthen ponds while increasing their profitability and social acceptability. Life cycle assessment (LCA) was used to evaluate the environmental footprint of semi-intensive and semi-extensive pond IMTA in comparison to semi-intensive conventional fishpond production (POLY).

Methods

The studied systems:

Species	Semi-intensive IMTA [# pond^{-1}/MW]	Semi-extensive IMTA [# pond^{-1}/MW]	Semi-intensive POLY [# pond^{-1}/MW]
Argyrosomus regius	2,700/175	-	8,000/9.5
Diplodus sargus	500/236	-	-
Sparus aurata	-	1,500/20	500/29.4
Mugil cephalus	320/268	-	-
Crassostrea gigas	24,000/1.46	44,875/0.32	
Ulva spp.	+	+	-
Final fish density (kg m^{-2})	2.5	0.1	2.5
Final oyster density(kg m^{-2})	1	0.5	-

- number; MW – Individual mean weight in gram

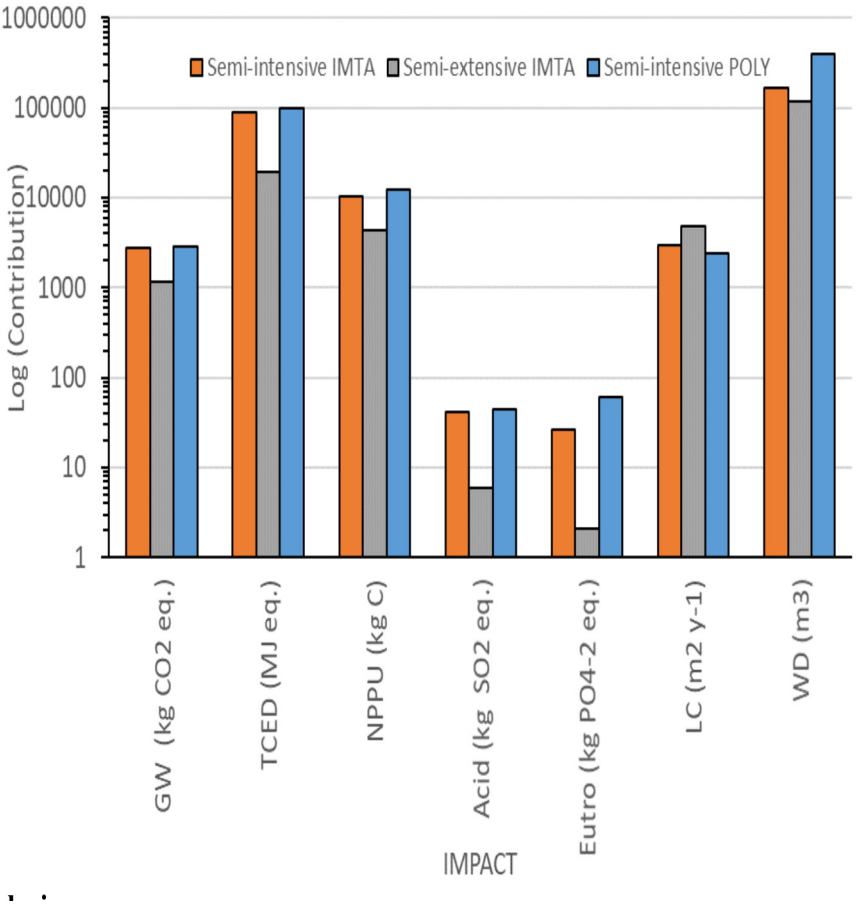
Scenario data for the systems considered in the study:

	Semi-intensive IMTA	Semi-extensive IMTA	Semi-intensive POLY
CYCLE LENGTH (months)	5.3	8.5	26
INPUTS			
Feed (kg)	1,888	89	10,975
Used sea water (m^3)	101,110	7,185	1,201,764
Fish biomass weight (kg)	677	45	91
Oyster flesh biomass weight (kg)	5.5	14.4	-
Main infrastructure components			
Total farm area (m^2)	90,000	285,000	90,000
Total farm pond area (m^2)	23,600	200,000	23,600
Area of production ponds (m^2)	700	665	1,700
OUTPUTS			
Fish biomass gain (kg)	1,099	65	6,137
Oyster flesh biomass gain (kg)	130	94	-
Associated downstream production			
Macroalgae biomass gain (kg)	1,224	35,400	-
Zootechnical performance			
Fish feed conversion ratio	1.72	0.56	1.79

The impact categories:

Global Warming (GW) in kg CO_2-equivalents, Net Primary Production Use (NPPU) in kg C, Total Cumulative Energy Demand (TCED) in MJ-equivalents, Acidification (Acid) in kg SO_2-equivalnets, Eutrophication (Eutro) in kg PO_4^- equivalents, Land Competition (LC) in m^2, and Water Dependence (WD) in m^3.

(Continued on next page)



Results

Comparative contributions of different impact categories of each rearing system calculated for 1 tonne of aquatic products as functional unit (Fig. bellow) show that eutrophication (Eutro), acidification potential (Acid) and total cumulative energy demand (TCED) showed the largest difference between the semi-intensive and semi-extensive production systems. Except for land competition (LC), IMTA systems had lower contribution to the impacts when compared to the polyculture system. This was most noticeable for the semi-extensive IMTA system that had the lowest impacts. The impact of the semi-intensive IMTA system on global warming was only slighter lower than that of the polyculture semi-intensive system. However, eutrophication and water dependence were also much lower.

Conclusions

Conclusions from the environmental impact study of pond integrated multi-trophic aquaculture (IMTA) in semi-extensive and semi-intensive systems in comparison to semi-intensive fishpond polyculture show that:

With exception of land competition, semi-extensive IMTA has an overall lower environmental impact compared to semi-intensive IMTA and semi-intensive fish polyculture,

To produce the same amount of fish biomass the semi-intensive IMTA is much less eutrophic and water dependent than semi-intensive fish polyculture,

The semi-intensive IMTA used less feed than the semi-intensive fishpond polyculture to produce the same amount of seafood biomass.

Introduction

Nutrition can have significant health implications for animals and, particularly in fish, best practices on diet formulation are of major importance, as feeds probably represent the leading expenditure to the aquaculture industry (Kiron, 2012). The term functional or fortified feeds is used to describe fish feeds that have added benefits beyond the fish essential nutritional requirements, with both health status and growth expected to improve (Li et al., 2009). Therefore, a shift away from chemotherapeutic and antibiotic treatments would be possible. Among functional commercial feeds like Ygeia+ (Sorgal), which are characterized as capable of providing the required nutrients for normal development, but also giving additional benefits, there is still a need to better understand their modulatory effects on immune response and disease resistance.

The aim of the present study was two-fold: i) to study the effects of Ygeia+ short-term feeding on immune-condition and oxidative stress status of European seabass (*Dicentrarchus labrax*); and ii) to assess the interactive effects of short-term feeding with Ygeia+ and vaccination in the immune response and disease resistance of European seabass.

Material and Methods

Two independent trials were performed with European seabass weighting 12-36 g in recirculating seawater systems (temperature 18 ºC; salinity 35; photoperiod 12L:12D). In both trials fish were fed for 5 and 10 days a control (commercial) diet or the Ygeia+ diet, both produced and provided by Sorgal. In the first trial, fish were inoculated with heat-inactivated *Photobacterium damselae piscicida* (1×10^6 cfu/mL) at the end of each feeding time, and the inflammatory response was assessed for 4, 24 and 48h. In the second trial, fish were vaccinated with AVAC VR/PD/TM (HIPRA) or sham injected after each feeding period. Following vaccination procedures, all fish were fed the control diet for 3 weeks and sampled for the assessment of immune parameters and oxidative stress biomarkers. Fish were also bath challenged with *Tenacibaculum maritimum* to evaluate if Ygeia+ can induce protection and the synergistic dietary effects with the vaccine.

Results

The first trial pointed to a positive effect of Ygeia+ with a tendency to increase circulating monocyte and neutrophil numbers following inflammation in fish fed Ygeia+ for 5 days. Neutrophilia and monocytosis tended to correlate well with the increase of plasma lysozyme at 4 h following an inflammatory insult. Humoral lysozyme levels also tended to be higher in Ygeia+ fed animals during all sampling points. Lipid peroxidation was significantly lower in Ygeia+ fed animals, when compared with control at 24 hours after inflammation, in animals fed for 5 days. Superoxide dismutase activity was also significantly lower in Ygeia+, in the same sampling time.

During the second trial, specific IgM augmented in all vaccinated groups, which also showed improved survival compared to non-vaccinated individuals. Moreover, vaccinated seabass fed Ygeia+ for 10 days increased total glutathione levels in liver, compared to their counterparts fed the control diet.

Discussion

In summary, functional diets such as Ygeia+ are important sustainable prophylactic strategies that deserve further attention, particularly regarding conditions where oxidative stress may occur. Indeed, the observed lower levels of lipid peroxidation and superoxide dismutase can be linked to a positive effect of Ygeia+ in the reduction of free reactive oxygen species in the liver. Considering all data from both studies, other feeding times should be considered to fine-tune Ygeia+ as a feeding strategy to improve European seabass robustness.

Introduction

Successful larval settlement and metamorphosis has been linked to the recognition of specific substrates or substratum-specific biochemical signals. In many intensive aquaculture systems, the required morphogenesis-inducing substances are often absent. Sea urchin settlement and metamorphosis cues are highly species-specific and may include microalgae, natural surfaces (e.g. porous rocks), adult conspecifics, coralline and other macroalgae, specific chemicals, and bacterial biofilms, particularly those found on the surface of macroalgae. Commercial abalone and urchin farms often use biofilms that develop in the systems naturally for larval settlement (Affan et al., 2015); but this method is often highly inconsistent and seasonal and largely considered ineffective for *Tripneustes gratilla* (<2% settlement, with poor post-settlement survival) (Mos et al., 2011). Certain cues may well induce settlement but not necessarily sustain growth and ensure survival of larvae during the post-settlement phase (Mos *et al*., 2011), because the settlement substrate is either indigestible or nutritionally poor. *T. gratilla* requires a diet capable of promoting high survival and growth during these fundamental stages of development. This study investigated settlement success, post-settlement survival and growth of *T. gratilla* during different periods of the juvenile phase fed a variety of natural and artificially created substrates/diets.

Materials and Methods

Nine settlement substrates were tested, including natural substrates of *Ulvella lens*, fresh *Ulva* and *Nitzschia,* as well as artificially created substrates using alginate with the addition of either dried *Ulva*, dried *Isochrysis galbana*, a probiotic *Vibrio midae* SY9, a combination of *V. midae* SY9 & an *Ulva* exctract, ethanol solvent (control) or no additive (control). Competent larvae were settled directly into small troughs (L:200×W:105×D:45mm) contained within a flow-through experimental system. Each treatment had 4 replicates within randomly assigned tanks. Competent larvae (n=35) were placed in each trough and the number of larvae to successfully completed metamorphosis within a 60h period was recorded. Successfully settled larvae were maintained in their respective treatments for a period of 4 weeks to assess post-settlement growth (by measuring test diameter of 10 random individuals) and survival, which was recorded weekly for each treatment using a Nikon SMZ1500 stereomicroscope. Substrates were replaced once a week when the individual troughs were cleaned. After 4 weeks, urchins from the best performing treatment (*U. lens*) were used to assess the effects of weaning urchins from post-larval feeds onto the macroalga *Ulva*. Urchins from the latter treatment were randomly divided into 2 treatments of 4 replicates each. One treatment continued to receive *U. lens* for three weeks before being fed fresh *Ulva* for an additional 3 weeks, whereas the second treatment group was offered fresh *Ulva* for the entire 6 week period.

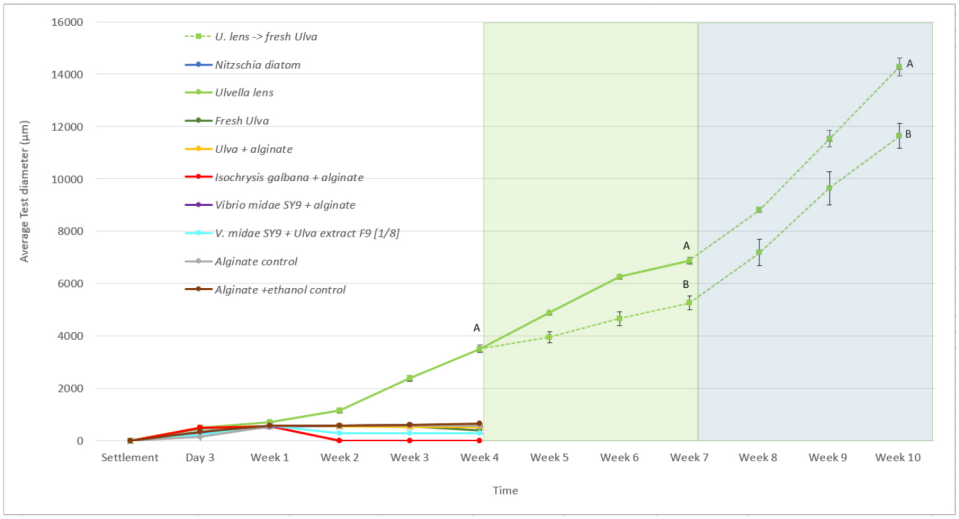

Figure 1: Average test diameter of juvenile *T. gratilla* over a 10 week period post settlement fed a variety of natural and artificial diets. Shaded areas represent dietary changes during weaning, from Ulvella to Ulva as indicated in the figure legend.

(Continued on next page)

Results and Discussion

Settlement success varied greatly between substrates. The 3 best performing treatments, not significantly different from each other, were *Ulva*, *Ulvella lens* and *Nitzschia*; which induced 67, 62 and 41% larval settlement, respectively. Settlement success was less than 30% for the remaining treatments, with no significant differences between them. Survival of larvae settled and maintained on the *U. lens* substrate by the end of the 4 week growth trial was significantly higher (61%) compared with all other treatments, which had an average survival < 20%.

Juvenile urchin test diameter (TD) at week 4 was significantly greater in the *U. lens* treatment (3507μm), compared with all other treatments that had an average TD of 508μm, with no significant differences between the latter treatments. Thus, diets other than *U. lens* do not appear to be suitable post-settlement diets for *T. gratilla*, even though both *Ulva* and *Nitzschia* induce high settlement. Following the dietary change at week 4, urchins maintained on *Ulvella* were significantly larger at week 7 (6874μm; Fig 1) compared to juveniles fed fresh *Ulva* (5260μm). After 7 weeks both treatments were offered only *Ulva*, but the difference in TD did not change between the 2 treatments and urchins maintained for 7 weeks on *Ulvella* remained significantly larger at the end of week 10 (14278μm TD), compared with juveniles transferred to a diet of fresh Ulva three weeks earlier (11638μm TD).

Our study suggests *Ulvella* is a superior substrate for *T. gratilla* larval production, capable of producing juvenile sea urchins of ca. 1.5cm in just 10 weeks post-settlement. These findings have important implications for the commercial production of this high value species, highlighting the importance of suitable substrates for both settlement and post-settlement feeding. The study further shows that the timing of weaning juveniles from post-settlement diets to adult feeds can have significant effects on growth and potential effects on overall production times, which could have significant effects on timelines for the production on urchins for harvest.

Introduction

In aquaculture, disease resistance is one of the main selected traits with growth performance, processing traits and flesh quality (Chavanne et al. 2016). Infectious Pancreatic Necrosis (IPN) is a highly contagious disease with vertical and horizontal transmissions (Dopazo 2020). IPN is encountered worldwide with initial episodes described in North America and Europe, but also in Asian countries since the 1980s (Dopazo 2020).

Different studies in rainbow trout have shown moderate genetic variability for IPN resistance (Rodríguez et al. 2019). However, there is little work to precisely characterize the architecture of IPN resistance in rainbow trout and analyses only included a single cohort of phenotyped fish (Ozaki et al. 2001, 2007; Rodríguez et al. 2019). Therefore, the two objectives of this study were to accurately estimate heritability of disease resistance and to detect quantitative trait loci (QTLs) associated with IPN resistance in two successive generations of a commercial French rainbow trout line.

Materials and Methods

The fish studied were produced in the 8th and 9th generations of selection (G8 and G9) of a commercial line of Milin Nevez breeding company (Bretagne Truite Group, France). In total 4,000 fish (2,000 from each generation) were challenged by immersion with IPN virus at the ANSES-SYSAAF Fortior Genetics platform. For the infection challenge in G8, a dose of approximately 1.10^5 $TCID_{50}$/mL of the strain NN193 was used in a total volume of 20L/tank. For the challenge in G9, a dose of approximately 1.10^5 $TCID_{50}$/mL of the strain NPI11125 was used in a total volume of 7L/tank. Fin samples were stored in alcohol filled jars and kept at +5°C (+/- 3°C). All the 372 parents of the phenotyped individuals as well as 1,885 and 2,000 phenotyped fish of G8 and G9, respectively, were genotyped for 57,501 SNPs with the Axiom™ Trout Genotyping array at the INRAE genotyping Platform Gentyane. After quality control, we retained for the GWAS 1,799 G8 and 1,978 G9 individuals genotyped for 25,512 SNPs. IPN resistance was calculated as a binary survival trait (S37, death/life at 37 days) and time to death (TD) with value of 40 attributed to all individuals still alive at 40 days. The average survival rate at 37 days was 61% and 78% for G8 and G9, respectively. The package BLUPf90 was used for the study with AIREMLf90 program for variance component estimation (Misztal et al. 2002) and POSTGSf90 program for GWAS (Aguilar et al. 2014).

Results

The heritability was estimated at intermediate values for the two traits: 0.20 and 0.25 for S37 and TD, respectively. Considering the joint analysis of data from the two cohorts, we identified the same two main QTLs for S37 and TD on the chromosomes 1 and 16 (Tableau 1).

Chr	Peak Position* (Mb)	Peak SNP	-log(p-value)	QTL Start (Mb)	QTL End (Mb)	% variance explained for QTL
1	11.96	Affx-88908615	8.94	10.17	17.06	3.1
16	0.30	Affx-88936423	7.96	0.30	2.75	1.2

Table 1: Summary statistics for QTL of IPN resistance (S37) detected based on GBLUP model with a threshold -log(p-value)=6.4, corresponding to a genome-wide significance threshold of 1% after Bonferroni correction.
* on the Arlee genome reference assembly (USDA_OmykA_1.1.).

(Continued on next page)

These QTLs were also observed in each of the analyses of single fish cohorts. The QTLs explained 3% and 1% of the genetic variance for chromosome 1 and 16, respectively.

In G8 cohort, the survival of fish with genotype Q_1Q_1 for Affx-88908615 is 65%, the survival of heterozygous fish Q_1q_1 is 56% and it is only 37% for q_1q_1 fish. In G9 cohort, survival rates were higher: respectively 81%, 71% and 64% for Q_1Q_1, Q_1q_1 and q_1q_1 genotypes at the peak SNP on chromosome 1. Furthermore, the combination of favorable alleles for the QTLs on chromosomes 1 and 16 allows an additional survival gain, with 87% of survival for Q_1Q_1-Q_2Q_2 fish and 73% of survival for Q_1Q_1-q_2q_2 fish in G9 cohort (respectively 72% and 60% in G8).

Discussion and Conclusion

The results show a moderate heritability for IPN resistance, similar to previous estimates in the literature. We detected two significant QTLs that are located on chromosomes 1 and 16 which were already identified in the literature as playing a role on IPN resistance (Santi et al. 2019; Ozaki et al. 2001, 2007). The QTL on chromosome 1 is located in the same region as previously described by Santi et al. (2019). The two QTLs are observed in each of the two studied cohorts and are therefore consistent QTLs in the population. The association of favourable alleles across QTLs allows an increase in survival up to 87% for G9 cohort. These QTLs offer the possibility of marker-assisted selection for rapid dissemination of genetic improvement for IPN resistance.

Introduction

The biological control of sea lice using cleaner fish has become a feasible option due to the increased occurrence of resistance towards medical treatments in salmon lice, *Lepeophtheirus salmonis*. Previous studies have shown up to 93–97% less sea lice infestation (adult female lice) in sea cages with lumpfish compared to salmon in sea cages without lumpfish present (Imsland et al., 2014a). Significant individual differences in feed intake and preference for sea lice has been seen (Imsland et al., 2014a-b, 2018), and genetic influence has been suggested to be a possible factor (Imsland et al., 2016a). The present study aims to investigate the observed variation in sea lice (*L. salmonis* and *Caligus elongatus*) foraging behaviour of lumpfish to reveal potential correlations between inclination to graze sea lice and genetic composition. Previous research has indicated a size-related (Imsland et al., 2016b) and sex-related (P. Reynolds, Gifas, unpublished data) sea lice grazing of lumpfish but whether this can differ in different families of lumpfish has not been studied before.

Material and methods

To investigate the possible family influence on sea lice grazing of lumpfish on Atlantic salmon, ten families of lumpfish (N = 480) with a mean (± SD) weight of 54.8 ± 9.2 g were distributed among ten sea cages (5 × 5 × 5 m) each stocked with 400 Atlantic salmon with a mean (± SD) weight of 621.4 ± 9.2 g. All the ten cages were stocked with 48 lumpfish (12% stocking density). The stocking of cages was such that each cage consisted of two random families where full- and paternal half-sib families were randomly allocated to the different cages. During the trial period gastric lavage was performed every two weeks to assess the feeding preferences of individual lumpfish. At the end of the study, all fish from each family were arranged into 9 size classes from 40 to 230 g. The fish humanely dispatched (metacaine 600 mg l^{-1}) and dissected to determine the sex.

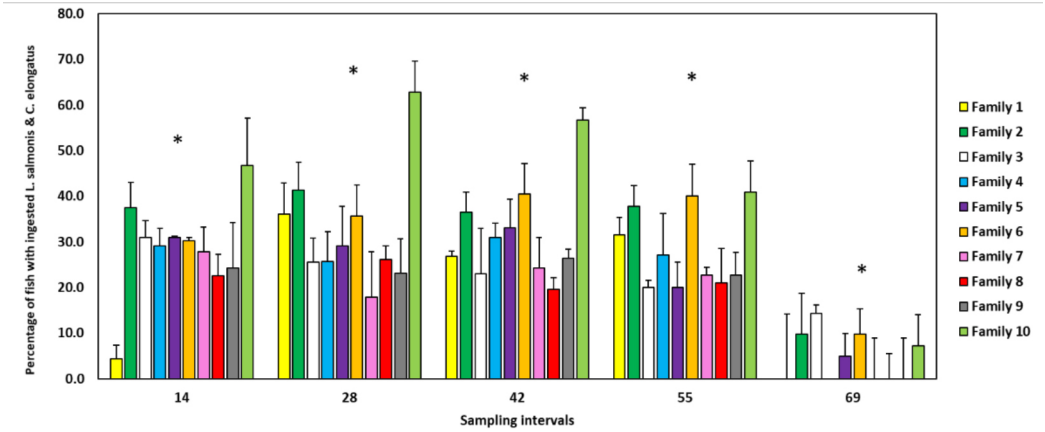

Fig. 1. Percentage values of eaten sea lice of the ten lumpfish families sampled at each sampling time point. Values are presented as means ± S.E. * indicates significant differences between the families.

(Continued on next page)

Results

Lumpfish from families 2, 6 and 10 had a significantly higher incidence of lice grazing of both *L. salmonis* and *C. elongatus* compared to the other families (Fig. 1). There was a trend for a reduction in sea lice grazing with increased size within each family. The results indicated that it was the smallest size classes of lumpfish (40-140 g) which exhibited higher sea lice grazing potential compared to the larger size classes within families. There were no clear differences in the lice grazing potential between male and female lumpfish within and between families

Discussion and conclusion

The lice grazing activity recorded during this study suggests a likely genetic effect, but influence may be from both male and female broodstock rather than an individual gender. Given that, the likely genetic effect can be used for future selection programmes for lumpfish grazing behaviour. Generally, it was found that it was the smallest size classes which exhibited higher sea lice grazing potential compared to the larger size classes.

The frequency of individuals to graze *L. salmonis* and *C. elongatus* on repeated occasions was significantly different between families. The highest percentage of repeat grazers were from families 2, 6 and 10 with the same individuals found to have consumed both species of sea lice in their stomachs in three or more of the five gastric lavage sampling points during the study period. As sea lice grazing efficacy is one trait that is strongly desirable in future breeding programmes then also the frequency of lice grazing by individuals within families should also be used as a selection criterion for such programmes.

MORTALITY OF GOLDFISH, *Carassius auratus*, AFTER OUTBREAK OF *Gyrodactylus kobayashii* INFECTION IN SOME FARMS OF GUILAN PROVINCE, NORTHERN IRAN

J, Daghigh Roohi*, Shamsi, S, A. Dalir Ghaffari

Inland water Aquaculture research center, Iranian fisheries Sciences Research Institute, Agricultural Research Education and Extension Organization (AREEO), Bandar Anzali, Iran
Email: javad_daghigh@yahoo.com

Introduction: Goldfish, *Carassius auratus*, widely distributed across Eurasia, is one of the earliest fish domesticated for ornamental purposes (Tu et al., 2015). This species has been brought to Iran from eastern Asia for ornamental purposes about 85 years ago. Iranian people buy a few goldfish in a crystal bowl for the celebrating the new year known as Nowruz. For this reason in Iran goldfish is regularly cultured in some of the warm-water fish ponds (Daghigh Roohi et al., 2016). The purpose of this study was to determine the cause of gradual daily losses in three goldfish farms located in Rasht the capital of Guilan Province, northern Iran.

Material and methods: During November 2018 a total of 58 fish with an average weight of 7.7 gr and a total length of 7.28 cm were sampled from farms with losses and transferred to the laboratory with water from the same pools. The fish were kept in several aquariums equipped with aeration systems until the survey. After preparing wet mounts of skin and gills Gyrodactylid parasaites identified with significant prevalence and severity. *Gyrodactylus* isolates were fixed by Ammonium picrate glycerin (Malmberg, 1970). The infection rate and intensity of parasites were determined according to Bush et al. (1998). In order to morphometric assessments on captured images, Image J software were used for 16 point to point distances. Drawing of parasites were done by drawing tube and then compared by identification keys and parasites identified. For molecular investigation the genomic DNA was extracted from one parasite specimen and 5.8SrDNA and ITS2 region of *Gyrodactylus* specimens were amplified by related primers in PCR (Plaisance *et al*., 2005). Purified fragments of PCR products were sequenced from both forward and reverse sites of each PCR product. The acquired sequences were subjected to a nucleotide Basic Local Alignment Search Tool (BLAST) in NCBI GenBank to confirm the *Gyrodactylus* species.

Results: In this study, the infection of fish with *Dactylogyrus* spp. and *Trichodina* sp. were 25.8% and 39.6% respectively. The intensity of infection with these parasites were limited and not dangerous. On the other hand 70.71% of the fish were infected with *Gyrodactylus* on their skin. Morphometric evaluation of these parasite showed that its species was *Gyrodactylus kobayashii* and molecular research also confirmed this. The obtained sequence was deposited in GenBank with accession number MZ148586. The number of these parasites was counted in each fish. The range of *G. kobayashii* in studied fish was 1-379 worms per fish.

Discussion and Conclusions: In this survey although *Dactylogyrus* and *Trichodina* parasites were also isolated from the studied fish, but the prevalence and severity to *Gyrodactylus* parasites showed that it is the main cause of mortality in gold fishes. Investigation showed 70.71% of fishes were infected to *Gyrodactylus kobayashii* , the mean and maximum intensity of infection was 26 and 379 parasites per fish respectively. Although Gyrodactylids are potensially highly pathogenic (Bakke et al., 2002; Jalali et al., 2005) the pathogenicity of different *Gyrodactylus* species is variable and parasite induced host death is clearly dependent on host species and size (Bakke et al., 2007). In 2015 a report was published on massive goldfish mortality (79.4% of initial stocked biomass) due to the outbreak of *Gyrodactylus kobayashii* from central China. The mean intensity of *G. kobayashii* in goldfish in China was 264.7 by range 100-450 in each fish (Tu et al., 2015). In this study the number of goldfish losses was lower than China, which seems to be due to the lower intentensity of parasitic infection.

Introduction

Use of whole genome sequence data (WGS) is expected to improve identification of quantitative trait loci (QTL) and prediction of genomic breeding values (Van den Berg et al., 2019). However, sequencing of large number of individuals is not cost efficient. An alternative is to use genotype imputation. It involves whole genome sequencing of few key individuals, while most individuals are genotyped with a small subset of genome-wide distributed markers (low-density genotyping panel). These sequence data are then used to impute the non-genotyped markers for the individuals genotyped at low-density. The objective of this study was to determine accuracy of WGS imputation in Pacific oyster (*Crassostrea gigas*) and their application for genome-wide association studies (GWAS) and genomic predictions.

Materials and Methods

Whole genome sequence data were available from 67 individuals (10 grandparents, 22 F1 and 35 F2) and 1,530 F2 individuals were genotyped with a lower density SNP array. After genotype quality control, the WGS data contained ~365K markers and the genotype array had ~11K markers. The 11K genotypes were then imputed to WGS using the 67 sequenced individuals as a reference. Beagle V5.0 (Browning and Browning, 2016) software was used for the imputation. Survival phenotypes (dead or alive) from a natural filed outbreak of Oyster Herpes Virus (OsHV-1) were available from 1,530 F2 individuals which belong to 8 families.

Two sets of genomic breeding values (GEBV) were estimated using the 11K SNP array and imputed SNPs. The following mixed model was fitted into the data using ASReml 4.0 (Gilmour et al., 2015):

$$y = X\beta + Zu + e$$

Where is a vector of phenotypes coded as 0 and 1 for dead and survived respectively, is a vector of fixed effect of the mean, is a vector of breeding values, is a vector of random residual effects and are incidence matrices. It is assumed that and , where is the genomic relationship matrices, is additive genetic variance and is random residual variance. Accuracy of prediction was computed using a cross-validation scheme by masking the phenotypes of ~ 20% of the offspring. The cross-validation process was repeated 20 times and the accuracy was computed as the correlation of the estimated breeding value with the phenotype weighted by the square root of heritability. GWAS was performed using the two SNP data sets by applying the same model above in GCTA program (Yang et al., 2011) with first 4 PCAs included as covariate and the SNP effects were also computed.

Results and Discussion

Imputation of 356K markers from 11K SNPs resulted an average Beagle R^2 of 0.52 (Figure 1) and only ~82K SNPs had a Beagle R^2 value higher than 0.6. Given the structure of the dataset, the observed imputation accuracy is lower than expected. This could be as a result of errors in linkage map due to small size of families used to construct linkage map, species with high level of individuals variation for ploidy, repeat components and structural variation, and sub-optimal selection of markers for the SNP array. For example, comparing the genetic maps of sequence data and array data reveled that only the middle section of most of the chromosomes is covered by the array data and that might have contributed for the observed lower imputation accuracy. In addition, it was also observed low pairwise linkage disequilibrium (LD) and faster decaying LD, which indicates that there are low number of shared haplotypes in this population and possible mapping errors. However, compared to the 11K, use of imputed WGS data amplified a putative QTL region and led to identification of more genomic regions associated with OsHV-1 resistance. On the other hand, use of imputed WGS data did not improve genomic prediction accuracy compared to 11K. The results pointed out that even if the use of imputed WG sequence improved the power of QTL detection, improving the genomic resources of this species, such as better genome resources, would help to improve imputation accuracies and hence use of genomic data in this species.

Introduction

Genomic selection can increase genetic gain in aquaculture breeding for many traits, especially for traits which are not measured on the candidates themselves such as disease resistance traits. However, its implementation in this industry has been challenged by staggering genotyping cost due to many individuals needed to genotype. The aim of this study was to examine the potential of selective genotyping of reference population for genomic selection for a sib-evaluated binary trait using in silico approach.

Materials and Methods

Survival data from 7,298 belonging to 348 full-sib families from MOWI population challenged with salmonoid alphavirus (SAV3) were available. study Families with family size of greater than 20 were selected (there were 225 families). All individuals were genotyped with the customized NOFSAL3 ~55k SNP. Even though, genotype data for all individuals were available, for this study the genotypes of a varying fraction of reference sibs were masked according to the selective genotyping strategy.

There were five selective genotyping strategies tested: 1) *Full Genotyping (**FG**)*: Genotyping all training sibs. 2) *Top-Bottom Genotyping (**TBG**)*: genotyping of 10 training sibs per family, aiming at 5 dead and 5 live sibs. For families with less than 5 sibs of one category, additional sibs of the other category were genotyped. 3) *Minor Category Genotyping (**MCG**):* selective genotyping of sibs with the least common (i.e., minor) binary category phenotype. 4) *Random Across family genotyping (**RAG**):* genotyping of randomly selected sibs across families. 5) *Random Within family Genotyping (**RWG**):* genotyping of 10 random sibs per family regardless of their phenotype. The average number of training sibs to genotype by the different genotyping strategies were FG = 4,055, TBG = 2,250, MCG = 745, RAG = 2,250 and RWG = 2250. The number of genotyped individuals in MCG strategy was low due to there are many families with mortality rate higher than 90%.

The performance of three were tested, that is, Best Linear Unbiased Predictions of breeding values using pedigree-based relationships (PBLUP), genomic relationships for genotyped individuals only (GBLUP) and a single-step approach (ssGBLUP) using both pedigree and genomic. were estimated using BLUPF90 (Misztal et al., 2018) by fitting the following mixed linear model:

where is a vector of phenotypes coded as 0 and 1 for dead and survived fish respectively, is a vector of fixed effect of the sex (2 levels), is a vector of breeding values, is a vector of random residual effects and are incidence matrices. It is assumed that and , where are genomic, combination of pedigree and genomic, and pedigree-based relationship matrices respectively, is additive genetic variance and is random residual variance.

Prediction accuracy and the bias of the prediction models were assessed based on 100 replication of a cross-validation scheme. In the cross-validation, the phenotypes of 20% of individuals from each family were masked and their breeding values were estimated using the genotypes and phenotypes of the reference population. The accuracy was computed as the correlation between the estimated breeding value (pedigree/genomic, PEBV/GEBV) with the phenotype and scaled by the square root of heritability of the trait (0.32). The bias was computed as the regression coefficient of phenotypes on either PEBV or GEBV. A regression coefficient that deviates from unity indicates either inflation or deflation of the breeding values. The means and standard errors for the prediction accuracy and biases were calculated from the 100 replications.

(Continued on next page)

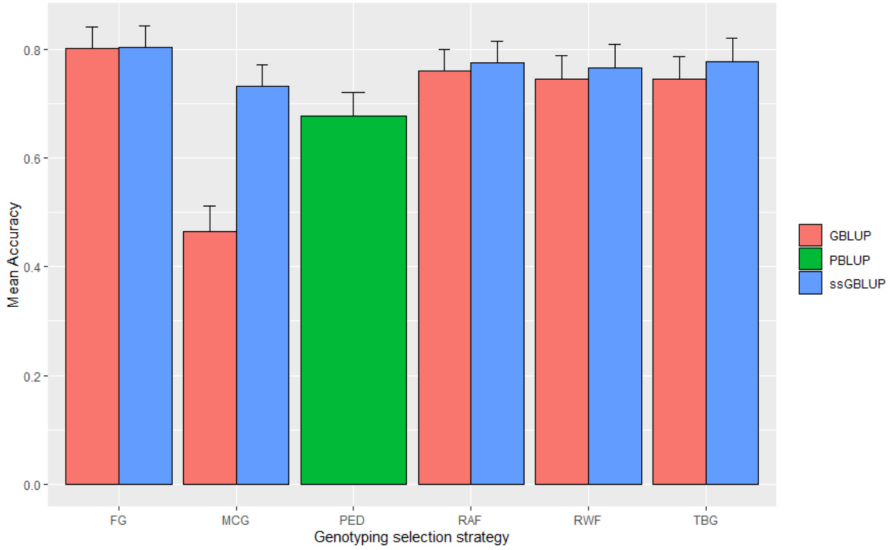

Figure 1: Mean prediction accuracy for the different selective genotyping strategies

Results and Discussion

Prediction accuracies for the different selective genotyping strategies are shown in Figure 1. As expected from the large family sizes, the average prediction accuracy for the classical family-based evaluation (i.e., PBLUP) was moderate, 0.67. The prediction accuracies for the different genotyping selection strategies were between 0.46 - 0.80 when standard GBLUP is used, and between 0.73 - 0.81 when ssGBLUP is implemented (Figure 1). Genomic models, except MCG with GBLUP, were found to increase prediction accuracies compared to PBLUP. For all the selection strategies, the prediction accuracy of ssGBLUP models were higher than the respective GBLUP models (Figure 1). This is because the ssGBLUP models use all the phenotype information by combing data from genotyped and ungenotyped individuals (Legarra et al., 2009). When applying ssGBLUP, the loss of prediction accuracy by genotyping a fraction of test sibs was limited for RAF, RWF and TBG approaches.

The prediction bias was lowest with the FG, RAG and RWG for both GBLUP and ssGBLUP models, while MCG and TGB strategies resulted in deflated GEBV. The results showed that selective genotyping strategies in combination with ssGBLUP approach could be used to minimize genotyping cost without compromising genomic prediction accuracy significantly.

Introduction

Striped catfish *Pangasianodon hypophthalmus* is the most important aquaculture species in Vietnam, with export turnover reaching US$2.3 billion in 2019 (FAO, 2020). In recent years the sector has been negatively affected by climate changes and dam constructions along the Mekong River, especially salinity increase (Nguyen et al., 2014). In response to these factors, the striped catfish industry is compelled to adapt its culture methods to a brackish water environment to maintain its sustainability. However, the capacity of striped catfish to cope with salinity increase is not totally understood, especially with regards to its physiological and immunological responses, and this has been investigated in the present study.

Materials and Methods

Farmed striped catfish juveniles were submitted to a progressive increase of salinity at the rate of 0.25, 0.5, 0.75 and 1 ppt per day in order to reach 5, 10, 15 and 20 ppt, respectively after 20 days (D20). Then, the fish were continuously cultured in the corresponding salinity during two weeks (D34). Samplings were done at D20 and D34 to assay plasma osmolality and ion concentrations, lysozyme and peroxidase activities, hematology, gill histology, digestive enzyme activities and gene expressions related to physiological and immunological responses in head kidney.

Results

After 20 days, plasma osmolality gradually increased according to salinity with the lowest value of 271 ± 4.5 mosm and the highest value of 426 ± 12.8 mosm at 0 and 20 ppt respectively (Fig. 1a). Histological observations of gills clearly showed interlamellar cell mass (ILCM) in fish kept in freshwater, which completely disappeared in fish held at 10 ppt and 20 ppt (Fig. 1b). Besides, salinity led to a remarkable increase of digestive enzymes, including aminopeptidase, leucine alanine and pepsin at D20. The expression of osmoregulation genes as *naka1* and *cfrt* significant increased with the osmotic environment. Similarly, salinity upregulated the gene expressions of *hsp60* at D20 while *hsp70* remained unchanged, except in fish at 20 ppt (Fig. 2).

Discussion

As reported in other catfish species (Eckert et al., 2001), plasma osmolality gradually increased with salinity. Salinity also affected the transcript levels of *naka1* as previously reported by (Zhu et al., 2018). In fish reared at 0 ppt, a thick ILCM was visible, while this ILCM was substantially reduced upon exposure to hypoxic conditions, probably for creating a greater surface area for oxygen uptake (Phuong et al., 2018). The decrease of RBC in the present study can reduce the capacity of oxygen transportation. Therefore, the fish may increase gill surface for oxygen uptake through decrease of ILCM area. However, further research is required to understand the exact mechanism. As reported by Schmitz et al. (2016), the expression of *hsp70* did not change significantly with the increase of salinity up to 20ppt. Generally, salinity significantly affected the physiological and immunological responses, however most of the modifications occurred at short-term, with a partial recovering of the striped catfish after acclimation.

Introduction

While most studies paid much attention to the physiological and immunological responses of striped catfish to salinity increase, how the intestinal-associated microbiota changes under hyperosmotic conditions in this species has not been investigated yet. The intestinal microbiota in striped catfish has not been studied using deep sequencing, except one study with limited phylum-level information (Sutriana et al., 2018). Moreover, the link between microbiota and host transcriptomics could shed light on how bacteria modulations interact with physiological and immunological aspects or vice versa.

Materials and Methods

Farmed striped catfish juveniles were submitted to a progressive increase of salinity at the rate of 0.25, 0.5, 0.75 and 1 psu per day in order to reach 5, 10, 15 and 20 psu respectively after 20 days (D20). Then, the fish were kept in the corresponding salinities during two weeks (D34). Intestinal samples were collected at D20 and D34 to assay microbiota using 16s rRNA sequencing and target gene expressions. For microbiota analysis, we used 16s rRNA and sequencing by Illumina Miseq. Data were processed using the UPARSE pipeline (Edgar, 2013). Alpha and beta diversity analyses (based on Bray-Curtis distance and ANOSIM test) were performed using QIIME2 (qiime2-2021.4). Relative abundances were plotted using phyloseq (1.34.0) in the R package (4.0.5). The significant abundant OTUs were calculated using Linear discriminant analysis effect size on Galaxy with p-value set at 0.05 and LDA log score threshold of 3.5. Regarding gene expression, extracted RNA was treated with a RTS DNAse™ kit (MO BIO Labs, USA) to avoid DNA contamination and then reverse transcribed to cDNA using a RevertAid RT Reverse Transcription Kit. The amplification of diluted cDNA was conducted using SsoAdvanced™ Universal SYBR® Green Supermix (Bio-Rad Lab, USA) on QuantStudio™ 5 Real-Time PCR System.

Results

Hypersalinity generally decreased the OTU richness, evenness and phylogenetic diversity through the study, except the latter one with increasing trend at D34. Bacteroides were the most predominant genus across treatments at D20 however their compositions were different (Figure 1). Additionally, *Vibrio* was significantly risen with salinity increase and long exposure time. Regarding transcriptomic aspects, expression of osmoregulatory genes including *atp1a1, atp1b2a, slc12a1, slc12a2* were up-regulated while *cftr* and *aqp1* expressions were down-regulated with salinity gradient. Hypersalinity also increased expression of *hsp* genes (Figure 2).

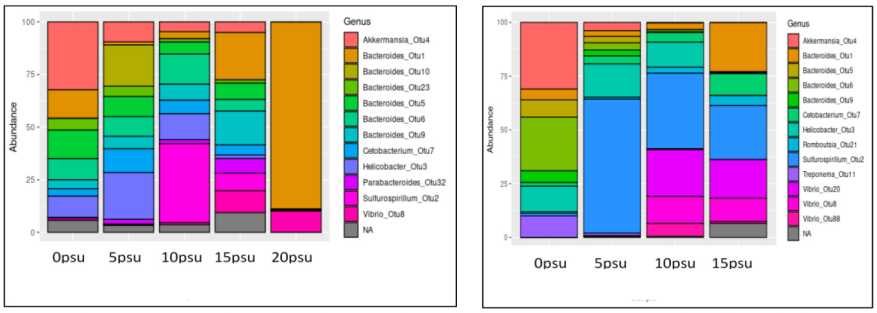

Figure 1. The mean relative abundance of predominant genera in striped catfish intestinal microbiota at D20 (A) and D34 (B).

(Continued on next page)

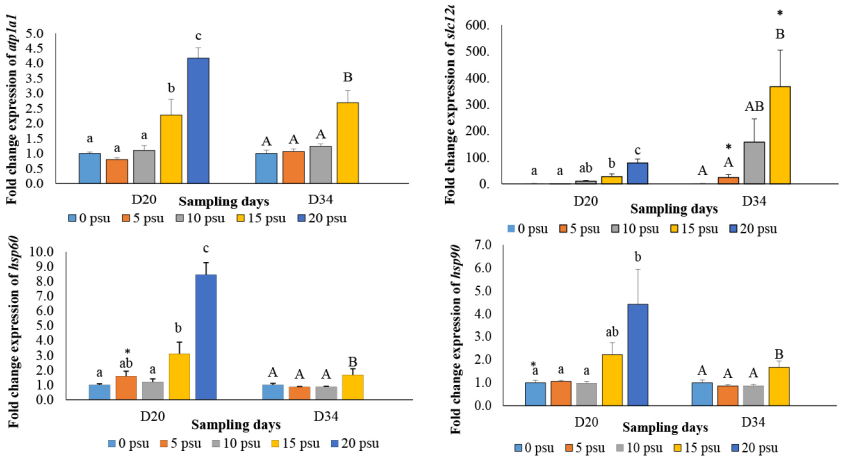

Figure 2. Fold change expressions of genes in intestinal striped catfish subject to different salinities. (A*) atp1a1*, (B) *slc12a1*, (C) *hsp60*, (D) *hsp90*

Discussion

Salinity was found to be a critical factor influencing microbiota communities, which reduced the diversity of intestinal microbiota (Dehler et al., 2017). The present study found that intestinal microbiota in freshwater striped catfish was predominant abundance of Bacteroidetes, Firmicutes, Verrucomicrobia and Proterobacteria. This was supported by previous research that these species were accounted for 90% in fish intestinal microbiota (Talwar et al., 2018). Vibrio was considered as a biomarker for salinity envrionment in fish intestinal microbiota (Zhao et al., 2020). The intestine contributed to the regulation of the osmoregulation process by altering the expression of genes related to ions and water transport. In general, the changes in the host transcriptome could lead to a decrease in the diversity of the microbiota under hyperosmotic conditions, i.e. 15 and 20 psu. This correlation might indicate that the anatomy and physiology including pH, osmolality, redox potential, compartment size and structure, passage rate and residence time, which are uneven in freshwater and seawater, significant affected the microbiota establishment (Ray and Ringø, 2014).

Introduction

Striped catfish (*Pangasianodon hypophthalmus*), a commercially important species cultured in Mekong Delta region in Southern Vietnam, is facing a significant challenge due to salinity intrusion as a result of climatic changes. Selection of new strains with high salinity tolerance allows economically feasible production of striped catfish in brackish environment. In this study, we demonstrated that survival rate and growth performance can be improved in striped catfish after a single generation of selection for ability to adapt to saline stress.

Materials and Methods

Production of base population: The fieldwork of the study has been conducted in College of Aquaculture and Fisheries, Can Tho University (CTU), Viet Nam from July/2017 to April/2021. The analysis of the samples and of the genetic data is performed in Liege University. Catfish broodstock have been selected from 3 different sources (An Giang, Vinh Long and Can Tho province, with 10 males and 10 females in each province), with average weights ranging from 5 to 7 kg. Principally, the selected broodstock had to be healthy, without visible injury or abnormal signs. A piece of fin (~1 cm^2) from each fish (i.e. 60 broodstock) has been collected and preserved in 95% ethanol for genetic analyses.

Spawning has been induced by injection with human chorionic gonadotrophin. A dry fertilization process has been used, where eggs and milt have been mixed gently. We have crossed twenty-nine females (~ 3000 eggs of each female) with thirty males to create 870 families (one female from Can Tho province could not be used due to the low quality of her eggs). Fertilization solution (3 g urea and 4 g salt in 1 L of water) has been added to the mixture of eggs and milt to trigger fertilization after 4 min. The fertilized eggs have then been transferred into boxes (one box per family) for incubation. The fertilized eggs have started to hatch 24 hours after fertilization. Fertilization rates varied from 83-90 % and the hatching rate was 61-73 %. The larvae have been transferred to rearing earthen ponds within 15 hours after hatching and fed live feed. From each family, 2000 good quality larvae (with no abnormal signs, uniform size, swimming actively and responding to external stimuli quickly) have been selected for nursing in two earthen ponds (leading to 1.740.000 larvae in total). After 47 days post-hatching (dph), 22.000 fries have been transferred from nursing ponds to CTU Recirculating Aquaculture System (RAS)

Selection principles: In RAS system, the fish were put progressively in the targeted saline conditions (10 ppt - parts per thousand). Subsequent sequential massal upward selection of 50% of the survival and healthy fast-growing fish at 3 stages of weight (100 g, 300 g and 1000 g) were implemented (selected group). In parallel, another set of fish was raised under similar conditions (pond, salinity, density, feed) and underwent a random selection process to serve as negative control (control group). At each time, approximately half of the fish were discarded. After 3 selection stages (~ one year), the average weight of selected group and random group were 1.380 ± 175 g and 793 ±230 g, respectively. In the third selection, all remaining fish were identified using Passive Integrated Transponders (PIT) tags. These PIT–tags were injected into muscle of fish and corresponding DNA samples were collected. The level of salinity was then decreased to 5 ppt and remained at this level until fish being mature.

(Continued on next page)

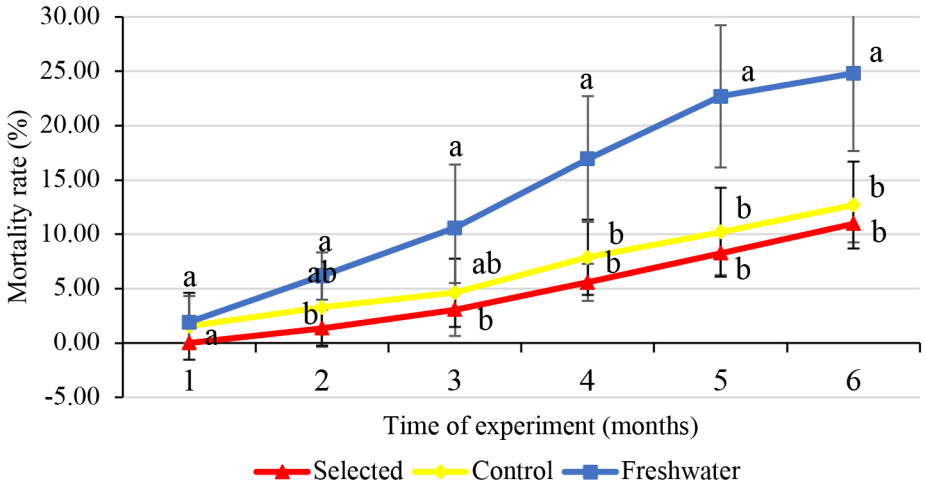

Figure 1: Accumulative mortality from three groups during culture experiment at 10 ppt

Evaluation of response to selection: To assess the efficiency of selection, the offspring of the selected, control and freshwater (fish matured in freshwater condition, representing normal broodstock in Mekong Delta) groups were challenged under different levels of salinity. To identify genetic relationships, a new algorithm using shallow sequencing information from the offspring was implemented, allowing parentage assignment in the selected and control groups based on genomic information. The rearing experiment was divided into four distinct periods according to each developmental stage of striped catfish: embryonic stage, larva to fry stage, fry to fingerling stage, fingerling to adult stage. For data collection, information on two major production traits (survival and growth) associated with the ability to adapt to salinity stress was recorded during the experiments.

Results

Preliminary results show that survival rate and growth performances of the offspring of the individuals from the selected group is better than for the two other groups, especially with freshwater group under saline stress. At 10 ppt level of salinity, in embryonic stage, hatching rate (%) of fertilized eggs is significantly higher in selected group (13.5%) compared to 10.4% in control group and 5% in freshwater group. For larva to fry stage, survival rate is also significantly higher in selected group (30%) compared to only 19% and 18% for control group and freshwater group, respectively. At 15ppt, only selected group and control group survived with 3.6% and 1.1% survival rates, respectively. We observed a similar trend for fingerling to adult stage, with selected group tending to live better in saline condition (Figure 1). For growth performance, in all experiments, the growth rate of selected group was higher than for control and freshwater group. These results suggest that selection to improve ability of striped catfish to adapt to saline stress can be achieved, in terms of increased survival rate and growth rate of the selected group following saline exposure.

PARENTAGE ASSIGNMENT OF STRIPED CATFISH (*Pangasianodon hypophthalmus*) WITH SHALLOW WHOLE GENOME SEQUENCING DATA

Introduction

Striped catfish (*Pangasianodon hypophthalmus*) is a species commonly cultured in the Mekong Delta region, Southern Vietnam. However, the genetic management of the broodstock of this species has not been studied extensively. This leads to potential risks associated to inbreeding, with potential negative effects on the growth and reproduction performances of the fish. Therefore, the pedigree information of broodstock in hatcheries, which is essential for a proper genetic management of the fish, is urgently required in order to sustain the high quality of seed to supply for catfish aquaculture in the Mekong Delta. Several previous studies on parentage assignment in other species have focused on using genetic data generated from micro-satellite markers and more recently from SNP arrays. In this study, we used the shallow whole genome sequencing (SWGS) data as an economic alternative to analyze parentage assignment of striped catfish instead of traditional array data.

Materials and Methods

Experimental fish and DNA sampling: The fieldwork of the study has been conducted in College of Aquaculture and Fisheries, Can Tho University, Viet Nam from July/2017 to April/2019. The analysis of the samples and of the genetic data has been performed in Liege University. Catfish broodstock have been selected from 3 different sources in three provinces (10 males and 10 females in each province). Spawning has been induced by injection with human chorionic gonadotrophin. Thirty females have been crossed with 30 males to create 900 full-sib families. From each family, 2,000 good quality larvae have been selected for nursing. After one-year culture, 500 individuals selected from the remaining offspring were used for parentage assignment. A piece of fin (~1 cm^2) from each fish (i.e. 60 broodstock and 500 offspring) has been collected and preserved in 95% ethanol for genetic analyses.

Preparation for genomic data: To prepare genomic data, we performed whole genome deep sequencing of one catfish with high fold coverage (~ 144 X), and used this information to establish a *de novo* draft reference genome. For 60 parents and 500 offspring, we used SWGS with fold coverage of ~ 1 to 2 X (parents) and ~ 0.5 X (offspring) per individual. We mapped SWGS data of 60 parents on the draft reference genome to identify genomic variants (5,900,000), including SNPs. Then, we extracted ~26,000 high quality SNPs from these variants and used the available sequencing data at these SNPs loci to infer the parents of the offspring.

Parentage assignment method: The use of SWGS data raises two challenges: First, for low-coverage (e.g., < 2 X), confirmed genotypes for offspring and parents are in most case not available. Second, read errors are common in next generation sequencing. To address these issues, we have developed a new parentage assignment algorithm based on a likelihood approach to identify the most suitable (i.e. likely) set of parents for each offspring. For each offspring, we have computed the likelihood for each possible parental couple, kept the most likely one and tested its significance as the putative couple of parents for this offspring

(Continued on next page)

Table 1: number of offspring per hatchery and sex of the breeder. The numbers between parentheses indicate the corresponding of parents involved in at least one couple.

Hatchery		An Giang	Can Tho	Vinh Long
Number of offspring	♀	430 (9)	34 (7)	6 (3)
	♂	114 (10)	204 (10)	152 (10)

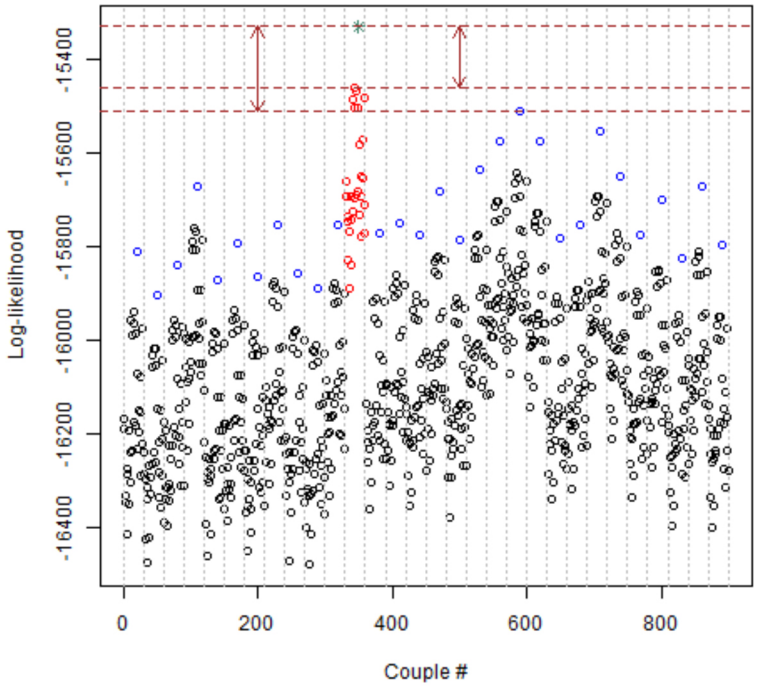

Figure 1 The results of parentage assignment for one offspring. Each dot represents the likelihood of one couple. The dotted vertical lines partition the graph into families sharing the same mother. The start represent the highest likelihood, the red dots correspond to likelihoods involving the "best" mother, and the blue dots to likelihoods involving the "best" father. The arrows represent the differences between the best and the next best likelihoods used to test the significance of the parental allocations.

Results

After running this analysis, all 470 striped catfish were significantly ($p < 0.05$) allocated to one couple of parents. Only one parent was unambiguously allocated for 26 of the remaining individuals (21 fathers and 5 mothers), and 4 could not be assigned to a unique couple. All fathers (30 fish) had offspring in the current population, while only 19 of the 30 mothers did. Most of the significantly allocated offspring (> 90%) were produced from mothers originating from An Giang hatchery, meanwhile, only 1.34% of offspring (6 individuals) originated from females from Vinh Long hatchery. The equilibrium was better for the males (Table 1). Significance in this study has been obtained by comparing the real differences between the best likelihood and the next best likelihood (Figure 1) involving the "best" father (mother) but not the "best" mother (father), to the corresponding distributions obtained by shuffling the sequencing data across the fathers and the mothers. These results suggest that SWGS data can be used for accurate parentage assignment using the appropriate algorithm and we believe that it will be a useful tool in parentage assignment not only for aquaculture but also for a wide range of animals.

ROTIFERS ENRICHED WITH MICROALGAE AS A NEW STRATEGY TO IMPROVE ZEBRAFISH REPRODUCTIVE PERFORMANCE

Introduction

Zebrafish (*Danio rerio*) has emerged as a successful animal model for many different areas such as aquaculture, genetics, development and human diseases[1]followed by Artemia nauplii until the fish reach subadult stage, the developmental time point at which they can be most easily transitioned onto a processed diet. However, the inclusion of Artemia is less than ideal, given its fluctuating availability and high costs. We tested whether or not we could replace Artemia with rotifers during our normal rearing sequence and still meet published performance standards for (i. Nowadays, it is considered the second most used model species worldwide, due to its advantageous characteristics such as the fully sequenced genome, 70% of homology with human genome, developed robust target mutagenesis technologies, embryo transparency, rapid growth and high fecundity[2]but their nutrition and housing requirements continue to elude researchers. Diet and housing density were predicted to affect weight change and reproductive success in 120 days postfertilization (dpf. Live feeds like rotifers (*Brachionus* sp.) are commonly used in zebrafish feeding on the different life stages. The use of live feeds stimulate natural predatory behaviour and reduce captivity stress, working as environmental enrichment, thus improving fish welfare, which benefits fish reproduction[3]. However, their nutritional profile is poor in HUFAs that play important roles in reproduction, especially in females, such as DHA, ARA and EPA, which can be manipulated by enrichment using different microalgae species[4]**.** Microalgae are natural fish preys composed of a variety of nutrients generally with a balanced composition. However, little is known about the effects of rotifers enriched with microalgae on fish reproductive performance. Therefore, this work aimed at improving zebrafish reproductive performance through dietary supplementation with rotifers enriched with different microalgae, (*Nannochloropsis* sp., *Skeletonema costatum*, *Tisochrysis lutea* and *Dunaliella salina*) and their combinations.

Materials and methods

The experimental design included eight dietary treatments composed of two controls: ZF (Zebrafeed®, Sparos Lda, Portugal) and N (rotifers enriched with *Nannochloropsis* sp., Phytobloom® Green Formula, Necton S.A., Portugal) given to zebrafish females. The dietary experimental groups were co-fed for 12 weeks with ZF and microalgae enriched rotifers: NS (*Nannochloropsis* sp. and *Skeletonema costatum*), NT (*Nannochloropsis* sp. and *Tisochrysis lutea*), ND (*Nannochloropsis* sp. and *Dunaliella salina*), NST (*Nannochloropsis* sp., *S. costatum* and *T. lutea*), NSD (*Nannochloropsis* sp., *S. costatum* and *D. salina*) and NTD (*Nannochloropsis* sp., *T. lutea* and *D. salina*). The reproductive performance was evaluated by counting the number of layed eggs, egg and yolk length determination for 8 breeding events. At 5 dpf, total length was measured in 20 larvae per group and the operculum mineralization assay was performed at 6 dpf, as described in Tarasco et al.[5].

Results

Females fed with rotifers enriched with ND produced a significantly higher number of eggs, while females fed with ZF and NST produced a significantly lower number of eggs (Fig. 1A). Egg morphometry parameters showed that females fed with NT layed eggs with significantly higher diameters (Fig. 1B) and yolk area (Fig. 1C).

Females fed ZF and NSD produced larvae with a significantly larger length when compared to NST and NTD (Fig. 2A). Larvae from females fed with ZF displayed a significantly higher mineralization area on the operculum when compared to all the treatments, except for N and ND (Fig. 2B).

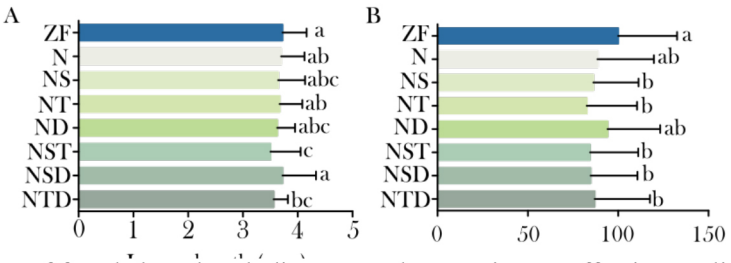

Figure 2: The effect of female broodstock dietary supplementation on offspring quality, namely on (A) larvae length and (B) operculum mineralization.

Discussion

This study investigated the effect of maternal diet supplementation with valuable microalgae species through rotifer enrichment. High-quality eggs are essential for proper offspring development, as they contain the nutritional reserves for embryo development. We observed that maternal diet influenced offspring quantity and quality. Females fed rotifers enriched with ND produced a higher number of eggs, which can be related to the *n*-3/*n*-6 ratio (1.34) from the diet. It was previously observed that low ratios of n-3/n-6 maximize the number of laid eggs[6,7] and that a ratio of 0.8 promotes high breeding success. The treatment with the higher number of laid eggs was also the one with the lowest egg area but without a negative impact on larvae size. Females fed NT enriched rotifers displayed eggs with significantly higher yolk and area, which can be influenced by the higher amount of total lipids in the diet. Therefore, these results indicate that ND supplementation is beneficial for reproduction, number of eggs and larvae size. This could also be explained by the higher amount of DHA, known to improve zebrafish female reproductive performance and larval quality[8]. The optimization of the *n*-3/*n*-6 ratio improved the levels of ARA, EPA and DHA and their transfer to eggs, also improving hatching success and larval quality. Overall, our results showed an improvement in the number of laid eggs using rotifers enriched with ND, working as a functional dietary supplement. The inclusion of these microalgae species represents a possible strategy for improving the reproductive capacities of other species produced in aquaculture. In this work, it was possible to verify that zebrafish represents an important biological model for testing products and ingredients for future applications in fish production.

Introduction

As the demand for eco-friendly farming practices and products in aquaculture continues, the industry has shifted to focus on improved maintenance of fish and shrimp health to enhance performance. This focus on the development of novel additives are increasingly applied in aquaculture, including plant-based products, phytogenic feed additives (PFA). A common usage of PFA's is to decrease bacterial pressure of pathogens including *Vibrio parahaemolyticus* and improve growth performance during challenge. This can be achieved because PFA's, specifically garlic and cinnamon, contain several bioactive molecules that can exert multiple effects on the gastrointestinal (GI) tract. This includes an antimicrobial effect by disrupting the cellular membrane of pathogens and the enhancement of the host immunity which aid in anti-inflammatory and antioxidant reactions results in the redirection of energy to maintain performance. The application rate of garlic and cinnamon can be a challenge in aquaculture as therapeutic concentrations during a bacterial challenge can be different for animals in healthy conditions. Therefore, the objective of the experiment was to 1) evaluate the efficacy of a blend of garlic and cinnamon in whiteleg shrimp (*Litopenaeus vannamei*) based on growth performance and immunity and 2) investigate immunity and growth changes after a *V. parahaemolyticus* challenge.

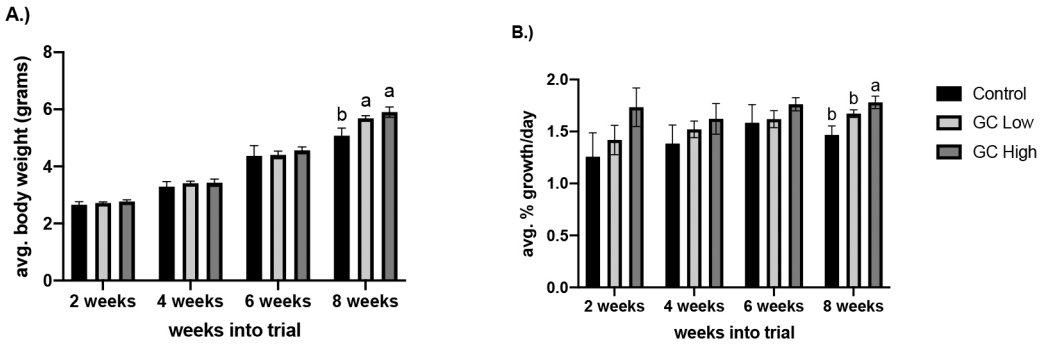

Figure 1. Average body weight (A) and specific growth rate (B) in whiteleg shrimp. Means within weeks with different superscripts are significant at $p \leq 0.05$.

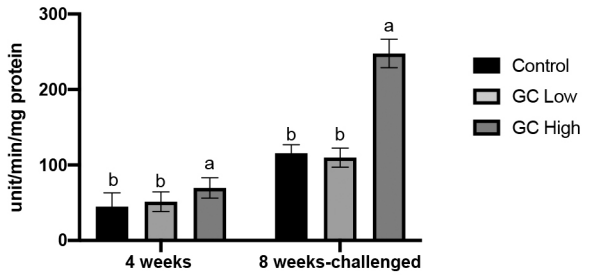

Figure 2. Average phenoloxidase activity in normal conditions and challenged conditions in whiteleg shrimp. Means within weeks with different superscripts are significant at $p \leq 0.05$.

(Continued on next page)

Materials and Methods

A total of 300 juvenile whiteleg shrimp (2.21 ± 0.06 g) were placed in one of the following three treatments: Control- basal diet with 1000 ppm of calcium carbonate as a placebo; GC Low – basal diet with 500 ppm of garlic and cinnamon blend (Excential Alliin Plus; Orffa Additives B.V.) and 500 ppm calcium carbonate and; GC High –basal diet with 1000 ppm of garlic and cinnamon blend. The experiment was carried out in 15 aquariums as a complete randomized design (n=5) with each of 240 L capacity that contained 120 L of 15 ppt saline water. The juvenile whiteleg shrimp were stocked at a density of 150 shrimp/m^3 (20 individual/aquarium). Water in each of the aquariums were changed 20% every three days. Aeration was applied into all experimental unit for maintaining DO > 5 mg/L in a semi-closed system. Feed were presented in pelleted form and placed in the aquariums three times a day at 2.5-3.0 % of cumulative body weight for eight weeks. One hour after feeding, remaining feed was removed to calculate feed intake. Growth performance including weight gain, specific growth rate, feed conversion ratio (FCR) and mortality were measured. Shrimp health and immune status was determined in normal/healthy conditions four weeks into the experiment by total hemocyte count, hemolymph protein and phenoloxidase activity. At eight weeks, each of the shrimp were challenged via injection with *V. parahaemolyticus.* Twelve hours later, each of the immune parameters from 4-weeks were repeated in addition to the record of the activities of lysozyme, super oxide dismutase and glutathione peroxidase.

Results and Discussion

The inclusion of garlic and cinnamon regardless of dosage resulted in an increased body weight gain by 20.9 % in GC Low and 30.0 % in GC High at the final week of the trial ($p < 0.05$) relative to the control group (Figure 1A) which also is represented in the increased specific growth rate difference in GC High (Figure 1B). While feed intake did not significantly change during the trial, the FCR lowered every collection point but became significant ($p < 0.05$) at 8 weeks with a 30-point and 39-point decrease in GC Low and GC High compared to the control, respectively (Control = 1.524; GC Low = 1.272; GC High = 1.183). The significant reduced FCR and weight gain may be attributed to the improved immune status of the GC High treatment at the time of the *Vibrio* challenge. Figure 2 shows that phenoloxidase activity before challenge at 4 weeks resulted in GC High having elevated activity which can act as defense enzymes against invading pathogens. Once the bacterial challenge occurred, there was an overall elevation ($p < 0.05$) between times of collection but only the GC High was significantly elevated among treatments. Lysozyme activity was also elevated in GC High (610 ± 148.44 unit/mL) relative to both GC Low (323.33 ± 73.11 unit/mL) and Control (226.67 ± 40.96 unit/mL).

Conclusions

Phytogenic feed additive garlic and cinnamon blend can create an environment within the host to maintain and improve weight gain and feed efficiency. However, an elevated dose at 1000 ppm can enhance innate host immunity during bacterial challenge effectively and maintain elevated weight gain during production.

MICROALGAE AS A SOURCE OF ANTI-INFLAMMATORY COMPOUNDS

Victória del Pino[1], Patricia Dogo[1], Alexandre Rodrigues[1], Mariana Carneiro[1], Hugo Pereira[2], João Navalho[1]

[1] Necton SA, Olhão, Portugal

The control of inflammation through nutrition is a growing trend in both humans and animals. In aquaculture, this dietary improvement is particularly relevant since traditional diets (e.g. soybean meal) include ingredients known to promote inflammation, thus reducing fish welfare and overall biological performance [1–3]. Consequently, bioprospection of novel sources of anti-inflammatory compounds for food and feed is a essencial. Macro- and microalgae possess valuable metabolites with relevant properties such as antioxidant and anti-inflammatory bioactivities [4,5]. The project Algae4IBD aims to develop new functional ingredients to prevent and treat Inflammatory Bowel Disease (IBD) using aquatic natural biological resources. In this framework, the project will take advantage of the vast alga biodiversity to find the most promising species with adequate bioactive compounds. After an intensive species screening, state-of-the-art cultivation, extraction, and processing technologies will be employed to obtain the target metabolites. Since the final goal is to develop new functional food and ingredients to prevent and treat inflammation, *in vitro*, *in vivo,* and *ex vivo* trials will be performed, including in the zebrafish model. The zebrafish model will be used to understand the effect of the selected algae *in vivo* in the diversity of the gut microbiome. The project includes four valuable microalgae species currently produced and commercialized by Necton, namely *Tisochrysis lutea*, *Skeletonema costatum*, *Phaeodactylum tricornutum,* and *Nannochloropsis oceanica*. These species present a valuable nutritional profile for fish and invertebrate nutrition, being particularly relevant for bivalve and shrimp aquaculture [6,7]. In addition, anti-inflammatory activities have been previously observed in these microalgae, increasing their value as an anti-inflammatory feed[4,8].

Introduction

The production of Gilthead seabream (*Sparus aurata*), together with European seabass (*Dicentrarchus labrax*), is the second most important aquaculture industry in the European Union (STECF, 2018) consisting of large companies as well as numerous small-medium sized companies which require a strong concentration on business development. However, the economic performance of these companies is generally rather poor mostly due to inefficiency and profitability issues. Therefore, a focus on increasing the production value rather than increasing production quantity would be a sustainable solution to improve profitability and adjust for long-term environmental and economic goals in the EU (Llorente et al., 2020).

The combination of Large Volumes (ϕ>30m^3) and low densities (≤ 16 larvae/L) has been demonstrated (Koumoundourous *et al*., 2004; Boglione *et al*., 2009; Prestinicola *et al*., 2013) to augment the survival rate and the morphological quality of hatchery-reared seabream. The aim of this study is to individuate which between 'large volume' and 'low density' is the main driver in attaining high quality seabream subadults. The design envisages to test the effects during the pre-ongrowing phase of seabream, carried out at a commercial scale of: A) larger and smaller tank volumes; and B) higher and lower stocking densities.

Methods

Experimental rearing was conducted at the Intituto Portugues do Mar e Atmosfera facilities in Olhão Portugal. Seabream with an average weight of 6.7 ± 2.5g and length of 7.8 ± 1.1cm were selected based on external inspection carried out by experienced technicians and the 'non-deformed' fish were stocked at 3 different densities (LD: 5kg/L; MD: 10kg/L; HD: 20kg/L) in both 500 L and 1000 L cylindrical tanks with a replacement rate of 100% tank volume/hour of natural seawater. Oxygen diffusers were placed at the bottom of tanks in order to maintain a O_2 saturation level above 70%. Light regime was based on natural light and photoperiod during the summer months of August and September in Southern Portugal. Tanks were shadowed with a mesh tarp. The water temperature in the tanks ranged 19-29° C throughout the ~60 days of rearing upon reaching an average final weight of ~55g/individual. The tanks were regularly controlled and managed in order to maintain the experimental densities throughout the experiment. Fish were fed 3% of their body weight/day with AquaGold 5 pellets (AquaSoja, Ovar, Portugal).

A sample of 161 seabream of those classified as 'non-deformed' used to begin the experimental rearing (T_0) were lethally anesthetized (MS-222) and fixed in 4% PFA and X-rayed (Gilardoni CPX 160/4 System, Unleaded film Kodak Mx 125, 55 Kv, 4 mA) for anatomical evaluation of skeletal elements. After ~60 days of experimental rearing (T_F), Over 100 seabream were sampled from each experimental condition, euthanized and X-rayed with a digital DXS Pro X-ray (Bruker).

Results and Discussion

There were no significant differences in survivorship between the conditions. Significant (Kruskal-Wallis, Dunn's *post hoc* with Bonferroni correction, $p<0.05$) smaller total lengths were found in the seabream reared in HD conditions with respect to LD seabream, regardless of the tank volumes (Fig. 1a). Significant differences were also found in the Fulton's condition factor (Fig. 1b) of HD versus LD seabream regardless of the tank volumes. Taking into consideration that the final weights were not significantly different, the metrics enhanced the point that seabream in the HD conditions were characterized by a positive allometric growth.

(Continued on next page)

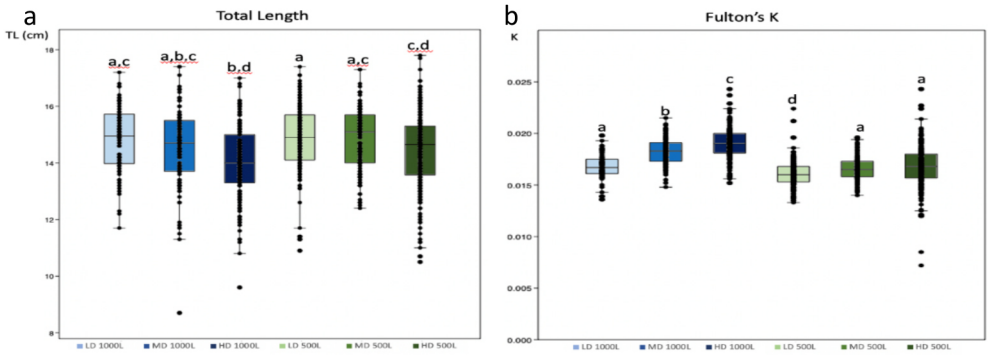

Fig. 1 Total Length (a) & Fulton's condition factor K (b) for individual Seabream fingerlings at T_F ($p<0.05$, Kruskal-Wallis, Dunn's *post hoc* with Bonferroni correction). Different letters highlight significant differences.

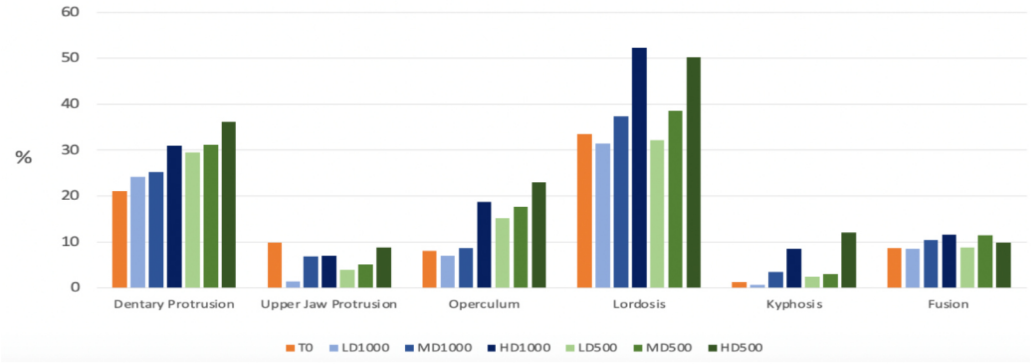

Fig. 2 Prevalence of individuals affected by severe anomaly types from T_0 (at the beginning of the experimental rearing) from T_F (final sampling) for the 6 density and volume conditions.

X-ray images showed a progressive augmentation of lordosis, kyphosis, jaw and opercular anomalies with increasing density, independently from the volume (Fig. 2). Consequently, stocking density seems to be a primary driver in increasing the frequency of these skeletal anomalies rather than the tank volume. When considering differences among fish reared in different tank volumes, the prevalence of particular anomaly types appeared different: i.e., at the same stocking density, the 1000 L rearing conditions yielded a lower prevalence of opercular and jaw anomalies and higher prevalence of both lordosis and vertebral body fusions, when compared to the 500 L conditions of the same density.

Lastly, although the initially selected seabream were labeled as 'non-deformed' upon external inspection; the X-rayed images tell a different story as the T_0 seabream did in fact have many skeletal deformities (Fig 2).

This project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under the Marie Skłodowska-Curie grant agreement No. 766347, BioMedAqu ETN 766347.

A NUMERICAL STUDY OF SHELLFISHERIES AQUACULTURE AND OFFSHORE RENEWABLE ENERGY CO-LOCATION IN THE IRISH SEA

Jonathan Demmer*; Matthew Lewis; Simon P. Neill

Address: School of Ocean Sciences, 4 Askew St, Menai Bridge LL59 5EG
Email: osp816@bangor.ac.uk

Introduction

The worldwide increase of demand for aquaculture and energy requires developing efficient tools to study the possibility of multi-use platforms at sea (MUPS) and reduce the anthropic pressure on space availability. Offshore renewable energy (ORE) in the Irish Sea will occupy approximately 14% (6,564 km^2) of the space in a close future. Blue mussels industry (*Mytilus edulis L.*) in North wales represents one third of the UK production and could be impacted by the development of other industries (Hambrey & Evans, 2016). Several studies defined a sustainable index (SI) for the co-location of aquaculture and offshore wind farms, which includes physical (i.e. wind velocity, depth range, tidal current) and biological (i.e. sea surface temperature, chlorophyll-a concentration) factors (Di Tullio *et al*., 2018). However, no studies took into account larvae dispersal as a factor for SI to determine the best location to catch shellfish. In order to determine the best suitable area for co-location, we used a lagrangian particle tracking model (PTM) coupled to hydrodynamic model to qualify and quantify: (1) the density distribution of mussel larvae; and (2) the connectivity between aquaculture (6 sites) and ORE (10 sites).

Material and methods

Telemac-2D depth average model with mesh density varying from 30 m to 5,000 m. The domain covered an area of 165,000 km2, which correspond to the whole Irish Sea as previous studies show that larvae can potentially travel up to 300 km (Van der Molen *et al*., 2007). A Lagrangian PTM was developed to predict mussel larvae dispersal from 6 sites for a pelagic larvae duration (PLD) of 45 days. Simulations were performed for two larvae behaviour (i.e. dispersal at the surface and at mid-water depth) during spring of two contrasted year (i.e. 2014 and 2018 showed different wind patterns).

Results

Density distribution showed the same results during spring 2014 and 2018 when larvae travel at mid-water depth. However, the density distribution varied during the PLD and according to the site of release.

Density distribution varied inter-annually when larvae travelled at the surface. Results also showed a difference between release sites and during the PLD.

Connectivity results showed that the site leasing 1 is the most connected with released sites for all simulated years and behaviour (Figure 1). However, the connectivity with leasing 1 site varied through the PLD (Figure 1). Furthermore, results showed that during spring 2014, aquaculture sites are connected with offshore wind farms located in the eastern Irish Sea (i.e. North Wales and North of England) whereas during 2018 they are connected with ORE located in the western Irish Sea (i.e. Dublin and North of Ireland) (Figure 1).

Discussion

The simulated larvae behaviours results showed that when larvae travel at the surface they encountered stronger currents (e.g. wind driven currents), which increased their dispersal. Results observed when mussel larvae travel at the surface are correlate with observations made by mussel farmers during the year 2014 and 2018. The results highlight the importance of vertical position of larvae in the water column to study potential multi-use platforms at sea. However, the leasing site 1 is potentially the best area to develop MUPS in the Irish Sea. This study shows the importance of considering larvae dispersal for the development of sustainable index to define best area for MUPS.

(Continued on next page)

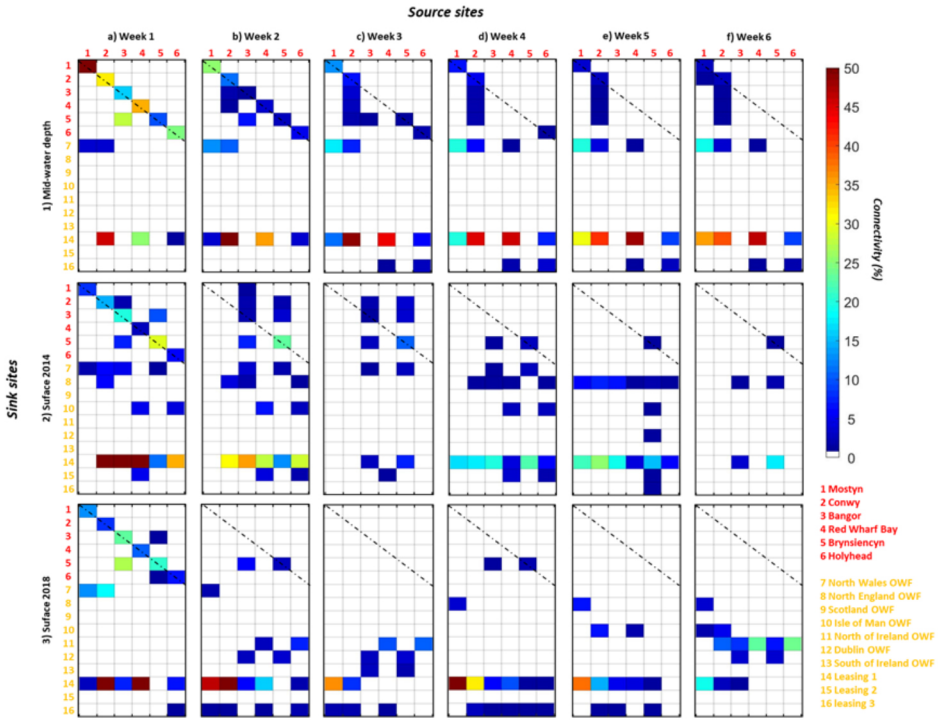

Figure 1: Connectivity matrices for particles when released from 6 sources site (1-6) at: 1) midwater depth; 2) surface during March and April in 2014; and 3) surface during March and April in 2018. Results are presented per week: (a) week 1; (b) week 2; (c) week 3; (d) week 4; (e) week 5; and (f) week 6. Connectivity between larvae from a source (column) with a sink (row) is highlighted by colour scale with high connectivity in red, low connectivity in blue and no connectivity in white. Self-recruitment (e.g. retention within the release site) is indicated by cells that cross the diagonal dashed line. Sites are colour coded as: red = source and sink sites and orange = sink sites only.

EFFECTS OF SYNBIOTIC DIETS ON RE-ESTABLISHMENT OF THE ATLANTIC SALMON GUT MICROBIOTA AFTER DYSBIOSIS TRIGGERED BY MEDICATED FEED

Anusha K.S. Dhanasiri[1*], Alexander Jaramillo-Torres[1], Abdelaziz A. A. Mohammed[1], Yanxian Li[1], Torunn Forberg[2], Åshild Krogdahl[1], Trond M. Kortner[1]

Introduction

Salmon aquaculture industry has rapidly expanded over the last decades with Norway and Chile being the main contributors. With this rapid growth, it has encountered alarms over environmental impacts and sustainability. Among the sustainability issues are factors affecting fish welfare and health including sea lice and disease outbreaks leading to chemical and antibiotic usage in some regions of global salmon farming. Antibiotic usage could lead to issues and concerns over the development of antibiotic resistance and undesirable effects on the host. Several studies have reported the presence of antibiotic resistant bacteria and/or antibiotic resistant genes in intestine of medicated fish and healthy fish, farming and non-farming sites indicting the significance of the antibiotic resistance related to salmon aquaculture industry. Antibiotics can trigger perturbations in host gut microbiome resulting in dysbiosis, leading to detrimental health effects. Even though, a few studies have reported the perturbations in gut microbiota of Atlantic salmon caused by some antibiotics, in depth understanding of antibiotic-induced dysbiosis and related health and physiological effects are lacking.

Synbotic, a mixture of probiotic and prebiotic agents, exerts beneficial affects to the host by increasing the survival and activity of probiotics and indigenous health promoting bacteria in the gut. Several previous studies described the beneficial effects of synbiotics on salmonoids. Mammalian studies showed concomitant use of probiotics, prebiotics and synbiotics with antibiotics could re-establish gut microbiota and prevent antibiotic resistance and antibiotic associated gastrointestinal disorders. However, the use of pre- pro- or synbiotics to assess similar effects in fish are scanty.

The present study attempted to address those research gaps by evaluating the effects of synbiotic diets on re-establishment of the Atlantic salmon gut microbiota after dysbiosis triggered by medicated feeds.

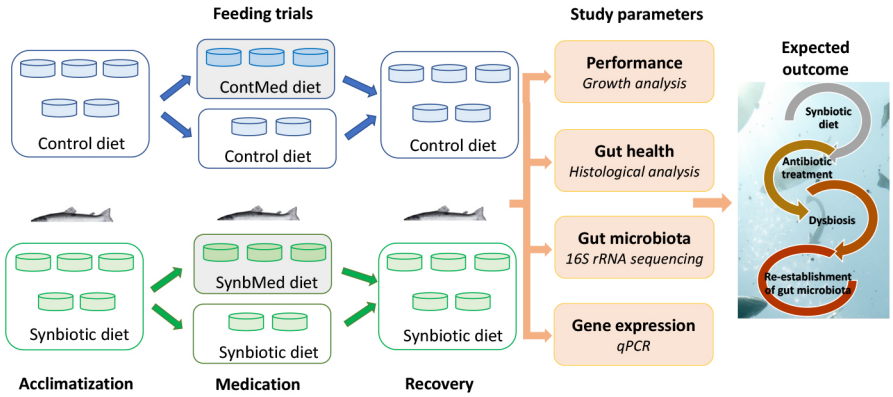

Figure 1. Systematic representation of experimental design used to evaluate the effect of synbiotic diets on re-establishment of the Atlantic salmon gut microbiota after dysbiosis triggered by medicated feeds.

(Continued on next page)

Materials and methods

Systematic representation of experimental design, experimental procedure and expected outcome is illustrated in the Figure 1. Post-smolt Atlantic salmon were fed with a control commercial diet and a synbiotic diet in which the commercial diet was supplemented with 0.04% *Pediococcus acidilactici* and 0.1% scFOS, for a period of five weeks. Each of the feed group had five pens. After the acclimatization period, fish in the three out of five pens in each of the groups were fed with medicated feeds containing either control diet + florfenicol (3.5ppm) or synbiotic diet + florfenicol (3.5ppm) for a period of two weeks. Then those fish were re-fed with their respective non-medicated diets i.e control or synbiotic diets, for another six weeks. The fish in the remaining two pens from each group were continuously fed with control or synbiotic diets until the end of the feeding trial.

Fish used for microbiota analysis were pit-tagged and digesta samples were collected at the start and end of the medicated feeding and end of the re-feeding period. Microbiota analysis was performed with 16S rRNA sequencing and subsequent bioinformatics analysis were carried out using QIIME2. Growth performance, histomorphology and transcriptomic changes were also evaluated.

Results and Discussion

Treatment with antibiotics negatively affected the thermal growth coefficient in both the control and synbiotic diet fed groups. However, the reduction in growth was less in the synbiotic group compared to the control group. Analysis of microbiota data is currently in progress and will be presented in the conference. We are expected to see that antibiotic treatment related perturbations in digesta-associated microbiota in both the groups. Moreover, we hypothesized that the fish fed with synbiotic feed would indicate rapid re-establishment of intestinal microbiota within a period of six weeks or earlier. Further, it was also hypothesized that this rapid maintenance of intestinal microbiota may positively impact in the reduction of the growth loss observed in those fishes. The knowledge generated in this study could be further explored to improve antibiotic related dysbiosis in gut microbiota and related physiological impacts in Atlantic salmon aquaculture industry.

CAN MEAGRE (*Argyrosomus regius*) BENEFIT FROM HIGH DIETARY PROTEIN HYDROLYSATE LEVELS AT EARLY DEVELOPMENTAL STAGES?

Introduction

Meagre (*Argyrosomus regius*) is an emerging fish species with potential for aquaculture diversification in Southern-European countries. During the early developmental stages, meagre larvae are extremely voracious and have exceptionally high growth rates. These features primarily suggest the need for an abundant supply of dietary amino acids (AA) for growth and energetic purposes (Conceição et al., 2011). On the other hand, such characteristics favour the opportunity for an early introduction of inert microdiets in meagre feeding regime. However, microdiets are largely composed by complex proteins that offer a reduced digestibility in comparison with live-prey. This holds true particularly at the onset of exogenous feeding, when larval digestive tract is still undergoing maturation. Dietary protein complexity in microdiets can be attenuated through the inclusion of protein hydrolysates, composed in a large fraction by di and tri-peptides with a high potential for bioactive properties. Such inclusion contributes for a higher amino acid absorption efficiency, favours the maturation of larval digestive tract and potentially positively affects stress and disease resistance (Conceição et al., 2011). Nevertheless, optimal inclusion levels for protein hydrolysates in microdiets for first feeding larvae are not yet determined. In fact, several studies have shown that inadequate inclusion levels may lead to detrimental effects on larval performance (Cahu et al., 1999; Kolkovski and Tandler, 2000). To this end, this study aimed at evaluating the effect of moderate and high dietary protein hydrolysate levels on the growth performance and survival of first-feeding meagre larvae.

Materials and methods

Meagre larvae were reared at IPMA facilities (Olhão, Portugal) according to standard zootechnical procedures from 3 to 31 days after hatching (DAH). To this end, larvae were initially distributed by 9 tanks of 200L at a density of 60 larvae/L. During the experimental period, larvae fed on one of the following microdiets (dietary treatments): MOD – moderate protein hydrolysate levels; and HIGH: high protein hydrolysate levels. Both diets were produced by fluid-bed agglomeration and contained 60% crude protein and 17% crude lipids. Additional ingredients to the protein hydrolysates included in both microdiets were as follows: fishmeal, squid meal, crustacean meals, wheat gluten, fish oil and soy lecithin. From 3 to 20 DAH larvae from both treatments were also co-fed rotifers and Artemia following IPMA feeding regime. Fish were sampled at 3, 16 and 31 DAH for determination of biometrical parameters and survival (endpoint only).

Results

At 16 days after hatching (DAH) the total length of larvae was not significantly different (Figure 1) between treatments. However, at 31 DAH meagre larvae fed with MOD diet presented a significantly higher total length than those fed the HIGH diet (20.5 vs 23.85 mm). At the end of the trial no significant differences were observed in regards to meagre larval survival (varying from 23.7 to 24.5 %) in the MOD and HIGH treatments.

Discussion

This study showed that meagre larvae did not benefit from the inclusion of high dietary protein hydrolysate levels after 2 weeks of development. At the end of this period, results did not show significant differences in larval performance of both MOD and HIGH treatments. However, at the end of the experimental period, larvae from the MOD treatment showed a significantly higher total length than larvae from the HIGH treatment. These findings suggest that high dietary protein hydrolysate levels may lead to detrimental performance results following two weeks of meagre development. Similar findings were previously reported for Senegalese sole (Canada et al., 2017) and gilthead seabream (Nunes, 2019) larvae. These results, obtained in different species, may be related to the increasing ability of larval digestive tract to deal with complex protein whilst maturating. In this sense, older larvae may be able to benefit from slow digestion and absorption of complex dietary proteins. In contrast, short peptides in protein hydrolysates may have a faster flow through the gut wall, potentially creating amino acid imbalances and increasing catabolism (Kolkovski and Tandler, 2000). Moreover, survival and growth results do not suggest benefits from eventual bioactivities of the used protein hydrolysates. Overall, high dietary protein hydrolysate levels do not seem recommended following the first two weeks of development of meagre and other marine fish species.

EVALUATION OF THE POTENTIAL OF TWO STRAINS OF *Bacillus subtilis* AS ORAL ADJUVANTS IN RAINBOW TROUT (*Oncorhynchus mykisS*)

F. Docando[1], C.R. Serra[2], P. Arense[1], N. Nuñez-Ortiz[1], P. Enes[2], A. Oliva-Teles[2], C. Tafalla[1] and P. Díaz-Rosales[1*]

Introduction

Oral vaccines are highly demanded by the aquaculture sector, which requests alternatives to labor-intensive injectable vaccines that involve individual handling of fish, provoking stress-related immunosuppression and handling mortalities. Despite this, most attempts to obtain effective oral vaccines have failed in fish and mammals. In this context, the search for mucosal adjuvants that when orally delivered along with antigens could help circumvent intestinal tolerance, and thus induce an adequate immune response to the antigen, is an important step for the development of effective oral vaccines. In the current work, we performed a series of experiments with rainbow trout (*Oncorhynchus mykiss*) aimed at establishing the adjuvant potential of two *Bacillus subtilis* spore-forming strains isolated from farmed fish, designated as FI99 and FI162.

Materials and methods

The effect of the two strains of *Bacillus subtilis* was first evaluated *in vitro* and *ex vivo* at transcriptional level. Thus, rainbow trout intestinal epithelial cell line RTgutGC and gut tissue sections, were incubated with different concentrations of FI99 and FI162 for 24 h and the expression of genes involved in immune response evaluated by real-time PCR. Moreover, the capacity of both strains to adhere to RTgutGC cells was evaluated by flow cytometry. Finally, the FI99 strain was selected to undertake an *in vivo* experiment. In this case, a single dose of the bacteria was orally administered (by force feeding) and the transcriptional effects studied in the spleen, kidney and gut after 1, 3 and 7 days.

Results

Although both strains had the capacity to modulate the transcription of several genes related to innate and adaptive immune responses, it was the FI99 strain that provoked more immune effects, also exerting a higher binding capacity to intestinal epithelial cells. Consequently, we selected this strain to establish the transcriptional effects in the spleen, kidney, and gut of rainbow trout at 1, 3, and 7 days after a single oral administration of the bacteria. In the gut, genes related to T cell activity as well as IgD were modulated by the bacteria, whereas in systemic tissues, genes involved in inflammation were the ones that were mostly affected, along with immunoglobulin and antimicrobial genes. Overall, the transcriptional effects of FI99 *in vivo* were more evident in spleen and kidney, than in the gut.

Discussion and conclusions

Although *Bacillus* spp. are well known for their probiotic properties, their potential as mucosal adjuvants had not yet been studied in depth in fish. Our results demonstrate that *B. subtilis* modulates the levels of transcription of a wide range of immune genes in the rainbow trout gut. Interestingly, significant differences were found in between the two strains tested in both their immunostimulatory and their binding capacity. Finally, we have established that a single oral administration of the FI99 strain is capable of regulating immune gene transcription locally as well as in systemic immune tissues, pointing to this probiotic strain as a good mucosal adjuvant candidate that would help to increase the immune response mounted against orally-delivered antigens.

Introduction

Enhancing host defense mechanisms with natural immunotherapeutic agents has become increasingly important for the treatment and prophylaxis of farmed fish diseases. Due to their immunotherapeutic potential, algae-derived molecules have been a focal point for aquaculture research (Harikrishnan et al., 2011). In fact, previous studies concerning the role of algal extracts as immunostimulants reported an improvement of innate immune responses in fish fed algal supplemented diets (del Rocío Quezada-Rodríguez & Fajer-Ávila, 2017). Thus, the present research intends to explore novel immunotherapeutics produced by macro- and microalgae and use such bioactive compounds as functional ingredients in diets for aquaculture using zebrafish larvae and juveniles as an experimental model.

Materials and methods

Methanolic (methanol/water, 50:50 v/v) extracts from the macroalgae *Fucus vesiculosus* and *Ulva rigida*, and ethanolic (ethanol/water, 80:20 v/v) extract from microalgae *Nannochloropsis gaditana* were obtained as described in Monteiro *et al*. (2019). Diets for larvae and juveniles zebrafish were formulated, and supplemented with the algal extracts. Thus, a plant-based diet was used as a control (diet C), and seven other diets were prepared similar to diet C, supplemented with 1g Kg^{-1} of each algal extract (*Fucus vesiculosus*, F; *Nannochloropsis gaditana*, N and *Ulva rigida*, U), or a combination of extracts (diets FN, FU, NU, FNU). A fishmeal-based diet was also included as a reference in zebrafish growth trial (C+). First, the effect of the dietary treatments on zebrafish larvae in a short-feeding trial was assesed by evaluating the immune response and intestinal morphology, by gene expression and histological analysis, respectively. Secondly, dietary treatments effect on zebrafish juveniles' growth performance, intestinal integrity and immune status was evaluated through growth and immune- related genes expression in the muscle and intestine, respectively, as well as, through histological analysis.

Results

In zebrafish larvae, most promising results were obtained with methanol extract from *F. vesiculosus*, which exerted an anti-inflammatory action when incorporated alone into zebrafish diets and promoted immune activation, by inducing the expression of pro-inflammatory cytokines, TNF-α and IL-1β when combined with the other extracts. Moreover, dietary inclusion of the extracts improved intestinal morphology compared to that of fish fed the control diet.

Regarding zebrafish juveniles, diet C+ outperformed the remaining dietary treatments, growth-wise. None of the extracts improved diet C negative effects. However, the inclusion of *U. rigida* and *N. gaditana* extracts promoted an immunomodulatory action after 1 week of trial, by upregulating cytokine expression. This effect subsided after 30 days, suggesting tolerance may be developed over time. In contrast, effects on growth-related genes were still observed after 5 weeks of feeding F, N, U, and FN diets. Algal extracts dietary inclusion did not compromise intestinal integrity.

(Continued on next page)

Discussion and conclusions

One major limitation of plant-based products is the presence of antinutritional factors, which fish are not able to metabolize and, when present in the diets, can cause several effects associated with digestive physiology and metabolism, impacting on fish welfare and resulting in reduced productivity (Oliva-Teles et al., 2015). This study showed that, although zebrafish is an omnivorous species, a plant-based diet (C) reduced zebrafish growth compared with a fishmeal based diet (C+). Although the C+ group performed better growth-wise, there was no specific pattern in growth-related gene expression that could explain the major differences observed in growth performance. Therefore, the exact mechanisms underlying the effects of dietary plant protein sources and algal extract supplementation on myogenic regulation related expression in fish remain unclear, and more studies should be conducted in the future.

The extracts effects on cytokine expression were only observed up to a week of feeding, suggesting that tolerance to the extract effect may be developed over time (Bricknell and Dalmo, 2005). Differences in gene expression observed among larvae and juveniles could be associated with the developmental stage and maturity of zebrafish immune system (Ito et al. 2008). Adding to the fact that extract supplementation does not compromise intestinal integrity, a short administration of *F. vesiculosus* extract to larvae and *U. rigida* and *N. gaditana* extracts to juveniles could stimulate periodically the fish immune system, defending fish from eventual disease risk, while reducing the costs of supplement feeding.

IMMUNE EFFECTS OF DNA VACCINATION AGAINST VIRAL HEMORRHAGIC SEPTICEMIA VIRUS IN RAINBOW TROUT (*Oncorhynchus mykiss*)

A. Arrogante, F. Docando, L. González, P. Díaz-Rosales* and C. Tafalla

Animal Health Research Center (CISA-INIA-CSIC), Madrid, Spain
E-mail: diaz.patricia@inia.es

Introduction

DNA vaccination has proved as an effective method for inducing a potent and enduring protection against different fish viruses, especially rhabdoviruses such as viral hemorrhagic septicemia virus (VHSV). The VHSV DNA vaccine consists in a eukaryotic expression plasmid that codes for the G glycoprotein. When intramuscularly injected, this vaccine is able to confer a strong and long-lasting protection to vaccinated fish. Nevertheless, the immune mechanisms through which this vaccine exerts its effects are still not clear. In this context, the main objective of this work was to increase our understanding of how DNA vaccines work in fish, by studying how leukocytes from vaccinated rainbow trout respond to a secondary encounter with the virus.

Materials and methods

Fish of approximately 50 g were intramuscularly injected with 10 μg of a VHSV DNA vaccine in 100 μl of saline solution. Control groups included fish injected with the empty plasmid or the same volume of saline solution. At days 14 and 28 days post-vaccination, fish from the different immunization groups were sacrificed and spleen and head-kidney leukocytes isolated. Leukocytes were then exposed *in vitro* to heat-inactivated virus or left untreated. The proliferation of IgM^+ B cells and the levels of transcription of different immune genes was evaluated.

Results

Head kidney leukocytes obtained from vaccinated fish proliferated when exposed to the inactivated virus *in vitro* to a greater extent than leukocytes obtained from unvaccinated fish. This proliferation was detected after 28 days but not at earlier time points or in splenic leukocytes. Regarding the transcriptional analyses conducted, spleen and head kidney leukocytes responded to inactivated VHSV by increasing the transcription of different immune genes, including pro-inflammatory cytokines and antimicrobial peptides. However, in most cases, no significant differences were observed between the responses of vaccinated and control groups. Notably, head kidney leukocytes obtained from vaccinated fish transcribed significantly higher levels of the innate receptor MDA5 in response to re-stimulation with the inactivated virus than leukocytes from control fish.

Discussion and conclusions

The fact that the differential proliferative response of B cells to VHSV *in vitro* found in head kidney leukocytes obtained from vaccinated fish was observed at late time points strongly suggests that it is at this point when B cells that specifically recognize VHSV (memory B cells) can be found in the head kidney. Additionally, the increased MDA5 transcription observed when leukocytes from vaccinated fish encounter the virus, strongly suggests that viral recognition is primed in vaccinated fish.

GENETIC VALIDATION OF THE XRAY METHOD FOR PHENOTYPING FEED INTAKE IN ATLANTIC SALMON

Gareth F. Difford*[1], B. Hatlen[1], B. Gjerde[1], O. H. Romarheim[1], G Baeverfjord[1], K Heia[1], A. Norris[2], A.K. Sonesson[1]

[2]MOWI Genetics AS, Bergen, Norway
Email: gareth.difford@nofima.no

Introduction

Feed plays a crucial role in the economic and environmental performance of Atlantic salmon production with the cost of feed accounting for over 50% of the total production cost (http://www.fiskeridir.no) and 73-80% of the carbon footprint (Winther et al., 2020). Improving the feed efficiency of Atlantic salmon has potential to be a win-win situation for improving profitability and resource efficiency. Direct selection for improved feed efficiency requires records of feed intake on replicated family groups in tanks through daily recording of the given and the wasted feed in each tank. Due to the large number of tanks required this is both costly and labour demanding and accesses half of the genetic variation. An alternative method is to feed with pellets containing radio opaque markers and use Xray radiography to count the total markers consumed by individual fish. The Xray method for daily feed intake has been shown to be heritable in rainbow trout (Kause et al., 2006) and chinook salmon (Walker et al., 2012), however estimates for Atlantic salmon are lacking. The advent of genomic selection and advances in digital radiography and image analysis offer the possibility to improve the feasibility of obtaining individual genomic breeding values for feed intake and feed efficiency of the breeding candidates. The objective of the present studies was to 1) estimate genomic parameters for Xray feed intake records and 2) validate individual Xray feed intake records with the "gold standard" tank feeding method at family level in replicate tanks.

Materials and methods

A total of 2450 Atlantic salmon parr from 35 nucleus families of the MOWI Genetics AS (MOWI ASA, ***Øyerhamn***, Norway) were PIT tagged and transported to Nofima's Research Station for Sustainable Aquaculture, Sunndalsøra. All fish were genotyped with a customized 65K SNP chip. The PIT-tagged fish were sorted by family and divided into two parallel trials; the first with a total of 700 fish equally split over two replicated tanks with an equal number of fish from all families in each of the two tanks (Xray trial) and the second trial with 1750 fish split into 70 tanks with two tanks per family and 25 fish per family (tank feeding trial). The tanks were divided in two different rooms in the same building.

In the **Xray trial**, fish were acclimated to the two tanks for three weeks. During this period fish were transitioned to a feeding regime where they received the entire daily feed ration over a six hour period. A day prior to Xray, the feed was switched to an identical dietary formulation including glass beadlets. After consuming the daily ration fish were anesthetised and Xrayed. Beadlets were counted using a customised image analysis software developed by Nofima. Number of recorded beadlets per fish were converted to the amount of feed intake (g) per fish (FI_{Xray}) using a calibration standard based on feed samples of known mass. FI_{Xray} was analysed by a mixed linear animal model using DMU (Madsen and Jensen, 2014) including the fixed effects of tank (with two levels), a fixed regression on time within the Xray recording day, a random animal additive genetic effects captured by the genomic relationship matrix. The heritability was estimated from variance components ($h^2 = Va/Vp$). The average feed intake per fish, per family and tank (FI_{XrayF}) was analysed by a linear model including the fixed effect of tank (with two levels) and a random effect of family. The variance components for the family effect was expressed relative to the total variance ($H^2 = Vf/Vp$).

In the **tank feeding trial**, daily feed rations and refusals were collected over 50 days. At day 50 the trial, fish were euthanized and recorded for body length and weight. The average family biomass per tank was modelled as a function of time throughout the trial and daily feed intake records (FI_{TF}) were matched to the Xray feed intake records of the Xray trial (FI_{Xray}) on an equal average family body weight basis. The accumulated feed intake per tank (FI_{TF}) was analysed by a linear model including the fixed effect of room (with two levels) and the random effect of family ($H^2 = Vf/Vp$). A bivariate analysis was run FI_{XrayF} and FI_{TF} with the fixed effects of tank (with two levels) for FI_{Xray} and the fixed effect of room for FI_{TF}, and the random effect of family for both traits. The covariance between random effects of family used to compute the correlation between for families between methods.

(Continued on next page)

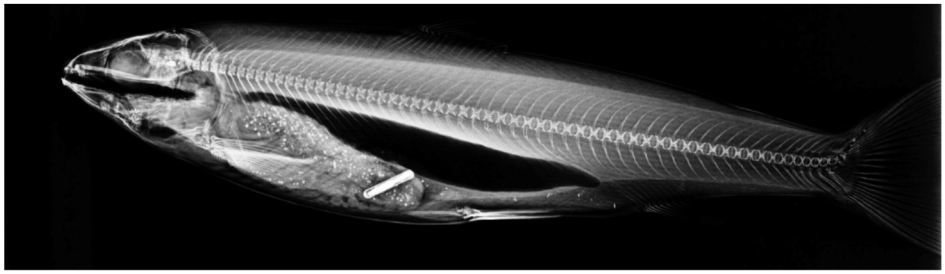

Figure 1. A digital Xray radiograph of an Atlantic salmon with radiopaque beadlets.

Table 1. Descriptive statistics for FI_{Xray} of individual records and family means as well for FI_{GS} of family means.

Trait	N	Level	Mean* ± SD	ICC† ± SE
FI_{Xray}	685	Individual	1.56 ± 0.28	0.22 ± 0.05
FI_{XrayF}	68	Family	1.56 ± 0.13	0.38 ± 0.02
FI_{TF}	70	Family	1.51 ± 0.41	0.37 ± 0.02

* Indicates average feed intake in grams per fish at measurement. † is the intraclass correlation coefficient for heritabilties, level indicates if the ICC is narrow sense heritability (h^2) or broadsense heritability (H^2).

Results

Results of the feed intake at individual and family level are presented in Table 1 along with their respective intraclass correlation coefficients. The heritability (h^2) of FI_{Xray} was 0.22 ± 0.05. The family means of FI_{Xray} explained 38% of the total variation which was very similar to the family effect (37%) of the total variation in the accumulated FI_{TF}. Crucially, the rank correlation between the families FI_{XrayF} and FI_{TF} was high and positive (0.85 ± 0.25).

Conclusion

For the first time, significant heritability of feed intake using the Xray method has been reported in Atlantic salmon. Validation at the family shows that a substantial proportion of the variation in feed intake among the families are co-explained by both methods. This demonstrates the feasibility of the Xray method for recording feed intake in Atlantic salmon and lays down the foundation for research into feed efficiency in Atlantic salmon.

Funding

The Xray trial was developed by the Nofima internal project "PrecisionVision", the gold standard trial was part of the EU project "NewTechAqua" (H2020 No 862658) and the EU project AquaImpact (H2020 No 818367).

Introduction

Few commercial multialgal diets formulated for bivalve's are available and generally lack important microalgae difficult to produce industrially, such as *Tisocrysis lutea* and *Skeletonema costatum*. Microalgae production in hatcheries is expensive (30-50% of total costs)[1], labour intensive and subjected to productivity fluctuations. Therefore, commercial microalgae diets are a major asset. The objective of a nursery is to achieve high larvae quantities of good quality and improve juvenile growth. Good quality nutrition is essential for broodstock maturation in order to generate high quality gametes and offspring, and to optimize juvenile growth. Oysters (*Crassostrea* spp.) depict the world's most produced mollusc species. Portuguese oyster (*Crassostrea angulata*) has a high potential for aquaculture, although its natural populations suffered a decline in the past decades. Therefore, *C. angulata* production is important for aquaculture, being simultaneously relevant for natural populations restocking and conservation. Commercial microalgae diets can improve aquaculture management. This work aims to develop commercial diets for bivalves, formulated with a blend of microalgae species commonly used in aquaculture for oyster nutrition applied to Portuguese oyster broodstock and juveniles.

Material and methods

Pilot liquid concentrated products (8% of dry weight-DW) of industrially produced microalgae were formulated. Diet 1 contained *Tetraselmis* sp., *Skeletonema* sp., *Tisocrysis lutea* and *Pavlova* sp. (8/16:6/16:1/16:1/16), while diet 2 was formulated with *Skeletonema* sp., *Tisocrysis lutea* (T-ISO clone) and *Tetraselmis* sp. (11/16:5/6:1/16). Diets´ biochemical analysis was performed. Controls were based on live algae: microalgae for broodstock were produced on site (*Tisocrysis lutea*, *Tetraselmis* sp. and *Skeletonema* sp.); juveniles from the control group were grown in Mira river (Odemira, Portugal) feeding on the naturally occurring microalgae. Animals were fed daily with an amount equivalent to 4% of the oyster dry meat (g) in DW of microalgae (mg). A preliminary experiment was performed in *C. angulata* broodstock, where the control and Diet 2 groups were conditioned in duplicate (each replica n=20) at 20±1°C, 20‰, being evaluated the oysters' weight, biometry and condition index. Gametes were extracted by gonadal incisions. Oocytes from females of control (n=2) and diet 2 treatment (n=2) were fertilized *in vitro* with sperm from a single control male in triplicate, to compare oocyte quality between treatments in this preliminary approach. Sperm concentration was quantified with a Neubauer chamber. The evaluation of oocyte fertilization and larvae survival (48 hours post fertilization) was conducted. Juveniles were directly placed in nets on the natural environment as control in duplicate (n=250 oysters per replica) or conditioned indoors and fed with Diet 1 and 2 for 3 months (duplicate, n=250). Juveniles were sampled (n=50) throughout time for measurements (survival, weight, length and width) (total n=3175) and collected for condition factor evaluation (n=266). The environmental conditions were daily monitored. IBM SPSS Statistics 26.0 software was used for statistical analysis, one-way ANOVA was used to compare differences between juvenile groups and Student´s t-test for *in vitro* fertilization data ($p<0.05$). A cluster analysis was applied to juvenile data and, subsequentially, a decision tree approach allowed to understand juvenile's growth pattern in the different size groups of oysters in the treatments.

Results

Proximal composition showed the proteins, lipids and ashes content of Diet 1 (23, 10.9, 63%) and Diet 2 (9.9, 2.1, 82.2%) respectively. The broodstock established in control group was heavier and had higher length (94.4±15.6g, 83.2±7.2mm) compared to Diet 2 treatment (56.8±18.5g, 69.7±7.5mm) in the beginning of the experiment. Preliminary results of oocytes obtained by the broodstock fed with Diet 2 showed 86.3±10.6% of fertilization rate, which was significantly lower compared to control (93.9±8.6%). For juvenile there were no significant differences in the survival rate in all treatments. Juveniles fed with Diet 2 showed higher and less variable weight and length gain (R^2=0.8542, R^2=0.7219) than Diet 1 (R^2=0.3101, R^2=0.4233) and control (R^2=0.1469, R^2=0.3733). Even though oysters in the control started with higher weight and biometric measurements, at the end of the trial there were no significant differences in all treatments regarding the wet weight and height (n=3175). To the group of juveniles collected for condition factor index evaluation, a K-means cluster

(Continued on next page)

analysis was applied to aggregate oysters by size groups (large, medium and small size groups). A decision tree approach was applied through a CHAID method to the clusters obtained, with wet weight as dependent variable (n=266). In small size oyster cluster group, Diet 1 and control promoted the highest wet weight below 40.6mm, while above this length, Diet 2 improved oyster's weight. In medium size oysters cluster group below 40.6m (33.5-34.8mm) Diet 1 showed the highest wet weight. In large size oysters cluster group below 40mm, Diet 1 and control had the highest weight, while in oysters above 40mm Diet 2 showed the highest value.

Discussion

Preliminary tests in *C. angulata* broostock showed that oysters fed on Diet 2 had an equivalent weight to the control group. Obtained oocytes with Diet 2 treatment exhibited high fertilization rate and larvae survival, although significantly lower than the control, which can be explained by the low number of animals. Therefore, in the future, a large-scale test will be performed with Diet 2 in oysters maturation and larvae quality. The growth of juvenile oysters with diets is more constant throughout time than in control, which suggests that natural environmental fluctuations promote variability in microalgae species and abundance, impacting oyster growth. In oysters below 40.6 mm, Diet 1 promoted equivalent weight to the natural environment. Higher protein and lipids content in Diet 1 can support the high requirements for growth of smaller oysters. Prototype Diet 2 promoted high and steady growth in Portuguese oyster juveniles. This is a balanced diet based on the microalgae species and proportions used in oysters hatcheries[2]. To enhance wet weight gain in Portuguese oysters a dietary protocol based on Diet 1 until 40.6 mm and Diet 2 after this length can be used. In conclusion, the formulation of microalgae diets, such as Diet 2, specifically developed for bivalves can simplify and support nurseries management.

Introduction

Microalgae are used in marine larval rearing in green water technique with synergistic effects beneficial for larvae. Marine fish show altricial larvae that hatch with immature organs such as eyes and gut essential to capture and digest preys. Microalgae in the water column applied through green water technique have beneficial effects in larvae since they allow the refraction of light and improve the observation of live prey, maintaining rotifers simultaneously enriched. Additionally, microalgae are known to vector beneficial probiotics that colonize larvae gut, improving environmental water quality, fish welfare and stress resistance. Industrially produced microalgae are a major asset in aquaculture, although still underused mainly due to the lack of specific product development and application protocols specifically adapted to the rearing systems. In marine larviculture the use of live microalgae produced within the facilities is still a common practice despite being labour intensive and prone to productivity fluctuations. There have been major advances in biotechnology improving the quality of microalgae biomass and increasing the number of microalgae strains available commercially. However, the application of this high-quality biomass in aquaculture presents some important challenges such as microalgae precipitation and stability in the water column, which may impair water quality. This disadvantage can be mitigated by the use of beneficial probionts through the modulation of the microbiota in the tank[1]. The application of probiotics as water conditioners has been thoroughly studied and it is a common practice in animal production, including aquaculture. The objective of this study was to develop new formulations for green water technique with industrially produced microalgae strains and probiotics using meagre (*Argyrosomus regius*) larval rearing as a case study.

Material and methods

The selection of microalgae strains and its typology was performed according to cellular dimensions, stability in water column and a technoeconomic study, after which *Nannochloropsis* sp. and *Chlorella* sp. spray dried were selected. Pilot product A (PPA) contained only microalgae and pilot product B (PPB) contained microalgae along with probiotic bacteria. An exploratory approach was performed to find adequate indicators of the formulation mixture quality to find mixing quality indicators adequate to the formulation. The hydration and the blending times were optimized with a set of tests. The colour of the blends was evaluated according to the RAL scale and the precipitation time was monitored after 24h in salt water. To investigate the effects of the selected conditions, an experimental design was set up with a control composed by live *Nannochloropsis* sp., a microalgae formulation and a formulation containing microalgae and probiotics. The experiment was performed in IPMA aquaculture research station (EPPO, Olhão) in open cylindroconical tanks (200L) in triplicate. Newly hatched larvae were introduced (43.25 larvae/L) with a water temperature of 21±1ºC, 37‰, a photoperiod of 10-14 D:L. Rotifers where introduced at mouth opening, artemia and microdiet (Caviar, Bernaqua®) where introduced at 10 days after hatching (DAH) (100-200µm) increasing the granulometry through development and fed *Ad libitum*. Environmental parameters were monitored (pH, salinity, oxygen, temperature, ammonia, nitrates). The microalgae present in the water column and its precipitation was monitored spectrophotometrically three times a week (1h, 2h and 3h after microalgae introduction). Larvae survival and growth was evaluated (n=15 per replica per time point) through total length and dry weight analysis. Microbiota was monitored in water and larvae (TSA, TCBS). A final stress challenge was applied in all treatments with a transport of 250 km. The environmental parameters were monitored (temperature, oxygen, pH, ammonia and nitrates), survival was evaluated on the arrival and 8 days afterwards.

Results and Discussion

The products revealed an adequate mixing rate of 3 min (129 rpm), being selected also an hydration time of 10 min followed by 5 min of blend. The mixture was sieved with a 50 µm mesh to remove the foam and microalgae agglomerates. The colour of the products according to RAL scale was for PPA 6028 and for PPB 6024. The quantities to be applied in the tanks were adjusted according to the turbidity measured with a probe (5±1 FTU). The microalgae dry weight in the tanks range from 0.01 to 0.04g/L.

(Continued on next page)

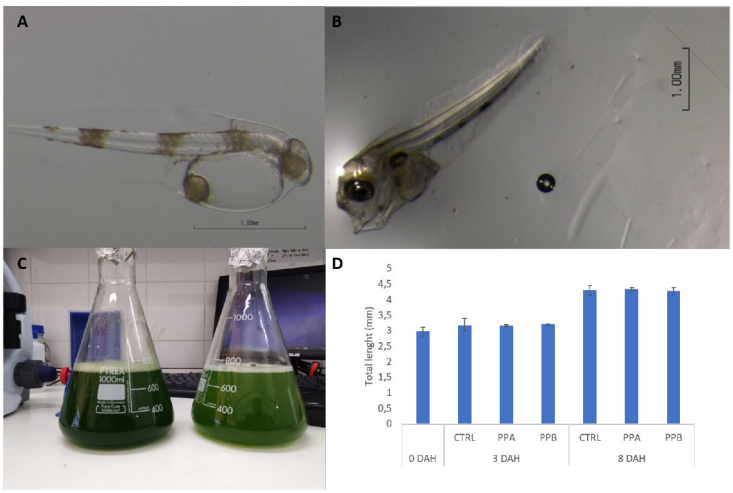

Fig 1– Meagre (*Argyrosomus regius*) larvae at A) hatching and B) 8 DAH; C) products suspension analysis A (left), pilot product B (right) and D) Total length (mm) of meagre larvae until 8 DAH.

Preliminary results showed similar growth of meagre larvae reared in green water with live microalgae or with formulated products. The combination of probiotics and microalgae allowed a higher stability of the microalgae in the water column compared with the product containing only microalgae. One hypothesis for this result is the generation of biosurfactant metabolites by the probiotics[2] contributing for the reduction of surface tension. This work will allow to understand the effect of formulated microalgae and probiotic products for green water technique applied in meagre larviculture and its effects on larvae and water bacterial communities, larvae welfare and stress resistance.

Introduction

Microalgae industrially produced for aquaculture purposes have several advantages over other biomass sources since they contain high variability of ingredients, different species present distinct nutritive profiles, being also possible to induce the production of target metabolites through the modulation of its cultivation methodology1. Fucoxanthin is a carotenoid produced by microalgae species with high aquaculture application such as Tisochrysis lutea, Phaeodactylum tricornutum, Chaetoceros muelleri or Thalassiosira pseudonana2. It is the most abundant xanthophyll in macro- and microalgae due to its celular photoprotection capacity. The interest in fucoxanthin for food and feed application is growing due to its advantageous properties such as antioxidant anti-proliferative, anti-obesity, anti-diabetic, anti-inflammatory and anti-angiogenic activities, that are beneficial for aquafeeds formulations, to improve fish nutrition and health3–4. Tisochrysis lutea is considered a valuable, premium microalgae species for live feed, fish and invertebrate nutrition, particularly due to its balanced biochemical profile that contains relevant fatty acids for fish nutrition such as EPA and DHA and adequate protein content to support animal growth. It has no cellular wall, being therefore more digestible than microalgae with cellulosic cell walls, although its nutritional benefits must yet be validated in the aquacultured species. Therefore, the production of Tisochrysis lutea biomass with high fucoxanthin content would add value to this microalga, to ultimately improve fish welfare. Hence, the present study aimed to validate a protocol to analyse spectrophotometrically the fucoxanthin content in Tisochrysis lutea industrial culture by a straightforward method previously developed5 for other microalga species. The validation of the protocol was performed by comparing the fucoxanthin levels obtained between this protocol and highly accurate methods to measure this pigment (HPLC).

Materials and methods

The fucoxanthin analysis was performed according to the methodology established by Wang et al.[5]especially diatoms and Chrysophyta. Recently, it has been shown to have anti-inflammatory, anti-tumor, and anti-obesityactivity in humans. Phaeodactylum tricornutum is a diatom with high economic potential due to its high content of fucoxanthin and eicosapentaenoic acid. In order to improve fucoxanthin production, physical and chemical mutagenesis could be applied to generate mutants. An accurate and rapid method to assess the fucoxanthin content is a prerequisite for a high-throughput screen of mutants. In this work, the content of fucoxanthin in P. tricornutum was determined using spectrophotometry instead of high performance liquid chromatography (HPLC in *Tisochrysis lutea* cultures. For that purpose, outdoors flat pannel green walls where inoculated at diferent concentrations: Low (L) (0.67±0.04 g/L), Medium (M) (1.07±0.05 g/L) and High (H) (1.50±0.05 g/L) cell concentration (n=2 each treatment). The cultures were monitored for three days, with 2 daily sample collections (morning and afternoon) to analyse fucoxanthine by two diferent methods. The validation of the spectrophotometric protocol was performed by comparing the pigment quantification through spectrophotometry[5]especially diatoms and Chrysophyta. Recently, it has been shown to have anti-inflammatory, anti-tumor, and anti-obesityactivity in humans. Phaeodactylum tricornutum is a diatom with high economic potential due to its high content of fucoxanthin and eicosapentaenoic acid. In order to improve fucoxanthin production, physical and chemical mutagenesis could be applied to generate mutants. An accurate and rapid method to assess the fucoxanthin content is a prerequisite for a high-throughput screen of mutants. In this work, the content of fucoxanthin in P. tricornutum was determined using spectrophotometry instead of high performance liquid chromatography (HPLC to HPLC (High Performance Liquid Chromatography) method according to Gao et al.[6]. Algal strain *Tisochrysis lutea* produced locally at Necton S.A. was grown photoautotrophically with Nutribloom® Plus. *Tisochrysis lutea* samples were analysed spectrophotometrically for cell concentration using a previously established calibration curve. For fucoxanthin analysis the cells were centrifuged at 4000x g for 10 min, the supernatant discarded and then rinsed with ddH_2O (1:1; v/v) for 3 min. Cells were recollected by centrifugation and pellets were suspended in ethanol (ethanol:algae culture volume = 1:1; v/v) for pigment extraction. Absorbance values were read

(Continued on next page)

at 445 nm and 663 nm (A_{445} and A_{663} range from 0.2 to 1) within 5 min. In parallel, a volume of culture was centrifuged and the cells diluted with culture medium Nutribloom® Plus (medium:algae culture volume = 1:1; v/v) for 3 min, and the absorbance measured at 750 nm. (A_{750} ranges from 0.1 to 0.8). The concentration of fucoxanthin in algal cells was determined through measuring the absorbance of cells suspended in culture medium at 750 nm and algal cell suspension in ethanol at 445 nm and 663 nm through the following Formula:

$$C\textit{fuc}' = 6.39 \times A_{445} - 5.18 \times A_{663} + 0.312 \times A_{750} - 5.27.$$

IBM SPSS Statistics 26.0 software was used for statistical analysis and data is expressed as average±SD. Independent t-test was used to compare differences between spectrophotometric and HPLC results ($p<0.05$).

Results

All data was normalized according to the same conditions, namely the quantification in both methodologies are expressed in relation to microalgae dry weight (including ash), since the spectrophotometric method includes the salt content of the culture and microalgae. The preliminary results of the present study showed that the levels of fucoxanthin in Low concentration culture measured through spetrophotometric method has no significant differences from the pigment quantification performed through HPLC (table 1).

Table 1- Comparison of fucoxanthin content in *Tisochrysis lutea* culture inoculated in Low concentration treatment measured through spectrophotometric (SPM) and HPLC method during 3 days of culture.

	Fucoxanthin (mg/g) SPM	**Fucoxanthin (mg/g) HPLC**
Day 1	11.25±1.84	10.21±0.68
Day 2	6.84±1.59	5.8±0.43
Day 3	6.13	5.74±1.81

Discussion

The use of HPLC analysis is considered to be the most accurate method to measure microalgae bioative compounds, such as the fucoxanthin pigment. However, for industrial purposes, a simple method for cultured-microalgae pigment analysis was previouly proposed for *Phaeodactylum tricornum* through spectrophotometry. The present study aimed to validate this methodology in *Tisochrysis lutea* produced industrially at Necton S.A. It was possible to observe that there were no significant differences on the fucoxanthin concentration evaluated through both methods in cultures with low cell concentration (L) (0.67±0.04 g/L). The evaluation of the remaining treatments (M, H) will allow a full validation of the protocol application for this microalgae species. Once the protocol is fully validated, the fucoxanthin levels in *T. lutea* will be investigated throughout its biomass processing steps, to understand the maintenance of the pigment in industrial biomass processing stages.

AQUACULTURE VIRTUAL CAREER DEVELOPMENT PLATFORM FOR THE SOUTH BALTIC REGION – INITIAL RESULTS AND FUTURE PERSPECTIVES

B. Dmochowska*, A. Bischoff-Lang, H. Łądkowska, N. Nika, A. Sutnikas

AquaVIP INTERREG SB project, communication: University of Gdańsk, Bażyńskiego 8, Gdańsk, 80-309, (Poland)
Email: b.dmochowska@ug.edu.pl

Introduction

Recognizing the significant demand for aquaculture professionals and a need for progress in innovative technologies in the South Baltic Region AquaVIP – Aquaculture Virtual Career Development Platform for the South Baltic Region, a three-year project led by Klaipeda Science and Technology Park, accompanied by University of Rostock, University of Gdańsk and Klaipeda University has undertaken a number of educational and research activities to meet the objective – to boost aquaculture labor market within the South Baltic region by fostering human resources capacity through cross-border training and networking.

The project focuses on: investigating best practices, testing innovative methods and tools, exchanging knowledge and experience related to human resource capacities for the aquaculture sector, training students and professionals in innovative aquaculture methods, cooperation and networking with organizations pursuing the same mission. AquaVIP target group includes stakeholders along the aquaculture value chain: aquaculture and related fields students, future employees willing to make a career in the aquaculture market in the South Baltic area, employees and entrepreneurs of micro or SMEs willing to improve their skills, farmers associations, NGOs, authorities interested in improving their skills and sustainable aquaculture development.

Materials and methods

AquaVIP project offer is carried out through AquaVIP experiments, AquaYouth, AquaProfi, and AquaTION services.

AquaVIP experiments performed in partners' facilities are foreseen as core activities for the training and networking. The research topics of the experiments include: recirculating aquaculture systems (RAS), artificial feed chains, aquaponics, microalgae, *Litopenaeus vannamei*, native Baltic Sea shrimps, technology optimization, new shrimp tower concept, brackish conditions in freshwater fish RAS, geothermal brine, and *Daphnia* sp. as feed for fish.

AquaYouth – "Aquaculture Youth career development" service includes summer schools on innovative aquaculture technologies such as recirculating aquaculture systems, aquaponics, and integrated systems, study visits in modern, innovative farms and AquaVIP facilities, students' panels during branch events, and guide in aquaculture career with jobs catalogue, jobs presentations, films on success stories and farms presentations.

The summer schools delivered by the University of Gdańsk and Klaipeda University in May and June/July 2021 were both successful and introduced participants from the region but also from all over the world to background theoretical skills in modern aquaculture biotechnology: main types, biological and technological processes and development trends as well as practical hands-on experience on modern aquaculture technology and innovative blue biotechnology-based approaches. They were based on real ongoing AquaVIP experiments in RAS in research facilities, and partner aquaculture companies. Reports and presentations form the summer schools are available at the project website: aquavip.edu.pl.

AquaProfi – "Aquaculture Professionals' success support" service includes aquaculture professional trainings at Rostock University and is dedicated on the one hand for fish farmers aiming at becoming master fish farmers, but also for aquaculture professionals who are generally looking for further training opportunities. Thanks to the theoretical contents and practical training farmers upgrade their skills in innovative solutions which increase their business capacity and expand employability in the sector.

AquaTION – "Aquaculture innovation – boosting education and business capacity" is an e-learning platform, which will be developed on the basis of state-of-the-art knowledge, experience form previous aquaculture projects, and experimental and training activities of the AquaVIP project. AquaTION will offer training in skills related to innovative and sustainable aquaculture, crucial for the future employees in the aquaculture sector of the South Baltic area. The aim of the platform is to expand and promote aquaculture as a blue and green economy sector among employers and employees already active in the labor market, willing to improve their skills, as well as aquaculture students willing to make a career in the aquaculture market in the South Baltic area.

(Continued on next page)

Results

In the framework of the AquaVIP project, we put a strong base for strengthening aquaculture programs in the universities, provide hands-on-experience for academic communities and create conditions for changes in the labor market. Innovative aquaculture will bring benefit to businesses in our region and society in general – as it provides healthy, secure and regionally produced high quality food. The use of innovative environmentally friendly production technologies will also open new and international markets, providing further new jobs and blue-green growth in the South Baltic area.

ACLIMATATION OF MACROALGAE *Ulva ohnoi* IN DIFFERENT SALINITIES IN THE BIOFLOC SYSTEM

Ana Paula Mariane de Morais, Leila Hayashi, Felipe do Nascimento Vieira*

Universidade Federal de Santa Catarina – UFSC
E-mail: felipe.vieira@ufsc.br

Introduction:
Macroalgae are commonly used in IMTA systems due to their ability to absorb nitrogen compounds and phosphate (TROELL et al., 2009). The *Ulva* genus stood out due to its ability to reach high biomasses with high protein content (ROBERTSON-ANDERSSON 2003), in addition to being found all over the world and abundant in estuary environments. (PEDERSEN, 1995; RIVERS E PECKOL, 1995).

There are several environmental factors that affect Ulva growth and nutrient absorption. Among them, salinity is considered the most important, due to its reduction negatively affecting the growth and absorption of macroalgae nutrients (FONG et al. 1996, MARTINS et al. 2001), therefore presenting a tolerance to salinities of 20 to 40 ‰ (WU et al. 2018). In this way, it is possible that macroalgae that tolerate high concentrations of salinity have different strategies for the growth and absorption of nutrients. Green algae have the ability to withstand variations in salinity and opportunistic growth, so they are capable of rapid colonization and growth when conditions are favorable (LITTLER, 1980; MSUYA; NEORI, 2008).

Given the importance of aquaculture, the BFT system stands out for its increased production, however, it generates an excess of organic matter, nitrogen compounds and phosphorus. Therefore, due to its ability to absorb nitrogen compounds, and phosphate, it is expected that the macroalgae will be able to consume the nitrogen excess compounds and phosphorus, which they tend to accumulate in the production environment. The objective of the work is to acclimatize the *Ulva onhoi* macroalgae in different salinities in the biofloc system to be integrated in a multitrophic system.

Material and methods:
The experiment was carried out in the Laboratory of Marine Cameroon (LCM) of the Federal University of Santa Catarina (UFSC). The macroalgae of the species (*U. ohnoi*) were collected from the sedimentation pond of the UFSC marine mollusk laboratory, taken to the LCM where cleaning was performed manually with seawater to remove epiphytes and adhered animals.

The experimental design consisted of four treatments with three repetitions each, totaling 12 experimental units named: S15: salinity 15 ‰; S20: 20 ‰ salinity; S25: salinity 25 ‰ and S30: salinity 30 ‰. The experimental units consisted of white square tanks with 40 liters of useful volume for macroalgae production, allocated in a greenhouse. To acclimatize the macroalgae in the units, 25% filtered biofloc water (Bidim Bag filter) was inserted and filled with seawater to reach the initial salinity of 30 ‰ for all treatments. The reduction of salinity was performed daily by total changes of water in the tanks according to the salinity for each treatment (15, 20, 25, and 30 ‰).

The macroalgae were populated at a density of 2 g L^{-1} with an individual heating and aeration system. The nutrients came from the biofloc and it was considered a photoperiod of 10 - 12 hours and natural irradiance, weighed weekly to accompany the growth, when it exceeded the initial weight of 80 g, the excess was collected to calculate the final biomass at the end of the experiment. The experiment lasted 3 weeks.

Results:
The results show that there was no significant difference in the increase in biomass of macroalgae between treatments ($P > 0.05$). All reached biomass of more than 1500 g. Thus, the macroalgae adapted to the four salinities tested without mortality and there was an increase in biomass in all treatments.

Conclusion:
The macroalgae grew in all the tested salinities, demonstrating that it can integrate the multitrophic system in the salinities in any of the four salinities tested, opening the possibility of integrating them with species that support a lower salinity.

Introduction

The integration of different species aims at optimizing the use of nutrients generated by a primary fed species by employing other species that can take advantage of the excess nutrients, thus improving the use of resources of the overall production system (Chopin et al., 2001). Two species with the potential to be integrated are Pacific white shrimp (*Litopenaeus vannamei*) and Nile tilapia (*Oreochromis niloticus*). Poli et al. (2019) evaluated different Nile tilapia densities (10, 20, 30% of the biomass relative to the shrimp biomass) and found gains in yield and nutrient recovery, along with a reduction in the sludge: biomass relationship as the fish densities increased. In this work, the fish were fed at the rate of 1% of their biomass and the feed conversion ratio (FCR) observed by the authors was 0.2, indicating a relevant contribution of the bioflocs in the nutrition of the fish. However, there are no studies assessing if reared fish without feed supplementation can still maintain adequate performances impacting the overall integrated system, which would allow a reduction in the system inputs.

The microalgae *Scenedesmus obliquus* is freshwater green algae rich in protein and lipid contents, in addition to the carotenoid lutein. Its inoculation along with *Chlorella* sp. in a biofloc system benefitted the immune system of the fish (Jung et al., 2017). As consequence, the inoculation of microalgae species in biofloc-based integrated systems may enhance the biofloc attractiveness and nutritional composition, increasing natural food consumption by the fish and improving their growth performance.

Therefore, this study evaluated the supplementation of *S. obliquus* and fish feed in a Nile tilapia and Pacific white shrimp integrated system using biofloc technology and their effects on growth performance, production of solids and water microbiology

Material and methods

A two-factor 62-day experiment was conducted, in which each factor had two levels, addition or no addition of the microalgae *Scenedesmus obliquus* (5 mg L^{-1} twice a week) and the provision or no provision of fish feed (1% of the fish biomass), adding up to four treatments that were evaluated in quadruplicate. In all cases, shrimp were fed four times a day, according to a feeding table. The experimental units consisted of 800 L (useful volume) tanks for the shrimp and 90 L (useful volume) tanks for the tilapia, maintained under continuous recirculation. The shrimp (2.16 ± 0.01 g) were stocked under a density of 400 shrimp m^{-3} (320 shrimp $tank^{-1}$) and the fish (1.53 ± 0.12 g) were stocked under a density of 522 fish m^{-3} (47 fish $tank^{-1}$). Growth performance, sludge production and water microbiology were evaluated.

Results and discussion

Shrimp achieved a final mean weight of 12.1 ± 0.6 g and a survival of 78.3 ± 7.1%, with no significant differences between treatments. Fish that were fed exhibited final mean weight and final biomass 58% higher when compared with unfed fish. Fish survival was higher in treatments with the addition of microalgae (93.9 ± 1.8%) compared with the treatments of no microalgae addition (86.2 ± 7.6%). Fish final biomass was also 14% higher when microalgae was added (Tabela 1). The overall system yield was higher in the treatments with the provision of fish feed (4.2 ± 0.2 kg m^{-3}) compared with no addition (3.9 ± 0.2 kg m^{-3}). Sludge production did not differ significantly between treatments (1.0 ± 0.1 kg $tank^{-1}$), the same occurring with the count of total heterotrophic bacteria and *Vibrio*.

Conclusion

This work suggest that fish feed supplementation at the rate of 1% of the biomass improved fish growth performance and system yield, without affecting sludge production and water microbiology. The addition of *S. obliquus* under the concentration of 5 mg L^{-1} $tank^{-1}$ twice a week improved fish survival and final biomass. However, it did not significantly affect the overall system performance, sludge production and water microbiology.

Table 1. Nile tilapia (*Oreochromis niloticus*) growth performance when reared in integration with Pacific white shrimp (*Litopenaeus vannamei*) using biofloc technology for 62 days, evaluating the addition of microalgae and fish feed in a factorial design.

Introduction

New emerging ingredients have risen in recent years in order to follow the world shift towards sustainable aquaculture. These alternative ingredients (e.g., insect products, by-products of fisheries, aquaculture and animal production, bacterial biomasses and algae-based products) tend to replace those commonly used up to date (e.g. fish meal, fish oil, soybean meal) due to sustainability issues (Gasco et al., 2018, Oswald et al., 2019). The results here presented show what effects on performance and fish metabolism may be expected when formulations based on emerging ingredients are used in gilthead seabream. This work is part of the GAIN project (H2020 grant 773330, European Union) which aims to develop a new generation of sustainable fish feeds specifically designed to facilitate aquaculture eco-intensification through increased circularity and resource utilization.

Material and Methods

Growth performance and liver gene expression was assessed in *Sparus aurata* fed with four different diets: 1) a control diet containing fish meal and traditional soy products (CTRL); 2) a diet rich in processed animal proteins derived from farm animal by-products (PAP); 3) a diet with alternative ingredients without the inclusion of PAP (NoPAP); and 4) a diet containing a mixture of alternative ingredients (MIX). This nutritional trial was performed with four replicates, each one with 55 fish with an initial weight of 30g, at a temperature of 22±0.35ºC, during 9 weeks. Liver samples were analyzed by PCR-array for expression of 42 genes.

Results

At the end of the trial, no statistical differences were found in final body weight (FBW), relative growth rate (RGR) and voluntary feed intake (VFI). However, fish fed control diet showed higher protein efficiency ratio (PER), when compared to fish fed with other formulations. Additionally, fish fed with control and NoPAP diets presented a lower feed conversion ratio (FCR) when compared with fish fed PAP and MIX diets. When comparing between groups, the NoPAP group showed up-regulation of lipid metabolism-related genes (*elovl6*, *fads2*, *scd1a*, and *scd1b*) and downregulation of the lipolytic transcription factor pparα, when compared to the control group (Figure 1). In contrast, fish fed PAP diet presented down-regulation of performance-related genes (*ghr-i*, *igf-i*), lipid metabolism-related genes (*elovl4*, *elovl5*, *scd1a*, *fads2* and *hl*) and antioxidant defence-related genes (*cpt1a* and *cs*).

Discussion and Conclusions

The increased expression of *scd*, *fads2* and *elovl6* enzymes in NOPAP group is a typical characteristic feature of a reduced supply of n-3 LC-PUFA. On the other hand, the hepatic expression of fish fed the PAP diet was mostly opposite with a marked down-regulated expression of elongases (*elovl4, elovl5*), having PUFA as main substrates. Therefore, the new sustainable formulations tested in this trial did not affect much the fish growth performance, but liver gene expression suggests several adaptations to the different feed formulations, in particular for lipid metabolism, GH/IFG system and antioxidant defence. Taking together these results the PAP diet may lead to lower performance in the long-term.

Introduction

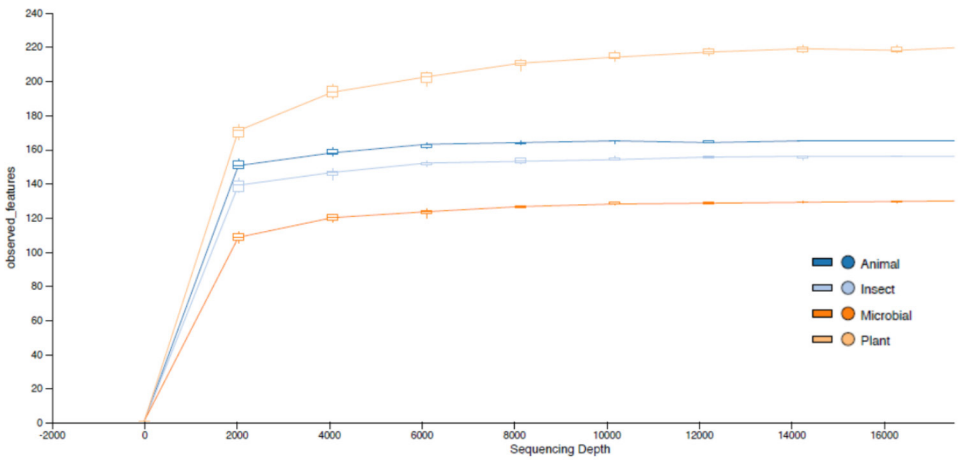
Among the major objectives of a more sustainable aquaculture, within aquaculture nutrition it is important to highlight the replacement of animal protein from marine origin for other protein alternatives such as: microalgae, seaweeds, microbial biomasses and insects. Those ingredients are rising as new emerging and sustainable ingredients, however not much is known about their effects in fish growth performance, health, and even less is known about effects in fish gut microbiome and metabolism in general. The objective of this trial was to assess the effect of different dietary protein sources on the growth performance and modulation of microbiome of Nile Tilapia (*Oreochromis niloticus*).

Materials and methods

A total of 180 Nile tilapia (*O. niloticus*) with initial body weight (IBW) of 12.14 ± 0.26 g, were transferred to 12 units (tanks of 90 L) totalling 15 fish per tank. The four diets were tested in triplicate and consisted on different protein sources such as: 1) a diet containing animal products (ANIMAL); 2) high levels of insect meal (INSECT); 3) two sources of bacterial biomass (MICROBIAL); and 4) plant products (PLANT). Fish were fed by hand, in two daily meals to satiation over 46 days. Fish were bulk weighed at the end of the trial and three fish per replica were sampled for intestinal microbiome analysis. Fish intestines were sampled following aseptically conditions to avoid contamination. DNA extraction was made using the DNA extraction High Pure PCR Template Preparation Kit (Roche, Portugal) preceded by a lysozyme lysis step as explained elsewhere (Falcinelli et al 2015). Illumina Sequencing by 16S rRNA gene amplification of the V1-V2 region was performed by Genoinseq (Centre for Neuroscience and cell Biology, Coimbra, Portugal) as previously described (Pereira et al., 2019). Sequences were filtered, denoised and merged using DADA2 (Callaham et al 2016) and downstream bioinformatic analysis was performed using Qiime2 version 2020.11 (Bolyen et al 2019).

Results

Final body weight (FBW) and standard growth rate (SGR) were higher in fish fed MICROBIAL and ANIMAL diets when compared to fish fed PLANT and INSECT diets. Additionally, feed conversion factor (FCR) was lower in fish fed ANIMAL diet when compared to fish fed PLANT and INSECT diets. Fat digestibility was higher in MICROBIAL and INSECT diets when compared to other diets. Regarding the microbiome analysis, it was possible to observe a reduction in abundance of Proteobacteria in fish fed INSECT, MICROBIAL and PLANT diets when compared to the reference diet (ANIMAL). Furthermore, PLANT diet influenced in the increase of observed features (Figure 1) when compared to ANIMAL diet, while MICROBIAL and INSECT decreased the bacterial diversity.



(Continued on next page)

Discussion and conclusion

Microbiota community modulation in Nile tilapia's intestines was evident after feeding with diets with alternative protein sources. Diets with higher fat digestibility were associated with the most relevant alterations in gut microbial modulation with a reduction in Proteobacteria abundance and overall, less diversity (MICROBIAL and INSECT). However, it is interesting that only in MICROBIAL group these changes are correlating with a better performance output. The most abundant phyla in Nile tilapia intestines were Fusobacteria and Bacteroidetes, mainly due to the strong presence of the *Cetobacterium* and *Paludibacter* from phyla respectively. These genera have also been found to be dominant in the gastrointestinal tracts of other freshwater species and have a positive impact in the digestion efficiency and metabolism of the hosts. Although no significant changes on the abundance of these phyla was observed, the reduction of Proteobacteria promoted several low-magnitude modulations in the microbial composition that might be involved in the observed performance differences. This study highlights the impact of different protein sources on tilapia's gut microbiome and provide insights on the axis diet-host-gut microbiome dynamics.

Introduction

Marine environment has been known as a rich source of bioactive compounds, such as proteins, amino acids, polysaccharides, fatty acids, vitamins, minerals, dietary fibers, sterols, pigments and polyphenols (Mišurcová et al., 2014), that have a huge functional and nutraceutical potential. Among these compounds, polysaccharides are recognized as one of the most promising sources of anti-inflammatory, antioxidant, antimicrobial, antiviral, anti-coagulant, and antitumor activities. Polysaccharides extraction is preceded by pretreatment with acetone and ethanol in order to remove compounds like polyphenols and pigments that are considered undesirable in polysaccharides extraction so those extracts are usually discarded. However, polyphenols and pigments are valuable biological resources of high exploitation potential. They are produced when these organisms are adapting to extreme environmental conditions (high salt concentration, low light, lower temperatures) they live in (Freile-Pelegrín and Robledo, 2013).

This study aimed to characterize and quantify polyphenols and pigments (spectrophotometric and HPLC analysis) in acetone and ethanol extracts from 10 different marine species from the Croatian coast of the Adriatic Sea: 2 green algae (*Ulva lactuca* and *Codium bursa*), 5 brown algae (*Fucus virsoides, Padina pavonica, Cystoseira barbata, Halopteris scoparia*, and *Cystoseira compressa*), 1 coral (*Eunicella cavolini*), 1 sea squirt (*Aplidium conicum*) and 1 sponge (*Chondrosia reniformis*).

Materials and methods

Ten marine organisms were collected from the coastal area of Croatia, washed in seawater and then rinsed with distilled water, frozen at -60 °C, freeze dried (CoolSafe lyophilizer, Model: 55-9 PRO, Labogene, Denmark) and milled. Extraction was performed in two successive steps: first 18 hours at room temperature with acetone and then 4 hours at 70 °C with 96 % ethanol. Extracts were filtered and stored at 4 °C until analysis.

Extracts were analyzed for total polyphenols (TP) content using spectrophotometric Folin-Ciocalteu method at 765 nm while chlorophyll-a (C_a), chlorophyll-b (C_b) and total carotenoids ($C_{(x+c)}$) content were measured at 470, 644.8, 648.6, 661.6 and 664.1 nm depending on the solvent used for extraction and quantified with appropriate equations (Lichtenthaler and Buschmann, 2001). HPLC system (Agilent Infinity 1260 system) equipped with Agilent photo-diode array detector (DAD) 1260 an automatic injector, Chemstation software and Zorbax Eclipse XDB-C18 column (4.5 x 250 mm, 5 um) (Agilent) was used for separation, identification and quantification of polyphenols according to Fecka and Turek (2008). The same HPLC system with C30 column Develosil, 5µm (250×4.6 mm I.D.) (Phenomenex, USA) was used for separation, identification and quantification of carotenoid and chlorophylls according to Castro-Puyana et al. (2016).

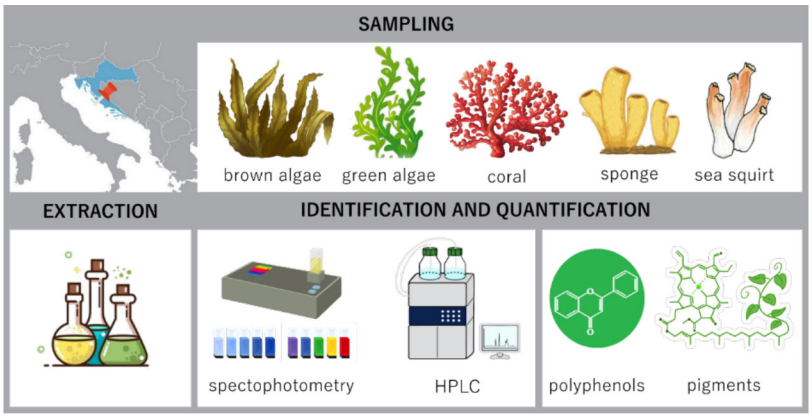

Figure 1. Schematic overview of the experimental design used in this research

(Continued on next page)

Results

The highest TP content in acetone and ethanol extracts were achieved in brown algae *C. barbata*, *C. compressa* and *F. virsoides*. Green algae *U. lactuca* and brown algae *F. virsoides* had the highest C_a and $C_{(x+c)}$ content among acetone extracts and *C. compressa* among ethanol extracts. The highest C_b content was achieved in green algae *U. lactuca*.

HPLC analysis also confirmed that brown algae have higher content of phenols than green algae. Detected phenols could be classified as hydroxybenzoic acid, ellagic acid and flavan-3-ols. Fucoxantine was predominant carotenoid in all brown algae, in acetone and ethanol extracts, followed by β-carotene, zeaxantine and lutein. These algae had significant amount of C_a but C_b was not detected. Opposite to the brown algae, green algae had significant amount of C_b and low amount of carotenoids. None of the carotenoids and chlorophylls were detected in coral *E. cavolini* and sponge *C. reniformis* while sea squirt *A. conicum* had only traces of C_a, fucoxantine and zeaxantine.

Discussion and conclusion

Different organisms have shown to have a diverse content of polyphenols and pigments and besides inherent characteristics of each species, environmental factors to which organisms are exposed, such as light, temperature, and salinity, may also affect their polyphenol and pigment contents (Osório et al., 2020). In general, results of our study showed that polyphenols and pigments content was significantly higher in brown algae, especially from *Cystoseira* and *Fucus* genus, while coral, sponge and sea squirt had very low content of polyphenols and pigments.

Brown algae contain high amount of phlorotannins, the most studied group of phenolic compounds from algae which possess a unique structure that is not found in terrestrial plants (Freile-Pelegrín and Robledo, 2013). Although the content of chlorophylls was higher than carotenoids in brown algae, the presence of fucoxanthin overlaps the presence of chlorophylls and other carotenoids in a macroscopic point of view and thus it is responsible for their brown color (Osório et al., 2020). Chlorophyll b is present only in plants and green algae what was confirmed by HPLC analysis.

Recirculating Aquaculture Systems (RAS) are a proven technology increasingly employed in the freshwater stage of Atlantic salmon production. Over the last decade many salmon producing regions have already begun to take advantage of the potential benefits of RAS technology in order to increase production and the overall size of Atlantic salmon smolt produced. The experience from a number of commercial farms is showing that smolts produced in RAS show better production performance in terms of growth and/or survival in sea cages than smolts from FT systems, however there is a need to verify these observations in a controlled manner (Ulgenes et al., 2008; Kolarevic et al 2014).

This study describes the design and performance of a small research recirculation system used in the production of Atlantic salmon smolts. Two commercial strains of Atlantic salmon were reared from first feeding to smolt in this RAS unit, the growth and performance was compared with fish reared in a conventional flowthrough system. The final weight achieved by the RAS stocks was 280g – Stock 1, 347g – Stock 2 and the flowthrough system, 89g – stock 1, 110g stock 2. After smoltification the fish were transferred to the Lehanagh Pool Marine Research Site, Marine Institute and the performance was monitored through four months post transfer.

A LONG-TERM DEVELOPMENTAL STUDY OF DEFORMITIES IN ATLANTIC SALMON: THE RECOVERY OF HYPER-RADIODENSE VERTEBRAE

Lucia Drábiková*, Per Gunnar Fjelldal, Adelbert De Clercq, M. Naveed Yousaf, Thea Morken, Charles McGurk, P. Eckhard Witten

Evolutionary Developmental Biology, Biology Department, Ghent University, Ghent, Belgium.
E-mail: Lucia.Drabikova@ugent.be

Introduction

Hyper-radiodense vertebrae (HDV) represent a frequently observed radiological deformity in Atlantic salmon *Salmo salar*, L. (Helland et al., 2006; Fraser et al., 2019). Increased radiodensity is caused by ectopic cartilage replacing adipose tissue in bone marrow spaces. In some cases, there are bent bone trabeculae due to anterior-posterior compression of the vertebral centrum (Helland et al., 2006). Animals have been observed with a single or up to four individual HDV. While HDV are found in freshwater stages, studies postulate that the deformity either disappears (Baeverfjord et al., 2009; Berge et al., 2009; Fjelldal et al., 2016) or exacerbates in seawater stages (Baeverfjord et al., 2009). Based on Helland et al. (2006) HDV is suggested to be related to mineral deficiency.

The specific fate of HDV in individual animals and factors inducing this deformity remain to be elucidated. This study comprised a seawater follow-up trial of animals previously subjected to deficient and excessive dietary phosphorus (P) in the freshwater (parr) stage (Drabikova et al., 2021). The study analysed HDV in individual PIT-tagged animals at (i) pre-smolt stage, (ii) seven months post seawater transfer, and (iii) at harvest size.

Materials and Methods

Atlantic salmon were studied from the parr stage (average weight 13.49 ± 1.50 g) until harvest size (average weight 4480.87 ± 1259.28 g). Parr were fed a diet with one of three levels of available P: low P (LP) (2.6 g/kg), regular P (RP) (5.9 g/kg), and high P (HP) (9.1 g/kg) for 11 weeks. Animals were subsequently PIT-tagged and fed regular commercial diets until harvest. Deformities were assessed on x-rays prior to smoltification, after seven months in seawater, and at harvest size. From each diet group, 45 animals (total no. 135) were x-rayed and assessed for HDV to progress or regress. A detailed analysis of vertebral anatomy and microstructures was conducted by Alizarin red S staining of mineralised bone and through serial histological sections.

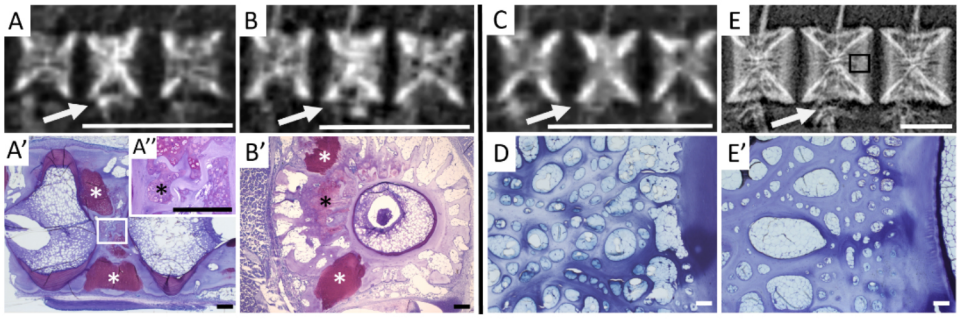

Fig 1. **Hyper-radiodense vertebrae (HDV)**. X-ray images (A-C,E, scale bar = 0.5 cm) and histological sections (A'-B',D,E', Toluidine blue staining, scale bar = 250 µm) of vertebrae from abdominal vertebral column region. HDV representatives (arrow in A-C; A'-B'), a regular (i.e. non-deformed) vertebra (D), and a fully recovered vertebral centrum with a HDV history (arrow in E,E'). (A-C) HDV with a characteristic increased radiodensity and anterior-posterior compression. (A') A parasagittal section of HD vertebra shown in (A) with ectopic cartilage tissue in bone marrow spaces. Intervertebral ligaments and spaces remain intact. (A'') Magnification of the white square in (A') shows detailed image of bent bone trabeculae and ectopic cartilage (asterisk). (B') Cross-section of HD vertebra shown in (B) with unilateral ectopic cartilage (left side) (black asterisk). The right side remains non-deformed. Regular cartilage at the bases of the vertebra is also present (white asterisks in A',B'). (C) HD vertebra present in an animal at the pre-smolt stage and (E) the same vertebra at harvest size. The black square in (E) shows the approximate location of (E').

(Continued on next page)

Results and Discussion

At the pre-smolt stage, HDV were detected in 30 out of 135 animals of which 26 had a LP diet history. Despite HDV, intervertebral spaces and ligaments remain intact (Fig. 1A-C).

All identified HDV had fully recovered seven months post seawater transfer with no traces of the previous deformity (Figure 1E-E'). All recovered HDV remained non-deformed for another six months until harvest. Bone trabeculae in recovered HDV were comparable with regular, non-deformed, vertebrae (Fig. 1 D,E').

HDV were observed to be uni-lateral, affecting the left side of the vertebra (Figure 1B'). This possibly relates to the uni-directional swimming in tanks with a small diameter (0.6 m). Bent bone trabeculae, a characteristic feature of HDV, are likely associated with soft, low-mineralised bone in animals with a LP diet history (Helland et al., 2006). This soft bone does not fracture under an increased compression load (Witten et al., 2019). Equally, bone trabeculae in HDV do not fracture but bend and are surrounded by ectopic cartilage (Fig. 1A'').

Introduction

Cultured Senegalese sole (*Solea senegalensis*) reared from egg to adult in captivity do not spawn spontaneously. Implementation of *in vitro* fertilisation procedures would appear to be a solution to this problem (Rasines et al., 2012). However, cultured sole produce small amounts of poor-quality sperm (González-López et al., 2020) that have been considered inadequate for *in vitro* fertilisation procedures. The sperm to egg ratio in fish has been observed to vary from 1,000s to 100,000s of sperm per egg (Beirão et al., 2019), with flatfish generally exhibiting the lowest sperm to egg ratios. The present study aimed to define the sperm to egg ratio required to achieve high levels of fertilisation on an experimental scale and using commercially relevant numbers of eggs.

Materials and Methods

The cultured Senegalese sole used were hatched and reared entirely in captivity (females of 1.53 ± 0.28 kg and males of 1.05 ± 0.25 kg). Fish were maintained in 10,000 L tanks in RAS (IRTAmar®) and fed a diet of polychaetes, mussels and pellets (Broodfeedlean, SPAROS). Photoperiod was natural and water temperature was constant 16 ± 1 ºC. Eggs were obtained by inducing ovulation by administering 5 µg/kg of GnRHa to females with mean oocyte diameter ≥ 600 µm. The females were held in total darkness until ovulation. Sperm was stripped from untreated culture males (González-López et al., 2020). Sperm concentration was measured (Thoma chamber) and motility assessed with ImageJ CASA. In a sperm to egg ratio experiment, sperm (n=5 males) was serially diluted with modified Leibovitz to obtain eight dilutions: 1:4; 1:19; 1:79; 1:319; 1:959; 1:2879; 1:5759; 1:11519 and triplicate fertilisations of 0.5 mL of eggs (n=5 females) were completed. After 24 hours of incubation (16ºC) the development of ≥ 50 eggs were determined per replica. In a proof of concept experiment > 100,000 eggs were fertilised with ≥ 150 µL of motile sperm in female – male pairs (n=7). Eggs were incubated and hatching rate assessed. In an egg viability experiment, three batches of eggs were stored at room temperature and fertilised at collection and at 30 - 60 minute intervals after collection. Egg development was assessed after 24 h. In a sperm collection experiment, the sperm quality (n = 13 males) was assessed when collected directly into a syringe containing Leibovitz (1:4), diluted in Leibovitz (1:4) 4 ± 2 minutes after collection and undiluted sperm.

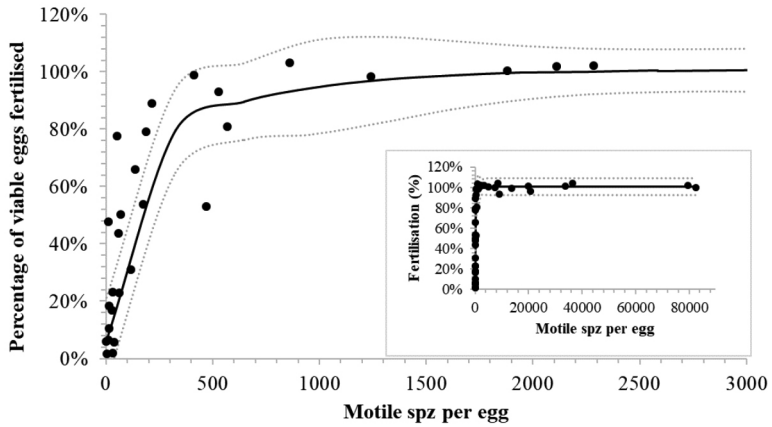

Figure 1. The percentage of viable eggs fertilised in relation to the number of motile spermatozoa (spz) per viable egg for Senegalese sole (*Solea senegalensis*). The insert figure shows the entire data set up to over 80,000 spz per egg and the large figure shows a close up of the data up to 3,000 motile spz per egg. The continuous line shows a non-linear regression and the dotted lines indicate 95% confidence intervals.

(Continued on next page)

Results and Discussion

Twenty eight males (60.9 % of 46 checked) had adequate sperm quantity and quality for the experiments. Eight (62% of 13 induced) females ovulated good quality eggs (82.6 ± 9.2 % fertilisation) that were used in the experiments. The mean time from GnRHa administration to ovulation was 41:57 ± 1:46 h, mean fecundity was 130,789 ± 36,723 eggs/fish or 87,174 ± 24,378 eggs/kg of body weight. In the sperm to egg ratio experiment the relationship between percentage fertilisation and sperm per egg was described by a non-linear regression based on an equation for an exponential rise to a maximum with double, five parameters ($R = 0.93$, $P < 0.0001$) (Fig. 1). Only 649 motile sperm fertilised 90 ± 13% (± 95% CI) of viable eggs and 1617 motile spz fertilised 99 ± 12% (± 95% CI) of viable eggs. In addition, percentage motility was negatively correlated to the number of sperm required to fertilise a viable egg ($R = -0.93$). However, there was no correlation between motile sperm required and percentage of viable eggs. In the proof-of-concept experiment the mean percentage hatch was 70 ± 14 % to produce 131,540 ± 34,448 larvae per fertilisation. The sperm from a single cultured male, mean volume of 145 ± 50 µL ($8 \pm 6.8 \times 10^8$ spermatozoa) was used to fertilise 190,512 ± 38,471 eggs, which gave a ratio of 592 ± 611 motile sperm per egg. The egg viability experiment indicated that the percentage of fertilised eggs gradually decreased with storage time with 81 ± 26% (± 95% CI) fertilisation after 30 minutes and 57 ± 20% (± 95% CI) after an hour. The sperm extraction experiment demonstrated that the percentage motility was significantly ($P < 0.05$) higher in samples collected directly into modified Leibovitz (33.4 ± 3.5%) compared to dilution 4 ± 2 minutes after collection (6.6 ± 1.6%) or undiluted sperm (2.9 ± 1.2%).

Senegalese sole was amongst the lowest sperm to egg ratio recorded in fish (Beirão et al., 2019). The possible relationship between low sperm to egg ratio and sole reproductive characteristics such as paired-spawning, gamete fertilisation in close proximity with no sperm competition will be discussed. Eggs should be fertilised as soon as possible after ovulation and sperm quality was improved with early dilution in modified Leibovitz. The low sperm to egg ratio was tested and shown to fertilise large amounts of eggs (>100,000) with the sperm from a single cultured male (approx., 200 µL of sperm per 100 mL of eggs).

Introduction

The sustainable aquaculture production of Senegalese sole (*Solea senegalensis*) has been frustrated by the failure of hatchery produced sole to spawn fertilised eggs. The present work has implemented *in vitro* fertilisation techniques on an industrial level to secure closing the biological cycle and sustainable aquaculture production. The project REARLING, funded by the Portugal 2020 program, Compete 2020, and the European Union through FEDER/ERDF lead by Safiestela Ltd. (www.sea8.eu) aimed to test and implement on an industrial scale technologies using *in vitro* fertilisation protocols, which had been demonstrated on a laboratory scale (Ramos-Júdez *et al*., 2021) and the application of recombinant gonadotropins (Rara Avis Biotec, https://www.raraavis-bio.com) to increase sperm production (Chauvigné *et al*., 2018).

Materials and Methods

The Senegalese sole females (0.9 ± 0.1 kg) used for industrial level *in vitro* fertilisation were hatched and reared entirely in Safiestela Ltd. The cultured females were the 1st generation reared in captivity from eggs spawned naturally in Safiestela Ltd facilities from wild sole captured in northern Portugal. Wild males (0.8 ± 0.1 kg) were used to provide sperm. Sole were maintained in 5000 L tanks in RAS and fed pelleted diets (Broodfeedlean, SPAROS), and fresh food. Photoperiod was natural and water temperature was constant 17 ± 1 ºC. For the data presented here a total of 165 cultured females and 171 wild males were used. The females were induced in groups from 2 to 25 females. Eggs were obtained by inducing ovulation with the administration of 25 µg kg^{-1} of GnRHa to females that had a mean oocyte diameter ≥ 600 µm. The females were held in total darkness until ovulation. Sperm was stripped from wild males. Sperm concentration and motility was assessed subjectively zero, low, medium and high. Sperm with high concentration and motility was used. A total of 0.1 mL of sperm was used for each 100 mL of eggs. Sperm was obtained first and stored over ice until the females ovulated and eggs were obtained. Eggs were incubated in large industrial egg incubators and percentage fertilisation and number of larvae obtained were assessed.

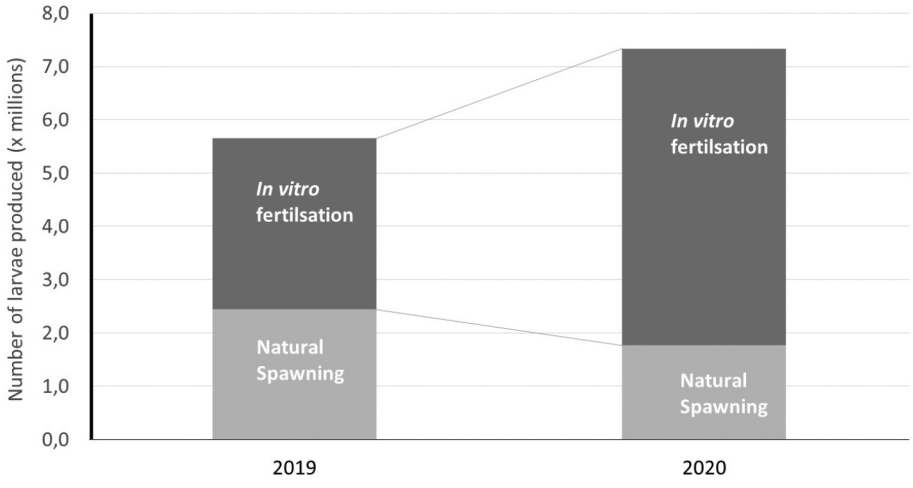

Figure 1. Number of Senegalese sole (*Solea senegalensis*) larvae produced from *in vitro* fertilisation (dark grey) and natural spawning (light grey) during the two years, 2019 and 2020, of the Rearling project coordinated by Safiestela Ltd.

(Continued on next page)

Results and Discussion

Approximately half of the males checked were rejected as sperm quantity or quality was insufficient. The average quantity of highly concentrated motile sperm obtained from a male was 0.1 mL. A total of 14 groups of females ranging from 2 to 25 females were induced. The mean time for females from GnRHa administration to ovulation was 40 h, and the mean volume of eggs obtained from a female was 100 mL. Approximately 12 males were required to fertilise a litre of eggs. Eggs from groups of females were incubated together. The mean percentage fertilisation of the 14 groups of eggs was 40.0 ± 18.1 %. Large numbers of larvae were produced for the larval rearing facility (Fig. 1).

In the first year (2019) of the project, 3.21 million larvae were produced using the *in vitro* fertilisation technology implemented in Safiestela Ltd. In comparison, 2.44 million larvae were obtained from naturally spawning wild broodstock. In the final year of the project (2020), the success of *in vitro* fertilisation enabled a large increase in the production of larvae with 5.57 million larvae produced from *in vitro* fertilisation and less than a quarter of all the larvae (1.77 million) being provided from naturally spawning wild broodstock. The *in vitro* fertilisation technology gave control over reproduction that has ensured that Safiestela Ltd has both increased production of the entire company and initiated a genetic breeding program based on desirable performance characteristics of the Safiestela Ltd stock.

In addition to the implantation of *in vitro* technologies, Safiestela Ltd used recombinant gonadotropins produced by the company RARA AVIS BIOTEC SL to increase good quality sperm from cultured Senegalese sole by approximately 10-fold. This gives the potential to ensure good quality sperm from all males avoiding discarding half of males checked for sperm and, therefore, both reducing time needed to evaluate males and the wasteful practice of growing male breeders that produce small qualities of poor sperm.

Taken together, the project has implemented *in vitro* fertilisation technologies and methods to enhance sperm production in the Senegalese sole. This has removed the reliance on sometimes unpredictable spawns from wild broodstocks, and Safiestela Ltd now has full control to program the timing and quantity of fertilised eggs that are produced.

Against the background of the stagnating EU aquaculture sector growth in contrast to the increasing sector size at world level (including Norway), it is important to address prevailing hindering factors such as import pressure or social pressure due to actual and perceived environmental impacts. Within the H2020 project Green Aquaculture Intensification (GAIN) innovative production tools based on the principles of circular economy were developed and evaluated in order to facilitate the paradigm shift of eco-intensification in European aquaculture. While the valorisation of side-stream products is beneficial for a more sustainable production, related changes in production practices, may impact capital investment, labour input or energy demand, all of which affect costs. We applied an established benchmarking approach to contrast today's economic performance of "typical farms" using the conventional ensilage method with their profitability when processing mortalities within a drying unit. Further, in-depth cost-benefit analyses were conducted for a theoretical decoupled algae aquaponics system (*Ulva lactuca*) utilizing disposal water from smolt RAS production; as well as an input-output based economic analysis for the valorisation of aquaculture fish by-products (FBP) on industry scale. The results reveal a promising economic balance for various market opportunities such as selling dried mortalities to the pet food sector or *Ulva lactuca* to the Asian market with the side-effect of reducing the nutrient load of European smolt waste water and potentially increasing smolt production. Processing various FBP into secondary products also proved to be promising approaches for fish protein hydrolysate, peptones and their further use as medium e.g. for lactic acid bacteria. The profitability of the examined pathways were based on accessible market prices. Further key aspects for future marketing success will also include market access and consumer demand.

GENETIC ANALYSIS OF SEVEN NATURAL POPULATIONS OF TENCH (*Tinca tinca* L. 1758.) IN HUNGARY – ESTABLISHMENT THE BIOLOGICAL BASIS OF SELECTIVE BREEDING

Introduction

Tench (*Tinca tinca* L. 1758.-) is a medium sized *Cyprinid* species with Euro-Siberian distribution and the species is considered native in the Danube catchment area in Hungary. The species main habitats are small shallow lakes, oxbow lakes, calm bays and streams with slow currents and with well warmed waters in summer and with plenty of submerged vegetation and muddy bottoms. As an eurythermal species the tench can survive even 37°C of water temperature for short periods of time, although the lethal temperature is 35.3°C for the species. During its evolution tench developed the ability to survive with extremely low levels of oxygen, which means that the species will survive with less than half the requirement of the common carp. These characteristics qualify the tench to successfully face the effects of climate change. Nowadays the production of the species is marginal in Hungary but with the changing environment the tench may become more important in Hungarian Aquaculture. In order to support the development of tench production, the development of a selective breeding programme is necessary for the species to utilize its genetic reserves. As a basic step of the selective breeding programme in the present study we studied the genetic variability of seven populations of the species living in natural habitats in Hungary using 12 microsatellite DNA markers.

Materials and methods

Fin samples were taken from 178 tench individuals from seven different natural populations in the country's eastern, central, and western regions. The simple salting out technique, as reported by Miller et al. 1988, was used to isolate DNA. The quality and quantity of the isolated DNA were assessed by the NanoDrop™ spectrophotometer. As described in the original publications, PCR amplification was performed using 12 microsatellite DNA markers (MTT-1, MTT-2, MTT-3, MTT-5, MTT-6, MTT-8, MTT-9, MT-3, MT-6, MT-8, CypG24, and MFW1). The PCR products were analyzed using an automated ABI Prism 3130 Genetic Analyzer. The length of fragments was assessed using the Genotyper 4.0 software. GenAlEx6.501 was used for the main statistical analysis. To identify genotyping errors, allele dropouts, and null alleles, MICRO-CHECKER version 2.2.3 was employed. A Bayesian clustering analysis was performed to assess the genetic relationship between populations and individual assignments using the statistical software STRUCTURE version 2.3.3.

Results

The results of the microsatellite analysis showed that the genetic variability of the examined seven tench populations is moderate. The populations deviated from Hardy-Weinberg equilibrium in case of 0 to 3 markers. The average number of alleles (Na) per locus ranged from 2.5 (Derecske) to 4.25 (Fertő Lake) while the allelic richness ranged from 2.06 (Derecske) to 3.32 (Fertő Lake) respectively. Altogether the lowest diversity was observed in the Derecske population, both the heterozigosity and private allelic richness was significantly lower in case of this stock and this population showed the highest F value. Fertő Lake and Szaporca (Drava River) represent the highest diversity in the study. The basic population genetic characteristics of the stocks are listed in **Table 1.** Four genetic clusters were detected by the Structure analysis (k=4). The first cluster is frequent in the North-West region (Fertő Lake), the second in the Middle-Eeast region (Kolon Lake, Derecske), the third in the Middle and South-West region (Csörnöc, Szaporca) and the fourth in the Eastern region (Cibakháza) of Hungary. Tisza Lake stock is a mixed population with equal frequency for all clusters (most probably as a result of human impact – tench is stocked regularly in this water body).

(Continued on next page)

AR_p	0.40 ± 0.42 a	0.12 ± 0.22 ab	0.16 ± 0.21 ab	0.02 ± 0.06 b	0.12 ± 0.31 ab	0.12±0.31 ab	0.10±0.29 ab

Table1. Basic population genetic characteristics of the stocks (Na:number of alleles; Neff:number of effective alleles; Ho:Heterozigosity observed; uHe: unbiased expected heterozigosity; F: Fixation index; AR: allelic richness; ARp: private allelic richness)

The pairwise Fst values between population pairs were low or moderate. The Nei's genetic distance ranged between 0.015 and 0.139 between population pairs. The 73% of molecular variance was found within individuals while 20% among individuals and only 7% of variance was found among populations.

Discussion and conclusion

The genetic variability of the local stocks ranges from low to moderate and the variability levels are lower compared to other *Cyprinids* such as Common carp (Kohlmann et al 2003), however they are similar and comparable to variability data described in Tench by Kohlmann et al. 2007. In order to start a successful selective breeding programme the inclusion of the greatest possible genetic diversity is necessary. Based on the results it is suggested to involve Fertő Lake and Szaporca populations in such a programme together with populations that represent high number of private alleles such as Csörnöc (ARp: 0.16).

Introduction

Economically viable microalgae companies established in Germany produce food supplements or extracts for cosmetic or pharmaceutical applications. However, these value chains generally do not consider side streams from agricultural production processes and often do not have sustainable energy or quality assurance concepts.

The aim of the planned project that has recently started (June 2021) is to establish an aquatic value chain with the production organism *Arthrospira platensis* predominately based on residue biogas waste streams (liquid digestate and heat) on side of the biogas plant. The main product is C Phycocyanin (C-PC) as a food, feed supplement and cosmetic raw material in organic quality.

Material & methods

Arthrospira platensis will be obtained from different German culture collections. The anaerobic digestate used to test biogas digestate will be obtained from the project partner INPUT who operates a biogas plant near Hannover (Lower Saxony) in an industrial scale with maize silage and animal manure (cattle slurry/manure, dry chicken manure). The operating parameters of the biogas plant are as follows: hydraulic retention time 30 days, organic loading rate 9-11 kg volatile solids (VS)/m3·day, anaerobic sludge concentration 8-9%, temperature 40-45 °C. Before using as a nutrient medium, anaerobic digestate will be processed. First the solids are separated from the liquid. Then, in series 1, digestate was centrifuged (MPW-251, Donserv, 5000 rpm for 5 min) and then pasteurized (30 min, 90 °C). In series 2, digestate was distilled at 100 °C in distillation flasks with the working volume of 200 cm^3.

In the planned experiment, the volume of liquid digestate used to prepare the culture medium constituted from 10 to 50 % of the medium volume. For dilution of the liquid digestate, deionized water was used. As a control, *A. platensis* will be grown on a 100 % synthetic medium (Zarrouk) without adding any liquid digestate (control) and four different digestate residue-based media (chemical conditions to be determined after chemical composition analysis of the digestate) (Figure 1). Growth of *A. platensis* will be determined by dry matter concentration following according to Bundesamt für Verbraucherschutz und Lebensmittelsicherheit [1]. Phycocyanin concentration will be determined following the protocol of Siegelman and Kycia 1978 [2].

Fig. 1: Experimental design of biogas liquid digestate testing for the cultivation of *Arthrospira platensis* and respectively Phycocyanin production.

(Continued on next page)

Expected results to be presented at EAS

At EAS 2021 preliminary growth results and phycocyanin contents of *A. platensis* grown on four different biogas digestate residue-based media will be presented. Experiments are currently conducted and first data will be available and analysed prior to this conference.

EX VIVO MODELISATION TO DETERMINE THE EFFECT OF A STANDARDIZED DRY GRAPE EXTRACT TO PROTECT SIBERIAN STURGEON *Acipenser baerii* RED BLOOD CELLS FROM OSMOTIC STRESS

P. Engler*, Y. Sakr, G. Le Reste, P. Garsi, S. Calvez and P. Chicoteau

Nor-Feed, 3 rue Amedeo Avogadro, 49070 Beaucouze, France
paul.engler@norfeed.net

Introduction

In aquaculture, oxidative stress can be induced by degraded water parameters such as salinity changes. Previous work showed that a standardized dry grape extract (SDGE) could be used in an *ex vivo* challenge to improve the stability of rainbow trout (*Oncorhynchus mykiss*) red blood cells (RBC) when exposed to an osmotic stress. The aim of this work was to extend the research on another anadromous species of fish, Siberian sturgeon (*Acipenser baerii*).

Material & methods

RBC solutions (RBCS, 25% v/v) were prepared from blood collected on healthy sturgeons, then mixed with phosphate buffer saline (PBS, pH = 7.4) and solutions of SDGE (Nor-Grape® WS, Nor-Feed) at various concentrations (1, 2, 3 and 6g/L in PBS). They were incubated at 56°C for 30 minutes, to induce a hemolysis reaction and were then centrifuged at 5000 rpm for 10 minutes at room temperature. The released hemoglobin was measured by spectrophotometry at 560 nm.

Results

Results evidenced that standardized dry grape extract at the two highest concentrations (3 and 6 g/L) reduced hemolysis of RBC to 32.4% and 35.6% respectively (Figure 1.), compared to the lowest concentration (1g/L, 95.5% hemolysis).

This work showed the positive impact of a SDGE on the stability of RBC from Siberian sturgeon when exposed to an osmotic stress, in a similar way than with rainbow trout RBC.

Discussion

Further research is required to establish if a dietary supplementation with a SDGE in the fish diet could evidence the same effect to manage oxidative stress, induced by the fluctuation of salinity, in order to reduce oxidative damage fish cells.

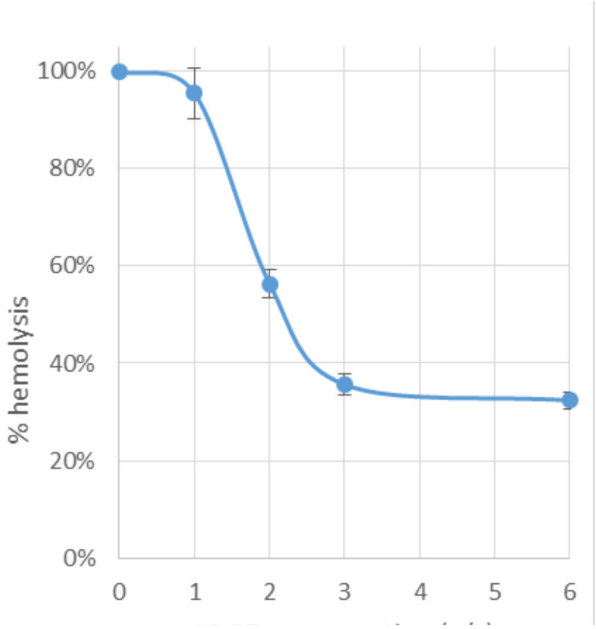

Figure 1. Effect of various SDGE solutions on hemolysis resistance of sturgeon RBC exposed to an osmotic stress.

SEARCH FOR BIOMARKERS OF RESISTANCE IN *R. decussatus* TO *P. olseni* PARASITE INFECTION

Introduction

The grooved carpet shell (*Ruditapes decussatus*) is a bivalve mollusc species with a distribution from NE-Atlantic coast and Mediterranean Sea. This species is highly desirable and sold at high prices being Portugal the top-seller (FAO, 2020). A decline on the species happened since the 90´s due to biotic and abiotic factors, such as parasite infection and degradation of the environment. Infection by *Perkinsus olseni* parasite is the main biotic factor that causes decrease of populations. It was first diagnosed in the 1980s, after introduction of the invasive species *Ruditapes philippinarum* from Asia for intensive production in Europe (Vilas et al., 2011). It has been observed that *Perkinsus* causes changes in humoral and cellular responses and rise of mortality in infected individuals. Epizootic studies indicates that temperature and salinity influence host-parasite interaction, especially in adults. Despite of lacking an adaptive immune system, this species has demonstrated to thrive in highly affected areas, reaching adult phase and surviving high parasite prevalence (Villalba et al., 2004)some of which are associated with mass mortalities. Life cycle involves vegetative proliferation within the host, by which a cell named trophozoite undergoes successive bipartitioning. Other stages have been observed in vitro or in vivo, depending on the species: hypnospore, zoosporangium and zoospore. Molecular taxonomy supports a close affinity between dinoflagellates and Perkinsus spp. Six species of Perkinsus are currently considered valid: P. marinus, P. olseni, P. qugwadi, P. chesapeaki, P. andrewsi and P. mediterraneus. Histology and, above all, incubation of host tissues in Ray's fluid thioglycollate medium (RFTM.

Several studies focused on host-parasite early interaction and markers of resistance (Fernández-Boo et al., 2016; Hasanuzzaman et al., 2017; Cruz et al., 2020)the effects of longer term infection were assessed in adult clams collected from a P. olseni-affected bed, by comparing moderate to very heavily infected clams with non-infected ones. Haemocyte and plasma proteins were separated by two-dimensional electrophoresis; spot patterns were qualitatively compared between treatments within each experiment and the spots indicating differential protein expression associated with P. olseni challenge or with field infection were processed for protein identification. Fifteen clam proteins (four in haemocytes and eleven in plasma, while none addressed the presence of tolerance/susceptibility signatures in different populations. Thus, this study seeks to identify markers of tolerance/susceptibility in populations of *R. decussatus* affected by *P. olseni* by looking at the haemolymph´s proteome profile of tolerant individuals in comparison with susceptible ones.

Table 1. *Number of identified proteins from the three analyses.*

Analysis	Exclusive Proteins			DE [a] proteins (A. R. [b] ≥ 1.50 and ≤ 0.67)[c]		
	Susceptible	Tolerant	Total	Suscep/ Toler	Toler/ Cont	Total
Susceptible vs. Tolerant	0	2	2	37	4	41
Tolerant vs. Control	12	1	13	25	90	115
Algarve	10	9	19	34	37	71
Naples	255	7	262	181	31	212
Pontevedra	23	1	24	198	12	210

[a] Differentially Expressed. [b] Abundance Ratio. [c] Considering abundance ratios obtained from Proteome Discoverer software (abundance ratio *p*-value was not considered).

(Continued on next page)

Materials and Methods

Five populations with high prevalence of the parasite across Europe namely, Pontevedra (Spain), Algarve (Portugal), Naples (Italy), Venice (Italy), and Izmir (Turkey) were sampled. A *Perkinsus*-free population (Noia, Spain) was used as control.

After *Perkinsus* diagnosis and haemolymph extraction, 5 individuals highly infected (susceptible) and 5 individual non- or low-infected (tolerant) were chosen at each population for a proteomics analysis by LC-MS. Three analyses were considered to identify markers of tolerance/susceptibility: i) Tolerant vs. Susceptible (in all populations); ii) Tolerant (in all populations) vs. Control (Noia population); iii) Tolerant vs. Susceptible (at each population). Expressed and exclusive proteins were identified according to Osório *et al*., 2021. Functional annotation was performed on identified protein from all analyses to pinpoint the expression profiles using the Blast2Go software.

Results and discussion

A substantial number of exclusive proteins was identified in the Naples population, followed by Pontevedra. The same tendency was observed in the differentially expressed proteins, being the number of predominant in the susceptible individuals in both exclusive and differentially expressed proteins (Table 1). These results indicate a higher response on affected individuals from these populations to parasite infection. Functions related to metabolism were most represented in susceptible than in tolerant individuals suggesting a higher production of energy to counteract the infection. Also, six proteins were differentially expressed in all tolerant individuals and seem to be possible markers of tolerance to *P. olseni* infection.

These results point towards a host generated tolerance suggesting an existence of adaptation mechanisms to parasite.

Introduction

The evaluation of aquaculture performance is a difficult task as full-scale aquaculture production is affected by numerous parameters, such as structure and size of culture units, environmental conditions (temperature, water flow, winds, fouling, etc.), husbandry (feed and feedig pracices, fish handling, monitoring, etc.), which are very difficult to be mimicked at reseach scale. The evaluation of performance should be addressed with a multidisciplinary approach, difficult to be mimicked at research scale, and very expensive at a pilot or commercial scale. Consequently, the evaluation of causes behind a poor zootechnical performance is a very difficult objective for aquaculture managers, as the above mentioned parameters are interrelated and the sector operates with low profitability margins and on a highly competitive international scale.

Material and Methods

Two fish farms in two different locations in the Mediterranean Sea - in East Mediterranean (Galaxidi Marine Farm, Phocis, Greece) and in West Mediterranean (Cudomar, Campello, Alicante, Spain)- were selected to carry out this case study.

Same batch of fish (seabream fry from Galaxidi) was selected for the experiment and 82,000 juveniles (3g) for each farm were transported in June 2018 to the 2 owgrowing cage farm locations. Fish were grown in the same type and diameter (16 m) sea cages in both farms. Initially ongrowing in the farms, until the fish reached 100 g average weight, was implemented using each farm standard feeds (provided by Irida in the case of Galaxidi and by Dibaq in the case of Cudomar). From 100 g until harvest (420-445 gr) the farms followed the recommendations designed by MedAID about feed composition and feeding practices obtained in the trials carried out in MedAid WP2:

1. Use of 45/16 Protein/Lipid and 25/16 FM/FO ratios during winter conditions and 44/20 Protein/Lipid and 16/7 FM/FO in summer
2. Use only 1 dose of food per day during ongrowing
3. The feeds were selected (Table 1) following the recommendation 1 and were distributed in only one dose per day (recommendation 2)

Every month fish were sampled to asses their growth in weight. Environmental conditions (temperature, salinity, oxygen, pH) and disease and/or mortality events were also recorded.

At the end of the ongrowing period around 1000 fish were sampled for assesing their final weight, fillet quality and biochemical composition. For that purposes the fish were slaughtered and eviscerated to record visceral weight, abdominal fat weight, heart weight and fillet yield

Table 1. Biochemical composition of the feeds used during the final ongrowing period in the sea cages

	Nutraplus SP	Vital M
Protein (%)	45.0	45.0
Fat (%)	16.0	20.0
Cellulose (%)	2.7	2.8
Ash (%)	6.5	8.0
Moisture (%)	9.0	10.0
Crude Energy (MJ/Kg)	20.2	21.1
Digestible Energy (MJ/Kg)	16.8	17.5
FM/FO	22/7	16/7

(Continued on next page)

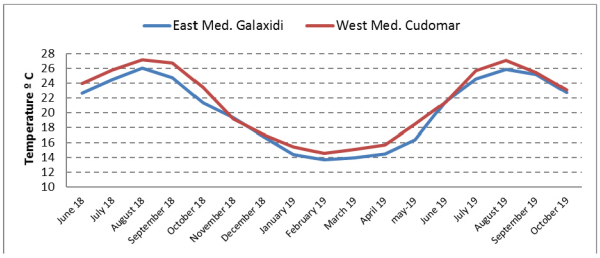

Fig 1. Evolution of monthly average water temperature during the ongrowing study.

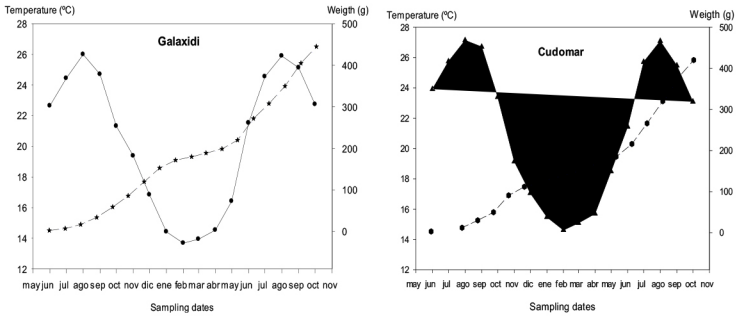

Fig 2. Results of temperature (^{0}C) and growth (g) obtained in Galaxidi and Cudomar sea cages.

Growth rate was evaluated as specific growth rate (SGR) and relative growth rate (RGR) Thermal growth Coefficient (TGC) and Feed Conversion Ration (FCR) were also calculated taken into account the feed provided during the ongrowing period (16 months) and the growth of the fish.

Results

The evolution of monthly average water temperature during the ongrowing study showed a similar pattern in both locations (East Mediterranean and West Mediterranean), with slighty higher temperatures in Alicante, Spain (Figure 1). Oxygen and salinity were also periodically recorded, being 8.19±0.23 mg/l of oxygen in Cudomar and 6.10±0.67 mg/l in Galaxidi and 37-38 ppt salinity in Cudomar and 39-40 ppt in Galaxidi.

FCR in East Med Galaxidi (1.85) was slightly higher in Galaxidi than Cudomar (1.65), although no statistically significant differences (Student's t test, P=0.955) in terms of growth (SGR, Fig. 2) or conversion rate (FCR) (Student's t test, P= 0.667) were found between the two sea cages.

Feeding with a lower cost diet (lower DP/DE and FM/FO) during low temperature months does not affect feed conversion performance. Moreover, our results at pilot scale are sligthy better than other references for commercial feed conversion for marine fish in the Mediterranean, such as that reported by García-García et al. (2016) for seabream (FCR= 2) grown for 18 months in Spanish Mediterranean (Murcia) from 12 g to 450 g in 25m diameter cages.

Althought it was not the purpose of this work to estimate the economic benefit of using a lower cost diet (10% cheaper) during low temperature months (February-June), our estimation showed a 3% reduction on the feed cost. Being the cost of feed the highest cost in seabream production, this measure would certainly be a well-meaning recommendation to be considered by Mediterranean farmers. Proximate and fatty acid composition of the fillet was also analysed and presented in the Congress.

Introduction

In order to implement the 2030 Sustainable Development Goals (SDGs) of the Food and Agriculture Organization of the United Nations (FAO), production capacities in aquaculture must be increased and resources must be conserved. This can only be achieved if fish health is improved and fish death rates are reduced, thus saving feed and water. It is therefore essential that aqua culturists and fish farmers are motivated to use suitable technological solutions such as monitoring systems. An optimally aligned monitoring system can balance farming conditions, animal health and efficient use of resources. These are prerequisites for sustainable aquaculture, the production of quality products and profitable sales. Because the knowledge of animal welfare in general is rudimentary the overall production success is reduced. Animal welfare is not only important from an ethical point of view, it also forms the basis for the harvest and thus, the revenue of each farm. Therefore, the goal is to develop a novel non-invasive monitoring concept and system for selected aquaculture organisms (AKO) with physicochemical sensors and image sensors via the cloud-based software AnFish including the determination of physical and chemical water parameters, activity patterns and the condition of the animals. Through this, we are able to assess stress and health conditions of aquatic organisms in different stages of production from hatching to harvest. This allows real-time optimization of fish production processes. Furthermore, with a software like this we are able to digitally certify farming conditions and aquaculture facilities.

Material & methods

Fishes are stocked in experimental units under various conditions (single housed to commercial conditions in terms of density, size, light, etc…). Numerous cameras are installed above the experimental units to record constantly. Image captures are recorded under various conditions. Further data recorded manually are the number of fish, weight and biomass, mortality, signs of illness and stress.

In addition, the standard built-in sensors continuously record the water quality. Furthermore, the work includes the extension of the software module for camera control around the digital focus, its porting for the new development platform (Raspberry Pi 4, Ubuntu), as well as the elimination of various driver problems.

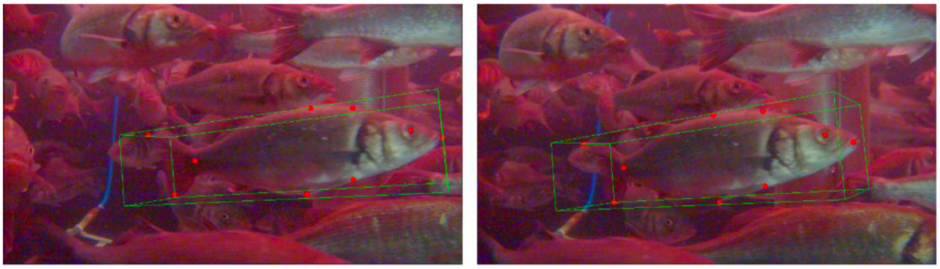

Figure 1 Visualization of a survey result with point features and enclosing 3D cuboid

(Continued on next page)

Results
At EAS 2021, preliminary results of the image analysis and the interaction of various physical/chemical sensors of the recordings will be presented. Currently, the final experiments are being performed and a higher-level analysis/model is being developed from the data, which will be available and analysed before the upcoming conference.

We would like to present:
- Overall experimental setup
- Preliminary results of digital/automated counting of fish primarily coupled to biomass as well as single individuals
- Stereo matching and the 3D reconstruction

Discussion and conclusion
Preliminary final results on automated counting as well as biomass determination of food fish (considered key data for successful software development) will be presented at EAS 2021. Reliability of initial data (number of digital counts vs. manual counts and vs. starvation condition) will be discussed and approaches for detection algorithms comparing metadata to a fish behavior database will be presented.

Introduction

Optimal husbandry conditions, healthy animals and innovative raw materials are prerequisites for the sustainable aquaculture of animal organisms, the production of quality products and profitable sales. Even if, from a human perspective, fish grow up successfully in aquaculture, knowledge about animal welfare itself is rudimentary and production success is reduced correspondingly.

Aquaculture always involves a high economic risk for the fish farmer, up to and including total loss caused by undetected diseases in the fish or even environmental toxins. Comprehensive monitoring of the fish kept can not only minimize these risks, but also improve the economic yield and ultimately make fish farming more environmentally friendly. To reduce these risks, MonitorFish GmbH has developed innovative software solutions such as ANFISH© and OptoFish©. MonitorFish GmbH is a startup company of the Berlin University of Applied Sciences which is intensively involved in the development of software solutions for the optimization of fish farm production management. Their software works cloud-based and uses artificial intelligence to improve their own analytical precision and speed. Within the project BioFiA a comprehensive approach to analyse stress in Atlantic salmon (Salmo salar) during different microalgae diets and at different salinities is conducted. In this framework, the MonitorFish software is adaptated to and validated within trials.

Material & methods

Biochip-based molecular indicators can be used to measure stress, health and welfare of aquatic organisms at different stages of production from hatching to harvesting, to certify husbandry conditions and aquaculture facilities and thus optimise fish production processes right through to the slaughter process.

Within the framework of the project, the use of such self-developed species-specific molecular biochips is planned for key production stages. Especially the juvenile life stages with high mortalities will be intensively considered. For this purpose, a comprehensive monitoring of the rearing conditions with physicochemical and image sensors (e.g. water parameters, activity patterns, health status) is carried out. This also includes the detection of bacteria and parasites. Big data analyses of the monitoring data are carried out using AI algorithms. The comprehensive sensory analysis allows an early assessment and even prediction of animal welfare in real time. The project focuses on the recording and reduction of negative influences in aquafarming, in particular juvenile development stages and the mechanical processing of fish, the influence of microbiological parameters on the health of aquaculture organisms and microalgae as innovative probiotic feeds. In addition, the product quality as food for humans is tested. The networking of the project with the subproject BaMS-AQUATOR will lead to the testing of industrial usability and feasibility studies.

MONITORFISH

Project partners are

- Christian-Albrechts-Universität zu Kiel, Institute for Animal Breeding and Husbandry
- Society for Marine Aquaculture (GMA) mbH
- Research Institute for Farm Animal Biology (FBN), Institute for Genome Biology, Dept. of Fish Genetics
- Max Rubner Institute (MRI), Federal Research Institute for Nutrition and Food
- Microganic GmbH
- MonitorFish GmbH
- University of Hamburg, Department of Microbiology & Biotechnology
- University of Rostock, Faculty of Agricultural and Environmental Sciences, Aquaculture and Sea Ranching
- Molecular Biology and Fish Genetics, Faculty of Agricultural and Environmental Sciences, University of Rostock, Rostock, Germany

For the Testings, fish are kept in experimental units under various conditions (single housing to commercial conditions in terms of density, size, light, etc...). Numerous cameras are installed above the experimental units, recording continuously. The image recordings are captured under different conditions. Other data that are collected manually are the number of fish, weight and biomass, mortality, signs of disease and stress.

Stress is identified by gene expression-based BioChips, blood parameter and stress hormone analyses, and MonitorFish GmbH as a project partner performs real-time monitoring of the fish. The company has a self-developed cloud-based technology for comprehensive real-time monitoring of fish in aquaculture for sustainable improvement of fish health. The system is allowing a non-invasive cloud-based real-time fish monitoring. Artificial neural networks (KNNs) are then used to establish relationships between water parameters, fish appearance and movement patterns. KNNs require only a fraction of data sets to generate a diagnostic correlation with recommended action. These data are supportive for functional classification of movement patterns in relation to physical and chemical characteristics of the water. Based on the evaluations of all variables, the software generates recommended actions to maintain optimal water quality and fish health for optimal productivity and yield. Thus, sensor analytics allow early assessment and even prediction of animal welfare in real time.

In the frame of the BioFia-project MonitorFish continuously records the water quality with standard built-in sensors and works on the extension of the software module for camera control to include digital focus, its porting for the new development platform (Raspberry Pi 4, Ubuntu) and the elimination of various driver problems.

In addition, other project partners are monitoring the fish for parasites, fillet quality is being tested, and the microbiology of the aquaculture filtration system during challenge experiments is being verified.

(Continued on next page)

Results

Preliminary results of the image analysis and the interaction of stress management in aquaculture will be presented at the AE2021. BioFia focuses on stress detection and visualisation for salmon. The main focus of the current experiments is:
- appetite/satiation detection
- Stress detection via movement behaviour

For both detections a much higher image rate than currently used will be necessary. A higher image rate also means a larger amount of data. It will also be evaluated whether this data can be processed on site with greater computing power or whether it should be loaded into a cloud in a correspondingly compressed form. At AE2021, the obstacles that are encountered in such complex experiments will be presented.

Discussion and conclusion

Preliminary results on automated feeding and how fish are stressed by the feeding procedure as well as by manual fish biomass determination (as key data for successful software development) will be presented at EAS 2021. The reliability of the baseline data (number of digital counts vs. manual counts and vs. starvation status) will be discussed and approaches for detection algorithms comparing metadata with a fish behavior database will be presented.

EFFECTS OF DIFFERENT MICROALGAL DIETS ON *Ostrea edulis* BROODSTOCK CONDITIONING AND REPRODUCTION. DEVELOPMENT OF A NON-DESTRUCTIVE TECHNIQUE FOR THE MONITORING OF OYSTER GAMETOGENESIS AND SEX DIFFERENTIATION

M. Fabra*, T. Bean, G. Watson and J. Preston

*Institute of Marine Sciences, University of Portsmouth, Portsmouth, UK
Email: monica.fabra@port.ac.uk

Reflecting the global decline of oyster reefs, the current distribution of the European flat oyster, *Ostrea edulis* (Linnaeus, 1758), across the UK and Europe represents only a small fraction of the historic distribution. Despite the numerous restoration projects conducted in the past decades, seed oyster supply is currently a key limiting factor for native oyster restoration. Several hatcheries are being established across Europe to assist in restoring *O. edulis* populations, providing oyster seed. However, *O. edulis* hatchery production is still prone to failure. The scarce capacity to produce large quantities of larvae is firstly due to *O. edulis* complex lifecycle which makes it difficult to manipulate spawning and fertilisation in a controlled environment. The knowledge gaps surrounding *O. edulis* biology and reproduction, and the factors responsible for the gametogenesis and sex differentiation, also make it difficult to control the sex ratio, leading to disproportionate gametic contribution. The biochemical composition of diet is important for broodstock reproduction, with fatty acid-enriched diets expected to provide sufficient reserves for the development of ovogonia, whilst low concentrations of fatty acids promote the development of more spermatogonia and male-based populations. The effects of four single microalgal diets (*Isochrysis galbana, Nannochloropsis oculata, Tetraselmis suecica, Thalassiosira pseudonana)* on *O. edulis* broodstock conditioning were assessed for oyster survival, growth, filtration rate, absorption efficiency and gonadal allocation of fatty acids. Techniques used to monitor the effectiveness of broodstock conditioning protocols, usually require destructive sampling of gonad tissue for histological analysis. This may involve the sacrifice of large numbers of oysters, which is undesirable for many restoration projects with limited broodstock. A novel non-sacrificial sampling technique was tested with effects on oyster survival, growth and filtration rate. If successful, this non-destructive approach will allow to monitor the gametogenesis and sex differentiation of individual oysters through the whole reproductive season, without sacrificing broodstock.

GENOMICALLY ASSISTED RECONSTRUCTION OF THE ANCESTRAL *Dicentrarchus labrax* L. MEDITERRANEAN LINEAGE

Introduction

Whole-genome sequences studies of sea bass have recently revealed two ancestral lineages that diverged in allopatry for 270,000 years in the Atlantic and the Mediterranean. A postglacial contact between those lineages resulted in an asymmetrical introgression from the Atlantic to the Mediterranean background (Figure 1 - Duranton et al. 2018). In our study the base western population (WM) is introgressed at 49% by Atlantic genome, while our east-Med population (EM) at 23%. We explored different strategies to reconstruct the ancestral Mediterranean lineage by local ancestry deconvolution.

Material and Methods

A candidate population (G1) of 605 individuals was obtained after a backcross between (WM × EM) females and EM sires. Every animal was genotyped on a 57k SNP chip. We used APIS to recover the pedigree, Lep-MAP3 to construct a genetic map, and Beagle 5.1 for the phasing of the genotypes. The local ancestry for each haplotype of admixed individuals was inferred with Loter. Haplotype-resolved Atlantic genomes and Mediterranean desintrogressed haplotype-resolved genomes were used as reference for both ancestral lineages (Duranton et al. 2018). A custom-made R script was used to simulate generations of selection across different breeding strategies (backcross, BC, intercross, IC, or combinations of those). Six selection criteria were tested on each type of crossing: whole genome admixture (further referred as Med-ratio), chromosome-based Med-ratio, rarefaction of homozygous Atlantic tracts or combinations of those. For each scenario, factorial matings of 24♀×24♂ across 8 generations were simulated and repeated 20 times.

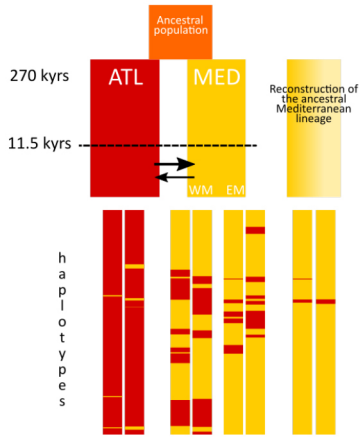

Figure 1. Divergence and introgression history of Atlantic and Mediterranean D. labrax populations (adapted from Duranton et al., 2018). The Atlantic and the Mediterranean populations diverged for 270k years; a postglacial contact between them resulted in asymmetrical introgression (black arrows). The Atlantic genomic background is in red, and the Mediterranean genomic background is in yellow. The aim of the study is to reconstruct the ancestral Mediterranean lineage, with a ~2 % of Atlantic introgression

(Continued on next page)

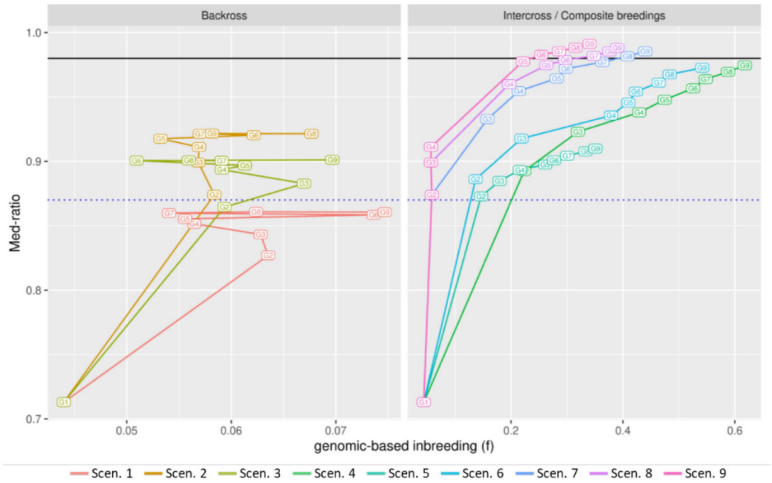

Figure 1. Evolution of mean genomic-based inbreeding and of mean Med-ratio over generations for breeding different scenarios. Solid black line represents the targeted Med-ratio to recover an ancestral Mediterranean lineage, while blue dashed line represents the mean Med-ratio observed in the present Eastern Mediterranean population

Results and Discussion

The Figure 2 display the evolution of the Med-ratio and the genomic-based inbreeding (f) across the generation for the different scenarios tested. We showed that from the candidate generation G1, displaying a Med-ratio level of 71%, a classical BC (Scenario 1) induced a stagnation at a Med-ratio level of 86% from G6. Other BC scenarios with selection of the Med-ratio (Scenarios 2 and 3) allowed to overcome the mean Med-ratio observed in the present Eastern Mediterranean population, maintaining a low level of inbreeding (below 7%), but did not allowed to reach the ancestral Mediterranean target. Pure IC strategies (Scenarios 4, 5 and 6) did not allow to reach the 98% Med-ratio target and induced a high level of inbreeding especially for Scenarios 4 and 6. The best performing strategies were those using the selection criteria on whole genome Med-ratio and including 1, 2 or 3 generations of BC followed by IC (for respectively Scenarios 7, 8 and 9). These strategies allowed to overcome the Med-ratio level of the actual EM population after just one extra generation, and to reach the breeding goal of a 98% pure Mediterranean strain at G6 for Scenario 7.

This recovered ancestral line will be key to understand the dynamics of speciation and secondary admixture in Mediterranean and Atlantic sea bass, and may represent a key resource for sea bass aquaculture in extreme environments.

Introduction

Nervous Necrosis Virus (NNV) is one of the major viral pathogens in aquaculture, affecting a wide range of fish species and causing high mortality rates. The gilthead sea bream (*Sparus aurata*) has long been considered resistant to NNV, until recently, when significant mortalities caused by a reassortant NNV strain were reported in sea bream hatcheries (Volpe et al. 2020). Since the larval stage is the most susceptible life-stage to NNV, vaccination is not a feasible option due to the immaturity of the immune system. Selective breeding to enhance resistance against the reassortant NNV strain might be a possibility as a disease preventive action. Here, we analysed for the first time the genetic basis of viral nervous necrosis (VNN) mortality in gilthead sea bream larvae and we assessed the accuracy in the genomic prediction of this trait.

Materials and methods

The experimental fish were generated at a commercial hatchery through controlled crosses in three independent full factorial matings (10 sires × 12 dams; 10 sires × 7 dams; 10 sires × 5 dams). At 15 days post-hatching (dph), larvae were transferred to the IZSVe experimental facility. At 19 dph, larvae were infected by immersion adding to the tank the reassortant strain VNNV/S.aurata/Farm1/461-1/Nov2014. The final infectious titre was verified by titration of the water ($10^{5.45}$ $TCID_{50}$/ml). The challenge trial ended at day 9, when no more symptomatic/dying larvae were detected for at least 24 hours. Larvae showing symptoms of VNN infection and surviving individuals were collected for DNA analysis and recorded as 0 (asymptomatic) or 1 (symptomatic). The experimental infection protocol was evaluated by the IZSVe Animal Welfare Body and Ethics Committee (Opinion CE.IZSVE.3/2016 of 24/10/216) and subsequently approved by the Italian Ministry of Health (Law decree 101/2017-PR of 02/02/2017). All the experimental fish and their parents were genotyped using the Med_Fish SNP array, which contains over 27,000 SNPs for the gilthead sea bream (Peñaloza et al. 2021). Variance components for mortality was estimated using Bayesian procedures with a univariate sire-dam threshold model. Heritability was computed using the sire variance only, to avoid potential non-genetic maternal effects. Genome-wide association analysis (GWAS) was performed to test the association between VNN mortality phenotype and SNPs. Genomic prediction of VNN mortality was performed implementing three Bayesian regression models: Bayes B (BB), Bayes C (BC) and Bayesian Ridge Regression (BRR; GBLUP equivalent). Prediction performance was assessed by means of 5 independently-generated 5-fold cross validations (CV). In each CV, 80% of the data were used to train the model and 20% served as a validation set. Three metrics were used to evaluate model performance in classification: Matthews correlation coefficient (MCC), the area under the ROC curve (AUC) and accuracy (ACC). Pedigree indices were estimated using an animal model through 5-fold CV: in each CV, 80% of the data was used to estimate the indices of the remaining 20% of the animals. Performance of the indices in classification of VNN mortality was assessed using the same metrics used for genomic prediction (MCC, AUC, ACC).

Table 1. Average metrics (AUC, ACC, MCC) of classification performance of VNN mortality in 5 independent 5-fold cross-validations; standard deviation (SD) in brackets

Bayesian model	Metric		
	AUC	ACC	MCC
BB	0.5813 (0.0166)	0.5694 (0.0162)	0.1752 (0.0239)
BC	0.5969 (0.0134)	0.5811 (0.0131)	0.1758 (0.0231)
BRR	0.6014 (0.0134)	0.5825 (0.0088)	0.1778 (0.0215)

(Continued on next page)

Results

First symptoms of VNN infection were detected at day 6 post-challenge, followed by a peak of two day; then mortality sharply decreased up to day 8. A total of 1184 individual larvae were collected (513 dying and 671 survivors). Genomic DNA was extracted from the tissue of 1044 larvae and 54 parents and used for individual genotyping. A total of 974 larvae, 47% symptomatic and 53% asymptomatic, were successfully genotyped and parentage assignment to a unique parental pair was achieved for all the 974 fish. Individuals were allocated to 160 families, with a number of offspring per family ranging from 1 to 55. After removing one sire and one dam that generated only one offspring, 972 individuals from 28 sires and 22 dams were retained. Overall, 26,591 SNPs with MAF > 0.05 were scored. The estimate of heritability for VNN mortality was moderate (h^2 = 0.1921; 95% highest posterior density intervals: 0.0006, 0.5790), with a probability being greater than 0.2 equal to 0.49. Classification of the observed VNN mortality using the genomic prediction of the phenotype of mortality as classifier was significantly more accurate than random guessing of the classes, with consistent results across Bayesian models (Table 1); using the pedigree indices to classify the mortality phenotype resulted in similar performances (AUC = 0.5875, ACC = 0.5798, MCC = 0.2550). The GWAS failed to identify any genome-wide QTL for VNN mortality overcoming the significance threshold.

Discussion

VNN is an emerging threat for gilthead sea bream hatcheries and this is the first study that explored the genetic basis of resistance to VNN in this species. Experimental infections in early developmental stages are scarcely reported, especially with adequate sample size to estimate variance components and genetic parameters. The estimate of heritability for VNN mortality suggests the feasibility of selective breeding programmes for increased resistance to VNN of fish larvae/juveniles, overcoming the problem of vaccination. The practical exploitation of genomic information due to the availability of genome-wide dense marker panels might offer the opportunity of developing prediction tools for the studied trait.

Introduction

Aquaculture production of rainbow trout (*Oncorhynchus mykiss*, Walbaum 1792) has become a modern multibillion dollar industry. However, the development of this sector has not been exempt from pitfalls related to the presence of pathogens. Among these, the recurrent presence of pathogens of bacterial origin can be highlighted, as is the case of *Yersinia ruckeri*, a Gram negative rod with rounded ends, not forming spores or capsules, but often with the presence of flagella that provides it variable mobility. *Y. ruckeri* is the causative agent of the infectious pathology known as Enteric Red Mouth Disease (ERM). ERM is a systemic infection that can affect *O. mykiss* for its entire life cycle, being especially susceptible the juvenile stages cultivated in fresh water. Although *Y. ruckeri* can affect different types of salmonid and non-salmonid fish, both in fresh and salt water, *O. mykiss* is the species that has been reported as the most sensitive and vulnerable to ERM, causing serious economic losses that can be as high as 30–70% of the stock in some cases. ERM has also been referred to as yersiniosis since affected fish do not always present the characteristic reddened areas of the mouth. Likewise, this term is used to distinguish a chronic infection compared to ERM that appears acutely. *Y. ruckeri* infection generally results in the development of acute or chronic septicaemia characterized by the presence of haemorrhages around the mouth and anus, at the base of the fins, and on the surface of internal organs. Although several studies have yet been performed regarding the pathogen features and virulence factors, few information about the host defence mechanisms activated after infection is available. Given this perspective, this study aimed to evaluate rainbow trout innate immune response against the infection with *Y. ruckeri*.

Materials and Methods

A time-course study was performed at CIIMAR (Matosinhos, Portugal) facilities with 72 rainbow trout (*Oncorhynchus mykiss*) juveniles (16.7 ± 4.4 g). After 2 weeks of acclimation, 12 fish were sampled before infection (time 0). The remaining animals were randomly selected and intraperitoneally (i.p.) injected with 100 μl PBS (placebo group) or 100 μl of exponentially growing *Y. ruckeri* ($2 * 10^8$ CFU mL^{-1}; infected group) and distributed as a complete randomized design in 6 recirculating seawater systems (i.e. triplicates *per* experimental condition). Two animals per tank (n = 6 *per* treatment) were sampled at 3, 6, 9, 24 and 48 h after i.p. injection. Fish were euthanized with 2-phenoxyethanol (0.5 mL L^{-1}) and blood samples were collected for haematological procedures. The remaining blood was centrifuged for plasma collection and innate humoral parameters (i.e. peroxidase, lysozyme, anti-protease, and nitric oxide activities) were evaluated.

Results

In general, the infection induced a host anemic state related with the hemolytic effect caused by the infection with *Y. ruckeri* since red blood cells and haemoglobin dropped their levels in infected animals compared to placebo individuals. In particular, red blood cells count showed significant differences between the placebo and the infected groups after 24 and 48 h. In relation to the haemoglobin parameter, differences were only recorded between the placebo group and the infected group at 48 h, being the value of this parameter lower in the infected group. Regarding haematocrit, significant differences were recorded between the control group (0 h) and the infected group after 48 h. Similarly to that observed for red blood cells and haemoglobin concentration , haematocrit also decreased significantly in infected animals compared to placebo

(Continued on next page)

individuals at times 24 and 48 h. Regarding white blood cells numbers, differences were verified between the control group (0 h) and the infected animals at times 3, 6, 9, 24, and 48 h. In all the cases, there was a sustained decrease in the white blood cells in infected specimens. Moreover, white blood cells also dropped in placebo trout at 6 and 9 h compared to the control group (0 h), a decreased most likely explained as a reaction to the injury produced by the injection of PBS; however, after 48 h the number of white blood cells returns to its basal state. On the other hand, there were no differences in the parameters of peroxidase, anti-protease, lysozyme, and the nitric oxide activity.

Discussion and Conclusion

The results of this study described some mechanisms that contribute to the immune response of *O. mykiss* against the infection with *Y. ruckeri*. The activation of defense mechanisms linked to haematological cellular parameters was verified, such as the amount of white blood cells, which decreased in number in the blood as the infection developed at times 3, 6, 9, 24, and 48 h respectively, presumably as a response of migration of white blood cells to the focus of the infection to combat it. On the other hand, there was a sustained decrease over time in both the number of red blood cells and hematocrit (being significant after 24 and 48 h, respectively), and also in haemoglobin (being significant after 48 h). These results show a preliminary vision of the effects caused in *O. mykiss* by infection with *Y. ruckeri*, which may be useful for the establishment of biomarkers that may be used for the early detection of ERM.

SPERMIATION ENHANCEMENT OF GREATER AMBERJACK *Seriola dumerili* IN RESPONSE TO GnRHa IMPLANTS OR hCG

Ioannis Fakriadis[1], Maria Papadaki[1] and Constantinos C. Mylonas[1]

[1]Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, P.O. Box 2214, Heraklion, Crete 71003, Greece
E-mail: fakriadis@hcmr.gr

Introduction

The greater amberjack (*Seriola dumerili*) is a species with high potential for the diversification of the aquaculture production, due to its excellent flesh quality and high worldwide consumer acceptability. However, reproductive dysfunctions in captivity have been observed in males, even more pronounced than in females (Zupa, et al., 2017). Additionally, sperm quality and quantity were not different after rearing in sea cages or in land-based tanks, but showing remarkable decreased milt production compared to the wild (Fakriadis, Mylonas, 2021). Agonists of gonadotropin-releasing hormone (GnRHa) and human chorionic gonadotropin (hCG) have been used to overcome these problems in many fishes, and the present study compared these hormonal spermiation enhancement methods in terms of plasma sex steroid production and sperm quality.

Materials and methods

Wild-captured breeders (11.6-20.0 kg) were kept in Aqualabs, Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, Heraklion, Crete, Greece, in a 40 m^3 tank under simulated photoperiod and temperature profile, and were fed with a broodstock diet (Skretting, Vitalis Cal, 22mm). Males, after blood and sperm collection, were treated either with a GnRHa implant (n=3) with an effective dose of 59±2 μg GnRHa kg^{-1} or hCG injection (n=4) with an effective dose of 617±46 IU kg^{-1} (day 0). Fish were sampled again for blood and sperm on day 3, 7 and 14 after the hormonal treatments. Plasma testosterone (T), 11-ketotestosterone, 17-β estradiol (E_2) and 17α,20β-dihydroxy-4-pregnen-3-one (17,20β-P) were quantified with the use of enzyme-linked immunosorbent assays (ELISAs). Sperm quantity was evaluated according to their spermiation condition –which is a measure of the available milt in the testes- after gentle abdominal pressure was applied, determined by a subjective scale from 0 to 3, as follows: Spermiation index S0 = no milt released, S1= only a drop of milt released after multiple stripping attempts, S2= milt was released easily after the first stripping attempt and S3= copious amounts of milt released with very little pressure. The sperm quality parameters that were evaluated included: (a) sperm density (number of spermatozoa ml^{-1} of milt), (b) survival of spermatozoa under cold storage at 4°C (spermatozoa survival, days), (c) initial percentage of spermatozoa showing forward motility immediately after activation (spermatozoa motility, %) and (d) duration of forward spermatozoa motility of ≥5% of the spermatozoa in the field of view (motility duration, min).

Results and discussion

Males did not release sperm after abdominal pressure on day 0. Half of the fish (n = 2) after hCG treatment were in S2 on day 3 and S3 on day 14 after treatment, while one fish was found to be in S2 3 days after treatment with GnRHa implants. Plasma T concentration increased significantly 7 days after treatment with GnRHa implants while it did not differ significantly after treatment with hCG (Figure 1), while 11-KT also increased significantly, but there was no difference between the different treatments. Both E2 and 17.20β-P did not differ significantly after treatments. Hormonal therapies did not affect significantly sperm motility and motility duration. Sperm density decreased significantly 3 days after hCG treatment, and remained decreased on day 7, but recovered to baseline on day 14 after treatment. Treatment with GnRHa implants caused a significant reduction in sperm density 14 days after treatment. Regarding the survival of sperm under cold storage, a significant reduction was observed 7 days after hCG treatment, while no changes were observed after treatment with GnRHa implants.

THE USE OF AN ENVIRONMENTAL ENRICHMENT MODULATES STRESS RESPONSE AND CHEMICAL COMMUNICATION IN SENEGALESE SOLE (*Solea senegalensis*)

Elvira Fatsini*, Zélia Vélez, Peter C. Hubbard, Catarina C.V. Oliveira, Catarina Marques, Florbela Soares, Pedro Pousão, Tomás Santos, Bernardete Rodrigues and Elsa Cabrita

Centre of Marine Sciences (CCMAR), Universidade do Algarve (Campus Gambelas), 8005-139, Faro (Portugal)

Introduction

Environmental enrichment is used to promote fish welfare and, in some cases, to reduce detrimental characteristics that fish develop in captive conditions. Senegalese sole is a promising species for European aquaculture, above all in the South of Europe, for its good growth rate and high market price (Morais et al. 2016). However, Senegalese sole shows a reproductive dysfunction related to the lack of reproductive behaviour which does not allow to close the cycle in captivity. Several approaches have been studied to increase knowledge and try to solve this disorder. The problem remains unsolved, and the production is based on breeders caught in nature. Recently, it has been observed that urine is the communication vehicle for reproduction in Senegalese sole and its potency variates depending on fish maturity and sex (Fatsini et al. 2017). Our hypothesis was that conditioning the sole to natural environmental factors in early life stages may help to develop healthier fish and future potential breeders. Therefore, the present study aimed to assess the effect of using a substrate (sand) as an environmental enrichment in the stress response and chemical communication of pre-pubertal Senegalese Sole (*Solea senegalensis*).

Material and methods

The present study was divided in two parts. The first part was carried out to monitor the evaluation of the stress response in sole established in different environmental conditions. For this purpose, a total of 1500 sole (~10g; 8 months) were established in 6 outdoor tanks in the experimental station of IPMA (Olhão, Portugal) maintaining natural temperature and photoperiod according to each season. The bottom of 3 tanks were covered by 2 cm of sand and the other 3 remained without sand (fiberglass). These fish were maintained in the same conditions for two years and 4 samplings (every 6 months) were conducted to collect blood samples (n=20 fish per treatment and sampling) to evaluate cortisol in plasma by ELISA. Biometric parameters were also registered. In the last sampling a total of 72 pre-pubertal fish (n=36 per treatment) were transported to Ramalhete station (Faro, Portugal) to conduct the second part of this study. This part was performed to observe the influence of the environment in chemical communication in sole using urine from sole reared with and without sand. The fish were divided in 6 tanks and 3 tanks had the same origin sand in the bottom to mimic the original conditions. Urine samples were collected from 24 fish (n=12 fish per treatment) and 4 different pools were made per sex and environment. A total of 22 sole (7 females from sand and 5 from fiberglass; 5 males from sand and 5 from fiberglass) were used as receivers to perform electro-olfactogram (EOG) to evaluate the olfactory sensitivity and potency for smelling the same urine pools. The EOG were performed in different months to avoid seasonal factor.

Results and discussion

Significant differences ($P < 0.05$) were observed in cortisol plasma levels of Senegalese sole reared with and without sand during the 1st, 2nd and 3rd samplings where the fish maintained in sand obtained higher levels of cortisol in plasma than sole without sand. This could be associated with the stress response to mechanical agitation in the moment of catching the fish (Bates et al. 2014). However, all blood samples were collected in the first 4 minutes after catching the fish to try to avoid the rising of basal levels, suggesting that fish reared with sand were more sensitive to stress disturbance. It was noted that sole reared in sand presented less locomotor activity than fish reared without sand, which might decrease the baseline levels of several physiological parameters including cortisol. In terms of biometric data, sole reared with sand grew faster than sole reared without sand. These results coincided with other species reared using substrates as environmental enrichment (Bates et al. 2014).

In relation with chemical communication, no differences were observed in the potency of urine from females and males reared under different conditions; however, differences were observed in the olfactory sensitivity between females and males reared with and without sand smelling males' urine. Intriguingly, the olfactory sensitivity from females reared with sand to urine was higher than females reared in fiberglass. However, this situation might not be conclusive because females presented high variability in olfactory responses including within the same condition. In the case of males, it was observed

(Continued on next page)

the opposite, males reared without sand had higher olfactory sensitivity than males reared with sand. Besides, the olfactory responses from males reared without sand are described by a three-parameter Hill curve, while responses from males reared with sand are better described by a linear regression. These results might be explained by the fact that males are smelling different compounds or the olfactory epithelium receptors have a different location changing the perception of the stimuli. Nonetheless, more studies are needed to understand the implications of these results in chemical communication and the use of sand as environmental enrichment for the correct development and maturation of F1 breeders.

Introduction

Senegalese sole is a promising species for European aquaculture. However, its production is not yet sustainable since breeders from aquaculture (F1 broodstock), unlike wild breeders, do not spawn naturally. Artificial fertilization and cryopreservation have been identified as potential solutions to counteract reproductive problems, however, the low volume of sperm produced by Senegalese sole males, specially F1 individuals, and the high male variability, make difficult the improvement of this technique (Cabrita et al., 2014). In the present study, several approaches were used to improve sperm quality parameters in F1 individuals trying to answer the following questions: (i) Could the cohabiting between wild and F1 males influence sperm quality?; (ii) Could the type of food affect the sperm quality of F1 males? (iii); Could diet supplementation with Vitamin C and β-Glucan influence sperm quality? Cohabiting has been previously demonstrated to positively influence F1 male reproduction (Fatsini et al., 2020). Related to nutrition, it has been observed that F1 fish fed with fresh food during a long period of time improved reproductive fitness including sperm quality (Martin et al., 2021). Diet supplementation with antioxidants and β-Glucan have positive effects in sperm quality in several fish species (Félix et al., 2021), including Senegalese sole. This study presents valuable results to keep investigating natural sources to improve sperm quality to ameliorate male reproductive performance in Senegalese sole.

Material and methods

A total of 157 male breeders (17 wild = 1657.4 ± 445.7 g; 140 F1 = 1020.6 ± 310.1 g) were randomly distributed in 4 different experimental groups in 8 tanks. These individuals were maintained in an open flow system with natural temperature according to season (11 - 22 ºC) in IFAPA-El Toruño facilities in circular tanks of 12 m^3. A total of 61 F1 females (1336.2 ± 286.6 g) were also added to the different experimental groups to simulate a functional broodstock unit. The fish distribution per group (in duplicate tanks) was as follow: 41 males (17 wild and 24 F1(F1cohab)) for cohabiting experiment fed with fresh feed, 36 F1 males for the fresh feeding group (F1f), 42 F1 males for the dry feeding group (F1d), 38 F1 males fed with dry feed supplemented with VitC (n=18) or with β-Glucan (n=20) (SPAROS lda.). Fish were maintained under these conditions for 6 months before the experiment started. Samplings to collect sperm were performed once a month from March to May. Before handling, fish were anesthetized with 2-phenoxyethanol (300 ppm), sperm was collected, and production and quality evaluated. Sperm was centrifuged to eliminate seminal plasma and possible urine contamination and resuspended with the same volume of Ringer. Sperm motility was evaluated using CASA system (ISAS Software, Proiser), viability was evaluated using PI probe by flow cytometry and DNA fragmentation was assessed by Komet assay technique developed by our group for Senegalese sole. Statistical differences were examined using a Student's t-test and Repeated-Measures ANOVA in SPSS v25.

Results and Discussion

Could the cohabiting between wild and F1 males influence sperm quality?

To respond to this question, sperm characteristics were compared between F1 males (F1f) and F1 cohabiting males (F1cohab) fed with fresh food and wild fish. No differences were observed in the percentage of motile spermatozoa (TM) and in curvilinear velocity (VCL). However, significant differences were found in straight-line velocity (VSL) = Wild (50.9 ± 18.5), F1cohab (48.8 ± 11.9); F1f (42.0 ± 12.0)), where wild fish sperm had significant higher VSL than F1f sperm ($P < 0.0001$) and also F1cohab sperm had significant higher VSL than F1f. No differences were observed in viability nor in DNA fragmentation. These preliminary results suggest that cohabiting might enhance sperm quality in F1 individuals. However, the differences among groups will be higher if the period of cohabitation would be longer, since these individuals were cohabiting for just 6 months before the experiment started. This situation was also observed by Fatsini et al. (2020), where in the first spawning season the fish did not react to the cohabitation influence, showing the importance of the establishment of the proper hierarchy and chemical effect in a specific population.

(Continued on next page)

Could the type of food affect the sperm quality of F1 males?

Comparisons were evaluated between F1 males fed on fresh feed (F1f) *and* F1 males fed with dry feed (F1d). No significant differences were observed in spermatozoa TM, VCL or VSL. No differences were observed in viability and DNA fragmentation, showing a tendency similar to motility parameters. These preliminary results propose that dry food might substitute fresh food in terms of sperm quality parameters. However, Martin et al. (2021) observed that feeding Senegalese sole juveniles with just fresh food significantly improved the reproductive performance of these animals at breeder stage.

Could diet supplementation with Vitamin C and β-Glucan influence sperm quality?

Differences were evaluated between F1 males fed on dry food and F1 males fed with diet supplemented with vitamin C (F1vitC) or β-Glucan (F1bgluc). No significant differences were observed in spermatozoa TM, VCL or VSL, although a slight tendency was observed for higher motility parameters in supplemented trials. No differences were observed in viability, showing the same tendency than motility parameters. The results suggest that these diets can be promising if provided periodically to potentially improve sperm quality in F1 males. This was previously observed with the administration of Vitamin E in Senegalese sole breeder's feeds (Beirão et al., 2015). More studies need to be conducted to improve supplementation efficiency in male reproductive performance.

SHORT-TERM EFFECT OF A LOW PROTEIN HIGH CARBOHYDRATE DIET ON GLUCOSE AND LIPID METABOLISM IN THE LIVER OF MATURE FEMALE AND MALE, AND NEOMALE RAINBOW TROUT

N. Favalier*, H. Li, M. Marchand, A. Surget, P. Maunas, N. Turonnet, S. Panserat and L. Marandel

Introduction

Aquaculture and more specifically carnivorous fish farming, such as trout production, is highly dependent on fish derived products such as fish meal (FM) and fish oil (FO) as sources of proteins and lipids, respectively, in the aquafeed formula. However, FM and FO rely on fishing from wild stocks, which can be seen as a hindrance to the sustainable development of salmonid farming [1]. This applies in particular to broodstocks, which are large animals that consume large amounts of feed. Carbohydrates represent good candidates for the replacement of FM [2]low polluted and nutrient rich high quality artificial feeds. Like terrestrial animals around 40 essential nutrients are required by the aquatic organisms which includes protein, carbohydrate, fatty acids, vitamins, minerals, growth factors and other energy sources essentially for maintaining growth, reproduction and other normal physiological functions. The variation in the nutritional requirements can be identified with warm water or cold water, finfish or shell fish and marine water or freshwater species. Successful production of good quality fishes can be achieved by feeding the fishes with nutritionally balanced feeds. The nutritional requirements of various fish species are fulfilled by a different animal and plant based artificial feeds. Standardization of feeding method is another innovative way for preserving sustainable production of aquatic organisms in cages, ponds and short seasonal tanks. Ideal fish protein concept is also the superlative advance towards maximizing the effective utilization of protein by the fishes through the production of cost efficient, nutritionally high and low polluted feeds.","language":"en","page":"7","source":"Zotero","title":"An overview on significance of fish nutrition in aquaculture industry","author":[{"family":"Prabu","given":"E"},{"family":"Felix","given":"S"},{"family":"Felix","given":"N"},{"family":"Ahilan","given":"B"},{"family":"Ruby","given":"P"}]}}],"schema":"https://github.com/citation-style-language/schema/raw/master/csl-citation.json"} . However, rainbow trout is considered as a poor user of digestible carbohydrates [3]. This is linked to several hypothesis such as the non-inhibition of the production of endogenous glucose through gluconeogenesis or the poor induction of *de novo* lipogenesis [4,5]if ever, regulated by carbohydrates, suggesting that this metabolic pathway is involved in this specific phenotype. In this study, we hypothesized that the fate of duplicated genes after the salmonid-specific 4th whole genome duplication (Ss4R when fed a high carbohydrate diet. If they have been deeply explored in juveniles, data concerning broodstock remained scarce. In this context, this study aimed to evaluate the consequences of feeding rainbow trout broodstocks with a high carbohydrate diet for two days on glucose and lipid metabolism.

Results

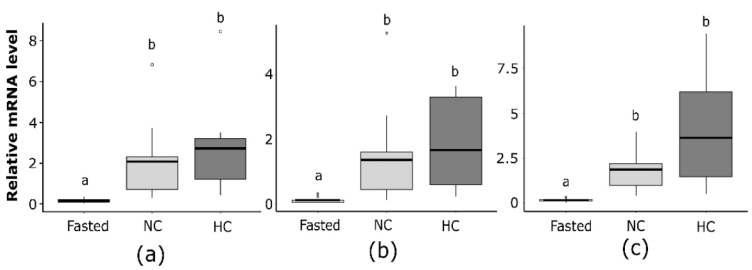

Figure 1 : Illustration of the up-regulation of the *de novo* lipogenesis with *aca alpha a* mRNA levels in (a) mature female, (b) mature male and (c) neomale 15 days fasted (Fasted, white) and then refed with either the NC (non-carbohydrate diet, grey) orthe HC diet (High-carbohydrate diet, dark grey). Data (n=9 fish per condition) were analysed with a Kruskal Wallis test, followed by a post hoc Tukey test in case of significant difference ($p<0,05$, indicated with different letters).

(Continued on next page)

Materials and methods

In the present study, we analysed the three sex commonly used in aquaculture as broodstocks, female, male and neomale that are for the latter masculinized females used to produce all-female lines. Mature female and male, and neomale rainbow trout were fed for two days with a low protein high carbohydrate diet (32% carbohydrates, 42% proteins - HC) or a diet containing no carbohydrates (0% carbohydrates, 66% proteins - NC).Six hours after the last meal, we analysed plasma metabolites, mRNA levels and enzymatic activities of glucose and lipid metabolism-related actors. All these parameters were studied in the liver that is the key organ for the regulation of intermediary metabolism.

Results

Results demonstrated that the glucose metabolism was regulated at the molecular level by the nutritional status in all sex irrespective of the diet composition. Glycolysis was up-regulated in fed neomales and females with an increase of mRNA levels of glucokinase and phosphofructokinase encoding genes as well as an increase in the enzymatic activity of the pyruvate kinase. Concerning gluconeogenesis only glucose-6-phosphatase coding genes were regulated by the nutritional status irrespective of diet composition with the repression of *g6pcb1b* and the induction of *g6pcb2a*. However, no differences in enzymatic activities were highlighted for this pathway. Finally, concerning the lipid metabolism, our results clearly demonstrated for neomales and males the up-regulation of the *de novo* lipogenesis and the down-regulation (example of *aca alpha-a*, figure 1) of the beta-oxidation,while only an up-regulation of the *de novo* lipogenesis occurred in females.

Discussion and conclusion

The present study investigated the glucose and lipid metabolism at the molecular level in mature female and male, and neomale rainbow trout fed for two days with a NC diet or a HC diet. The results obtained for the glucose metabolism highlighted an activation of the glycolysis pathway by the nutritional status in all sex irrespectively of the diet. The up-regulation of the *de novo* lipogenesis was also demonstrated in fed animals. These data point out that carbohydrate intake during a short period (5 meals) does not induce specific metabolic changes after two days of feeding in mature female and male, and neomale. Moreover, we demonstrated for the first time sex differences regarding the effect of two days feeding on metabolism, especially with neomales displaying more differences in the regulation of the glucose and lipid metabolism than male and female broodstock. Such differences may be explained by the fact that neomales are still immature fish. In conclusion, there is no negative effect of feeding mature female and male, and neomale rainbow trout with a high carbohydrate diet for a short period of time.

IS THERE A MELATONIN PROTECTIVE EFFECT DURING GILTHEAD SEABREAM SPERM CRYOPRESERVATION?

F. Félix*, R. Antunes, L. Leoni, C.C.V. Oliveira, E. Cabrita

Introduction

Melatonin is widely present in nature and is commonly known for the regulation of circadian rhythms (Falcón et al., 2010). For many years, it was thought to be produced only by the pineal organ, but both autocrine and paracrine mechanisms of action are already described in different organs (Félix et al., 2021). Its important role in fish gonad maturation have been studied in fish, providing evidences of antioxidant capacity (Maitra and Hasan, 2016). Therefore, our hypothesis is that melatonin antioxidant properties may provide additional protection to sperm during cryopreservation, reducing oxidative stress. Cryopreservation has been used as a tool to help in artificial reproduction in many aquaculture species. Since these protocols for gilthead seabream (*Sparus aurata*) are well stablished (Cabrita et al., 2005), we aim to understand the effect of endogenously produced melatonin by night at the spermatozoa quality level and its effect as a supplemented antioxidant on a cryopreservation medium.

Methodology

For this experiment, gilthead seabream broodstock was acquired from a semi-intensive aquaculture, Aqualvor (Portugal) and maintained at the Ramalhete station at the University of Algarve. Fish had a mean body weight of 520 ± 14g and were kept under a controlled short photoperiod of 8h light: 16h darkness, in order to simulate the normal environmental conditions of the reproductive season (Bromage, 2001). Sperm samples were collected by abdominal massage at two different points, mid light (ML) and mid dark (MD) (6 males at each point), avoiding any contamination, and kept at 4ºC until analysis. Afterwards, a cryopreservation protocol developed by our group was used (Cabrita et al., 2005), supplemented with melatonin (MEL) to evaluate its protection role. According to the available literature, three different MEL concentrations were chosen: 0.001 mM, 0.01 mM and 0.1mM melatonin, together with a control group without MEL. Sperm motility and concentration were assessed using a Computer Assisted Sperm Analysis software (CASA) to check potential differences in fresh and cryopreserved sperm quality between day and night. On a second experiment, cell viability and DNA fragmentation, by Comet assay, were tested (N=8) as described by Cabrita et al. (2005) for gilthead seabream sperm. For cell viability, samples were diluted 1:100 in 1% NaCl and a mix of Propidium Iodide (PI) and SYBR-green dyes were used to stain non-viable and viable cells, respectively. Three photos of different fields were taken per sample, and at least 100 cells per field were counted under a fluorescent microscope (Nikon E200, Tokyo, Japan) using the "cell counter" feature from ImageJ (Java) software. Results were expressed as percentage of viable cells. Statistical analysis was performed using SPSS software (IBM). Data that assumed normality and homogeneity of variance was analyzed with a T-test or One-way ANOVA, followed by a Student–Newman–Keuls (SNK) *post-hoc* test to identify statistical differences between groups. Mann-Whytney or Kruskal-Wallis nonparametric tests were respectively applied to data that did not assume the above mentioned principles.

Results

Results from day and night cryopreservation experiment revealed that cell concentration at MD was higher than ML, and all motility parameters analyzed, total motility (TM), progressive motility (PM), curvilinear velocity (VCL), straight line velocity (VSL) and linearity (LIN), revealed to be influenced by melatonin. Although TM in fresh samples from ML and MD points did not differ, all cryopreserved treatments, including the control only with DMSO, had higher TM and VCL values at nighttime. Regarding DNA fragmentation, no differences were observed between treatments in Tail DNA (%), but Olive Tail Moment (OTM) was consistently higher at ML.

Discussion

The present results can be explained by the potential antioxidant activity of melatonin (Mironczuk-Chodakowska et al., 2018) when supplemented in the cryoprotectant medium, as described by Gao et al. (2019) for paddlefish (*Polyodon spathula*) sperm. However, the fact that control group also revealed an increase in TM and VCL at MD may suggest that the higher levels of melatonin endogenous production at night (Reiter, 1991) can have an important role in spermatozoa protection, especially during cryopreservation (Len et al., 2019). Further research is needed in order to understand this melatonin mechanism of action (Zhao et al., 2019) and either if it is produced locally in the testis or absorbed by the blood stream (Acuna-Castroviejo et al., 2007; Falcón et al., 2010).

Introduction

In recent years, hydrogen sulfide (H_2S) incidents leading to acute and severe fish mortality has been identified as one of the most important challenges for marine, land-based recirculating aquaculture systems (RAS). It has been demonstrated that the highest potential for H_2S production in RAS is in saline environments with high sulfate (SO_4^{2-}) content (Letelier-Gordo et al., 2020) and in RAS biofilters with the higher sulfate-reducing microbial activity (Rojas-Tirado et al., 2021). Other factors can also play an important role in H_2S incidents, such as organic matter and nitrate availability. Therefore, it is important to find solutions that reduce the risk of H_2S -related incidents in RAS. The presence, level and availability of sulfate is still one of the key drivers of H_2S-related incidents. One of the options to prevent H_2S formation is to remove sulfate from the seawater intake via nanomembrane filtration to use in saline-environment RAS.

Material & Methods

A nanofiltration membrane setup (Hydronautics, Nitto-Group Company, USA) was installed at a commercial salmon smolt farm in Vestland county (Norway) to remove the SO_4^{2-} ions of the seawater intake. The farm was operated at 15-17 ppt and with a feed loading of 1.3-2.2 kg feed/m^3 of make-up water. At continuous and constant operation, the membrane maintained the SO_4^{2-} levels in the farm water at 102 mg SO_4^{2-}/L. The sulfate content of the local seawater varies between 2181-2830 mg SO_4^{2-}/L. This means that, before mixing with freshwater to a salinity of 17 ppt, the constant operation of the membrane had the capacity to decrease sulfate by 10 to 14 times.

Mature RAS nanofiltered water, freshwater and seawater, and mature moving bed biofilter elements (BTW 15, Biowater Technologies, USA) were obtained from the farm only after two consecutive weeks of membrane operation without significant downtime. 400 mL of biofilter elements (ca. 278 biomedia elements) were incubated in closed glass bottles with 2 L of nanomembrane filtered water (n =3) or 2 L of unfiltered water (n = 3) to a salinity of 15 ppt. Initial sulfate levels in the filtered water (102 mg SO_4^{2-}/L) were 10-fold lower than in the unfiltered water (1060 mg SO_4^{2-}/L).

Water samples were collected from each reactor every second day and analyzed for O_2, pH, temperature, ORP (oxy-redox potential), total sulfide and H_2S, sCOD (dissolved chemical oxygen demand), NH_4^+, NO_2^-, NO_3^-, PO_4^{3-}, and SO_4^{2-}. All reactors were spiked with 180 mg acetate/L on day 27 to maximize H_2S production. The trial lasted 42 days. TCOD (total chemical oxygen demand) from water and biomedia, and microbial samples from biomedia and water of each reactor were collected at the start (day 0) and end of the trial (day 42).

Results

Data analysis is ongoing, and we expect to present the results during the conference.

Introduction

Plant feedstuffs (PF) have non-starch polysaccharides (NSP) that may negatively impact fish growth, feed utilization and nutrients digestion (Kokou & Fountoulaki, 2018). Given the increasing utilization of PF in fish diets as replacers of fishmeal, innovative strategies need to be considered to increase PF nutritional value. One of such strategies is the use of carbohydrases to digest NSP (Castillo & Gatlin, 2015). This work aims to assess the potential of using carbohydrases produced by solid-state fermentation (SSF) of brewer's spent grain (BSG), either directly incorporated in the diets or used to pre-treat the diet PF mixture, on growth, feed utilization, body composition and digestive enzymes activities of European seabass (*Dicentrarchus labrax*) juveniles.

Materials and Methods

BSG was fermented (SSF) with *Aspergillus ibericus* (MUM 03.49) for 7 days, with 75% moisture and at 25 °C. Then, an aqueous extraction was carried out in the fermented product (5 ml distilled water/g fermented BSG) and the enriched-carbohydrases extract was lyophilized. Five isonitrogenous (50% crude protein) and isolipidic (18% crude lipids) diets were formulated to contain 25% fishery products and 55.4% PF: a control diet (with no carbohydrases); two diets similar to the control but inclusing 0.4% (BSG4) and 0.8% (BSG8) lyophilized SSF-carbohydrases, corresponding to 4000 and 8000 U cellulase/kg diet, respectively (28230 and 56460 U xylanase/kg, respectively); two diets similar to the control but with the PF-mixture pre-treated (4 h, 45 °C, 40% moisture) with the lyophilized SSF-carbohydrases in sodium citrate buffer (0.05 N, pH 4.8) at the concentration of 4000 (PreBSG4) and 8000 U cellulase/kg PF (PreBSG8). European seabass (*Dicentrarchus labrax*) juveniles (IBW 21.5±1 g) were randomly distributed in 18 groups (18 fish/group). The trial lasted 66 days and fish were fed twice a day, 6 days a week. At the end of the trial, fish were bulked weighed and body composition (n=3) and activities of intestinal digestive enzymes (n=9) measured. All experimental diets were compared to the control diet (Dunnett's test). Two-way-Anova was carried out with BSG levels (0.4% and 0.8%) and incorporation method (IM) (direct or as pre-treatment) as factors.

Results

Compared to the control, fish fed the BSG8 diet showed higher growth, although the PreBSG4 diet also showed similar values but with no significant differences. Further, FI was lower while PER was higher in fish fed both pre-treated diets, and FE was higher in the PreBSG4 group. BSG levels did not affect growth performance and feed utilization of the fish, while pre-treatment of the PF improved PER and NR (% NI) compared to groups fed the diets directly supplemented with the extract. Whole-body dry matter and lipid content were also affected by the inclusion method of SSF-carbohydrases at 0.8%, as BSG8 group presented higher values than PreBSG8 group. Energy body content was similar among groups. Amylase, lipase, and trypsin activities were not affected by diet composition. Total alkaline proteases (TAP) from the 0.4% groups exhibited higher activities when fish were fed the preBSG4 diet.

Trypsin	0.479	0.527	0.676

Mean ± standard error mean (SEM), n=3. Two-way-Anova (Fixed factors): BSG levels (0.4% and 0.8%); incorporation method (IM) (direct incorporation or pretreating PF prior inclusion in diets). *Denotes significant differences $p<0.05$ between control diet and each test diet (Dunnett test).

**Two-way ANOVA-excluding the control diet (Sig. differences at $p<0.05$). If interaction was significant, one-way ANOVA was performed for each factor, and means in the same line with different small or capital letters indicate significant differences ($p<0.05$) between both supplementation levels (0.4% or 0.8%) or incorporation method (IM: BSG vs PreBSG), respectively; means with no letters are not significantly different ($p\geq0.05$).

IBW, initial body weight; FBW, final body weight; ABW, average body weight; DGI, Daily growth index; FI, feed intake; FE, feed efficiency; PER, protein efficiency ratio. TAP, total alkaline proteases.

ABW: (IBW + FBW)/2 ; [1]DGI: ((FBW1/3 - IBW1/3)/time (days)) × 100 ; [2]FE: wet weight gain/dry feed intake ; [3]PER: wet weight gain/crude protein intake ; [4]NR = ((FBW × carcass N content) - (IBW × carcass N content))/(ABW × the number of days) ; [5]Energy retention = ((FBW × carcass energy content) - (IBW × carcass energy content))/(ABW × the number of days).

Conclusions

The use of SSF-carbohydrases promoted the growth and feed efficiency of European seabass juveniles compared to fish fed the control diet. Direct supplementation of 0.8% SSF-carbohydrases in the diet promoted growth performance but did not affect feed efficiency, while pre-treatment of PF with 0.4% SSF-carbohydrases promoted growth performance and decreased feed intake, thus improving feed efficiency.

Introduction

The aquaculture industry continues to grow faster than any other sector of food production. The need to make aquaculture as sustainable and more environmentally conscious as possible is becoming clearer everyday (FAO, 2020). With this in mind, the replacement of fishmeal and fish oil in aquafeeds has been studied in Atlantic salmon (*Salmo salar*) (e.g., Bendiksen et al., 2011) with many products emerging as potential alternatives to conventional ones (e.g., Hodar et al., 2020). One of the main objectives of the EU project GAIN is to evaluate new ingredients that are already commercially available using different formulation concepts that consider all the fish nutritional needs. GAIN diets are based on circular economy principles and maximize resource efficiency, while contributing to zero waste in the agri-food value chain, being cost-effective feeds, and having good social acceptability. The present study aims to understand the actual effects of these novel feed formulations on growth performance, nutritional status, immunity and oxidative status.

Methods

Quadruplicate groups of Atlantic salmon were fed *ad libitum* with three different diets. Two diets were developed to facilitate the eco-intensification of aquaculture through increased circularity and resource utilization (NOPAP - formula without processed animal protein - and PAP - formula with processed animal protein). The third diet was a commercial-like formulation that was used as a control. After a 96-day feeding trial, plasma samples were collected to evaluate humoral parameters (protease, anti-protease, bactericidal activity, and IgM). Liver and head kidney tissues (collected at day 45 and 96) were used for the simultaneous profiling by PCR array of a panel of 38 or 28 genes, respectively, as markers of growth performance, lipid and energy metabolism, and immune and antioxidant activities. Liver samples were also used to analyse lipid peroxidation. In addition, after 45 and 96 days, the lice count and fish welfare were also assessed by standard methods. The dorsal skin and foregut were collected at days 45 and 96 for mucosal mapping (mucous cell area, density, and barrier status).

Results

Growth performance was adequate and comparable to commercial standards for the novel diets tested. Other parameters analysed, including those related to key performance indicators, intestinal and skin dorsal mucosal mapping, plasma innate immune defences, and lipid peroxidation in the liver did not significantly differ across diets. Regarding head kidney gene expression, at Day 45, 2 out of 28 genes in the array were differentially expressed ($p<0.05$). Gene expression of fish fed with novel feed formulations showed a pro-inflammatory profile evidenced by the up regulation of *il-8,* and a down regulation of *il-10*.At Day 96, the same genes continued to be differentially expressed, but gene *clec1b* (membrane protein) was also up-regulated. However, the rest of the analyses do not support this pro-inflammatory profile. A longer trial may bring light to some of the current results. In turn, the liver had a differential gene expression only at the second sampling point (Day 96), where 4 out of 38 genes in the array were affected, including growth performance (*igf2*), lipid metabolism, elongases (*elovl4*), and energy metabolism (*ucp2l* and *sirt1*). These transcriptomic changes may be attributed to an initial response to the experimental diets. Cross-analysis of gene expression by time points and dietary treatment (two-way ANOVA) yielded only 2 out of 38 genes that had significantly different expression across treatments. The differentially expressed genes were related to growth performance (i*gf2*) and lipid metabolism (*elovl4*).

(Continued on next page)

Conclusions

The novel feed formulations of the GAIN project for Atlantic Salmon seem to be viable options for the near future. In any case, all results are related to the formulation itself and cannot be attributed to a specific ingredient alteration. More studies are necessary to understand the cost-benefit of these new formulations and their market acceptability to optimize sustainability within the current/predictable European regulatory framework.

Introduction:
Aquaculture long-term sustainability has been deeply questioned since it requests increasing amounts of fish oil and meal (FO and FM, respectively; limited resources) as main raw materials for aquafeeds. During the last decades, a large effort has been focused to identify alternative raw materials (ARMs; e.g. soybean, insect, algae and single cell's meal, animal by-products meal, plant-derived oils, microalgae and krill oils, etc.) to substitute FO and FM (reviewed in Turchini et al., 2018). Nowadays, soybean meal (SBM) is still one of the main ARMs currently used in commercial fish diets. However, it is imported in some regions (e.g. Europe). Thus, the identification of locally produced crops able to partially or totally substitute SBM is an urgent need to reduce not only the dependency of SBM from third countries, but also to reduce the carbon footprint.

A two-step screening protocol, including a first set of in vitro assays followed by in vivo test, is proposed to evaluate different protein sources of vegetable origin locally produced in Europe as more sustainable sources for rainbow trout (*Oncorhynchus mykiss*) diets.

Materials and Methods:
Experimental design: Different meals obtained from cultivars of Narbone vetch (*Vicia narbonensis*), in addition to red vetchling (*Lathyrus cicera*) and green pea (*Pisum sativum*) meals (NVM, RVM and PM, respectively) were tested as alternatives to the use of soybean (*Glycine max*) meal (SM). In a first approach, this selection was based on nutritional, economical and environmental factors. Afterwards, a complementary characterization of the nutritional aspect of each ARM was done, including: amino acid profile, buffering capacity, soluble protein content, etc. Also, the presence and their stability/activity of some nutritionally limiting factors (e.g. non-starch polysaccharides, phytate) as well as their *in vitro* digestibility after treatment with an exogenous enzyme was evaluated. In a second step, the most promising ARM to partially replace soy protein concentrate (SPC) in rainbow trout diets was evaluated *in vivo*.

Five experimental diets (iso-nitrogenous, -lipidic and -energetic) were formulated: one diet with FM and SPC as main protein sources (Control), and 4 diets were SPC was partially replaced by 33% or 66% of NVM (the selected ARM) previously treated with exogenous enzyme Rovabio® phytase (A33E and A66E) or not (A33 and A66). Thirteen fish (38.04 ± 0.07 g and 15.10 ± 0.07 cm) per 500 L tank were randomly allocated. Diets were tested in triplicate (15 tanks connected to recirculating aquaculture systems (RAS)). Fish were daily hand-fed (3% of daily feed intake) during 63 days. Rearing conditions were: 14.5 ± 0.3 °C, >8.0 mg/L of dissolved oxygen, and 12:12-h light:dark cycle. All procedures were approved by the Bioethical Committee of ITACyL (Nº 2018/31/CEEA).

Fish sampling, growth performance and histopathological assement: Final body wet weight (FBW) and furcal length (FFL), weight gain (WG), condition factor (CF), SGR, FCR, viscerosomatic (VSI) and hepatosomatic indexes (HSI) were calculated.

Statistical analysis: Results are given as mean values ± standard deviations. Data was checked for normality (Kolmogorov–Smirnov test) and homoscedasticity of variance (Bartlett's test). Results were compared by means of one-way ANOVA and Tukey or Dunnett´s multiple-comparison test. The level of significance was set at $p < 0.05$.

(Continued on next page)

Results and Discussion:
ARMs showed a lower buffer capacity (81.63 to 95.09 μmol H+ per (g * ΔpH)) than SM (248.69 μmol H+ per (g * ΔpH); ANOVA, $P < 0.05$). Alkaline proteases inhibition was higher (47 to 69% of inhibition) in all of them when compared to that of SM (24.18%; ANOVA, $P < 0.05$). Protein solubility was variable in all ARMs (from 2.69 to 4.60 mg/g), while in SM it was 3.76 mg/g. Regarding the presence of phytate, while NVM showed similar content to the one reported in SM, RVM and PM had less than the 50% of the phytate present in SM. While NVM and SM had similar content in phenolic compounds (1.3 and 1.2 g/kg) RVM and PM had lower content (0.8 and 0.9 g/kg). Furthermore, total soluble phosphorus was also lower in RVM and PM than in NVM and SM. Based on these results, NVM autoclaved or not was selected for additional *in vitro* characterization.

Enzymatic pre-treatment of NVM autoclaved or not and SM was able to remove all the phytate, and increased the availability of pentoses and reducing sugars. In not autoclaved NVM, the amount of reducing sugars was increased by 5 times with the enzymatic pre-treatment. Autoclaving is a process that already reduce the presence of phytate in NVM, but it is expensive an unpractical for large quantities. Thus, not autoclaved NVM was selected to partially replace SM in the *in vivo* assay to validate this screening tool.

As shown in Table 1, results of the growth performance trial suggested that 33% of SPC can be substituted by NVM when previously treated with exogenous enzyme. Thus, present screening tool might help to identify/optimize the use of ARMs in fish diets.

Introduction:
Fat-soluble vitamins (FSVs) play essential roles in vertebrate's development and homeostasis. Thus, efficient and sustainable fish farming deeply depends on the optimization of their dietary levels (Hamre et al., 2013). Although their nutritional minimum requirements have been fixed (at least in salmonids; NRC 2011) through unifactorial nutritional-dose-response trials (Fernández et al., 2018), little is known on their metabolism. Furthermore, the different FSVs have genes in common involved on the processes of assimilation and transport from intestine to liver and target tissues (Fernández et al., 2018). Therefore, how these genes are modulated in response to dietary FSVs contents through a multifactorial and integrative manner, might help to further develop precision fish farming and defining fully nutritionally balanced diets.

Here, growth performance, histopathological status of the digestive system, liver FSV's content and the expression of genes involved in the FSVs metabolism were explored in rainbow trout (*O. mykiss*) juveniles fed with diets containing different levels of FSVs.

Materials and Methods:
Experimental design: All procedures were approved by the Bioethical Committee of ITACyL (Nº 2018/35/CEEA). Nine experimental diets (isonitrogenous, isolipidic and isoenergetic) were specifically formulated to contain: the reference content on vitamin A (VA), D (VD), E (VE) and K (VK) (NRC 2011) and/or 10 or 0.2 times the reference content of each vitamin. Twenty-one fish (94.04 ± 0.81 g mean weight and 20.28 ± 0.09 cm) per 500 L tank were randomly allocated. Experimental diets were tested in triplicate (27 tanks connected to recirculating aquaculture systems (RAS), 9 tanks per RAS unit). Fish were daily hand-fed (3% of daily feed intake) during 90 days. Rearing conditions were: 14.5 ± 0.3 °C, >8.0 mg/L of dissolved oxygen, and 12:12-h light:dark cycle.

Fish sampling, growth performance and histopathological assessment: Final body wet weight (FBW) and furcal length (FFL), weight gain (WG), condition factor (CF), SGR, FCR, viscerosomatic (VSI) and hepatosomatic indexes (HSI) were calculated. In addition, 3 fish from each tank were randomly sampled and sacrificed with an overdose of MS222 to dissect liver and intestine to perform histological, HPLC/DAD and gene expression analyses. Samples for histological analyses were fixed in 10% buffered paraformaldehyde (pH 7.4) during 24 h, dehydrated, embedded in paraffin blocks, sectioned and stained with Haematoxylin-Eosin or Alcian blue periodic acid-Schiff (PAS) solutions. Standard histomorphometric analyses were conducted (Gisbert et al., 2008; Silva et al., 2015).

HPLC/DAD analysis: FSVs content in diets and livers (from 6 fish per dietary group) were extracted, concentrated and quantified using an Agilent HPLC/DAD 1200 equipment.

Expression analysis of genes involved in fat-soluble vitamins metabolism: Total RNA was extracted with TRI-Reagent from 6 fish (2 from each tank) from each dietary group. 1 μg of total RNA was reverse-transcribed, and gene expression was quantified using SsoFast EVAgreen Supermix (Bio-Rad) in a StepOnePlus Real-Time PCR system. The studied genes were previously identified in Fernández et al. (2018).

Statistical analysis: Results are given as mean values ± standard deviations. Data was checked for normality (Kolmogorov–Smirnov test) and homoscedasticity of variance (Bartlett's test). Results were compared by means of one-way ANOVA and Tukey multiple-comparison test. The level of significance was set at $P < 0.05$.

(Continued on next page)

Results and Discussion:
Only slight differences in particular growth performance indexes were found after 90 days of feeding (Table 1). Increased dietary VD content induced a higher condition factor, while reduced VE content lead lower SGR and HSI. While lower dietary VK content decreased SGR, HSI and VSI; and increased VK content decreased condition factor, SGR and HSI.

FSVs content in fish livers reflected that of experimental diets. FSVs dietary content has also affected histopathological status of the digestive system, particularly at the proximal intestine. High dietary VA, VE and VK content increased goblet cells density when compared to low VA, VE and VK, respectively. Fish fed high dietary VK content also have thicker muscular and serosa layers compared to that of fish fed on low VK content.

Finally, we are currently studying how is the expression of some genes involved in FSVs metabolism accordingly to the dietary content included in fish diets, and results will be discussed. These results show how dietary FSVs content altered fish growth and physiology, brings new insights on how their metabolism is adapted and key knowledge on biomarkers to design fully nutritionally balanced diets regarding FSVs.

Introduction:
Due to the limited availability of fish meal and oil from wild fisheries, aquaculture sustainability largely depends on the implementation of alternative raw materials in aquafeeds. Among the different alternatives considered, insects have recently attracted the attention as suitable alternatives (Nogales-Mérida et al., 2018). Different species of insects have been evaluated, but we recently found mealworm (*Tenebrio molitor*; TM) as the most promising to replace fish meal up to 30% (Melenchón et al., 2021). Different reports have shown how high levels of fish meal substitution with insect meal might impact fish physiology, but the nutritional causes are not fully understood.

Here, we assessed the effects on fish growth, histopathological status on the digestive system, the content of fat-soluble vitamins (FSVs) and the related gene expression when substituting 50% of fish meal with TM meal (either defatted or not) in rainbow trout (*Oncorhynchus mykiss*) diets.

Materials and Methods:
Experimental design: All procedures were approved by the Bioethical Committee of ITACyL (Nº 2018/35/CEEA). Three experimental diets (isoproteic and isolipidic) were specifically formulated with fish meal (Control), fish meal 50% substituted with defatted TM meal (TD50) and fish meal 50% substituted with TM meal (T50), all of them supplemented with an equal amount of mineral and vitamin premix and tested in triplicates. Twenty-one fish (46.2 ± 0.21 g mean weight and 15.9 ± 0.12 cm) per 500 L tank were randomly allocated in 9 tanks connected to a recirculating aquaculture system (RAS). Fish were daily hand-fed to apparent satiation (up to 3% of daily feed intake) during 68 days. Rearing conditions were: 14.5 ± 0.3 °C, >8.0 mg/L of dissolved oxygen, and 12:12-h light:dark cycle.

Fish sampling, growth performance and histopathological assessment: Final body wet weight (BW) and furcal length (FL), WG, CF, SGR, FCR, viscerosomatic (VSI) and hepatosomatic indexes (HSI) were calculated. In addition, 3 fish from each tank were sacrificed to dissect liver and intestine to perform histological, HPLC/DAD and gene expression analyses. Samples for histology were fixed in 10% buffered paraformaldehyde (pH 7.4) during 24 h, dehydrated, embedded in paraffin blocks, sectioned and stained with Haematoxylin-Eosin or Alcian blue periodic acid-Schiff (PAS) solutions. Standard histomorphometric analyses were conducted (Gisbert et al., 2008; Silva et al., 2015).

HPLC/DAD analysis: FSVs content in diets and livers (from 6 fish per dietary group) were extracted, concentrated and quantified using an Agilent HPLC/DAD 1200 equipment.

Expression analysis of genes involved in fat-soluble vitamins metabolism: Total RNA was extracted with TRI-Reagent from 6 fish (2 from each tank) from each dietary group. 1 μg of total RNA was reverse-transcribed, and gene expression was quantified using SsoFast EVAgreen Supermix (Bio-Rad) in a StepOnePlus Real-Time PCR system. The studied genes were previously identified in Fernández et al. (2018).

Statistical analysis: Results are given as mean values ± standard deviations. Data was checked for normality (Kolmogorov–Smirnov test) and homoscedasticity of variance (Bartlett's test). Results were compared by means of one-way ANOVA and Tukey multiple-comparison test. The level of significance was set at $P < 0.05$.

(Continued on next page)

Results and Discussion:
Only fish fed with T50 diet showed significant differences when compared with the Control group, particularly with reduced body weight and weight gain as well as increased feed conversion rate (Table 1; ANOVA, $P < 0.05$).

No major impacts on the histopathological status of the digestive system have been found among the fish fed the different experimental diets. Only a slightly increased width of the serosa layer in fish fed T50 diet when compared with fish fed Control diet was found (ANOVA, $P < 0.05$), with TD50 group showing intermediate values.

Significant differences were found in the FSVs content in fish livers (ANOVA, $P < 0.05$). In particular, total vitamin A was only significantly reduced in fish fed TD50 diet when compared with the one of fish from Control group, with fish fed T50 diet showing intermediate values. In contrast, independently of being defatted or not, a 50% fish meal substitution by TM meal led to reduced vitamin K levels in fish liver.

Finally, the expression of some genes involved in FSVs metabolism is being studied and results will be presented. Altogether, present results show that although TM meal can partially replace fish meal in rainbow trout diets, dietary FSVs content should be corrected in the premix in order to avoid any potential physiological impact of their deficiency.

Introduction

European sea bass (*dicentrarchus labrax*) and gilthead sea bream (*sparus aurata*) are both an economically important cultured fish species along the Mediterranean coast. In 2018 the two species represented a 38% of the total value of the European aquaculture sector (STECF, 2021) ranking the second and third species respectively after the Atlantic salmon. The EU is one of the largest producers of sea bass and sea bream in the world, being Greece the largest producer within the EU followed by Spain. Aquaculture of sea bass and sea bream is an industry with a high economic competitiveness in which the profitability of operations is very important and sensible to different operational factors and production scenarios. Despite of its importance, there are few empirical studies about this topic so far. Hence, it would be very interesting for this industry to analyze how changes in different key operational factors affect the economic performance of production facilities. The aim of this work, which is part of the MedAID project funded by the European Commission (H2020, GA727315), is to analyze these economic effects or impacts in the European sea bass and sea bream aquaculture industry at the micro (farm) level.

Methodology

To carry out this analysis, we have designed a deterministic static model, which we have named MedAID Model for Economic Simulation (MMES), composed of a production sub-model and an economic sub-model (see Figure 1) and programmed with the spreadsheet Excel to simulate the annual income statement of a standard (average) aquaculture farm. The model can be employed to simulate the annual economic results of a grow-out facility for growing up sea bass and sea bream as well as a hatchery facility to culture sea bass and sea bream fry and larvae in the Mediterranean Sea. To obtain the baseline values of the model parameters, we have used data from representative facilities from six European countries (Croatia, Cyprus, France, Greece, Italy, and Spain) collected in a survey conducted in MedAID's WP1.

With the former model, a sensitivity analysis has been applied to identify the most important, highly sensitive, parameters in the model. Thus, we have examined the sensitivity of the baseline model results to different assumptions about some key model parameters such as the unit sales price, the survival rate, the harvested weight, the tank or cage density, the growth rate, the fingerling unit cost, the feed unit cost, or the feed conversion ratio (FCR). Each of these model parameters has been varied one by one maintaining the rest of parameters constant (*ceteris paribus*) by 10%, 20% and 30% above and below its baseline value, what allows us to analyze the impacts of those variations on the indicators of economic performance employed in this research such as the gross operating profit, the net operating profit, the average operating cost, and the break-even point. Four different production scenarios have been designed to run the sensitivity analysis. These scenarios have been chosen based on actual data from different European facilities producing sea bass and sea bream, which have been surveyed in the MedAID project. In Table 1 we summarize the four production scenarios.

Results

The economic impact of model parameters changes shows that the unit sales price (p) is the model parameter with the largest impact for all scenarios (i.e., hatcheries and grow-out facilities), followed by survival rate (s) and harvested weight (w_1) parameters in hatcheries and by survival rate (s), feed unit cost (p_f) and FCR (r) in grow-out facilities. On the other hand, the feed unit cost (p_f) and feed conversion ratio (r) are the model parameters with the lowest impact on profits of a hatchery facility (scenario 1), whereas the harvested weight (w_1) and fingerling unit cost (p_j) are the model parameters with the lowest impact on profits of a grow-out facility (scenarios 2, 3 and 4). All these effects are briefly summarized in Table 2 for a standard hatchery facility (scenario 1) and Table 3 for a standard grow-out facility (scenarios 2, 3 and 4).

Introduction

The grooved carpet shell clam (*Ruditapes decussatus*) is a highly desirable species in the European market. Its population has been in a constant decline due to biotic and abiotic factors, namely, habitat degradation by anthropogenic actions in the case of abiotic factors but also due to competition with alien species and pathogens in the case of biotic factors. The introduction of the alien species *Ruditapes philippinarum* in the decade of 60´s in France and England constitutes one of the main problems due to habitat loss and competition against a faster growth clam [1], also, some introductions of the alien species from Asia in the 80´s brings the Apicomplexan parasite *Perkinsus olseni* to European waters [2, 3]. This parasite not only provoke mortalities in the native clams but also it is able to impairs their reproduction by decreasing the quality of gametes and survival of the larvae [4].

Taking all these details into account, our study is focused on the effect of different doses of the parasite in the ability of clams to survive and to fight against the disease. Also, some genes previously identify as potentially involved in the response to infection were studied in gill and hemocytes during the progression of the infection.

Material and methods

A total of 540 *R. decussatus* clams (43.7 ± 2.9 mm length) were purchased from the fisheries association of San Bartolomé de Noia (Galicia, NW Spain) a known spot for being *P. olseni* free bed. Clams were transferred to CIIMAR facilities and they were placed in 10 tanks (54 clams per tank) at 19ºC. After that, clams from 9 tanks were notched in the shell and injected in the adductor muscle with 100μL of two different doses of parasites (3 tanks with 5000 cells/clam – Low Infection (LI); 3 tanks with 500,000 cells/clam – High infection (HI)) and 3 tanks with marine filtered sea water (control), also one tank was untouched to check it out the effect of the injection into the clams (C-).

At 24 hours, 48 hours, 1, 2 and 4 weeks after injection, 5 clams per tank (15 per treatment) were sampled. Hemolymph was extracted by a 1mL insulin syringe, centrifuged at 2500 rpm, 10 min and 4ºC to separate hemocytes from plasma. Hemocytes were immediately stored at -80ºC. One piece of gill was collected and placed in 0.5 ml of RNA later (Invitrogen, US) and stored at -80ºC. Also, one hemigill was placed in 10 ml of RFTM medium (Casas & Villalba 2012) for *P. olseni* diagnosis and quantification and other was placed in ethanol 96% for DNA extraction and qPCR diagnosis of the parasite according to Rios, Aranguren [5].

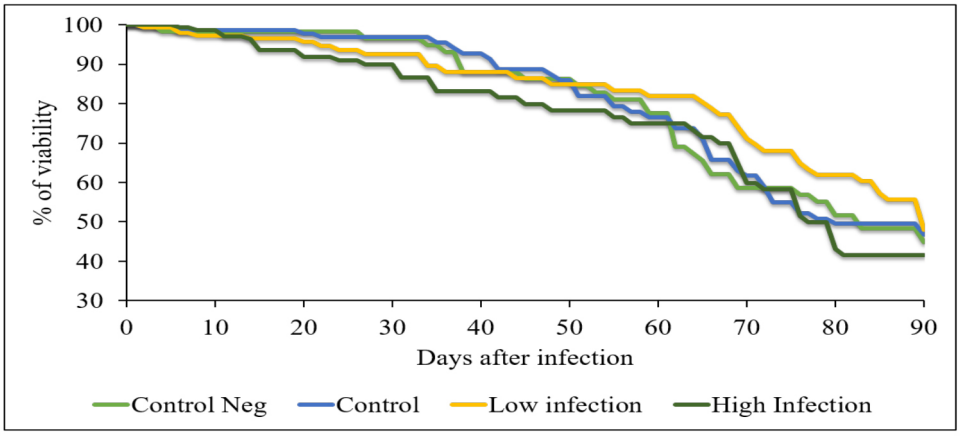

Fig. 1. Mortality curve of clams after infection by two doses of parasites. Y axis represents percentage of survival while x axis represents days after infection.

(Continued on next page)

Results

No differences in mortality was seen among the different treatments during the 3 months of trial (Fig.1). Infection trial was successful and a high correspondence parasite load was obtained by two diagnosis methods: RFTM and qPCR.

Regarding the gene expression results, a high expression was seen in adiponectin in both tissues at all times and infection load, while most of the other genes seem to be down-regulated at first 48 hours to recover after that in gills while no differences were seen in hemocytes.

P. olseni was not able to provoke a high mortality in a small period of time in adult clams although some studies reported high mortalities in juveniles [6]. Regarding the experimental infection, all parasites migrate quickly from adductor muscle to gills and a high parasite load was seen 24 hours post-infection in HI clams suggesting an active infection and confirming the effectiveness of the infection protocol. Also, no differences in mortality were recorded between both control tanks suggesting that notched and injection have not any harmful effect on clams.

Finally, gene expression study shows that adiponectin seems to be the most relevant marker of infection for *Perkinsus* infection in clams.

COLD SEAWATER PRE-TREATMENT AFFECTS THE SPERMATOGENESIS AND THE REPRODUCTIVE PERFORMANCE OF MALE EUROPEAN EELS

Introduction

The European eel (*Anguilla anguilla*) is a highly valued species targeted for aquaculture production. However, it is considered a critically endangered species by CITES, and reproduction in captivity seems to be the only realistic alternative to solve both economic and ecological problems (Asturiano, 2020). It is possible to obtain gametes for artificial fertilization but it requires hormonal treatment, which is a time-consuming and expensive process (Gallego et al., 2012). Moreover, the variable response to these treatments results in high mortality rates during the early stages of development, which could be caused (at least in part) by low sperm quality and uncontrolled epigenetic factors (Herráez et al., 2017). Considering the environmental conditions experienced during eels oceanic migration, the effects of low temperature combined with hormonal treatment have been used to better understand the onset of eel maturation (Peñaranda et al., 2016). Thus, the present study considers the use of low temperature as a pre-treatment before starting a standard hormonal treatment and evaluates its impact on eel maturation and male reproductive performance.

Material and Methods

Eighty-eight male European eels were maintained for 3-4 days in freshwater at 20 ºC. Then, 6 males were sacrificed, as initial control, and the rest were changed to seawater at 10 ºC, except the control group, which was changed to seawater but maintained at 20 ºC. Low water temperature pre-treatments were applied during 1, 2 or 4 weeks to groups of 20 males. Once finished each pre-treatment, 8 fish per group were sacrificed for sampling. The temperature of the water of the remaining males was increased to 20 ºC in 3-4 days and they started receiving standard hormonal treatment (weekly administration of recombinant chorionic human gonadotropin, rhCG; Ovitrelle, Spain, 1.5 IU/g fish). From sacrificed fish (controls and pre-treated) biometric parameters were measured. Blood and testis samples were used to perform steroid (T, 11-KT and E2) analyses and histology, respectively. Once eels were spermiating, sperm volume, motility and kinetic parameters were evaluated weekly using a CASA system.

Results

The eye, fin and hepatosomatic indexes from 1-week, 2- and 4-weeks pre-treated fish were significantly higher than those of the control group. The gonadosomatic indexes registered in the control group were unusually high and significantly differed with 1-week pre-treatment group but not with the 2- and 4-weeks groups. Androgen levels (T, 11-KT) were significantly higher after 4-weeks of pre-treatment in comparison with the control. The E2 levels did not show the same increasing profile. The control and 1-week pre-treated males showed significantly higher percentages of undifferentiated and differentiated type A spermatogonia in comparison with early spermatogonia type B. The males after 2- and 4-weeks of pre-treatment revealed a significantly increased proportion of differentiated spermatogonia type A. After the rhCG treatment, males from the 4-weeks pre-treatment group started to produce sperm earlier than males from the other groups. The sperm volume in the 4-weeks pre-treatment group increased during the first weeks of spermiation and in the control group at the end of the experiment, but no significant differences were found. Sperm motility and kinetics parameters were low in pre-treated groups throughout the whole experiment while in the control group increased significantly at the end of the hormonal treatment.

(Continued on next page)

Discussion

The onset of maturation in the European eel is controlled by environmental conditions found during their migration. The application of pre-treatments can be important to induce maturation in aquaculture eels, which do not encounter these conditions (Palstra and van den Thillart, 2009). Several factors such as temperature, salinity, forced swimming and pressure have been used as part of pre-treatments applied to eels (reviewed by Asturiano et al., 2020). Rozenfeld et al. (2019) evaluated the effects of cold seawater in European eel maturation without hormonal treatment. In eels treated at 10 ºC, the T and 11-KT levels were higher and there was an increase in the proliferation of differentiated type A spermatogonia. Our results also corroborate that low-temperature pre-treatment (4-weeks at 10 °C) induces an early sexual development, thus leading to the release of androgens which promote the proliferation of type A spermatogonia. However, the low sperm quality found in the pre-treated groups revealed that thermal pre-treatment followed by rhCG treatment at high temperatures impairs spermatogenesis. Low-temperature pre-treatments induce testis cell proliferation and synchronization but inhibit further maturation. Peñaranda et al. (2016) suggested that low seawater temperature inhibits the gene expression of enzymes responsible for the synthesis of maturation-inducing steroids (MIS) during eels oceanic migration. Thus, the premature maturation of the testis is prevented before eels arrive to the spawning areas and a temperature threshold is reached allowing the change of the steroidogenic pathway to change from androgens to MIS. In our experiment, low-temperature pre-treated males had a time-dependent and fast response to rhCG treatment (in comparison with control males maintained at 20 °C), but their spermiation period was shorter and their sperm motility parameters were significantly lower. If this is evidencing a lower rate of gene expression in the testis, and thus limiting the final sperm maturation process, is an open question that requires further research.

Introduction

The continuous increase in demand for fish puts pressure on the aquaculture industry to find alternatives to the limited fisheries-based dietary protein sources to avoid overexploitation of marine resources. The traditional fish meal is now being successfully replaced with more economically and environmentally sustainable ingredients. In this context, seaweeds and microalgae, the natural sources of nutrients and bioactive compounds, can improve fish growth and overall health. Furthermore, nutritional manipulation of the intestinal microbiota can have a positive impact on fish welfare and nutrition.

The macroalga *Gracilaria gracilis* and microalga *Nannochloropsis oceanica* have been recently explored by the feed industry, but the impact of the inclusion of such products on the gut microbiota of European seabass (*Dicentrarchus labrax*) is poorly understood. We evaluated the impact of seaweed *G. gracilis* and microalga *N. oceanica*, single or blended, on the composition of microbial community in the intestine of European seabass.

Materials and Methods

European seabass (30 g) in triplicate tanks were fed four diets for 106 days at CIIMAR facility (Matosinhos, Portugal): a commercial-based diet (CTRL) and three experimental diets with the inclusion of 8 % *G. gracilis* (GRA), 8 % *N. oceanica* (NAN), or a blend of 4 % of each alga (NANGRA), at the expense of fish meal and wheat meal. At the end of the trial, mucus from the posterior intestine was collected under sterile conditions. After DNA extraction, the V3-V4 region of the 16S rRNA was amplified and sequenced employing an Illumina® MiSeq platform. After quality filtering, taxonomic assignment of the representative bacterial ASVs was performed using the RDP classifier. The R packages "iNEXT" and "phyloseq" were used to calculate alpha diversity and then employing the functions in "ggplot2", plots were generated for overall species richness, Shannon diversity and Simpson diversity. Kruskal-Wallis test followed by Dunn's test was employed to detect significant differences. The package "microbiome" was employed to determine relative abundance of core taxa and then "DESeq2" was used to identify the OTUs that were differently abundant in the study groups.

Results and Discussion

Illumina sequencing reads were assigned to 4,371 ASVs. The inclusion of the seaweed *G. gracilis* and the microalga *N. oceanica* on diets for European seabass had a significant impact on the alpha diversity: species richness was significantly lower in fish that consumed the GRA diet compared to CTRL; while Shannon and the Simpson diversity measures were significantly reduced in fish fed both GRA and NAN diets compared to fish fed CTRL. Neverthless, when algae were included in a blend (NANGRA diet), the alpha diversity measures remained similar to those observed for fish that consumed the CTRL diet.

Core microbial taxa (prevalence and detection thresholds of 90 and 20 %, respectively) of the posterior intestine were composed of the genera *Flavobacterium*, *Parcubacteria* and *Lactobacillus*. The most abundant phyla in the posterior intestine were Proteobacteria, Actinobacteria, Bacteroidetes and Firmicutes. Compared to the CTRL fish, the inclusion of the tested algae, single or blended, led to a decrease or increase of specific groups of bacteria. The incorporation of the seaweed *G. gracilis* and the microalga *N. oceanica*, single or blended, led to a decrease in Acidobacteria (*Gp4*) and Firmicutes (*Clostridium sensu stricto* and *Exiguobacterium*); and an increase in Bacteroidetes (*Kordia*) and Proteobacteria (*Acinetobacter*). The diet GRA, in particular, led to a decrease in Acidobacteria (*Gp6*), Nitrospirae (*Nitrospira*), Proteobacteria (*Rhizobium*, *Roseateles* and *Sphingobium*) and Verrucomicrobia (*Opitutus*). The diet NAN was associated with a reduction in Bacteroidetes (*Muricauda*) and Proteobacteria (*Ruminobacter*); and an increase in Firmicutes (*Clostridium XI*) and Proteobacteria (*Massilia*). Concerning NANGRA, the decrease in the genera *Opitutus*, *Muricauda* and *Gp6*, and increase in *Massilia* reflected the differences observed with the inclusion of single algae *G. gracilis* or *N. oceanica*. The blend resulted in the decrease of only a single genus (*Pseudomonas*) that belongs to Proteobacteria, which is the predominant phyla in the gut microbiota of different marine fish species, including European seabass.

(Continued on next page)

Conclusion

Overall, results indicate that the inclusion of seaweed *G. Gracilis* and microalga *N. oceanica* leads to a reduction of the gut microbial alpha diversity, while the blend attenuates these effects. Further clarification on the fuction of each specific group of bacteria affected by these dietary treatments will allow for a better undertanding on the impact of the tested algae, single or in combination, on the gut microbiota of European seabass.

Introduction

Current aquafeeds for carnivorous farmed fish species, such as European seabass (*Dicentrarchus labrax*), include moderate to low levels of fish meal and fish oil that are mostly replaced by high levels of plant products (PP). However, such formulations may compromise fish growth and have a negative impact on fish intestinal health. In this context, algae are natural products rich in bioactive compounds that may be included in feeds with high levels of PP to counteract the negative effects of such diets.

Intestinal integrity plays a crucial role in fish health, but detailed studies on the impact of novel formulations on fish intestine histomorphology are time-consuming and scarce. Here we applied both semi-quantitative and quantitative analysis to understand if the inclusion of a micro- and macroalgae blend in practical diets for European seabass provides some beneficial histomorphological changes in the intestine.

Materials and Methods

European seabass juveniles (11 g) were fed for 12 weeks with four diets in triplicate: a commercial-based diet (CTRL), that followed the current tendencies in aquafeeds, with already high levels of vegetable products and moderate levels of fish meal (12.5 %) and fish oil (13.2 %); and three experimental diets with the inclusion of increasing levels (i.e. 2, 4 and 6 %) of a commercial algae blend (blend 2, 4 and 6, respectively). The blend consisted of two microalgae (*Nannochloropsis oceanica* and *Chlorella vulgaris*) and two macroalgae (*Gracilaria gracilis and Ulva rigida*).

At the end of the feeding trial, anterior and posterior intestine samples from 9 fish per treatment (3 fish per tank) were collected and processed according to standard histological techniques. Sections were stained with hematoxylin and eosin for semi-quantitative scoring and Alcian blue/PAS (pH 2.5) for quantitative analysis. Micrographs of one section of each sample were evaluated using a light microscope with a camera. A continuous scale scoring system (1-5) was used to evaluate histomorphological changes in the intestine: submucosa and lamina propria width and cellularity; mucosal folds integrity; inflammatory infiltrates; and enterocytes nucleus position. For the quantitative analysis, Olympus cellSens Dimension Desktop imaging software was used to measure, in each section, the following parameters: cross-sectional perimeter (mm); *muscularis* thickness (μm); submucosa width (μm), lamina propria width (μm); total villus area (mm^2); villus length (μm); and goblet cells (GC) number and GC area. The *muscularis*, submucosa, and lamina propria were measured in eight selected points of each transverse section, and villus length was measured in the eight highest folds. Automatic counting of acid and neutral GC and villus area was performed on each cross-sectional area.

Results and Discussion

After the 12-weeks feeding trial, European seabass fed diets with the algae blend had a significantly higher final body weight and length compared to those fed the CTRL, with the highest values being registered for fish fed the blend 6. A larger perimeter was observed in both cross-sectional anterior and posterior intestinal sections in fish consuming blend 4 and 6 diets, compared to those fed the CTRL. A thicker *muscularis* was also observed in all fish fed the algae blend, but differences were only significant for the posterior intestine. Increased villus area and length were observed in the anterior intestine of fish fed the highest blend inclusion (6 %) compared to CTRL, but not in the posterior section. Such increased absorption area in the anterior part could explain the improved growth performance of those fish.

In both the anterior and posterior intestine, the number of goblet cells (GC) was higher in fish fed blend 6 diet compared to CTRL; the total number of acid GC increased significantly in the posterior intestinal section of these fish. Therefore, the blend diet (6 %) seems to be associated with increased mucus production that could favour nutrient digestibility, while the higher number of acid GC in the posterior intestine could be associated with improved resistance against pathogenic microorganisms.

(Continued on next page)

In the posterior intestine, the enterocytes of fish fed the CTRL showed a slight loss of their architecture, evidencing a minor nucleus displacement from their normal basal position, compared to those from blend 6. Therefore, the inclusion of the algae blend may allow a recovery of the normal intestinal structure often compromised by diets with high levels of plant products. In both anterior and posterior portions, the blend diets led to increased submucosa width, and increased cellularity could also be observed in the posterior intestine. Nevertheless, the level of inflammatory infiltrates remained similar among treatments.

Results indicate that the quantitative analysis could provide accurate information concerning lamina propria, submucosa, and *muscularis* width, as well as villus length. Also, the automatic counting of acid and neutral GC and villus area determination are fast and reliable procedures. However, the semi-quantitative evaluation seems a relevant complementary approach, providing important information regarding gut structure (enterocytes nucleus position) and the presence of inflammatory infiltrates.

Conclusion

Overall, results indicate that inclusion of a micro- and macroalgae blend, especially at the higher inclusion level (6 %), in diets for European seabass, results in some beneficial histomorphological changes in both anterior and posterior intestine that could partially explain the improved growth performance observed in fish fed the supplemented diets. Future studies on the topic of fish gut histomorphology should take advantage of quantitative analysis, coupled with a semi-quantitative approach, to have a deep understanding of the impact of novel diets on intestine structure and function.

Introduction

One of the most devastating bacterial diseases, associated with high mortality and economic losses, of wild and farmed marine fish is tenacibaculosis, caused by Gram-negative bacterium *Tenacibaculum maritimum* (Avendaño-Herrera *et al*., 2006). Knowledge regarding the pathogenesis of *T. maritimum* is scarce and can only be improved through the identification of the key virulence factors required for host colonization and disease progression and the host-pathogen interactions occurring during infection. The present study was conceived to evaluate European seabass (*Dicentrarchus labrax*) systemic and mucosal immune responses against *T. maritimum* infection. For that, seabass juveniles were bath-infected and changes in blood and plasma parameters as well as in the expression of immune-related genes in skin, distal gut and head-kidney were evaluated.

Materials and methods

A time-course trial was performed, in which groups of seabass (31.9 ± 6.9 g) were bath-challenged for 2 h in aerated seawater with 5 x 10^5 CFU mL^{-1} *T. maritimum* (challenged fish) or marine broth instead of bacteria (mock-challenged fish). Undisturbed fish randomly selected from the groups just before infection were used as controls (time 0). Following 4, 8, 24 and 48 h post-challenge, 8 fish from each treatment were randomly selected, euthanized and head-kidney (HK), distal gut and skin collected for total RNA extraction. RNA was retro-transcribed to cDNA and expression of immune-related genes was analysed by RT-qPCR and normalized with *40s* and *ef1b*. Blood samples were also collected for assessing haematological parameters (i.e., total white and red blood cells counts, haematocrit, haemoglobin, mean corpuscular volume, mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration) and for collecting plasma to evaluate innate humoral parameters (i.e., peroxidase, protease, antiprotease, bactericidal and nitric oxide activities). To determine the severity of the challenge, a lethality trial was performed in parallel, using the same bacterial inoculum/ challenge protocol used for the time-course trial.

Results

Challenge with *T. maritimum* induced 40% mortality, whereas no mortality occurred in mock-challenged fish. The number of erythrocytes decreased in the blood of challenged fish at 8 h post-infection, when compared to control (time 0). Regarding leucocyte numbers, the levels of circulating neutrophils in challenged fish increased at 8 h post-challenge compared to control fish and mock-challenged individuals. Lymphopenia was observed at 8 h and 24 h in challenged fish compared to the controls and mock-challenged. However, no significant differences were observed for the remaining evaluated haematological parameters. Similarly, no significant changes were observed among the plasma humoral parameters evaluated. At the transcriptional level, an up-regulation of *il-1β* gene expression was detected in the distal gut and HK tissues at 8 h post-challenge, whereas *il-10* transcripts, were up-regulated at 8 h in the HK and at 24 h in skin and distal gut for the challenged fish. The expression of *mmp9* gene also increased at 8 and 24 h post-challenge in distal gut and skin, respectively. Moreover, *cxcr4* and *il-8* transcripts increased at 8 and 24 h in skin whilst in the HK the response was delayed for *il-8*, with an up-regulation at 48 h for the challenged fish.

(Continued on next page)

Discussion and conclusion

The up-regulation of some innate immune-related genes such as *il-1β*, *il-8*, *mmp9* and *cxcr4* in mucosal tissues (i.e. skin and gut) following *T. maritimum* infection by bath, suggest that a local response was triggered. This immune response can be explained by *T. maritimum* capacity to adhere, colonize and degrade mucosal tissues (Avendaño-Herrera *et al*., 2006). The abrasion and damage in the tissues can subsequently lead to a systemic infection. However, the absence of changes in the plasma innate humoral parameters supports the occurrence of a poor immune response at the systemic level. Nevertheless, it cannot be disregarded that cytokines *il-1β* and *il-10* were up-regulated in the HK as early as 8 h post-challenge, suggesting signs of a response at a systemic level. The neutrophilia in challenged fish is likely due to the migration of these cells to peripheral infected tissues. This interpretation is further supported by the enhancement of *mmp9* and *cxcr4* transcripts in distal gut and skin. The observed lymphopenia may be related with the immune response to *T. maritimum*. An acute challenge, such as an infection, can lead to the redistribution of lymphocytes, from the blood to other body compartments where they are needed (Davis *et al*., 2008), resulting in a decrease in circulating lymphocytes. Further work is required to disclosure the dynamics stablished between the local and systemic immune responses triggered by *T. maritimum* infection, as well as to better understand *T. maritimum* - host interactions.

Introduction

The use and sharing of open ocean space by different activities of the Blue Economy is regarded by some as means to overcome difficulties and challenges from the high energyand dynamic environment, difficult logistics and cutting on high capital and operational costs. One of the classical examples is the multi-use of space by windfarms and aquaculture. The synergies of systems include the sharing of capital costs regarding mooring system and working platforms, plus a reduction in operational costs resulting from such as logistics and transports, maintenance teams and proximity of energy production – consumption. This presentation deals with the conceptual project OIPS for a multi-use platform of a defined floating windfarm, to be installed North Eastern Porto Santo Island (Portugal), at 70m depth single/double mooring and the choice of compatiblefish farming system, for the most efficient and sustainable production of both energy andfood.

Methods

We performed a internet survey of multi-purpose ocean platform projects associated withfish farming systems. The analysis included an assessment of technology readiness levels(TRL) of the different design systems proposed.

Results and Discussion

Several large concept projects co-financed by European funds have addressed this theme.Assuming an operation in offshore waters, interactions with the local environment and other social-economical activities are minimized and consequently, less stakeholders are involved. The interactive design and engineering of both energy and food production units depends upon the technical efficiency of systems and must have in account particularly, their operational compatibility to maximize and harmonize the outputs of the systems. The availability and quality of environmental data, particularly waves, wind and currents are critical for this purpose. The multi-use energy-producing platform provides for the reserve of energy to guarantee for its autonomy. Electronic sensors, video cameras and an AUV ensure the remote control and high automation of operations (including maintenance works), the online surveillance of the feed and livestock, and security of all facilities. TRLanalysis of similar projects shows the need to develop innovative equipment to cope withthe increment on operating loads of the windfarm platform (permanent fish farm cages and occasional service boat) under the site environmental conditions. These include the adoption of new materials and systems resistant to traction work, with small radius, such as cable and nets *dyneema*®. At low depths, separate mooring systems are advisable; thechoice of a single mooring point on the wind platform, and in a catenary in aquaculture, determines the choice of a heterogeneous type of anchorage.

AQUASENSE—A REAL-TIME PRECISION AQUACULTURE PLATFORM FOR INDUSTRY

Introduction

The EU Horizon 2020 Green Aquaculture Intensification in Europe (GAIN) project aims to promote eco-intensification of aquaculture by investigating several complementary strategies, including feed improvements, better use of secondary products, and precision aquaculture.

The development of precision aquaculture has four requirements: (i) deployment of sensors that supply environmental data on drivers of growth, welfare, disease, and mortality; (ii) detection of measurable response metrics from cultivated species—growth and mortality rates are the most significant; (iii) coupling and interpretation of these input and response data in order to obtain quasi- or real-time information on the cultivation process, providing farmers with meaningful indicators; and (iv) integrated platforms where industry stakeholders can easily access, process, and make use of data and information in order to optimise their activity in terms of production, environmental, and economic outcomes.

We present a blueprint of the AquaSense platform (https://aquasen.se), which was designed to meet these requirements, as part of the GAIN approach to increasing aquaculture yield in Europe by making better and more sustainable use of existing space and resources.

Methodology

AquaSense is a cloud-based platform that enables users to retrieve environmental data acquired using sensors deployed in or near cultivation structures such as cages, longlines, or trestles, and use those data to apply state-of-the-art mathematical models of growth and environmental effects.

AquaSense clients enter (or use stored) data on culture practice, including the duration of the culture period, initial stocking density, and mortality rates (Fig. 1), and the platform retrieves the relevant environmental data from a storage hub. For finfish, water temperature is the main driver of growth, and for bivalves such as mussels or oysters, data on the natural food supply are also retrieved, since theseorganisms are organic extractors and do not require additional feeding.

The well-tested (e.g. Ferreira et al, 2012; Saurel et al, 2014; Cubillo et al, 2016) 'Aqua' series of models (Fig. 2) is used to predict growth and environmental effects for key species grown in Europe, including Atlantic salmon (*Salmo salar*), Rainbow trout (*Onchorhynchus mykiss*), European seabass (*Dicentrarchus labrax*), gilthead bream (*Sparus aurata*), Pacific oyster (*Magallana gigas*), blue mussel (*Mytilus edulis*), Mediterranean mussel (*M. galloprovincialis*), and Manila clam (*Ruditapes philippinarum*).

Apart from growth, AquaFish (Fig. 2) provides outputs on feed ingestion and particulate waste, oxygen consumption, and excretory products.

The AquaSense platform simulates the growth of the selected culture organism based on the culture data and environmental drivers retrieved from *in situ* sensors and scales up the results to the cages (or other structures such as mussel longlines) defined by the farmer.

(Continued on next page)

These results at the farm and individual scale are displayedto the user in graphical form for easy interpretation. Any growth period, starting weight, etc can be simulated by the user.

Results and Discussion

Example results from the application of AquaSense to Atlantic salmon in Norway are shown below (Fig. 3).

In addition to these results, individual performance metrics are also provided, together with growth curves over the culture period (Fig. 4).

The outputs from AquaSense help farmers review how the harvested crop relates to changes in environmental conditions and evaluate the emissions footprint of their activity. The first component is important in terms of optimising production and understanding deviations from expected growth performance, and the second helps farm managers and water authorities assess the sustainability of the activity, particularly in light of co-use of water bodies, source apportionment of nutrient emissions, and legislative compliance.

In order to expand the reach of this system, GAIN has developed an Affiliate Farm Programme (AFP) for both finfish and shellfish farms. Implementation of the AFP will leverage data collection both at the farm and at the broader-scale level, and automatically ensure a clear and valuable legacy for the European aquaculture industry.

In a similar way to the connection of households to the electrical grid, farmers within the AFP will support the installation of relevant sensors, which will require an initial investment of about 10-20 k€, depending on choices, and will then be connected to the AquaSense platform—the incentive is to obtain access to a management system that will help industry stakeholders implement a precision aquaculture model for eco-intensification.

At a later stage, using data available from the Maritime and Environmental Thresholds for Aquaculture (META) platform (https://longline.co.uk/meta/), AquaSense will be extended to support traceability and environmental performance, including animal welfare, e.g. by identifying critical periods for parameters such as dissolved oxygen and water temperature for matches/exceedances to known species thresholds, thus providing consumers with greater confidence with respect to farmed products.

Introduction and Modelling Approach

The SUCCESS (System for Understanding Carrying Capacity, Ecological, and Social Sustainability) modelling framework was applied to Dundrum Bay, Northern Ireland. SUCCESS addresses (i) the partitioning of nutrient and bacterial loading from land; (ii) the circulation of water and water properties within Dundrum Bay and the exchange with the Irish Sea; (iii) the growth of bivalve shellfish in Inner Dundrum Bay; (iv) the biogeochemistry of Dundrum Bay, as it relates to ecosystem sustainability, in particular with respect to carrying capacity for bivalve cultivation. Each model has a number of uses *per se* and addresses different management challenges, and the linkages among models allow the whole set to be leveraged for improved decision-support.

Dundrum Bay is located on the southeast coast of County Down, Northern Ireland. Inner Dundrum Bay is a small, sheltered bay connected to the more exposed south facing Outer Dundum Bay by an inlet channel. Inner Dundrum Bay has two parts which extend on a SSW-NNE axis. The larger northern part (Inner Dundrum North) is approximately 3 km long and up to 1 km wide. The smaller southern part (Inner Dundrum South) extends for approximately 2 km to the SW and is up to 500 m wide, both drain to the Outer Bay via the Dundrum Outer channel. The Inner Bay is intertidal except for the inlet channel: it is a mesotidal embayment which is flushed through a single tidal inlet ~200 m wide and ~1 km long. This embayment exchanges most of its volume every tidal cycle due to the tidal oscillation at the mouth of the inlet linking the bay with the neighbouring shelf. This places a large emphasis on the circulation mechanisms of outer Dundrum Bay, where the greater part of the dispersion of land-based pollutants will take place.

The catchment area is approximately 150 km^2 and contains the four main rivers draining into the bay. Land use is approximately 80% agricultural, predominantly pastureland for sheep and cattle, but also pig and poultry farms. There are seven urban wastewater networks in the catchment. Up to 65% of the overall catchment's major freshwater sources may impact the Inner South area and 35% potentially affect the Inner North.

The designated shellfish waters in Dundrum cover an area of approximately 2.12 km^2 and are located in the inner bay (DOENI, 2009a). Aquaculture in the Inner Dundrum Bay area occurs in two licensed areas, where there is a history of shellfish cultivation since 1980. The licensed shellfish area covers 51.6 ha in the north (Pacific oyster and blue mussel) and 11.8 ha in the south (blue mussel), but shellfish culture is in the proximity of the main charted river channels: approx. 12 ha in the north side and 6 ha in the south side.

The well-tested EcoWin.NET (EWN) ecological model (e.g. Nobre et al, 2010; Bricker et al, 2018) was used within the SUCCESS framework to analyse the role of bivalves in top-down control of eutrophication symptoms.

Results and Discussion

Example results from the Soil and Water Assessment (SWAT) hydrological model (e.g. Nunes et al, 2017) and the EWN model application to eutrophication control are shown below.

(Continued on next page)

Shows the exports of nitrogen, phosphorus, and enteric bacteria from the catchment to Dundrum Bay. The nutrient input to the bay affects primary production, and the bacterial load is important in determining shellfish quality and restrictions to harvest. As expected, the exports are the most important from October to March, when rainfall and streamflow are the highest. During this period, bacteria and nutrient exports are more important in March and November compared to the December, January, and February. This can be explained by the stop in organic manure application between October 15th and February 1st. The bacteria and nutrient export peaks are observed one month after stopping and resuming slurry/manure application. This seems to indicate a delay of about one month between the input and the export of bacteria and nutrients. In addition, the period with no fertiliser application appears to be more efficient in reducing bacteria than nutrients exports. Finally, TP relative exports are the highest in summer, most likely due to the continuous nature of the final effluents that are the largest sources of TP.

Shows the effect of shellfish cultivation on the percentile 90 of chlorophyll in three EWN boxes: Box 2 and Box 4 are the surface boxes where shellfish are grown, and Box 6 is in the centre of the inlet channel.

The increase in the typical chlorophyll maximum ranges from 3.8 to 5.1%. For the surface boxes where cultivation takes place, the southern part of the inner bay shows a higher difference, but more interestingly, the inlet channel shows the highest difference—these results suggest that the effect of top-down control occurs in a broader area of the bay, since the benthic filter-feeders are removing food from the water passing through the cultivation sites. Changes to cultivation practice will thus be reflected in a more general way on bay-scale eutrophication.

Shows the change in chlorophyll concentration for the inner part of Dundrum Bay. Box 1 in the inner bay and box 29, the lower depth layer of the inlet channel, show the greatest differences when shellfish are switched off in the EWN model. Although the difference never exceeds 1 mg L^{-1}, partly due to the short water residence time, it reaches a 23% reduction in box 1 and a 30% reduction in box 29. The latter is particularly interesting because it shows a pronounced vertical gradient—box 6 only has a maximum reduction of 15%, and neither box 6 nor box 29 are shellfish cultivation areas.

The bay-scale assessment of differences in chlorophyll concentration—one of the primary symptoms of eutrophication—due to top-down control by farmed shellfish, can only be made by means of an ecosystem model. Models such as FARM (e.g. Saurel et al, 2014) or ABC (Ferreira et al, 2021) can determine food depletion within a farm, but they cannot predict what the resulting effect will be at the full bay scale.

Since phytoplankton abundance, biomass, and composition is one of the biological quality elements in the EU Water Framework Directive (2000/60/EC), and since both abundance and biomass are usually represented by chlorophyll as a proxy, system-scale models are a valuable management tool for considering different scenarios for eutrophication management.

The SUCCESS framework provides a model chain that allows managers to review options with respect to land use and coastal boundaries and analyse the consequences of different options, be they source control of emissions or complementary approaches such as enhanced shellfish culture for top-down control of eutrophication.

METAL-AMINO ACID COMPLEXES ARE A COST-EFFECTIVE STRATEGY TO HELP REDUCING FISH MEAL IN EUROPEAN SEABASS DIETS

Introduction

Comparison of the trace mineral (TM) composition of different protein sources to that of fish meal (FM), expose significant limitations in Zn, Se, and Fe, among other nutrients. In addition to lower TM content, antinutritional factors such as phytic acid, found in many plant meals used to replace FM, are not digested by fish. They have negative effects on mineral availability, causing difficulty in meeting TM needs. Trace mineral stability and absorption processes affect availability and ultimately animal performance. Metal-Amino Acid complexes (Metal-AA complexes, a mixture of a single specific metal complexed with different AAs in a 1:1 ratio) are taken up by AA-transporters, instead of metal ion transporters, reducing the risk for transport saturation and improving absorption efficiency. Furthermore, metal-AA complexes are more stable and minimally antagonized by other dietary ingredients, like phytic acid (Paripatananont and Lovell, 1995). Metal AA-complexes supplemented at half-rate of inorganic sources proved to maintain or even improve growth performance of European seabass and Atlantic salmon, respectively. Moreover, partial or complete replacement at 0.5x rate of inorganic minerals with metal-AA complexes reduced skin lesions in Atlantic salmon after infestation with *Caligus* and increased number of goblet cells in intestine and skin of European seabass, indicating enhanced barrier defense mechanisms against pathogens. In the latter study, conducted in collaboration with HCMR, evaluation included different TM premixes by source and level in 20% FM diets, reflecting FM inclusion levels practiced in commercial diets. A follow-up study at HCMR, co-funded by AQUAEXCEL EU programme, assessed how adjusting inclusion of a complete metal-AA complex premix contributes to a cost-effective reduction of FM from 20 to 10%, in European seabass diets.

Materials and methods

Quadruplicate groups of European sea bass with an initial body weight of 47 g were fed to apparent satiety for 12 weeks, one of 3 diets formulated to vary in their FM level (20 or 10%), and adjusted for their TM content. Control diet had 20% FM (FM20) and was supplemented with 50 ppm Zn as Availa®Zn, 40 ppm Fe as Availa®Fe, 12 ppm Mn as Availa®Mn, 3 ppm Cu as Availa®Cu, and 0.12 ppm Se as Availa®Se, (Zinpro Performance Minerals, Availa®Mins line). Two additional diets were formulated to reduce FM level in Control diet by 50% (10% FM) and supplemented with same premix at 1.5x (FM10, 1.5x) or 2x (FM10, 2x) used in the Control diet. Analyzed TM composition of FM20 and FM10 diets are shown in Table 1.

Results and discussion

Adjusting mineral premix in FM10, at 1.5 or 2x the level used in FM20, maintained specific growth rate (between 0.74-0.77) and even slightly increased whole body Zn content (31ppm in FM20 vs 33ppm in diets FM10) of European seabass, though not statistically significant. Yet, specific growth rate (0.76 vs 0.74) and feed conversion ratio (FCR, 1.44 vs 1.51) were improved when TM premix was adjusted at 2x compared with 1.5x that in FM20 (Figure 1). Results indicate that adjusting the dietary TM content of FM10 to similar levels of that in FM20 may not be enough to sustain seabass performance Increasing the TM inclusion level from 1.5 to 2x of that used in FM20 improved SGR and FCR by 3 and 5%, respectively, reverting performance levels closer to that observed with FM20. This may be, at least partly, explained by likely lower nutrient availability in FM10, because of its higher plant protein content and antinutritional factors, compared to FM20 diet. A recent study shows performance and health of European seabass fed 10% FM or FMK-based diets could be kept similar, but required dietary levels of approximately 200–285 ppm Zn, 260–320 ppm Fe, 70–90 ppm Mn, and 0.8–1.0 ppm Se. While confirming the possibility of reducing FM in seabass diets, without negatively impacting performance, this scenario required Zn levels to surpass upper EU allowed levels in seabass diets (Table 1). In this study, it was shown that supplementation with metal-AA complexes contributes to a cost-effective reduction of FM from 20 to 10%, while respecting upper EU limits for TM supplementation, and TM content of seabass feeds. The exception was dietary Se content in the feed, that could not be kept at or below 0.5 ppm. Ingredient contribution to dietary Se content in aqua feeds, mainly contribution of FM and other marine ingredients, makes it practically impossible to keep Se levels in diets within allowed EU levels. Overall, it was shown that metal-AA complexes allow FM to be reduced from 20 to 10% without significantly affecting growth or FCR, while respecting upper EU limits for TMs in seabass diets. This strategy resulted in an 8.5% savings on feed cost, translating into a more sustainable and cost-efficient solution for the industry.

Introduction

Finfish aquaculture is a source of dissolved nutrients which can affect water quality in the wider environment (Howarth et al. 2019). Therefore, the potential effects of dissolved nutrient loading must be considered if management is to transition towards an Ecosystem Approach to Aquaculture (EAA). Understanding the extent and effects of dissolved nutrient plumes emanating from fish farms has been identified as one of the largest knowledge gaps in transitioning towards the EAA (Jansen et al. 2018). In this study, the dispersion of dissolved nitrogen from a rainbow trout farm in Port Mouton (Nova Scotia, Canada) was investigated using a fully spatial hydrodynamic model. The ecosystem level effects were evaluated as the potential for dissolved nitrogen toxicity on a foundation seagrass species, particularly given that seagrass has declined in Port Mouton over time.

Material and Methods

Dissolved nitrogen loading was calculated by applying nutritional mass balance model to growth estimates from a Thermal Growth Coefficient model. Both models were parameterized for the observed conditions in Port Mouton. The spatio-temporal dynamics of dissolved nitrogen was simulated by coupling a tracer sub-model to a hydrodynamic model constructed in FVCOM (Finite Volume Community Ocean Model). The tracer submodel was restricted to advection-dispersion dynamics, omitting any chemical and biological processes. These conservative tracer simulations maximized nitrogen levels, and consequently, were considered a worst-case scenario to inform ecosystem level effects under a precautionary approach. A range of scenarios were applied for different stocking densities, background conditions and aquaculture practices.

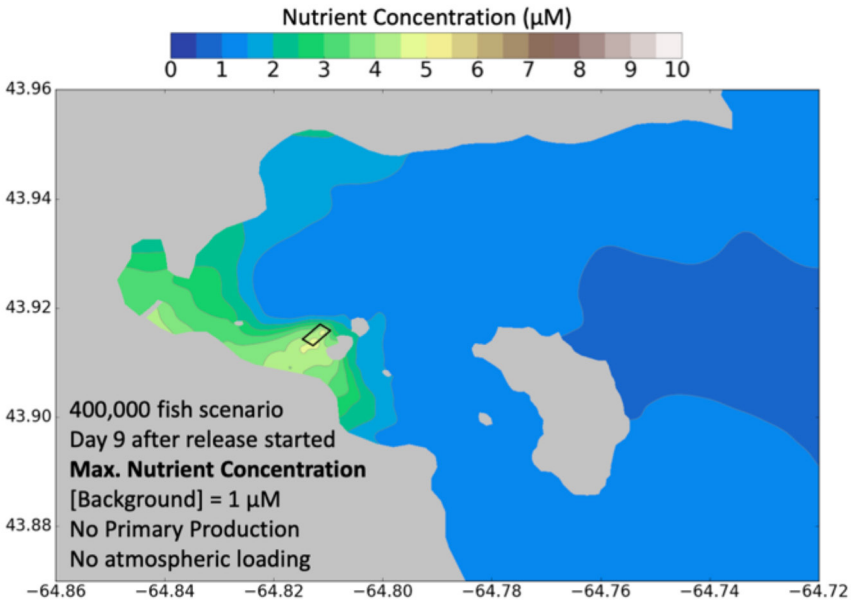

Fig. 1. Maximum predicted nutrient concentration (µM) in the 400,000 fish scenario after 9 days using as a background nutrient concentration of 1µM, no primary production, and no atmospheric loading.

(Continued on next page)

Results and Discussion

The aquaculture scenarios simulated in Port Mouton suggest that the maximum concentration of dissolved nitrogen would not exceed 6 μM in the center of the farm under the most adverse conditions (2 μM background nitrogen, 500,000 fish, peak of production, and no uptake of nutrients by primary producers). This concentration would drop to < 5 μM for the most common scenario taking into account the aquaculture practices at the farm (Fig. 1). These values are below the toxicity threshold for seagrass reported in the literature. To the best of our knowledge, the lowest value tested in the literature for ammonium toxicity was 9 μM (van Katwijk et al. 1997). These authors reported that toxicity for *Zostera marina* occurs at ammonium concentrations between 9 and 25 μM, with no effects at 9 μM and evident necrosis at 25μM.

Models are simplifications of the real-world and this is not an exception; however, the assumptions to simplify the model were directed to simulate the worst-case scenario and would maximize the buildup of dissolved nutrients, and consequently, toxicity for seagrass. First, the model did not distinguish between chemical forms of nitrogen, which represents the worst-case scenario to define toxicity for seagrass, given that the toxicity is specific to each nitrogenous compound (e.g. van Katwijk et al. 1997). Second, only background concentration of dissolved nutrients and the contribution of the farm were used as sources of nitrogen, and more importantly, no sinks were included in the model in the most stringent scenarios. This approach implies that dissolved nitrogen can only leave the system through the exchange with the open ocean, which increases the residence time of dissolved nitrogen in the system, increasing potential for toxicity. Third, background concentration of dissolved nitrogen exceeded observed values in adjacent waters (Johnson et al. 2018), which accounts for uncertainty. Fourth, the biomass of fish was overestimated in some scenarios, and it was simulated during peak of production, which represents the worst-case scenario in terms of excretion of nitrogenous products. These four considerations ensure a precautionary approach when evaluating the model's predictions for dissolved nitrogen in the context of potential toxicity for seagrass.

The simulation of dissolved nitrogen as a conservative tracer using a fully-spatial hydrodynamic model suggests that the maximum concentration of nitrogen caused by a trout farm is unlikely to be toxic for seagrass in Port Mouton Bay. This conclusion is grounded in the analysis of precautionary worst-case scenarios that aim to maximize the buildup of dissolved nitrogen in the bay. This outcome suggests that the decline of seagrass reported in some parts of the bay are unlikely to have been triggered by dissolved nutrients discharged from the farm.

Introduction

Under a circular economy context, reutilization and recycling agro-industrial by-products are of utmost importance. The European Union produces 95% of world olive oil and 65% of wine, generating a vast waste prone to cause environmental detriment due to their high organic content and low biodegradability. The presence of important bioactive compounds in olive oil and wine wastes is well documented. Still, their high fiber and low protein levels are significant constraints for their use in animal nutrition. Solid-state fermentation (SSF) is a green biotechnological process that can utilize agroindustrial by-products like those from wineries and olive mills (grape pomace, vine-shoot trimmings, olive pomace) as substrates for microbial growth. SSF allows for the release of several value-added bioactive compounds, as phenolic antioxidants. In 2019, 263 215 tons of European sea bass were produced globally by the aquaculture industry. Intensive aquaculture conditions due to overcrowding and environmental conditions (water quality, hypoxia) and husbandry handling stressors (grading, transport, crowding, and vaccination) may induce fish inflammatory responses. Dietary fortification with natural immunostimulants may increase fish immunocompetence, contributing to decrease susceptibility of fish to stress. This trial aimed to evaluate the efficiency of extract produced through SSF of the olive mill and winery waste as dietary immunostimulants in European sea bass.

Materials and methods

A previously optimized mixture of olive mill and winery wastes (Filipe et al., 2019) was submitted to SSF by *Aspergillus ibericus* (MUM-01.29; Micoteca da Universidade do Minho (UM). After fermentation, an aqueous extraction was performed using a 1:5 ratio of solid/water (w/v) for 30 minutes with constant stirring. Another extract was also prepared from the same optimized mixture but without applying the fermentation process. The recovered extracts were then lyophilized (FWO and UWO, fermented and unfermented extracts, respectively). Four isolipidic and isoproteic diets (18% lipids, 50% protein) were formulated with 0 (control diet), 0.34, and 0.68% of FWO or with 0.19% of UWO, to reach an antioxidant activity of 0 (control diet), 683 (FWO4 diet); 1365 (FWO8 diet) and 683 (UWO diet) µmol Trolox/kg of diet. After the feeding trial of 66 days, fish were submitted to an inflammatory insult. Twenty-four fish per dietary treatment (60 g of mean body weight) were divided into two groups and intraperitoneally injected with a formalin-killed aqueous bacterin of *P. damselae subsp. piscicida* or with PBS solution (control group). 4h and 24h post-injection, the blood and head-kidney of six fish from each group were sampled. The activity of lysozyme, peroxidase, bactericidal capacity, protease, anti-protease, and ACH50 was determined in plasma samples. Immune gene expression of interleukin-1β beta (il-1β), interleukin 6 (il-6), interleukin 8 (il-8), caspase 3 (casp3), caspase 9 (casp9), cyclooxygenase 2 (cox2), and tumor necrosis factor-alpha (tnfα) was analyzed through q-RT PCR in head-kidney tissue samples.

Results

Screening the plasma innate humoral response showed an increase of ACH50 in fish fed with FWO 8 and UWO diets, at 4h post-injection, and a decrease in peroxidase activity with UWO diet at 24h, relative to the control diet.

Irrespective of the post-injection time, compared to the control diet FWO4 and UWO diets reduced pro-inflammatory cytokines (IL β1, IL 6, IL 8), casp3, casp9, and TNF-α, while the FWO8 diet increased COX2. Comparing the sampling points, in the control diet IL β1, IL 6, IL 8, and casp3 expression increased at 24h, while their expression was not affected with the test diets.

In the intestine, at both times post-injection, and relative to the control diet, IL-8, casp3, casp9, and TNF-α expression were increased in fish fed the FWO4 diet, while casp3 and casp9 were increased in fish fed the UWO diet.

(Continued on next page)

Conclusion

Regardless of fermentation, dietary fortification with olive mill and winery by-product extracts modulated fish response to an inflammatory insult.-

Present results underline the importance of further studying the potential of FWO and UWO extracts as a part of the circular economy strategy, contributing to more efficient use of resources for a greener and more competitive aquaculture.

EFFECTS OF PARTIAL SUBSTITUTION OF DIETARY PROTEIN SOURCES WITH DUCKWEED (*Lemna* sp.) MEAL ON THE RAINBOW TROUT (*Oncorhynchus mykiss*) GROWTH PERFORMANCES

Fiordelmondo E., Mariotti F., Magi G.E., Roncarati A.

School of Biosciences and Veterinary Medicine, Camerino University, Italy

Introduction

Feed's composition plays a crucial role in the rearing of the main fish species of interest to aquaculture due to the capacity to influence and shape composition and quality of fish meat. In farming conditions, fish need high quality feeds to obtain excellent growth and healthy animal status. In fact, raw materials used as feedstuff guarantee a balanced diet rich in essential active ingredients which improve fish healthy, fish welfare, and production performances in terms of yield. Aquaculture has been dependent on the capture of pelagic fish to use as feedstuff. Due to the rising prices of fishmeal and fish oil, they are substituted by alternative ingredients (Gasco et al., 2020) such as plant-based proteins (Parisi et al., 2020). In this context, duckweed (*Lemna* spp.) can be purposed as source of protein, lipid, and minerals (Chakrabarti et al., 2018). In an Italian rainbow trout farm, a trial was performed to evaluate if the duckweed meal can be used in partial substitution of the conventional feedstuffs used as protein source in fish feeding. An experimental diet including duckweed meal was formulated and compared with the control diet. At the end of the trial, zootechnical performances of rainbow trout fed with the duckweed inclusion were compared to those of fish fed with the standard diet.

Materials and Methods

Duckweed meal was included in the formulation of an experimental diet (LM) at 20% of the protein source represented by soybean meal, fish meal, wheat flour and gluten wheat meal. The protein content (41%) and lipid rate (20%) of LM diet were equal to the control diet (LC) formulated with the same feedstuffs except duckweed meal.

A total of 270 rainbow trout (mean body weight 124.5 ± 0.7 g) was randomly allocated in 6 tanks at the initial stocking density of 6.2 kg/m^3. At the end of the trial (90 days), fish were weighed, the final length was recorded, and the condition index was determined. Fish were administered twice a day (8 a.m. and 3 p.m.) by hand at the apparent satiation level collecting the unconsumed feed.

The following zootechnical performances were evaluated in the two different groups: final body weight (g); final mean length (cm); weight gain (g); survival rate (%).

Data collected were subjected to one-way analysis of variance (ANOVA) using SPSS 25 (Version 25.0, Armonk, NY, USA) (IBM). Means of each value was calculated and considered significant with a value of $p < 0.01$ and compared using the Student-Newman-Keuls (SNK) test.

Sanitary conditions, such as fin erosion, parasites and bacterial diseases, were also investigated.

Results and discussion

At the end of the trial, fish fed with LM showed a mean value of final body weight of 340.53±4.3g, final length of 31.2± 1.3cm, weight gain of 216.03±2.8g, and survival rate of 98± 1%. Fish fed with LC showed a mean of final body weight of 31.0± 1.2cm, final length of 20.0± 0.6cm, weight gain of 224.3± 2.6cm, and survival rate of 99± 0%. All fish showed a good health condition, without signs of illness such as fin erosion, parasites or bacterial diseases.

Looking to these results, no significant statistic differences in terms of growth and survival were observed comparing the values obtained from fish fed with the inclusion of *Lemna* to those obtained from ones fed without *Lemna*. Our results are in agreement with previous studies concerning the investigation of the digestibility of duckweed in other fish species, such as carp (Pípalová et al., 2003) and tilapia (El-Shafai et al., 2004). In fact, in the present trial rainbow trout looked to respond well to the partial vegetable protein source administered. Based on these preliminary results, *Lemna* could be included in the rainbow trout diet without negative effects on fish growth and animal health.

Introduction

Aquaculture growth will unavoidably involve the implementation of innovative and sustainable production strategies, being functional feeds among the most promising ones. A wide spectrum of phytogenics, particularly those containing terpenes and organosulfur compounds, are increasingly studied in aquafeeds due to their growth promoting, antimicrobial, immunostimulant, antioxidant, anti-inflammatory and sedative properties (Reverter et al. 2021). Although the impact of such phytogenics upon fish mucosal immunity has been extensively evaluated, most of the studies fail in addressing the mechanisms underlying their pharmacological effects. Under this context, the present set of studies describe a holistic approach for evaluating the antiparasitic and antibacterial properties of a feed additive composed by microencapsulated carvacrol, thymol and garlic essential oil, as well as seeking to decipher its mode of action upon gilthead seabream mucosal tissues.

Materials and Methods

This presentation is based on recently developed results from our group. In particular, analyses performed in gills (Firmino et al. 2020), intestine (Firmino et al. 2021b) and skin (Firmino et al. 2021a) showed that these three tissues positively responded to the dietary administration of the phytogenics-based additive, although some variations in the mucosal transcriptional responses were observed among the different tissues. Besides, by combining the results obtained together with a profound literature review on the physiological and immunological mucosal responses of fish fed phytogenics, novel mechanisms are hypothesized to explain the mechanisms of cell activation that may be responsible for such mucosal immune-related responses.

Results and Discussion

From a global point of view, 759 DEGs were obtained in the gills of fish fed the phytogenics-supplemented diet, of which 53 of those DEGs were also modulated in the intestine and another 40 DEGs were also modulated in the skin. In the intestine, 581 DEGs were obtained; of them, 31 were modulated in the skin as well. Regarding the skin analysis, 534 total DEGs were obtained (*Figure 1*). Only 5 DEGs were shared among the three tissues analysed, suggesting tissue-dependent divergences in the mucosal responses. The different sets of common DEGs did not reveal noteworthy interactions when merged and submitted to an enrichment analysis. The fact that the modulation of genes that are differentially expressed in more than one of the studied tissues seems not to be connected and associated to specific biological processes reinforce the idea that each mucosal tissue responds in a distinct and singular way to the dietary administration of the functional feed additive. In this context, the gill was unexpectedly the tissue that revealed the highest number of DEGs promoted by the phytogenics-supplemented diet, rather than the intestine, which is the site of absorption of the feed additive and, *a priori*, the site where the major changes with regard to gene expression were expected. This difference in tissue susceptibility may be a consequence of the combination of several factors, such as the gills particular functionality and the mode of action of the phytogenics bioactive compounds.

The intrinsic physiology and anatomy of each mucosal tissue, the extrinsic environment that they are subjected to, their specific microbiota composition and/or its modulation are factors conditioning the different transcriptional profiles obtained (Cabillon and Lazado 2019). Additionally, the potential degradation of the bioactive compounds along the digestive tract and their different pharmacokinetics within each target tissue may also affect tissue-specific responses (Michiels et al. 2008). It is suggested that the terpenes and organosulfurs present in the studied feed additive display their mucosal immunomodulatory activity through the activation of Transient Receptor Potential (TRP) ion channels (Xu et al. 2006). In this sense, bioactive compounds may activate TRP channels leading to intracellular Ca^{2+} increase and non-canonical activation of the TAK complex. In parallel, stimulation by pathogen-associated molecular patterns (PAMPs) may facilitate the activation of TLR and TRP signalling pathways, which would explain the fish improved ability to cope with pathogenic challenges. This hypothesis opens interesting questions about at which extent gills, as a site of significant immunity and presence of ion channels due to its role in osmoregulation, may be susceptible to functional feed additives and recognized as promising target tissues for dietary therapeutic strategies.

EFFECT OF WATER TEMPERATURE AND PHOTOPERIOD ON BRAIN AND PITUTITARY MATURATION HORMONES DURING FRESHWATER PRODUCTION STAGE OF ATLATNIC SALMON (*Salmo salar L.*)

Introduction

Early sexual maturation of Atlantic salmon during the freshwater phase of production is an ongoing economic and welfare issue for the industry. Early sexual maturation leads to risk of mortality after sea water transfer and/or the loss of production value due to change of energy utilization from body growth and sea water adeptness to gonad development.

The complex series of morphological and physiological changes that occurs during sexual maturation is driven through the activation of the brain-pituitary-gonad (BPG) axis. Recently, the understanding of how the BPG axis is activated to cause gonad development in mammals and birds has progressed drastically. Pars-tuberalis Thyrotrophin (PT-TSH) is stimulated either by melatonin (mammals; Klosen et al., 2013) or deep brain photoreceptors (birds; Yoshimura et al., 2013) which then causes a similar cascade of signaling events which leads to the release of follicle stimulating hormone (FSH) and Luteinizing hormone (LH) from the pituitary and subsequently gonad development. These gonadotrophs have been well studied in male Atlantic salmon yet the brain regulation of gonadotrophs release is less understood. The recent discovery of dorsal pituitary tshbb in Atlantic salmon suggests the possibility of a similar pathway which could lead to a better understand of the neuroendocrine regulation of sexual maturation (Fleming et al., 2019).

This study investigated the expression of brain Deiodinase 2 (*dio2b*), Gonadotropin releasing hormone (*GnRH*), and Kisspeptin receptor (*GPR54*) along with pituitary Thyrotropin b (*tshbb*), *FSH* and Luteinizing hormone (*LH*) as well as Gonadal somatic index (GSI).

Materials and methods

On October 28th, 2019, 1000 Atlantic salmon parr were randomly distributed among 8 0.5m^3tanks. Fish were raised under constant light (LD24:0) from first feeding. After transfer, fish were acclimated at 12.5°C for 1-week whereafter half the tanks were raised to 15°C while the remaining 4 tanks stayed at 12.5°C. The fish remained at their respected temperatures and continuous light until Feb 1st when a LD12:12 "winter-signal" was introduced to two of the 12.5°C and two of the 15°C tanks while the other tanks remained on continuous light (LD24:0). The winter signal lasted 5 weeks whereafter returned to continuous light. The experiment continued until May and all fish were fed in full ration using commercial feeds (Biomar).

8 samplings took place during the experiment where 6 males per tank were randomly selected and killed with an overdose of benzocaine (Benzoak vet.® 20%, ACD Pharma AS, Norway). Body length and weight were recorded and blood was collected from the caudal vein for sex steriod measuermets. Gonads were taken for GSI and gene expression measurements. Brain and pituitary were sampled for gene expression measurements. All gene expression analysis was done using qPCR.

Results

Sexual maturation was highest in the 15°C continuous light fish with an increase of GSI happening as early mid-February. The increase of GSI steadily increased until the end of the experiment where nearly 75% of the male salmon where sexually mature. The 15°C winter signal fish also had high occurrence of sexual maturation at the end of the experiment approaching 100% of the males sampled. Maturation at 12.5°C was lower with ~50% of the fish in the winter signal and ~25% of the fish in the continuous light became sexually mature. Majority of the sexual maturation in both 12.5°C conditions and the 15°C winter single condition occurred after the winter signal.

GnRH and GPR54 were both higher expressed in the 15°C fish while both 12.5°C conditions remained consistently low in comparison. This increase of GnRH and GPR54 expression was not seen in the 12.5°C fish. *Tshbb* had a robust response to the end of the winter with a sharp increase of expression which was not observed in the continuous light conditions. Nearly identical expression levels were observed between both winter signal conditions irrelevant of water temperature.

(Continued on next page)

Discussion

In the current study, high water temperatures resulted in a high occurrence of sexual maturation. Comparable levels of maturation have been observed in similar water temperatures in previous experiments and suggests that the use of high-water temperature during the freshwater stage of production leads to early sexual maturation (Fjelldal et al., 2018).

The two groups given the winter signal had an increase of *tshbb* after the winter signal ended. This increase of *tshbb* was not seen in the continuous light condition fish suggesting increasing day length after the winter signal stimulates the production of *tshbb*. Irachi et al, observed a similar increase of *tshbb* expression after returning to long day photoperiod (Irachi et al., 2021). These results suggest that *tshbb* is directly influenced by day length. The exact role of tshbb needs to be further studied however it is clear that continuous light inhibits the expression during the freshwater stage.

Genes expressed in the diencephalon region of the brain (*dio2b*, *GnRH*, *GPR54*) showed differential expression between temperatures. Little difference was observed between photoperiod conditions. Despite higher expression in 15°C than 12.5°C sexual maturation was still observed in all conditions. These results suggest that despite differential expression, the basal levels needed for maturation are already met at 12.5°C. Further experiments will be needed to better understand the threshold levels of certain genes which active the BPG axis to cause early sexual maturation and how temperature plays a role in this signaling pathway.

Introduction
The growing human population has continued to intensify global food. Hence, there are crucial needs for sustainable food production systems that ensure a healthy food supply. Aquaponics is an innovative food production method that uses wastewater from fish culture to cultivate vegetables in hydroponics; in a confined coupled or decoupled system (Lennard & Goddek, 2019). However, pest and disease management, among other challenges, has limited the adoption of aquaponics for commercial purposes (Stouvenakers et al., 2019). The interactions in various aquaponics designs expose fish and biofilter units of aquaponics to pest and pathogen treatments. Hence, consensus efforts are urgently required to establish approaches that pose little or no adverse effects on fish and biofilter. We aimed to evaluate disease management steps and techniques in hydroponics to qualify as suitable techniques for different aquaponic designs. There are sufficient biocontrol and natural pesticides to deal with pests, though natural pesticides can slightly affect nitrification (Rašković et al., 2021). In contrast, there are scanty and less effective measures for fungi pathogens, causing considerable damages in aquaponics. Hence, we assessed the use of biological control against powdery mildew pathogen in aquaponics systems.

Materials and Methods
A meta-analysis of 168 peer-reviewed articles about pest and disease management in hydroponics and intensive fish culture systems was conducted to establish suitable steps and techniques for different aquaponics designs. The assessment of integrated pest and disease management steps and techniques was based on the potential of IPDM to have detrimental effects on fish and nitrifying bacteria.

To assess the use of biocontrol agents (BCA) against powdery mildew, detached cucumber leaves were pretreated with the suspension of conidia of *Lecanicillium lecanii* (LLE), *Isaria fumosorosea* (IFR), *Trichoderma virens* (TVI), and inoculated with *Podosphaera xanthii* under different relative humidity conditions (RH), ≥ 95%, 65-73%, and ≤40% RH. The domination and inhibition capacity of the BCAs was assessed by disease severity scored using a manipulated 12-grade scale (Horsfall and Barratt, 1945) and disease reduction percentage after three weeks.

Results
Adoption of integrated pest and disease management techniques (IPDM).

Non-chemical preventive measures in hydroponics and intensive aquaculture systems are highly proficient for all designs and do not affect fish and biofilter in decoupled and coupled aquaponics. While cultural and physical controls are primarily safe for all aquaponics designs, chemical control (pesticides) is unsuitable for coupled systems (where the wastewater is constantly recircled for reuse). For example, pesticides can have positive or negative effects on nitrification (Figure 1).

Biological control of powdery mildew
The three microbial control agents significantly suppressed the disease at a 10^7 CFU/ml concentration compared with the control. More importantly, under greenhouse conditions (65-73% RH), a significant disease reduction (DR) percentage of 85% against the powdery mildew disease was recorded in *L. lecanii*-pretreated leaves (Figure 2A).

Conclusion
Pest infestations in aquaponics systems can be primarily controlled using preventive, cultural, and biological control approaches. On the other hand, common pathogens such as powdery mildew are more problematic. Preventive inoculation of *L. lecanii, T. virens*, and *I. fumosorosea* in leaves can significantly reduce the outbreak of powdery mildew.

Introduction

Nanotechnology has been widely used in medicine and in several industries, including aquaculture. Among the numerous nanoparticles (NPs) currently in production and use, titanium dioxide (TiO_2) NPs are emerging for their extensive application in consumer products, including textiles, paints or health-care products. As a new class of emerging pollutants with eco-toxicological impacts on marine ecosystems, there is a growing need to assess the risk of engineered nanoparticles (ENPs) to aquatic ecosystems and, consequently, to human health (Matranga et al., 2012). Most data in this field are the result of toxicity studies conducted mainly for short-term exposure periods in model organisms with no commercial interest (Khosravi-Katuli et al., 2017). To date, there is still paucity of knowledge of the molecular pathways involved in the mechanisms associated to NP exposure in aquatic organisms, especially in species with commercial value and produced in aquaculture facilities. The current study work aims to examine the expression of genes involved in several molecular pathways by long-term exposure to TiO_2 NPs with different sizes in one of the most valuable seafood products of European Atlantic coast aquacultures, the turbot *Scophthalmus maximus*.

Materials and Methods

Turbots (*Scophthalmus maximus*) were maintained under controlled conditions in 1 m^3 tanks (50 fish per tank, n=3) with constantly running TiO_2 NPs-free seawater. Citrate-coated titanium dioxide nanoparticles (TiO_2 NPs, Ø 5 nm and Ø 25 nm) were incorporated in the commercial dry pellet diet (0 and 1.5 mg/kg) and fish were fed daily with approximately a food/weight ratio of 1%, periodically adjusted during the experiment taking into account weight gain [average initial weight 45.0 g ± 1.0 g (NPs Ø 25 nm) and 73.0 g ± 0.5 g (NPs Ø 5 nm)]. Liver samples of 3 fish per tank were collected after 14 and 28 days of exposure and stored in RNAlater at -80 ºC. Total RNA was extracted and purified to further cDNA synthesis. Quantitative polymerase chain reaction (qPCR) was performed to analyse gene expression levels of *NRF2* (nuclear factor erythroid 2–related factor 2), *NFkB1* (nuclear factor kappa B subunit 1), *GR1* (glucocorticoid receptor 1), *THRαb* (thyroid hormone receptor alpha b), *PPARαb* (peroxisome proliferator-activated receptor alpha b) and *FASN* (fatty acid synthase). The changes in target gene expression levels in relation to two housekeeping genes [*18S* (18S rRNA) and *EF1α* (elongation factor 1-alpha)] were calculated using the Pfaffl method (Pfaffl, 2001).

Results and Discussion

Given its commercial interest, turbot was used as a model for bioaccumulation assays to study the effects of TiO_2 NPs in the expression of genes involved in several pathways. To assess any minor potential changes, turbots were exposed to TiO_2 NPs at higher concentrations than the expected in nature and European aquaculture systems. The analyses of gene expression levels in turbot liver, a key organ in detoxification processes, were conducted in transcription factors that regulate transcription of genes related to the response to oxidative stress (*NRF2*), immune response (*NFkB1*), endocrine system (*GR1*, *THRαb*), fatty acid β-oxidation (*PPARαb*), and in the fatty acid synthase gene (*FASN*) responsible for fatty acid synthesis. The relative expression levels of *NRF2* and *NFkB1* were higher in presence of Ø 25 nm TiO_2 NPs comparing with the exposure to Ø 5 nm TiO_2 NPs. These observations are in accordance with previous studies which have described a stimulation of immune system with the production of ROS and oxidative damage in fish exposed to TiO_2 NPs (Diniz et al. 2013; Tang et al., 2019; Bobori et al. 2020). Both *THRαb* and *GR1* relative expression levels increased after 14 days of exposure to Ø 25 nm TiO_2 NPs. After 28 days of exposure, the relative expression levels of these transcription factors were equivalent to the control group, suggesting the reversibility of alterations in metabolism and stress response, and an adaptation of fish to the system with the time. In terms of lipid metabolism, the presence of TiO_2 NPs led to a minor reduction of fatty acid β-oxidation activation. However, the production of energy through the breaking down of long fatty acids was stimulated after 28 days of exposure to Ø 5 nm TiO_2 NPs. The relative expression levels of *FASN* were slightly lower after 14 days of exposure, indicating a decrease of long-chain fatty acid production. However, after 28 days of exposure the relative expression levels of *FASN* are comparable to the control. During the Ø 25 nm TiO_2 NPs assay, a reduction in fish

(Continued on next page)

feeding rate was observed, probably due to changes in food palatability, which has affected fish weight gain. Nevertheless, in the Ø 5 nm TiO_2 NPs assay, no differences in fish weight increase were observed. No other behavioural changes were observed during both trials and no mortality or pathological signs were recorded. The exposure of turbots to smaller TiO_2 NPs (Ø 5 nm) resulted in less prominent changes in relative gene expression.

Conclusions

This study demonstrated that the effects on gene expression in turbot liver, the main site for regulating redox, lipid metabolism and detoxification, depend not only on the time of exposure to NPs but also on the NPs size itself. The recovered expression pattern points to a minor and late reactiveness of smaller TiO_2 NPs. Although our results suggest a potential alteration of hepatic function in turbot when exposed to high concentrations of TiO_2 NPs, further studies using metabolomic approaches are needed.

NUTRITIONAL PROPERTIES OF MARINE AND FRESHWATER MICROALGAE FOR BIVALVES' PRODUCTION IMPROVEMENT

Joana Fonseca*, Margarida Costa, Helena Cardoso, Gonçalo Espirito Santo, Inês Guerra, Pedro Cunha, Nádia Correia, Joana Teles, Joana Silva

ALLMICROALGAE Natural Products S.A., Rua 25 de Abril s/n, 2445-413 Pataias, Portugal
Email: joana.fonseca.95@gmail.com

Introduction

In the last years, natural stocks of bivalves have been decreasing due to overfishing, environmental stresses, and diseases. The production of these organisms through aquaculture has become crucial for natural stock recovery and to support human consumption - the main reasons for the high economic growth of this sector. To get an optimized production is essential to have an appropriate blend of microalgae adjusted to each stage of the bivalves' life cycle which represents 30% of the total seed production cost. Microalgae present high diversity of biochemical profiles, therefore, it is essential to explore the potential of different microalgae that can have beneficial biochemical features, key to bivalves' production. Besides the use of microalgae as a live feed, the use of microalgae concentrates and/or dried algae could also be an option that would reduce bivalves' production costs [1].

Material and methods

Five species of microalgae were produced at Allmicroalgae facilities. Marine microalgae (*Nannochloropsis oceanica, Phaeodactylum tricornutum* and *Tetraselmis chui)* were cultivated autotrophically in 35 m^3 outdoor industrial photobioreactors (PBR's). The freshwater microalgae *Chlorella vulgaris* prevenient from 5 m^3 industrial fermenter (heterotrophic culture) was grown autotrophically in 70 m^3 outdoor industrial PBR's and *Arthrospira platensis* were produced at 100 m^3 thin-layer cascade reactors (the only reactor available for *A. plantensis* production at Allmicroalgae). For all species, productivity rate was calculated. Microalgal cells were harvested by centrifugation and spray-dried for biochemical analysis. In order to determine the CHN composition, a Vario el III (Vario EL, Element Analyser System, GmbH, Hanau, Germany) was used following manufacturer instructions. Total protein content was achieved by multiplying the percentage of nitrogen by the 6.25 factor [2]. For the total lipid content, the Soxhlet method was used and carbohydrate content was calculated by subtracting the weight of proteins, lipids and ashes from the total dry weight of biomass. To estimate composition in eicosapentaenoic acid (EPA), the GC-FID method was used, and results are presented as % of Total Lipids.

Results

Among all species produced, freshwater microalgae *C. vulgaris* and *A. platensis* showed the best productivity values (0.083 and 0.077 g/L/day, respectively), however these microalgae were produced in different types of reactors with different cultivation methods which can justify these results. *T. chui* showed the best productivity achieved in the 35 m^3 tubular PBR's (0.058 g/L/day), followed by *N. oceanica* (0.042 g/L/day) and *P. tricornutum* that reached the lowest productivity value observed (0.028 g/L/day). The highest protein content was reached by *A. platensis* and *C. vulgaris* (60-70 and 54-65%, respectively), followed by *T. chui* and *P. tricornutum,* which presented similar values (35-46%). *N. oceanica* presented the lowest protein content (29-38%), however, this species revealed the higher lipid content (12-15%) and showed to be EPA-rich presenting it at 26-35% total lipids, the highest value observed after *P. tricornutum*, with 28-40% EPA. *T. chui* showed 7-9% EPA and the freshwater microalgae *C. vulgaris* and *A. platensis* did not present this polyunsaturated fatty acid in their composition. Regarding carbohydrates composition, *T. chui* showed the highest value (20-32%), followed by *N. oceanica*, which presented 15-20%. On the opposite, the lowest carbohydrate content was reached by *P. tricornutum* and *A. platensis* (3-7 and 2-10%, respectively).

Discussion and conclusions

The five species of microalgae produced at Allmicroalgae facilities showed to be biochemically very diverse. This variability of lipid and protein levels, fatty acids and carbohydrates, bring vast advantages for bivalves' production since they have different needs during their entire life cycle (from larval to adult stages).

Adults fed to obtain gametes for fertilization and posterior larvae development need a protein-rich diet. A possible diet including *T. chui* and *P. tricornutum* (already used for bivalves feeding), complemented with *A. platensis* and *C. vulgaris* could be applied in adult feeding since these are the microalgae with highest protein content. Although both algae are freshwater microalgae, they could be used as concentrates or dried algae [3] which avoid the salinity change of bivalves'

culture medium and promote an easier application of feed. On the other hand, after larvae hatching, *N. oceanica* could be an excellent option to include in a diet with *Tisochrysis lutea* (usually used for larval stages), since it has high EPA content, which is very important for clams such as *R. decussatus* [4]. Furthermore, *N. oceanica* is a marine microalga thus can be used as a live diet, as microalgae concentrate or as dried algae. After metamorphosis, at post-larvae and juvenile stages, the use of a diet composed by *T. chui* would be important for bivalves such as the oyster *Ostrea edulis* that presented higher growth when fed with a diet rich in carbohydrates [5].

To conclude, the production of different microalgae in a reproducible manner throughout the entire year could bring several advantages for bivalve producers. Using suitable microalgae species to each stage of bivalves' life cycle will undoubtedly reduce the costs of production, allowing a reduction of mortality and the achievement of clams, oysters and mussels with high quality and high economical value in a shorter term. However, experimental studies will be crucial to confirm the potential of the microalgae described.

Introduction

Concerns with animal welfare impose the adoption of practices that reduce stress. Several normal aquaculture practices such as weighing, sorting, transportation, and others provoke stress on fish. In this scope, anesthetic agents have been used to mitigate stress during several routine operations. The present study aimed to determine the optimal dose of three anesthetics (tricaine methanesulfonate, MS-222; 2-phenoxyethanol, 2-PE; and clove oil) to induce deep anesthesia in gilthead seabream (*Sparus aurata*) juveniles. The effects of anesthesia on hematology, plasma metabolites profile, cortisol levels, the hepatic activity of key enzymes of intermediary metabolism, and heat shock protein gene expression were evaluated and compared to non-anesthetized fish.

Material and Methods

Anesthesia induction and recovery time

The anesthesia induction and recovery time of the target anesthetics: 2-phenoxyethanol (2-PE; VWR), tricaine methanesulfonate (MS-222; Sigma-Aldrich), and clove oil (CO) extracted from the *Eugenia caryophyllata* tree, were measured.

MS-222 was mixed (1:2) with 95% sodium bicarbonate to make a stock solution of 1 mg/mL with a resulting pH of 7.3. The stock solution was added into 80-L tanks containing system water to achieve concentrations of 50, 100, 150, 200, and 250 mg/L. 2PE (Merck) was added to the 80-L tank to achieve concentrations of 0.15, 0.3, 0.45, and 0.6 mL/L. Clove oil (BioVer; 100% pure extract) was mixed (1:10) with 95% ethanol for the concentrations 0.2, 0.4, 0.6, 0.8, and 1 mL/L. To achieve the desired concentration, appropriate volumes of 2-PE and stock solutions of MS222 and clove oil were pre-solubilized into the water from the experimental system to facilitate its administration and then added to the anesthetic tank. Tanks containing only system water were prepared for assessing the recovery trial.

For each anesthetic and each concentration, 9 fish were randomly selected and transferred, one at a time, to the anesthetic tank. Fish were considered fully anesthetized (deep anesthesia) when showing a total loss of reactivity, no reaction to handling, and were lying on the bottom of the tank.

Effect of anesthesia on hematology, plasma metabolites, plasma cortisol, and hepatic enzymes activity

Gilthead seabream juveniles with an average body weight of 151g were unfed for 24h and randomly distributed (3 fish per tank) to triplicate anesthesia tanks containing the optimum concentration of each anesthetic (established in the previous trials). The same procedure was applied to the control group (without anesthesia).

As soon as fish reached deep anesthesia, blood was collected for plasma cortisol and metabolites analysis, and liver was collected for enzymes activity and gene expression.

(Continued on next page)

Results

Optimal doses for anesthesia for ongrowing gilthead seabream, were determined to be 0.45 mL/L for 2-PE, 150 mg/L for MS-222, and 0.6 mL/L for clove oil based on the necessary time to reach deep anesthesia and to be fully recovred.

For each anesthetic, induction time was directly related to the anesthetic concentration.

At the lowest concentration, 2-PE had the highest time for induction of deep anesthesia, while clove oil had the lowest anesthesia induction time.

Regardless of dietary treatment, deep anesthesia did not affect hematocrit and hemoglobin levels. Plasma glucose levels were higher in non-anesthetized than in anesthetized fish, regardless of the anesthetics used. Lactate and triglyceride levels were lower in clove oil anesthetized fish than in the other groups. No differences were observed in plasma protein, albumin, and cholesterol levels between non-anesthetized and anesthetized fish.

Alanine aminotransferase and aspartate aminotransferase activities in the control group were lower than in the 2-PE group, while glutamate-dehydrogenase was not affected by treatments. Hexokinase activity was lower in the clove oil group than in the other groups, while glucose-6-phosphate dehydrogenase activity was lower in the clove oil group than in the MS-222 group.

Gene expression of heat shock protein 70 kDa was not affected by the anesthetic treatments.

Conclusion

Relatively to the non-anesthetized fish, glycemia was reduced in all the anesthetized groups. Plasma glucose secretion is recognized as a secondary response to stress.So the reduction of glycemia, plasma cortisol level, lactate and RBC count observed in the fish anesthetized with clove oil, compared to the other anesthetics, suggests that clove oil was the most effective anesthetic tested, as it inhibits the primary and secondary stress responses and its by-products.

STUDIES ON F1 PROGENY OF GYNOGENETIC SIBERIAN STURGEON *Acipenser baerii* FEMALE – APPLICATION OF MOLECULAR ANALYSIS AND GONADAL HISTOLOGY

D. Fopp-Bayat*, J. Szadkowska, M. Szczepkowski, B. Szczepkowska, K. Naumowicz, E. Ziomek

University of Warmia and Mazury in Olsztyn, Oczapowskiego 5, 10-719 Olsztyn (Poland)
E-mail: foppik@uwm.edu.pl

Introduction

The aim of the present study was application of molecular analysis and gonadal histology for analysis of F1 progeny of a gynogenetic Siberian sturgeon *Acipenser baerii* female. Additionally the gonad morphology and GSI index were analysed in studied fish.

Histological analysis was used to assess gonadal development, sex differentiation and the sex ratio in the progeny of the gynogenetic Siberian sturgeon female. Genetic analysis, based on microsatellite DNA loci genotyping, was carried out for identification of genotypes in Siberian sturgeon offspring. This study provides valuable information on the influence of meiotic gynogenesis on selected reproductive parameters in the progeny of subsequent generations.

Materials and methods

Ovulated eggs, obtained from gynogenetic Siberian sturgeon female were fertilized by sperm of Siberian sturgeon male. Obtained progeny was reared until gonad sampling (~20 months). Samples for histological analyses were collected from 30 randomly selected offspring of the studied gynogenetic Siberian sturgeon female. Different types of sex cells (characteristic for male or female gonads) were identified, and images were acquired. The sexual maturity of all sampled gonads was evaluated according to the procedure described by Sakun and Bucka (1968). The gonadosomatic index (GSI) was calculated based on the body weights and gonad weights of fish, determined upon sampling.

Fin clips from each randomly selected specimen were sampled for genetic analysis and segregation of alleles at five microsatellite loci were analyzed, according to the procedure described by Fopp-Bayat (2007).

Results and discussion

Both female and male individuals were identified in the examined offspring of gynogenetic Siberian sturgeon female. The sex of seven individuals was not identified based on the results of histological analyses, and they were regarded as "unidentified". Only sexually undifferentiated cells were identified in their gonads.

In sturgeon females, oogonia and previtellogenic oocytes were identified, which indicates that all females were in stages I and II of gonad development. Gonads of examined male were significantly more differentiated (in comparison to females gonads) and four developmental stages were identified: 1) stage I characterized by the presence of spermatogonia and undifferentiated gonocytes, 2) stage II, 3) stage II/III, and 4) stage III/IV where all types of male reproductive cells were observed.

Microsatellite genotypes of analyzed individuals were not linked to gender, therefore no sexual-specific genotypes were identified.

The present study set out to determine the degree of sexual maturity in the offspring of the gynogenetic Siberian sturgeon female. In the future, the results should be compared with the observations made in the progeny of other gynogenetic females. These findings will be used to identify potential defects in the gonadal development of the offspring of gynogenetic mothers.

EFFECTS OF PROCESSING AND EXOGENOUS DIETARY ENZYME INCLUSION IN PLANT MEAL BASED DIETS; PRELIMINARY RESULTS ON GROWTH PERFORMANCE, FEED UTILIZATION, AND NUTRIENT DIGESTIBILITY IN SEABASS *(Dicentrarchus labrax)*

Fountoulaki E.*[a], Vasilaki A.[a], Nikoloudaki Ch., Pyrenis G.[a], Henry M[a]. and Nengas. I.[a]

Introduction

The limited availability of marine ingredients for aquafeeds led the feed industry to replace them with sustainable and cost efficient alternatives of different origin, plant or terrestrial. The major limitation in the use of plant raw materials is related to their high amount of anti-nutritional factors (ANF's) such as protease inhibitors, non-starch polysaccharides (NSP) and phytate (Francis et al., 2001), which affect growth parameters, feed utilization, nutrient digestibility etc. Processing technologies of the raw materials and feeds (heating, soaking, extrusion, enzyme addition etc) can be a valuable tool to enhance digestive utilization of nutrients (Kraugerud & Svilus 2011, de Vries et al., 2012). Exogenous enzymes have been investigated in fish (Lemos & Tacon 2015) where addition to diets has resulted in increased utilization of phytate phosphorus, other trace elements and protein, while the potential of NSP enzymes (xylanase) in fish diets as a way to improve growth and feed utilization is limited in fish and specifically in sea bass non existing. The aim of the present study was to investigate the effects of raw material processing as well as enzyme addition in plant meal based diets for seabass (*Dicentrarchus labrax*) on growth performance, feed utilization and nutrient digestibility.

Materials and methods

European seabass juveniles (~19.5g) were fed 5 experimental diets for 3 months at 24^{0}C water temperature, *at libitum*. Two control diets were formulated; a positive (CTRL+) containing 20% fish meal (FM), 24% soya protein concentrate (SPC), and 22% corn gluten (CGM), while the negative control (CTRL-) contained 10% of each of the following raw materials: rape seed meal, sunflower meal, and guar meal replacing almost half of the FM, SPC and CGM which were added at 15%, 12%, and 10% respectively. The raw materials were subjected to thermal processing prior their inclusion in the diet (diet Treated) while in the other two diets the enzymes phytase and xylanase were added by coating in diet Phy-Xyl and a commercial exogenous enzymes complex: Synergen™ (Alltech) in diet Synergen. All diets were isonitrogenous and isoenergetic containing 48% protein, 17% fat.

Results

After 83 days of feeding, fish significantly improved growth performance and feed utilization (SGR, FCR) in those diets where the thermal processing or the enzymes was added compared to the negative control diet (CTRL-). Furthermore Phy-Xyl diet showed significantly higher SGR than the other two diets, Treated and Synergen. Protein efficiency was also improved either by heat treatment of the raw materials or by the enzyme addition, the major effect being evident in diet Synergen. Concerning nutrient digestibility (ADC), protein was high for all diets but significantly higher in the Synergen diet, while fat ADC was significantly higher in the Phy-Xyl diet.

Discussion & Conclusions

The supplementation of exogenus enzymes as feed additives to improve growth, feed utilization, and nutrient digestibility of plant–based feedstuffs has been studied extensively in poultry and swine industry as a way to reduce the anti-nutritional effects of NSP and phytic acid. In the present study it was evident that exogenous enzymes supplementation has a great potential in sea bass by showing to improve significantly SGR and FCR as in other species (Atlantic salmon, Carp, Rainbow trout, Japanese sea bass, African catfish). The effectiveness of the enzymes used in the present study in reducing the anti-nutritional effect of NSP and phytate was more evident for Phy-Xyl diet compared to Synergen and Treated diet. Digestibility of protein was improved by the addition of Synergen as the product contains proteases which facilitate protein digestion while fat digestibility was the highest by the supplementation of xylanase & phytase. In fish endogenous digestive enzymes that hydrolyze NSP seems to be very low or not existing. One of the most important benefits of this enzyme is the reduction of the NSP induced digesta viscosity which result to a better digestibility of the fat.

RECOVERY OF HAEMAL LORDOSIS IN EUROPEAN SEA BASS *Dicentrarchus labrax* (LINNAEUS, 1758)

S. Fragkoulis[1]*, Ch. Kourkouta[1], A. Printzi[1], G. Geladakis[1], D. Kerasovitis[2] and G. Koumoundouros[1]

1, Biology Department, University of Crete, Heraklion, Greece.

Email: stefanos_fragkoulis@hotmail.com

Introduction

Haemal lordosis is a frequent vertebral abnormality in finfish aquaculture, with significant and variable effects on fish externally morphology (Fragkoulis *et al*. 2019, 2021). In most of the fish species studied so far, haemal lordosis develops during the late metamorphosis and early juvenile period, mainly due to elevated fish swimming activity (Sfakianakis *et al*. 2006, Palstra *et al*. 2020, Printzi *et al*. 2021). Despite the significance abnormalities for the product quality, it was recently shown that haemal lordosis can substantially recover during the growth of seabream in sea cages (Fragkoulis *et al*. 2019).

In the present study we examined whether haemal lordosis may recover in European sea bass, the species where swimming-induced lordosis was first described (Divanach *et al*. 1997).

Material and Methods

Fifty-six sea bass juveniles (77±6 mm standard length, SL) with lordotic external morphology (dorsally shifted caudal peduncle) were selected from one reared population. All fish were anaesthetised, tagged electronically (FDX-B, Trovan Ltd, USA), photographed on their left side and returned to the sea cage until the end of the on-growing period (234±16 mm SL). At that stage, fish were anaesthetised, photographed and tag-identified. Subsequently, a representative sample of fish with a recovered and lordotic external morphology was radiographically examined.

Results & Discussion

At the end of the examined period (353 dpt), the 57% (32 out of 56) of the fish with severe lordotic morphology presented normal external phenotype, whereas 7% (4 out of 56) presented light lordotic morphology. The rest 36% of the fish (20 out of 56) continued presenting a lordotic external morphology. The radiographic examination of the fish, verified the macroscopically observed lordosis recovery. The 32% of specimens with recovered external morphology (28 out of 41) presented a completely normal vertebral column (Fig. 1Bi), whereas the 18% presented minor abnormalities of individual centra (Fig. 1Bii). The rest 50% of the recovered fish presented a light bending of the vertebral column (Fig. 1Biii).

Concerning severely lordotic fish that turned into fish with light lordotic external morphology, 40% presented light vertebral bending, whereas 60% presented either minor abnormalities of individual centra, severe lordosis, or a counterbalancing kyphosis anteriorly to lordosis (Fig. 1A, 1Bii-Bv). Finally, all fish with severe lordotic external morphology, presented a severe vertebral bending (Fig. 1Bv).

In the present study we showed that the external morphology of lordotic sea bass juveniles may completely recover during the on-growing period. The recorded recovery rate of lordosis in sea bass (57%) is higher than that previously reported for seabream (44%, Fragkoulis *et al*. 2019). Fragkoulis *et al*. (2019), assumed that the rearing in the sea cages, might be responsible for the recovery, due to the adaptability of the vertebrae in the less intense water current velocities, compared to conditions in the tanks. Our results do not contradict this hypothesis, since the recovery was observed during the on-growing period. Similarly, our radiographic findings on the anatomy of the lordosis recovery are in total agreement with Fragkoulis *et al*. (2019), with the same phenotypes observed in both studies. Our results show that lordosis recovery is not species-specific and has to be taken into consideration during the quality control at the end of the hatchery phase. Further morphometric analysis in the future, could provide useful indices for the accurate discrimination between abnormal fish, on the basis of their recovery potential.

Introduction

There is an increasing effort to integrate environmental data obtained from diverse sources to improve management systems for aquaculture. As part of this effort, the EU Horizon 2020 programmes has funded research projects to develop technological innovations for sustainable growth in the aquaculture sector as a contribution to precision aquaculture in the blue economy. Green Aquaculture Intensification in Europe (GAIN) is one of these projects which includes as one of its study sites, an offshore longline system in the SW of Portugal for the aquaculture of bivalves.

In the case of the offshore aquaculture industry, there are substantial benefits to continuous monitoring of conditions for water quality and productivity. On one hand, regular manual sampling allows for an accurate and assessment of the status of the water quality at the moment of collection, offering the possibility of having additional measurements, if required for a specific parameter. However, recent studies indicate that low frequency data collection in aquaculture might not be sufficient to provide an adequate image of the relevant biogeochemical processes for an improved production (Sampaio *et al*., 2021)producers should adopt tools and protocols for environmental monitoring and management of these enterprises. There are currently issues concerning the efficacy of data collection procedures and limnological sampling at low frequency, which is widely used by managers and aquaculture surveillance agencies. In this context, the present study evaluated the effectiveness of high-frequency (HF. Continuous monitoring with data logger-based sensors deployed at the bivalve aquaculture sites overcome this limitation but such equipment requires frequent maintenance and are often subject to adverse weather conditions which might cause severe interruption in data acquisition. Satellite remote sensing data, with its synoptic view of neighbouring phenomena, is especially useful to forecast short-term adverse or beneficial conditions for the cultured species, however its accuracy is significantly decreased by adjacency effects and periods of cloud cover, especially if offshore aquaculture is located near the coast (Icely et al.,2013). Blending the three approaches might be best for periods with cloud-cover to overcoming the caveats for the individual monitoring techniques, thereby, providing enhanced view of the biogeochemical processes responsible for cultured species production and to manage and mitigate risks with adverse oceanographic conditions.

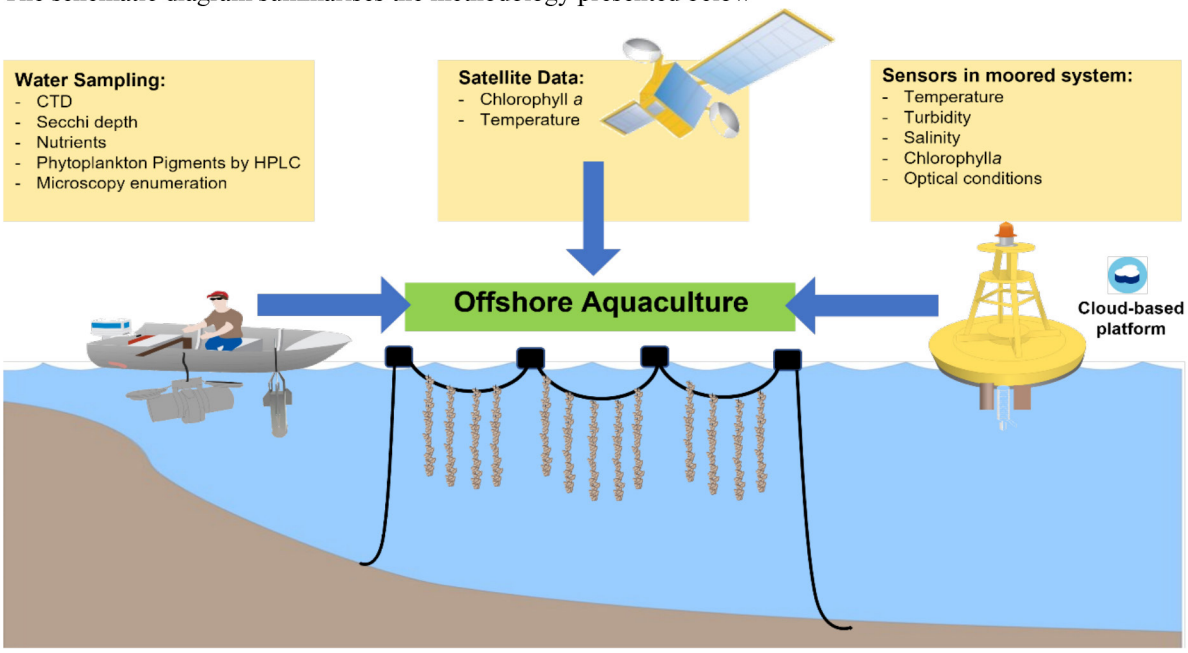
This poster shows how historical data, as well a sampling programme funded at an offshore longline for mussel aquaculture at Sagres SW Portugal, have contributed to the objectives of the project.

Methodology

Data was collected from June 2018 till October 2020. In the case of offshore longlines for mussel aquaculture at Sagres, SW Portugal, the data are supplied from a solar powered data logger with sensors installed on a signal buoy for offshore mussel aquaculture to estimate sub-surface temperature, salinity, fluorescence, turbidity, and optical conditions. Data from these sensors are transmitted every two hours to a cloud-based platform or downloaded manually and subsequently transferred to the platform. Classical oceanographic sampling has also been implemented to calibrate and validate the sensor's data, with the deployment of: a CTD for conductivity and temperature profiles; a Secchi disc for water clarity; and a Niskin flask for water samples to estimate chlorophyll, total suspended matter, nutrients, as well as pigment and microscopical analysis to determine the microplankton community. This *in situ* data has also been complemented with satellite data, again from different sources such as the Copernicus Marine Service (EU) and the National Oceanic and Atmospheric Administration environmental data access programme (USA).

(Continued on next page)

The schematic diagram summarises the methodology presented below



Results and Discussion

With this approach, it has been possible to compare the quality of data obtained from different sources. For example, how does chlorophyll obtained from near real time fluorescence measurements compare with chlorophyll products from satellite images, and chlorophyll estimates with spectrophotometric and High-Performance Liquid Chromatographic (HPLC) techniques for *in situ* water samples; there is generally good agreement between datasets, with spectrophotometric measurements overestimating Chlorophyll *a* values for higher ranges, as expected (Santos *et al*., 2003). These data are now available to reduce uncertainties associated with models that are available for farmers to improve their farming practices.

Microscopic analysis revealed interesting results, especially concerning HAB groups. *Pseudo-nitzschia* blooms were detected in August 2019, June and August 2020, both coinciding with high levels of Chlorophyll a (2-5 $mg.m^{-3}$). Alert levels of *Gymnodinium catenatum* were found in the end of October 2020 (960 $cell.l^{-1}$), whereas values of Chlorophyll *a* were of 0.8 $mg.m^{-3}$. The relation of these communities with other pigments such as peridinin is in progress. These observations confirm that the relationship between Chlorophyll *a* (the *proxy* for phytoplankton community used by optical sensors) and HAB is complex, reinforcing the importance of maintaining *in situ* sampling in aquaculture monitoring programs to complement optical sensors (buoy and or satellite based) information.

Conclusion

The data from the Sagres site has contributed to precision products developed over the duration of the GAIN project, some of which are being presented in oral contributions at this conference. For example, Fearghal et al "A cloud platform for precision aquaculture" led be IBM Research and Ferreira et al. "AquaSense – a real -time precision aquaculture platform for industry" led be Longline Environment Ltd.

Introduction

The European Seabass, *Dicentrarchus labrax*, is the second most important marine finfish species produced in the Mediterranean area with and annual fry production of over 500million. The majority of the fry are produced using the Green Water Technique (algae, rotifers and Artemia), but around 20% is produced without algae and rotifers, keeping the larvae in the dark until around 9dph and starting first exogenous feeding with Artemia instead of rotifers. This technique is normally resulting in a slower growth of the larvae and lower robustness compared to the green water technique.

In this study, new feeding protocols were developed to improve the performance of Seabass during larval rearing without the use of rotifers, introducing a rotifer substitution diet from the time of mouth opening. For the classic green water technique, a variant was studied introducing the new diet at 5dph and reducing the normal rotifer quantities with around 50-60%.

Materials and methods

Seabass experiment

Nearly hatched Seabass larvae, originating from the same pool of eggs, were stocked at the a density of around 80 larvae.l^{-1} in 1,000l larval rearing tanks. Four different feeding protocols were used:

1. Full live food Control using a standard diet from 18dph onwards
2. Improved Live food Control with 50% Rotifer Substitution and using the new diet from 4dph
3. Clear water technique without rotifers using the Rotifer substitution diet
4. Green Water technique without rotifers using the Rotifer substitution diet

In all treatments, *Artemia* has been fed from 10dph onwards. A photoperiod of 14L/10D was used and the treatments were done in triplicate.

During the larval rearing period, weekly biometrics were carried out to compare growth rates. A salinity stress test was done at the end of the trial to determine the stress resistance. At 56dph, larval survival, produced biomass per tank and deformity levels were evaluated.

Results

The growth of the Seabass larvae during the period of 56days showed a superior growth up to 14dph for the Full Live Food Control. Later, the growth accelerated in the treatments where the rotifer substitution diet was used. At 56dph, the treatment with 50% rotifer substitution had the lowest weight, even if the difference with the other treatments was not significant.

Average survival rate was highest for treatment 4, without rotifers, using the rotifer substitution diet and green water (65%). The lowest survival rate was obtained in the clear water treatment (45%). The survival rate of the improved LFC was slightly higher than the standard LFC (55 versus 52%). Combining the data of survival and average weights, tank biomasses were compared and lowest values were obtained for the Clear water technique. The highest biomass was obtained in the Green water technique without rotifers, using the new diet at the start of exogeneous feeding. Tank biomasses for the other two treatments showed intermediate and similar values.

Regarding the stress resistance, treatments without rotifers or with low amounts of rotifers, but adding the dry diet from the early beginning, were performing like the LFC.

Deformity levels showed a higher percentage of head deformities in the Clear water treatment, where no algae were used. The treatment showing the highest percentage of fish without any deformity was the improved Live Food Control, using the new diet fed from mouth opening. In the treatments where no rotifers were fed, the green water treatment showed significant less deformities compared to the clear water treatment.

(Continued on next page)

Conclusions

This study shows that Seabass larvae can be reared obtaining a high survival rate and good fry quality when the rotifer substitution diet is used from the first days of exogeneous feeding. The treatments where no rotifers were used, but in which high-quality marine algae were added during the larval rearing water until 11days post hatch, resulted in the best treatment. The treatment with 50% of rotifer substitution performed less in terms of growth compared to the standard LFC, but the quality of the produced fry improved in terms of deformities. The lower growth could be explained by the fact that the Seabass larvae preferred rotifers above the rotifer substitution diet when administered in the same period. As such, a lower amount of dry feed was ingested, resulting in a suboptimal growth.

The use of high-quality marine algae is fundamental to obtain optimal growth and quality in the larval rearing of Seabass. Even in the absence of rotifers, but using algae and the rotifer substitution diet, results are excellent. This allows the simplification of larval rearing protocols for Seabass without compromising the growth, neither the quality of the produced fry.

WHO IS THE BEST SURROGATE FOR GERM STEM CELL TRANSPLANTATION IN FISH?

Introduction
Surrogate reproduction technology in fish has potential for aquaculture as well as endangered species preservation and propagation. Species with some unfavourable biological characteristics for culturing such as a late maturation or a large body size are ideal candidates for surrogate reproduction using smaller and faster-maturing host. One of the general prerequisites for the successful surrogacy and the pure donor-derived gamete production is the sterility of the host. Various sterilization methods have been developed and used in fish surrogacy; however, a direct comparison of available methods is missing. Such a knowledge gap hinders choice for the surrogate in various fish species, including those in high commercial demand such as tuna or sturgeons, where is a particular limitation from the point of the live material availability and difficulty to perform a high throughput assessment of different surrogates. Yet, large sturgeons or tuna species are one of the most prominent candidates for surrogacy.

Materials and methods
Transgenic zebrafish expressing EGFP protein in germ cells exclusively was utilized in this study as a model species to answer whether and to which extent different sterilization strategies can affect the surrogacy. Germ cell-depleted recipients (produced using knockdown of *dead end* gene) (MO), triploid recipients (3n), and zebrafish x pearl danio hybrid (H) recipients were tested as they represent the most frequently used types of surrogates. Spermatogonia isolated from vas::EGFP transgenic strain were intraperitoneally transplanted into swim-up 5-day old zebrafish. Transplantation success, survival, gonadal development, and reproductive output of the fish was analysed.

Results
Post-transplantation survival in MO T group was comparable to the controls, while survival performance of 3n T, H T and control groups was slightly lower. Altogether, overall survival from transplantation to 6 months of age was in all groups (included transplanted groups) from 65 to 85 %. The transplantation success evaluated two-week post-transplantation showed consistent results across different sterilization methods of the EGFP positive cells in recipients. Most of the EGFP positive cells were located in the posterior or medial part of the body cavity. The highest incidence of adult germline chimeras was observed in the MO T group, followed by 3n T group. Interestingly, % of adult germline chimeras in H T and AB T group were almost equal Intraperitoneally transplanted GSCs were capable of establishing donor-derived spermatogenesis in all tested sterilization treatments as well in non-sterilized AB recipients. Observed gross gonadal development was prominent MO T group which gained the largest increment in gonadal development (comparing transplanted group with their respective sterilization control). In MO T group, transplanted GSCs were able to frequently reconstitute spermatogenesis unilaterally or even bilaterally into fully developed testes in term of length and width.

The sperm concentration and total amount of produced sperm in germline chimeras was influenced by the fact that the testes comprised of donor-derived germ cells are not reaching their full size compared to controls. MO recipients males produced highest volume of sperm, concentration of spermatozoa, total number of spermatozoa and finally also total motile spermatozoa among tested sterilized recipients (Fig. 1).

Comparison of transplanted recipients with AB and vas::EGFP controls showed poor performance of H T recipients, in semi-artificial fertilization trials, while MO T and 3n T males showed performance comparable to one of the controls (AB C or vas::EGFP). In vitro fertilization resulted in higher progeny production in all groups including controls. Importantly, the percentage of swim-up larvae was statistically comparable amongst all groups except the H T group.

(Continued on next page)

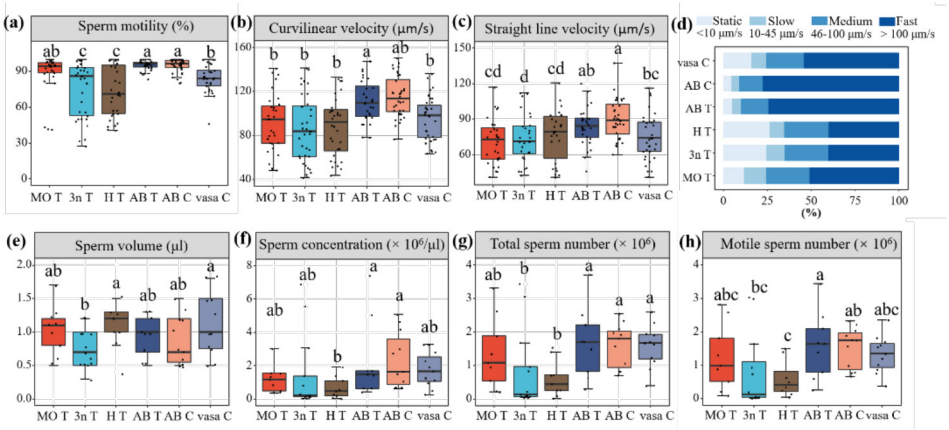

Figure 1. Sperm and spermatozoa motility parameters in germline chimeras and controls.

Discussion

GSCs manipulation is potent biotechnology to ameliorate breeding of aquaculture species and preserve valuable genetic resources in environmentally relevant or even endangered species. This study aimed to identify best sterilization treatment - essential factor influencing the surrogacy success rate. The presented study assessed various sterilization treatments in fish for surrogates preparation and their influence on gonadal development and reproductive output in germline chimeras. Of the utmost importance, germ cell-free gonads were identified as the best environment for transplanted cells yielding the highest transplantation success and gonadal development. Importantly, reproductive performance of males including quantity and motility parameters and fertilization rate clearly favours germ cell depleted recipients. The use of triploid and hybrid males from the point of view of the production of sufficient quantity and quality sperm proves to be risky to achieve stable results. Moreover, only germ cell depleted recipient retained reproductive characteristics of the donor strain. Presented findings should help in decision on what type of sterilization should be used prior to transplantation and surrogacy induction, especially in non-model fish species.

LEARNING FROM THE DEVELOPMENT OF MARICULTURE IN GREECE

K. Frangoudes*[1] and A. Conides[2]

[1] UMR AMURE, IUEM, Université de Brest, rue Dumont d'Urville, 29280 Plouzané, France
Katia.Frangoudes@univ-brest.fr
[2] Hellenic Center for Marine Research, Greece

Introduction
The development of mariculture in Greece started in the 80's. This new activity appeared as a financial opportunity and attracted investors among which few fishers. Private investments supported by EU subsidies contributed to the creation of a high number of aquaculture units of different size in the whole country. The creation of each aquaculture unit was subject to multiple authorizations given by different ministries (fisheries, archaeology, maritime transport, economy, etc.) and an acceptance by the municipality. Since then all aquaculture units were created without any specific marine planning and they often caused negatives reactions from local residents.

Methodology
Through interviews realised in the west coast of Greece with mariculture farmers, civil servants of district and regional fisheries authorities, natura 2000 employees, touristic activity and fishers we tried the capture the nature of the arguments used in favour and against aquaculture during the first period and nowadays. Additional interviews with national authorities (ministries of environment and agriculture and fisheries) and aquaculture experts brought more light concerning expectations about the law related to marine spatial planning which is still not implemented in the country despite the high demand of farmers.

Results
The analysis of this qualitative data will discuss first the current perspectives of development of mariculture in Greece in relation to marine spatial planning and second, based on the Greek example, provide information to others Mediterranean countries wishing to develop mariculture about how to overcome and mitigate social protests.

GENOMIC SELECTION OF RESISTANCE TO *Flavobacterium columnare* IN RAINBOW TROUT USING LOW DENSITY SNP PANELS

C. Fraslin[1]*, A. Kause[2], A. Nousiainen[2], H. Koskinen[2], R.D, Houston[1]

Introduction

Columnaris disease (CD), caused by *Flavobacterium columnare* is an emerging disease affecting rainbow trout (*Oncorhynchus mykiss*) aquaculture worldwide. With no commercial vaccine available so far, selection to improve host resistance is of major importance for trout farmers. In aquaculture breeding, genomic selection has been increasingly used for traits that are difficult to measure on candidate fish (such as disease resistance traits). Previous studies suggested that rainbow trout resistance to CD could be improved by selective breeding, and that genomic selection was a useful approach to speed up this process (Silva et al., 2019). However, genomic selection can be prohibitively expensive as it requires genotyping of a large number of fish with high density genotyping arrays. The aim of this study was to assess the efficiency of genomic selection using low-density SNP panels for this disease resistance trait.

Material and methods

In May 2019, 105 rainbow trout families (from 33 dams and 48 sires) were produced from the Finnish national breeding programme maintained by Luke and their eggs were pooled. In June 2019, around 30,000 fry were separated into three fingerling tanks at the farm of Hanka-Taimen Oy (expected average of ~100 fish per family per tank). The fish were monitored daily for mortality, and when suspected signs of *F. columnare* were observed, the dying fish were sent to a veterinarian for a diagnosis. Once the presence of *F. columnare* was confirmed, the fish were treated with an approved treatment against CD to stop the outbreak. Simultaneously, about 510 fish with clear signs of CD per tank were randomly sampled among fish that died during the first 5 days of the disease outbreak. A piece of tail was sampled from those 1,531 fish for DNA extraction and genotyping. Thereafter, the fish rearing continued in the tanks, and in September-October 2019 tissue sample of 1,519 live randomly sampled fish were collected among the surviving fish. In total, 3,054 challenged fish and 81 parents were genotyped using the 57K SNP Axiom™ Trout Genotyping Array. After quality controls (QC), 27,907 SNPs were retained and used as the HD panel.

Resistance was analysed as a binary trait (0=alive; 1=dead) with the rearing tank as a fixed effect in the statistical model. The (genomic) estimated breeding values [(G)EBV] of fish were obtained using pedigree-based BLUP and genomic BLUP (GBLUP) computed with BLUPF90 software (Misztal et al., 2002). The efficiency of pedigree-based or genomic prediction was estimated using Monte-Carlo "leave-one-group-out" method by removing the known phenotype from 20% of the fish, and then using the remaining 80% fish and their information to predict the (G)EBVs of the 20% validation fish group. This was repeated 20 times. Accuracy of prediction was computed as the mean over the 20 replicates of the correlation between the (G)EBV and the true phenotype of fish in the validation group, divided by the square root of the genomic based heritability.

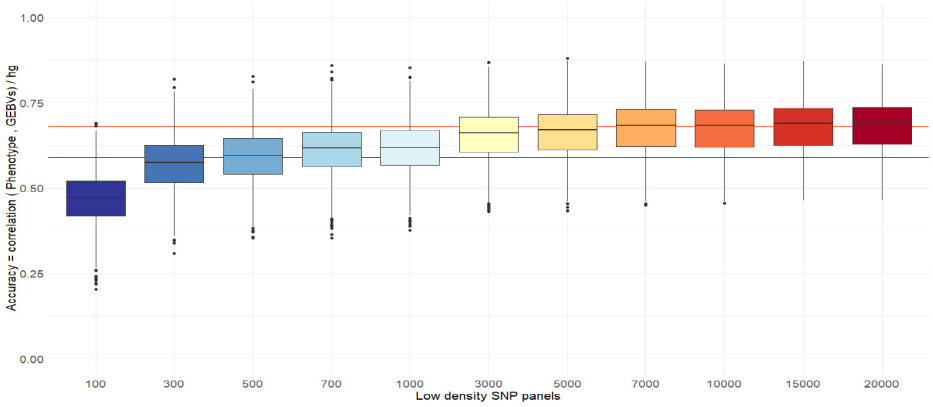

Figure 1. Accuracy of genomic prediction for different low-density SNP panels. The red line is the average accuracy for GBLUP using the HD panel, the blue line the average accuracy for PBLUP.

(Continued on next page)

The impact of reducing the SNP density on genomic prediction was tested with eleven low to medium density *in silico* SNP panels. For each panel, SNPs were sampled from the 28K QC-filtered SNPs from the HD panel using the CVrepGPAcalc package (Tsairidou et al., 2020). The SNPs were randomly sampled within each chromosome without replacement, with the number of SNP sampled from a given chromosome being proportional to the physical length of the chromosome in the *O. mykiss* reference genome (Omyk_0.1, (Gao et al., 2018)). For each target density, 10 replicate panels were generated, which were allowed to overlap by chance. Genetic parameters and GEBVs were estimated as described above for each low-density panel.

Results and discussion

Pedigree based heritability was estimated to be 0.18 (± 0.038) on the observed scale, and genomic heritability was estimated to be 0.21 (± 0.029) on the observed scale. Pedigree-based prediction accuracy was 0.59 (± 0.080) and the use of genomic evaluation increased the prediction accuracy by 14% for the GBLUP (0.68 ± 0.076). Decreasing the number of SNPs used for the prediction tended to decrease the accuracy of genomic prediction (Figure 1). Accuracies obtained with 300 to 1000 SNPs were close to the accuracy of PBLUP. However, prediction accuracies obtained with SNP density panels from 3K and above were close to the accuracy obtained with the HD panel, suggesting that 3K may be a cost-effective SNP density at which to genotype in future studies and commercial practice.

Conclusion

In this study, we showed that using low density SNP panels (down to 5K or even 3K) would results in comparable accuracy than with the 28K HD SNPs panel. Reducing the SNP density is one way towards a more affordable genomic selection without losing efficiency. Approximately 3K SNP panels may provide a more affordable route to genomic prediction of breeding values with small compromise in accuracy.

Acknowledgment

This study is part of the AquaIMPACT project and was funded by the European Union's Horizon 2020 research and innovation programme under grant agreement No 818367. The skilled staff of Savon Taimen Oy and Hanka-Taimen Oy are thanked for their expertise in data collection and fish rearing.

Introduction:
Even though considered illegal and several regulatory guidelines are in enforcement, food fraud is still a recurrent practice through all food supply chain. In the case of seafood products, missing the identification of species and repackaging of products, constitute the most common frauds. Therefore, the development of appropriate analytical approaches, to be used against food fraud is necessary[1]. The aim of the present study is to evaluate, for the first time, the possibility to differentiate between fish from two different mariculture farms located in Madeira island, using mass fingerprint of fish mucus combined with multivariate analysis.

Material and Methods:
Sparus aurata mucus was collected at two different farms both explored by IlhaPeixe SA. One located at Baia D'abra, Caniçal (32°44'31.4"N 016°41'26.7"W), and the other at Campanário, Ribeira Brava (32°39'38.1"N 017°03'22.1"W). A volume between 5-10ml of mucus were collected at fish capture. Mucus samples were cleaned with a chloroform/methanol precipitation method. The aqueous layer and pellet were analyzed using a MALDI-TOF MS. The MALDI full spectra were exported and analyzed using MASS-UP software, for biomarker discovery and multivariate analysis.

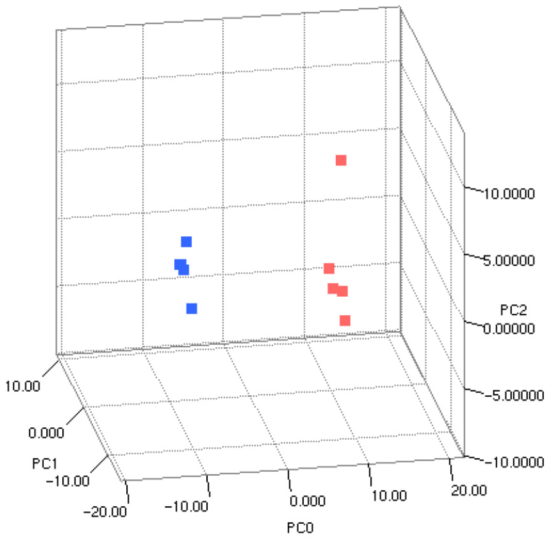

Figure 2 - PCA results for mucus samples analysis. Blue – Caniçal. Red - Ribeira Brava

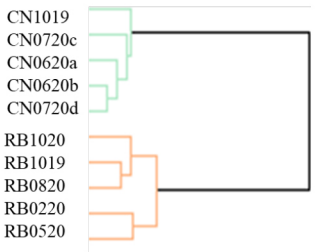

Figure 1 - HCA results of mucus samples. Code represents location, month, and year.

(Continued on next page)

Results:
Figure1, is the representation of the PCA analysis results for the data containing samples from Caniçal (blue) and Ribeira Brava (red). The eigenvalue for the three first components are PC0-395.4, PC1- 63.0 and PC2-60.0. The variances were 0.51, 0.082 and 0.078, respectively. The figure 2 shows the hierarchical cluster analysis (HCA) obtained from the analysis of the peaks lists. The results of the agglomerative HCA were expressed as dendrograms, for better results representation. It was also possible to obtain a list of potential biomarkers for each location, a total of 35 peaks with 17 for Caniçal and 18 for Ribeira Brava.

Conclusion:
The results indicate that there are differences between the mass peaks of samples from different origins. The discriminant peaks are good candidates' biomarkers to differentiate between the two sea farm sites. Further analysis must be done in order to access if the discriminant peaks are still detected at selling points or if others will arise, mostly influenced by the product degradation.

SOLUTIONS TO A BETTER FUTURE FOR AQUACULTURE AT MADEIRA ARCHIPELAGO

A. Friedrich*

The Oceanum Portugal Project,
E-mail: arthurfriedrich@gmail.com

The future of Aquaculture at Madeira Island

The consumption of dried codfish is a long time tradition in Portugal. Codfish is the most frequently consumed fish at Madeira Archipelago. Curiously, codfish does not inhabit Madeira's seawaters. Norway is the source of the majority of codfish consumed on Madeira, where it grows in aquaculture farms.

Although Madeira's population is a large consumer of aquaculture products, raise fish in the archipelago's waters is not simple. Besides the open water challenges, aquaculture producers face political and social pressures. Accordingly to local newspapers, popular associations and political oppositions parties declare themselves against aquaculture sea-cages. The protesters claim the removal of aquaculture sea-cages assuming they harm the sea view and are prejudicial to tourism and the environment, while few jobs are generated. Opposition to aquaculture is not exclusive of Madeira's Island, but at the archipelago, it affects the picture policymakers, entrepreneurs and scientists want to draw as the future of aquaculture, not permitting the activity to achieve its full potential.

The future of aquaculture is only possible if objections are considered but also contested in a process to construct the desired outcome. The social process of finding consensus is strategy making. The stakeholders must create the strategic decision process, which will guide the implementation of actions necessary to create the best version of aquaculture.

Strategy making as a tool

To create strategy, though, the stakeholders must be on the same page, which is only possible throughout education. A variety of initiatives have been developed in recent years to promote ocean literacy and promote educational activities. One of them is the Young4Ocean Forum.

The Young4Ocean Forum is an online platform supported by the European Commission for young EU changemakers passionate about the sea. The common goal is to shape a future with a healthy ocean that sustains us all. The Young4Ocean is an opportunity for the youth to speak up for their generation, share ideas and present their projects. It also permits the accreditation as an EU Young Ocean Advocate, which provide access to additional benefits such as coaching & mentoring and resources to develop a project.

Platforms as the Young4Ocean Forum are essential to reinforce the connection between youngsters. Credible information is available to members to deepen their knowledge and apply it to their projects. Access to high-quality data and specialists empower the youth to actively discuss and build the strategy for the sea in their local community. Defend aquaculture on Madeira Island is an example.

Cohesion and divergence are critical to effective strategy making. According to the book *Making Strategy*, written by Fran Ackerman e Colin Eden, professors at Strathclyde University Business School, sometimes strategy making needs to encourage divergence of thinking rather than risk too much cohesion. Conflict, to a certain extension, generate the energy necessary to boost creativity.

Madeira's aquaculture conflict brings people out of the status quo zone, and consequently, boosts creativity. People search for alternatives to change the status quo in two scenarios, to survive throughout crises or to improve and achieve better results. Madeira's economy faces a crisis due to covid-19, and its society needs to leave the status quo. The Oceanum Portugal project was born to help Madeira solve this problem while promoting aquaculture.

The Oceanum Portugal project mission is to integrate Madeira Island Sea Nature tourism, aquaculture and local restaurants to improve their business results under the triple bottom line concept. The triple bottom line concept defines that businesses should not aim for profit only but also care about the social and environmental outcomes of their actions. Therefore, the project's main objective is to integrate enterprises under the blue economy concept of profitably, which means exploring the sea and, at the same time, respecting and preserving the environment.

(Continued on next page)

Oceanum Portugal aims to integrate local business (Nature Tourism and Local Restaurants) with the aquaculture sector that has the potential to be an alternative to make Madeira Island economically heterogeneous and resilient, generating jobs and improving R&D investments in the industry. The project will analyze the companies' performances and then make a strategic formulation to integrate them while promoting them on social media.

Oceanum Portugal team will evaluate the relationship between the company's mission with the actual activities they promote. Second, the team will assess its resources and capabilities (Resource-Based View) defended by R. Grant and J. Barney and make an external analysis to evaluate how the companies face the five environmental forces proposed by Porter. These will lead to the strategic options that will drive the action plan to integrate the enterprises, always focusing on achieving the triple bottom line. Finally, the project will also promote the companies on social media to improve their visibility.

Who are the bene iciaries?
The project targets business owners or managers from the three sectors: Sea nature tourism, aquaculture and local restaurants placed on Madeira Island.

Enterprises from the three sectors will benefit from receiving management consulting services and social media visibility when associated with Oceanum Portugal. Therefore, the association created between the aquaculture sector, nature tourism and local restaurants will aggregate value to their products and improve their resilience.

Next Steps
Promote aquaculture and define its future is a matter of establishing consensus and act. Join the Youth for Ocean Forum is a perfect opportunity to gain knowledge and contact the best people in the field. In addition, it is possible to submit your project to become a Young Ocean Advocate and receive mentoring and coaching from field specialists.
Join at the Maritime Forum on European Commission Official Website:

COMMERCIAL FEED REPLACEMENT FOR A SUSTAINABLE AND SELF-SUFFICIENT INTEGRATED MARINE AQUAPONIC PRODUCTION

Lorenzo Rossi[1], Carlo Bibbiani[1], Alberto Pardossi[2], Chiara Sangiacomo[1], Baldassare Fronte[1*]

1 Department of Veterinary Science, University of Pisa, Pisa, Italy
2 Department of Agriculture Food and Environment, University of Pisa, Pisa, Italy.

Introduction

Since Aquaculture is asked to produce sustainable animal proteins for the future growing world population, the large use of commercial feeds may represent a relevant bottleneck. Grains such as soybean, corn, wheat, barley, and even more precious raw materials such as fish oil and fishmeal, are commonly produced far away from the consumption sites. Moreover, their intensive production represents itself a severe hazard in terms of environmental pollution, soil and sea overexploitation, and biodiversity reduction. Yet, the overseas transportation of large quantities of raw materials and final products is characterized by a very high Carbon Footprint. In this context, an environmentally sustainable alternative to intensive aquaculture might be the Integrated Multi-Trophic Aquaculture approach. Stemming from IMTA, the Self-sufficient Integrated MultiTrophic AquaPonic system (SIMTAP, H2020 PRIMA-Programme) encompasses four consecutive trophic levels, starting from microalgae, deposit- and filter-feeder organisms (DFFO), fish and plants, reared in a recirculating system using saltwater.

In the SIMTAP system, micro- and macro-algae are raised for feeding DFFO, which in turn are harvested for feeding (or partially sold) fish; finally, solid fish wastes "feed-back" DFFO, while soluble wastes such as nitrogen and phosphorous are absorbed by hydroponically grown halophytes, salt-tolerant glicophytes and macro-algae, with that bio-remediating the recirculating water.

The DFFO are heterotrophic species such as polychaetes, bivalves, and echinoderms, which may represent a sustainable, nutritionally valuable, alternative to fish oil and fish meal in fish nutrition.

To evaluate how the use of these organisms may affect the growth performances of carnivorous fish species, two different trials have been carried out so far. The first consisted in the diet inclusion of increasing rates of mussels, until totally replacing the commercial feed. In the second trial, the commercial feed was fully replaced by a mixture of mussels and clams.

Material and Methods

All the experimental procedures were approved by the Organism for Animal Welfare of the University of Pisa and the Italian Ministry of Health (authorization code: B290E.N.AHZ). The trials were carried out using six cylindric 420 L tanks of the SIMTAP system located at the Department of Agricultural Food and Environment of the University of Pisa (Pisa, Italy).

Juveniles of Gilthead Sea Bream (*Sparus aurata*) were used and daily fed at 3% (on dry matter base) of their live body weight (BW). The diet ingredients used were the following: INVE© O. range P15 as commercial feed; frozen mussels (*Mytilus platensis*) and clams (*Chamelea gallina*) as feed replacers. The fish biomass of each tank was weighed every week in order to adjust the amount of diet to be supplied; then, Feed Conversion Rate (FCR), Condition factor (Kf) and Specific Growth Rate (SGR) were calculated per each tank and dietary treatment. On day 0 and at the end of the experiment, fish were weighed and measured individually (total length, TL). At the end of the experiments, 25 fish from each tank were also euthanized with an overdose of tricaine methanesulfonate (MS222©), dissected for abdominal viscera and liver weight determination, and calculating Viscera-Somatic (VSI) and Hepato-Somatic (HSI)
indexes.

Experiment 1: 1,243 fish (mean weight 4.95±1.120 g; mean total lengths 7.39±0,600 cm) were distributed in the 6 dietary treatments: F100M0 (100% feed), F80M20 (80% feed, 20% mussels), F60M40 (60% feed and 40% mussels), F40M60 (40% feed, 60% mussels), F20M80 (20% feed, 20% mussels) and F0M100 (100% mussels). After tawing, mussels were minced, and diets supplied 4 time per day.

Water temperature, salinity and pH approximately maintained at 24 °C, 32 g L^{-1}, 7.6, respectively, and DO above 6 mg L^{-1}.

Experiment 2: 1,255 fish (mean weight 6,78±1,41 g; mean total lengths 8,06±0,65 cm) were used. Again, fish were divided into 2 dietary treatments and 3 replicates: F100 (100% feed) and M100, this latter consisting of a mixture of 50% and 50% tawed and minced mussels and clams, respectively. Water temperature, salinity and pH were kept at 22 °C, 25 g L^{-1}, 7.5, respectively, and DO above 6 mg L^{-1}.

Statistical analysis: One-Way ANOVA followed by Tukey-Kramer HSD (Honestly Significant Difference) for the Experiment 1 and Student's test for the Experiment 2 were used for statistical analysis of growth performance parameters. Differences were considered significant at $P<0.05$.

Results

Experiment 1: thawed minced mussels showed significantly higher palatability than dry commercial feed, with fish intensively competing for catching mussel particles. On day 0, groups F100M0, F0M100 showed significantly lower ($P<0.05$) initial BW (4.76±1.074 and 4.76±1.042 g, respectively) than groups F80M20, F60M40 and F40M60 (4.86±1.076, 5.10±1.216 and 5.17±1.078, respectively). These differences were not anymore significant on day 28 and 35 while on day 42 the group fed 100% mussels (F0M100) showed the lowest BW (13.02±2.608), significantly different ($P<0.05$) from the group fed 100% commercial feed (14.69±3.498). Moreover, this latter group showed a significantly lower ($P<0.05$) BW than the group fed 60% commercial feed and 40% mussels (15.57±3.327). The group F0M100 showed the highest cumulative FCR (1.11), followed by the group F80M20 (1.06), F20M80 (1.04), F40M60 (1.02), F100M0 (1.01), and F60M40 (0.98).

Experiment 2: as observed in Experiment 1, fish fed on thawed minced mussels and clams showed higher competitiveness for the diet than those fed on commercial feed. Regarding initial BW and TL no significant differences were observed among treatments: 6.82±1.446 g and 8.08±0.638 cm for F100 and 6.75±1.378 g and 8.04±0.657 cm for M100. On day 48 of the experimental period, treatment F100 showed significantly higher BW and TL than M100: 23.62±4.471 g and 11.66±0.837 cm for F100, 20.83±3.943 and 11.40±0.704 cm for M100. Mean weight gain was significantly higher for treatment F100 than for M100: 3,522.12±90.015 g and 2,884.16±150.177 g, respectively. Also, FCR was significantly different among treatments: 0.88±0.050 for F100 and 1.05±0.062 for M100. Statistical analysis of TL, SGR, Kf, VSI and HSI data of both experiments is in progress.

Discussion and Conclusion

In general, results suggest better Gilthead Sea Bream growth performances when mixed diets are used. In fact, the use of mussels as only diet ingredient reduced fish growth by 11.3% and 16.4% in comparison to commercial feed and to a diet consisting of a mixture 60% commercial feed and 40% mussels, respectively. Similar results were observed also when a diet consisting of 50% mussels and 50% clams rather than mussels only was used. Probably, the enrichment of the wet diet mixture with the introduction of additional ingredients such as polychaetes and/or echinoderms, may improve its nutritional value and fish growth performances enhanced.

SOIL-BASED AQUAPONICS: THE EFFECTS OF SOIL ADDITION AS INVESTIGATED IN FOUR DIFFERENT TRIALS

Lorenzo Fruscella*, Benz Kotzen, Sarah Milliken

School of Design, University of Greenwich, Park Row, London SE10 9LS
l.fruscella@gre.ac.uk

Introduction

Aquaponics is an innovative and sustainable food production technology, identified by the European Commission as one of the ten technologies that will change our lives. In the EU, because of the lack of soil, aquaponics is considered a type of hydroponics, and it is therefore excluded from organic certification. This exclusion is considered to hinder the development of aquaponics, as it makes it difficult for producers to increase their earnings and effectively market their products. This research explores ways through which different soil substrates (inert potting soil, nutrient-rich potting soil, certified top soil, artificial soil for raised beds) can be included in coupled and de-coupled aquaponics, thus taking it one step closer to organic certification. By including soil in aquaponics, this research can ultimately help the technology with its marketability, commercialisation, public acceptance, and popularity. The research is done through four different trials, and is to take place between April and August 2021. The trials aim at investigating the effects that soil has on the health, growth, and quality of the plants and the fish, while examining how the soil microbiome is affected by the use of aquaponic water and processed sludge. This presentation will include results from the trials, and possible analyses and conclusions, depending on their development. The four trials and their description are listed below.

Trial 1: Basil cultivation in pots

This trial investigates the effects of aquaponic water and processed sludge on plant growth and quality and soil microbiome in basil (*Ocimum basilicum*) cultivated in pots. Five treatments are used: basil in pots filled with inert potting soil watered with aquaponic water, basil in pots filled with inert potting soil watered with aquaponic water and sludge, basil in pots filled with nutrient-rich potting soil watered with tap water, basil in pots filled with nutrient-rich potting soil watered with aquaponic water, basil in pots filled with nutrient-rich potting soil watered with aquaponic water and sludge. The effects of the use of the different substrates and water type on plant health, quality, and growth, as well as soil microbiome composition are investigated. Each treatment is replicated three times.

Trial 2: Basil and Nile tilapia coupled aquaponics

This trial investigates the effects of aquaponic water on the growth and quality of basil (*Ocimum basilicum*) grown in soil-filled pots, as well as potential effects of soil addition to fish health. The growth of plants in soil-based aquaponic systems is compared to that of conventional aquaponics. The design of the soil-based aquaponic systems is inspired by conventional coupled aquaponics, however the plant units are designed to allow the plant roots in soil filled pots continuous access the aquaponics water. Four different treatments are used, all involving tanks will fish with a tray at the top, where water is recirculated between the fish and plant units. Treatments are the following: conventional soil-less aquaponics, soil-based aquaponics with inert soil in pots, soil-based aquaponics with nutrient-rich soil in pots, pots filled with nutrient-rich soil and watered with tap water. Each treatment is replicated three times.

Trial 3: Onions cultivation in raised beds

This treatment investigates the effect of watering onions (*Allium cepa*) cultivated in raised beds and watered with water from different sources; the aim of the study is to compare the effects of manure, currently allowed in organic production, and aquaponic water and aquaponic water with sludge as fertiliser on the growth and quality of the plants. Four outside raised beds are divided into four sub-units, for a total of 16 sub-units. Each subunit is devoted to the cultivation of onion sets. The four treatments, each replicated four times, are the following: onions watered with tap water, onions supplied with horse manure and watered with tap water, onions watered with aquaponic water, and onions watered with aquaponic water with sludge.

(Continued on next page)

Trial 4: Bok Choy cultivation in outside containers

This treatment investigates the effect of watering bok choys (*Brassica rapa*) cultivated in raised beds and watered with water from different sources; the aim of the study is to compare the effects of manure, currently allowed in organic production, and aquaponic water and aquaponic water with sludge as fertiliser on the growth and quality of the plants. A total of twelve 20L rectangular containers are used, for a total of four treatments. The treatments, each replicated four times, are the following: plants watered with tap water, plants supplied with horse manure and watered with tap water, plants watered with aquaponic water, and plants watered with aquaponic water with sludge.

Trials estimated timeline:

- Basil cultivation in pots: April – June 2021(trial started)
- Basil and Nile tilapia coupled aquaponics: May – July 2021(to begin on May 10th)
- Onions Cultivation in Raised Beds: April – August 2021(trial started)
- Bok Choy Cultivation in outside containers: May – July 2021(to begin on May 17th)

IN VITRO TOOLS TO UNDERSTAND THE DIETARY EFFECTS N THE INTESTINAL INTEGRITY AND PHYSIOLOGY OF GILTHEAD SEA BREAM *Sparus aurata*

Introduction
Diet formulation and the inclusion of new ingredients are fundamental for performance indexes in fish aquaculture. However, there is a lack of tangible and reliable diagnostic tools to assess the animal's dietary effects on protein processing from digestion to absorption. The gut works as a selective barrier allowing nutrients in and denying entry to pathogens. It is possible to analyze the functions of the intestine ex-vivo if the tissue is kept alive and reflects in vivo functionality. When the tissue is opened flat and mounted between the two compartments of the Ussing chamber, transport, and epithelial properties can be studied using epithelial electrophysiology.

Material and methods
48 sibling seabream juveniles (189.96 ±10.01 g initial average individual body weight) were distributed in 4 tanks of a marine (32 psu) recirculating aquaculture system (RAS) held at 20ºC. A group of 12 animals were stocked per tank. Fish were fed either a control diet (diet A) or the same diet to which a digestive enhancing additive (Aqualyso, Adisseo) was added (diet B). Both diets were prepared following the same protocol except for the addition of the feed additive. Fish were fed manually twice per day 6 days per week. Trial lasted 4 weeks.

Epithelial electrophysiology in Ussing chambers
The anterior intestine, was isolated and mounted as previously described (Gregorio et al., 2013) with apical (luminal) and basolateral (blood side) sides of the tissue identified on a tissue holder of 0.25-0.30 cm^2 and positioned between two half-chambers containing 2 ml of physiological saline. Bioelectrical parameters for each tissue were recorded continuously during the *in vitro* period onto Labscribe3 running in a MacIntosh computer using IWorx188 and Lab-Trax-4 data acquisition systems, from the time of mounting for 90 min. Epithelial resistance (Rt, $\Omega.cm^2$) was manually calculated (using Ohm's law) from the current deflections induced by a bilateral +2 mV pulse of 3 s every minute. e.

Electrogenic amino acid transport
The mid intestine of sea bream juveniles was isolated and mounted as described above for the anterior intestine. In this subset of experiments the apical side of the preparation is stimulated with an amino acid mixture (M 5550 MEM [50X], Sigma-Aldrich). The amino acid pool consists of a complex mixture of essential amin acids

The principle of the test is that the epithelium is stimulated by the presence of amino acids, thus generating a change in the current due to the cotransport of amino acids with ions (Broer, 2008). In the seabream mid-intestine, the response is concentration dependent, relatively quick and plateaus within 30 min of amino acid addition. Therefore, sequential effects of different concentrations can be quantified in each epithelial preparation. Here sequential concentrations of 8 and 16 mM were used.

Results & conclusions
The time-response in vitro in the Ussing chamber experiment shows a typical progression to plateau values in both Diet A and Diet B. Dietary manipulation was without significant effect on tissue resistance, indicating that tissue selectivity was not compromised by dietary composition manipulations.

Electrogenic, transcellular, ion dependent amino acid transport is significantly a consistently increased in the mid intestine of fish fed Diet B. Our system provides a functional in vitro picture of tissues conditioned in vivo. The interpretation of these results points to a better capacity of dietary amino acid transport in fish fed Diet B, and the likely incorporation for tissue a muscle growth. However, we may need to exercise caution with this set of results, as only essential amino acids were present in the amino acid pool tested.

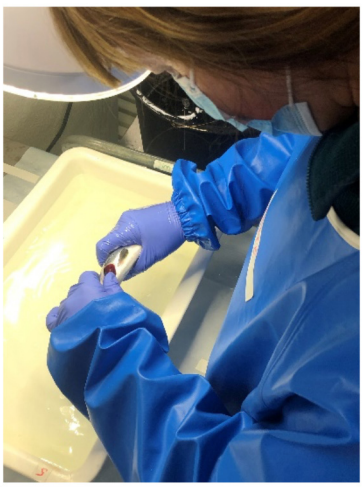
Introduction

Amoebic gill disease (AGD) is a parasitic infestation affecting Atlantic salmon, particularly during the seawater phase of production. It is caused by the amphizoic marine amoeba *Neoparamoeba perurans*. Upon attachment on the gills, the amoeba trophozoites elicit a localised tissue response including epithelial hyperplasia, hypertrophy and lamellar fusion and the gross pathology is characterised by raised white mucoid lesions. These white plaques are used to grade the severity of AGD infection through visual inspection. Freshwater and oxidative therapeutics are used to treat AGD, the former being the most commonly used. Despite offering alternative options for freshwater bathing, oxidative therapeutics often have conflicting treatment resolutions. In addition, there is a significant knowledge gap on the underlying physiological processes on how salmon respond to these treatments. In this study, we explored the efficacy of peracetic acid (PAA) in treating AGD and the physiological responses of salmon smolts during the treatment.

Materials and methods

AGD in smolts was induced by bath exposure to the parasites for 1 hr. Thereafter, the disease was allowed to develop with routine monitoring of the gill score (GS 0 = clear of lesions → GS 5 = extensive lesions). When the gill score (GS) reached 1-2, fish were treated with PAA via bath exposure. Three commercial PAA products were tested (Perfektoxid, AQUADes and ADDIAqua) at a concentration of 5 ppm. Two exposure durations were evaluated – 30 mins and 60 mins. Uninfected fish were likewise treated similarly. Sampling was performed 1 day and 2 weeks after treatment. The disease status of the fish was assessed by visual pathology of the gills and qPCR quantification of the parasites (gill swabs and water samples). The gills and olfactory organs were subjected to histological evaluation and gene expression analysis of key biomarkers for oxidative stress. Systemic oxidative stress was determined by quantifying the level of reactive oxygen species and total antioxidant capacity in plasma.



Gill scoring of salmon experimentally infected with AGD.

(Continued on next page)

Results and Discussion

Gill score and parasite load: The infected-untreated group had an average GS of 2.8 two weeks post-treatment. Except for the group treated with ADDIAqua, groups treated with PAA for 1 hr had an almost similar GS with the infected-untreated group. Fish treated with PAA for 30 mins registered lower GS than the infected-untreated and 1 hr-treated groups. The lowest GS (1.9) was in AQUADes treated group, followed by ADDIAqua (2.1), then with Perfektoxid (2.4) for 30 mins. qPCR analysis of the parasite on the gills did not provide a clear tendency either among the groups or between sampling points. The level of the parasite in the rearing water increased through time in all PAA-treated groups, which might indicate an ongoing parasite shedding post-treatment.

Histology: AGD-infected fish displayed the typical pathology, which was increased hyperplasia. Two weeks post-treatment, the number of lamellar hyperplasia cases in the 30-min treated group was lower than the infected-untreated and 1-hr PAA-treated groups. This increased hyperplasia likewise resulted in increased lamellar fusion. Epithelial lifting was prevalent in all groups. The mucous cell number in the lamella but not in the filament increased following treatment, and neither inter-treatment nor temporal differences were found to influence this profile. PAA-treated fish exhibited a compromised olfactory organ architecture two weeks post-treatment. There was a tendency for the mucosal tip of the olfactory lamella to increase in size especially in Perfektoxid-treated group, regardless of the exposure duration. The thickness of the lamellar epithelium and *lamina propia* did not demonstrate substantial changes among treatment groups and through time.

Gene expression: Thirteen biomarkers for oxidative stress were evaluated in the gills and olfactory organs. Overall, PAA treatments resulted in the modulation of the expression of the marker genes and the changes were pronounced 1 day after than at 2 weeks post-treatment. This indicates that mucosal oxidative stress was triggered, though not chronic. Unlike in other response variables where treatment duration elicited strong differential responses among the groups, the gene expression profile in the gills and olfactory organ revealed no such general distinction.

Systemic oxidative stress: ROS levels in the plasma increased through time, especially in the group treated for 30 mins. The groups exposed to AQUADes and Perfektoxid for 30 mins had higher ROS levels than the infected-untreated group two weeks post-treatment. There was a large fish-to-fish variation in the total antioxidant capacity (TAC) in the plasma of the experimental fish. No significant differences in plasma TAC were found among treatments and between sampling points.

Conclusions

This study demonstrated that PAA treatment of AGD in salmon smolts resulted in quite varied response profiles. Disease resolution was not fully established as assessed by visual pathology, histopathology and qPCR, though there were indications that the type of PAA product might play a role in its treatment efficacy. Future studies should be directed at standardising the PAA treatment protocol. From physiological aspects, salmon were able to respond to PAA treatments despite being in a diseased state. AGD however, could trigger changes in the expression PAA was demonstrated to trigger local oxidative stress, though the heightened state did not last long.

HOW MACHINE LEARNING AND ARTIFICIAL INTELLIGENCE HAVE SIGNIFICANTLY IMPROVED OPEN OCEAN FISH FARMING

Langley Gace *

Innovasea Systems, Inc.
425 Ericksen Avenue NE
Suite 101
Bainbridge Island, WA 98110
LGace@InnovaSea.com

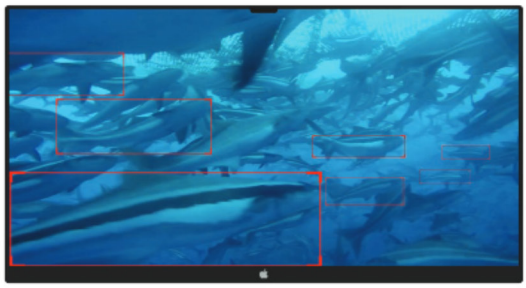
Open ocean fish farming has changed dramatically in the past few years. The industry is embracing the significant advantages that machine learning and artificial intelligence (AI) have to offer as well as affordable high definition underwater cameras. Feeding submerged pens is one operation that has benefited significantly from these technological advancements.

Efficient feeding is critical to a farm's profitability as well as reducing its impact on the local environment. Feed-related expenses are often responsible for 50% or more of a farm's operating costs. The 10% improvement in the FCRe (2.0-1.8) can potentially equal more than $1.1 million savings annually on a 3000 ton farm.

Until recently, all feed was delivered via forced air from the feed barge to the pen located at the surface. With the advent of submerged pens, feed then had to be delivered via a slurry of water. In addition to requiring less power, there are several other advantages, such as providing a cushion of fluid to deliver more of the pellet to the pen.

High-definition underwater cameras are no longer cost-prohibitive, allowing the farmer to observe feeding and other activities in all the pens from the safety and comfort of their office on the feed barge or remotely on land. Video from these cameras are analyzed by AI algorithms to identify pellet waste and fish satiation. These programs help the feed manager to reduce feed waste, optimize feed rate, and to determine when the fish have been adequately fed.

Stereoscopic biomass estimation cameras constantly measure fish dimensions within the pen. The onboard algorithms then provide any near real-time biomass estimation within 3% accuracy. This data is critical to the farm managers enabling them to optimize feed schedules as well as predict harvest mass and schedules.



ANTIMICROBIAL PEPTIDE ANALYSES OF SELECTED AND NAÏVE *Crassostrea gigas* OYSTERS TO *VIbrio aesturianus* PATHOGEN

Introduction

Oysters are filter-feeder animals and as a result they are in permanent contact to diverse communities of microorganisms [1]. Bacterial and virus outbreaks represent a major threat to the oyster industry, being responsible for severe diseases that often leads to massive oyster mortality and harsh economic losses [2, 3]. Pathogen recognition and disease control in oysters are mediated by an innate immune system, in which antimicrobial peptides play a key rule. In this study, the susceptibility of naïve or selected oysters *Crassostrea gigas* to infection with *Vibrio aestuarianus* has been approached, regarding mortality and expression of genes which codify for antimicrobial peptides.

Material and Methods

Six families of *C. gigas*, 3 naïve and 3 selected for their higher resistance to *V. aestuarianus*, were tested for infection with *V. aestuarianus*. 12 oysters per family were distributed in each tank (72 oysters/tank). All oysters for three of the tanks were injected with 100 μl of bacterial suspension (10^6 bacteria/oyster) into the adductor muscle (infected condition), while oysters of the three other tanks were injected with artificial sea water (control conditions). Mortality was recorded every day during 30 days, and for each tank, three live oysters of each family were sampled at 24h, 48h and 72h post-infection, for haemolymph, mucus and tissue collection. Haemolymph was centrifuged and haemocytes were kept on trizol for gene expression studies by real-time PCR. Plasma was used for protein and NO quantifications. Also, mucus was kept at -80ºC for further studies of antimicrobial activity and tissue will be used for *V. aestuarianus* quantification to verify the infection progression.

Results

Results of cumulative mortality reveal higher mortality in the infected conditions (mean = 51%) than of control condition (mean = 6%). Then, when infected with *V. aestuarianus*, selected families showed a lower mortality (mean = 32%) than naïve oysters (mean = 70%) (figure 1). Regarding protein content and NO, no significant differences were found among resistant and naïve oysters in plasma; still, results seem to point to higher protein content of the resistant animals even in control conditions. Four families were selected for gene expression analysis based on mortality results (the two best and the two worst). Overall, resistant and naïve families show different patterns of gene expression. For control conditions, in general, genes were higher expressed in resistant oysters. Additionally, either facing a bacterial challenge or in control conditions, some genes involved in host defense, as for instance defensin (Cg-Defhs), exhibited a higher expression in resistant families, at all sample time points.

Discussion

The ability to defend against a pathogen can be affected by environmental, genetic factors or combination of both [4]. It is also known that recognition of microbial products leads to production of a large range of antimicrobial molecules [5]. Therefore, in our study, families of naïve and selected oysters were chosen to be submitted to a bacterial challenge with *V. aesturianus*. Results of mortality are in agreement with the selection scheme developed, indicating that the selected families have a higher resistance to the infection by *V. aestuarianus*. Moreover, it appears to be in accordance with expression results of genes related with defense against pathogens. The higher levels of defensins in resistant families and other genes involved in host defense can be associated with a more efficient response to infection. Antimicrobial activity studies are also being performed in mucus samples of all families in order to understand if there is a different profile among resistant and naïve families.

(Continued on next page)

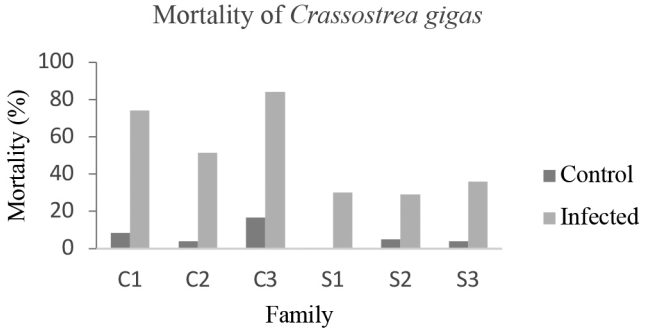

Figure 1: Cumulative mortality of six families of oysters *Crassostrea gigas*, naïve (C1, C2 and C3) or selected (S1, S2 and S3), after infection with *Vibrio aesturianus* (light grey). For control conditions (dark grey) oysters were injected with artificial seawater.

WHAT ARE THE MOST IMPORTANT DRIVERS FOR BUYING NEW AQUACULTURE FISH PRODUCTS? THE CASE OF FRENCH AND GERMAN CONSUMERS

Sonia García Muñoz[1]*, Raquel Llorente[1], Irene Peral[1]

[1]AZTI, Basque Research and Technology Alliance (BRTA), Food Research, Parque Tecnológico de Bizkaia, Astondo Bidea, Edificio 609, 48160 Derio, Bizkaia, Spain
*E-mail: sgarcia@azti.es

Introduction

Fish consumption in the European Union (EU) shows a growing tendency in the last decade (FAO, 2020). However, as wild fish cannot meet the fish global demand, the aquaculture has become the most suitable alternative to fill these growing needs (Carrillo *et al*., 2020). Thus, new food products based on aquaculture products are required on the market to fill the consumers needs. For this reason, AZTI (Spain) has successfully developed four new food products based on aquaculture species (seabass, gilthead seabream and meagre) in the frame of H2020 MedAID project.

The new fishery products from aquaculture were designed following a consumer-centred approach, since involving consumers during the development of new products has been proved to be the best alternative for increasing market success rate (Banović *et al*., 2016). In fact, these products were successfully evaluated by Spanish consumers (García-Muñoz et al., 2021). However, the most important drivers for buying these new products in a European context were unknown. Hence, these products were evaluated in France and Germany, since the household expenditure per capita for fishery and aquaculture products of these two countries are between the highest in the EU (EUMOFA, 2019).

The aims of this study were (i) to validate the new aquaculture products in a European context, (ii) to know the consumers fishery and aquaculture consumption habits and (iii) to analyse the most important drivers for buying new fishery products from aquaculture.

Materials and methods

This cross-sectional study was developed in two European countries (Germany and France) involving 1,000 fish consumers (500 per country). Fish consumers (50% female, 50% males) between 25 and 65 years old (mean age ± SD: 44.51 ± 11.14) evaluated pictures and information about the new fish products (Grilled seabass with lemon, Sea and mountain burger, Seabream breaded bites and Organic seabream with couscous). The questionnaire included questions regarding fish consumption habits, products associations, purchase intention, drivers for buying fishery and aquaculture products, and socio-demographic characteristics.

Results

Differences were observed between French and German consumers regarding frequency of fish consumption, the most consumed fish at home, the origin of the fish purchased and consumed (i.e., wild, aquaculture), and the fish cooking method used by participants at home. It should be considered that around 25% of the participants had never consumed fish from aquaculture. Regarding the products validation, French and Germans consumers preferred Seabream breaded bites and Organic seabass with cous-cous. These products were also selected for increasing consumers day-to-day fish intake.
Organic seabass with cous-cous obtained the highest purchase intention in France, meanwhile Seabream breaded bites obtained it in Germany.

When information about the products was provided to consumers (i.e., percentage of aquaculture fish in the final recipe, storage conditions, servings and packing weight, product sensory description, Nutri-Score label, recipe suggestion and cooked products pictures), the purchase intention increased up to 13%.

Finally, the consumers identified taste, healthy product and percentage of fish contained as the most important drivers for buying fishery and aquaculture products. In addition, when consumers felt both that they would like to taste the products and they would like the product taste, higher purchase intention was obtained. Also, similar results were achieved when the products were familiar for consumers and when they felt that they could easily prepare them. Moreover, the purchase intention was positively related to product tasty appeal, packaging that fits with consumer needs, and the good image of the product.

(Continued on next page)

Conclusions

Consumption habits for new aquaculture products seem to be related with product associations and purchase intention. Moreover, based on the differences detected between French and Germany consumers, it is highly recommended to follow a consumer-centred approach to better understand fishery and aquaculture consumer needs and consumption habits in each market niche.

Finally, the insights found in this study regarding the identification of fish consumption habits, preferences and purchase drivers might increase market success rate and purchase intention percentage of the new aquaculture products. In this way, the competitiveness and growth of the Mediterranean aquaculture industry might be improved.

Introduction
Deployment of lice-eating cleaner fish in salmon cages is considered one of the most effective and sustainable methods to control sea lice infestations. The lumpfish (*Cyclopterus lumpus*) is the most used and commercially produced species of cleaner fish in Norway (Nordland, 2017). The Norwegian lumpfish production is currently characterized by variable growth and survival during the larval stages (Powell et al. 2017). Little is still known about nutritional requirements and the functional behavior during development of lumpfish larvae. How larval and juvenile behavioral responses are affected by the nutritional quality of the first feed is also not well known, and this may be critical for larval quality and the juvenile's capacity to eat the lice off the salmon when it is transferred to the sea cages. The objective of this study was to describe and evaluate the ontogenetic development of feeding behavioural responses in lumpfish larvae from hatching to 33 days post hatch (dph), in relation to larval size and nutritional quality of the first feed, based on growth, survival, swimming and feeding activity.

Material and methods
Larval groups received five different dietary treatments: 1) formulated diet (control), 2) cirripedia (frozen preserved plankton from Planktonic AS), 3) enriched *Artemia*, 4) copepods (*Acartia tonsa*) (from CFEED AS) and 5) a combination of *Acartia tonsa* and cirripedia (2-22 days post hatch). The larvae were fed formulated diet either for the full period or weaned from *Artemia* and cirripedia nauplii to the formulated diet between 20-22 days post hatch. All groups were fed the same formulated diet until the experiment ended at 33 days post hatch. All feeding behaviour observations were recorded by video. At 16 dph, 22 dph and 28 dph, 10 larvae from each tank were randomly sampled into individual 1litre plastic bottles and starved for 3 hours. After 3 hours an amount of live prey (350 cirripedia/ml + 350 *Artemia* nauplii/ml) were added. For 2 minutes larvae were recorded. The parameters observed during the records were: number of seconds each larva swam, number of second attached to a substrate, orientating itself in the tank, number of successful and unsuccessful attacks, type of attack performed (swimming or attacked) and number of seconds of the swimming attacks.

Results
Feeding behaviour was found to be different both through the ontogeny development as well as among the treatments, especially at 22 days post hatch (dph) and 28 dph. Lumpfish larvae showed more swimming activity at 16 dph compared with 22 dph and 28 dph. Larvae fed more at 22 dph and 28 dph and they used more time for the swimming attacks at 28 dph. Larvae fed on *Artemia* were more active swimmers and they also orientated more. However, at 28 dph, cirripedia treatment larvae showed more swimming activity and performed more successful attacks compared with the other treatments ($P < 0.05$). Lumpfish larvae from copepods and formulated diet treatments swam less, spent more time attached and less time orientating. Also, they performed a smaller number of successful attacks ($P < 0.05$) showing a lower predatory instinct.

Artemia treatment resulted in significantly better growth and survival than other diets. Cirripedia diet resulted in initial slow growth, catching up with *Artemia* group after weaning to formulated diet. Formulated diet presented low growth and poor survival compared to other diets.

Feeding enrichment *Artemia* during the start feeding resulted in better results based on growth, survival, and swimming and feeding activity of lumpfish larvae than other treatment diets. However, after the weaning period those lumpfish larvae fed cirripedia showed similar growth and more successful attacks.

(Continued on next page)

Conclusions

The difference in feed quality of the diet treatments during the 33 dph start feeding of lumpfish larvae, affected the larvae behaviour activity and performance. The results of this study indicate a high correlation between live feed quality and the effects on growth, survival and feeding behavioural responses in lumpfish larvae, suggesting the high importance of early nutritional quality on the larval feeding behaviour, which is currently not well known in lumpfish.

DOES DIETARY LINOLENIC/LINOLEIC ACID RATIO AFFECT INTESTINAL OXIDATIVE STRESS BIOMARKERS IN GILTHEAD SEA BREAM?

I. García-Meilán*[1], I. Agredano, [1], A. Profitós [1], R. Fontanillas [2], E. Capilla[1], I. Navarro[1], and A. Gallardo [1]

E-mail: irene.garcia@ub.edu

Introduction

Among vegetable oils, soybean oil, which is rich in n-6 fatty acids, mainly linoleic (C18:3 n-6) is commonly used to partially replace fish oil in fish feeds, while others like linseed oil are less employed. Despite this, linseed oil is one of the richest plant sources of n-3 fatty acids with 75% of polyunsaturated fatty acids (PUFA), mainly α-linolenic acid (ALA, C18:3 n-3); and it seems to be a good alternative as total or partial fish oil replacement, since linseed oil use has been successful in some species. Dietary lipid profile affects membrane composition and modifies lipid peroxidation (LPO) levels, which could negatively affect membrane structure and fluidity, and intestinal permeability. In this sense, LPO production and the antioxidant status could affect digestion and absorption processes, modifying therefore nutrient availability. The aim of the study was to investigate the effect of increasing the dietary linolenic/linoleic ratio on LPO and antioxidant capacities at intestinal level in gilthead sea bream (*Sparus aurata*).

Materials and methods

Two isonitrogenous (46%) and isolipidic (22.2%) diets were formulated and produced by Skretting ARC (Norway) in which a 25% of dietary oil came from fish oil to meet eicosapentaenoic and docosahexaenoic acids requirements and 75% was vegetal oil. The vegetable oils used were soybean (S) and linseed (L) oils and diets were named accordingly. Diet S contained soybean oil as the only vegetable oil, and diet SL contained both oils with a S/L ratio of 3.8. The linolenic/linoleic ratio was 0.12 for S diet and 0.32 for SL diet.

One-hundred ten gilthead sea bream with an initial weight of 81.52g were distributed in tanks and fed *ad libitum* twice a day with the corresponding diet for 18 weeks. No differences in final weight were found between S and SL fish; being on average 255.7 ± 7.7 g. Once the growth trial finished, fish were sacrificed at 24h post-feeding and samples of pyloric caeca and proximal intestine were collected. LPO levels, superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR) and glutathione-S-transferase (GST) activities were determined. Gene expression of antioxidant enzymes (*sod1, sod2, cat, gpx1, gpx4, gr, gst3*) was analysed by quantitative PCR.

Results

The partial dietary substitution of soybean oil for linseed oil (diet SL) resulted in increased activities of the antioxidant enzymes SOD (x1.8), CAT (x1.5), GR (x1.7) and GST (x2.1) in pyloric caeca (Fig. 1), while GPx activity was not modified. Instead, in the proximal intestine, only SOD activity increased (x1.8) (Fig. 1). No changes in gene expression of the antioxidant enzymes were found in pyloric caeca or proximal intestine. Up-regulation of these enzymes could not deal with the increase in oxidative stress, and LPO levels were 51.4 fold higher in pyloric caeca and 3.4 fold higher in proximal intestine of SL fed fish than in S fed ones (Fig. 1). The SL group fed the diet with a higher linolenic/linoleic ratio, showed a high individual variability in LPO levels. Thus, in pyloric caeca 67% of fish showed LPO levels up to 0.150 nMol · mg prot^{-1}, whereas the remaining 33% showed a of LPO level above 1. SL fed fish were subdivided into two groups according to their level of LPO (L-SL, low LPO and H-SL, high LPO). H-SL animals showed superior CAT (x1.9) and GR (x2.0) activities in pyloric caeca, and a lower relative intestinal length (-38.2%) in comparison to L-SL group (Table 1).

Discussion and conclusion

Data showed that the partial dietary substitution of soybean oil by linseed oil, which leads to an increase in linolenic/linoleic ratio, could negatively affect oxidative stress control at intestinal level, especially in pyloric caeca of those fish that were not able to adapt its relative intestinal length, suggesting that its use in fish feeds formulation should be limited.

Introduction

Palm oil, rich in saturated and monounsaturated fatty acids (MUFA) (50 and 40%, respectively) and rapeseed oil, rich in MUFA (57%), mainly oleic acid, are commonly used to partially replace fish oil in fish diets due to their price, availability, and good growth results in most fish species. Moreover, linseed oil, is one of the richest plant sources of n-3 fatty acids with 75% of polyunsaturated fatty acids (PUFA), mainly α-linolenic acid (ALA, C18:3 n-3), and although less frequently used, fish oil replacement by linseed oil has been successful in some fish species. Dietary lipid profile affects membrane composition and modifies lipid peroxidation (LPO), which could negatively affect membrane structure and fluidity, and intestinal permeability. In this sense, LPO production and the antioxidant status could affect digestion and absorption processes, modifying therefore nutrient availability. The aim of the study was to investigate the effect of different dietary fatty acid profiles on LPO and antioxidant capacities at intestinal level in gilthead sea bream (*Sparus aurata*).

Materials and methods

Five isonitrogenous (46%) diets were formulated and produced by Skretting ARC (Norway) in which 25% of dietary oil was provided as fish oil, to meet eicosapentaenoic and docosahexaenoic acids requirements, and 75% was vegetal oil. The vegetable oils used were palm (P), rapeseed (R) and linseed (L) oils and diets were named based on the oil they contained. Diet P contained palm oil as the only vegetable oil, diet R rapeseed oil, and diets PL, RL and PRL a combination of vegetable oils. These last three diets contained a similar amount of n-3 (0.88%), higher than in the P diet (0.4%) and the R diet (0.72%). P and PL diets were rich in saturated fatty acids and R and RL in MUFA.

Two-hundred eighty-six gilthead sea bream with an initial weight of 81.8g were distributed in tanks and fed *ad libitum* twice a day with the corresponding diet for 18 weeks. Once the growth trial finished, fish were sacrificed at 24h post-feeding and samples of pyloric caeca and proximal intestine were collected. LPO levels, superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR) and glutathione-S-transferase (GST) activities were determined. Gene expression of antioxidant enzymes (*sod1, sod2, cat, gpx1, gpx4, gr, gst3*) was analysed by quantitative PCR.

Results

Gilthead sea bream fed the mono- and di-substituted diets showed higher LPO levels in the proximal intestine versus the pyloric caeca (x 2.9–5.6) (Fig. 1). This pattern was also observed for CAT, GR and GST activities, but not for SOD and GPx ones, which were similar in the two intestinal segments of these fish (Fig. 1). On the other hand, PRL animals showed similar LPO levels in both intestinal segments, showing the highest LPO amount in pyloric caeca and the lowest in the proximal intestine (Fig. 1). PRL fed fish showed differences between segments for SOD and GPx activities, being SOD activity lower in proximal intestine and that of GPx in pyloric caeca (Fig. 1). In addition, PL fed animals presented the highest LPO production (Fig. 1). SOD and GR activities were higher in fish fed mono-substituted diets, whereas CAT activity was higher in animals fed di-substituted diets (Fig. 1). GPx activity tended to be higher in animals fed P and PL diets (Fig. 1). The ratio of GST activity between proximal intestine and pyloric caeca was maintained between the different groups studied (range of 1.8-2) (Fig. 1). The gene expression of antioxidant enzymes was not significantly affected by diet, except for *gpx4* expression that was modulated in PI. Finally, animal growth did not show significant differences between groups either (average weight of 264.9 ± 6.24 g).

(Continued on next page)

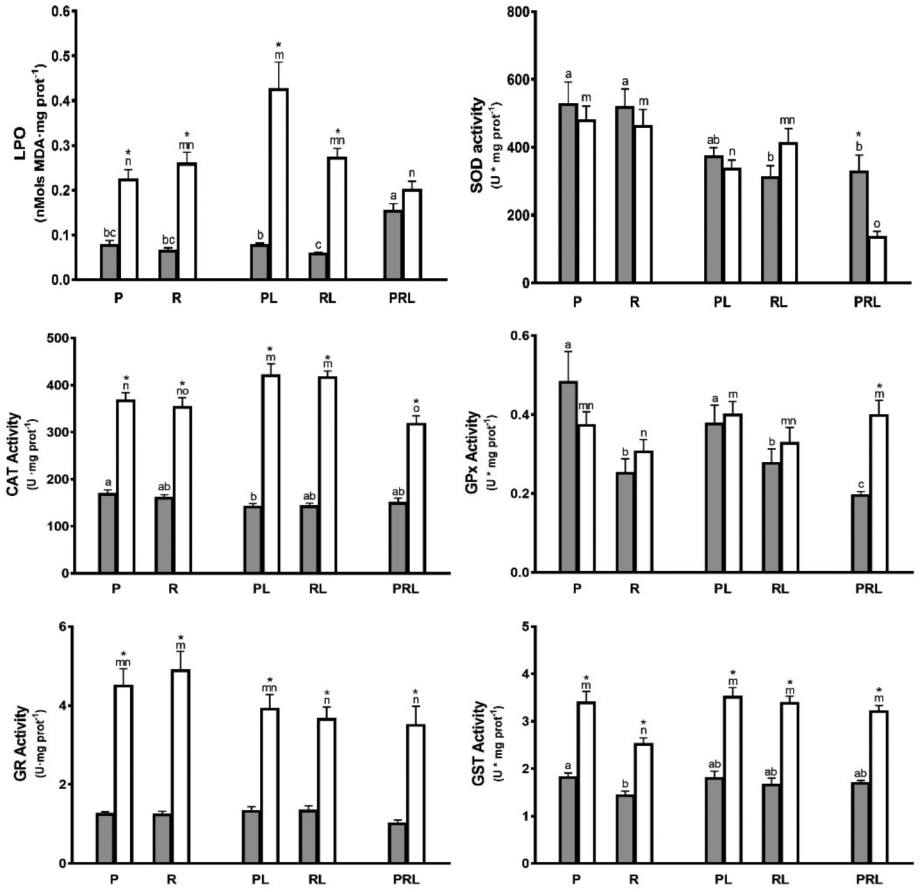

Figure 1. Lipid peroxidation (LPO) levels and SOD**,** CAT, GPx, GR and GST activities at 24h post-feeding in pyloric caeca (PC, grey bars) and proximal intestine (PI, white bars) of gilthead sea bream fed experimental diets. Values are presented as mean ± SEM (n=6 for P and R fed fish; n=9 for PL, RL and PLR fed fish). Significant differences between experimental conditions are shown by letters (a-c for PC and m-o for PI), and between intestinal regions with *.

Discussion and conclusion

LPO levels were higher both in proximal intestine of gilthead sea bream fed PL diet and in pyloric caeca of fish fed PRL diet compared to those fish fed with P diet, probably due to the increase of dietary unsaturated fatty acids content, in agreement with other studies. Despite this, no increase in peroxidation levels was found in RL fed gilthead sea bream in comparison to the R fed group.

In conclusion, data showed that dietary LO inclusion triggered LPO production when it was blended with palm oil, and diminished SOD activity regardless of the oil blend added. Although a similar up-regulation in CAT activity was found in both PL and RL fed fish, in the former, levels of LPO were higher, suggesting that those fish could had more problems to deal with oxidative stress.

EFFECTS OF AN ACUTE HYPOXIC STRESS ON PHYSIOLOGICAL RESPONSE AND SKIN IMMUNITY GENE EXPRESSION IN RAINBOW TROUT *Oncorhynchus mykiss*

I. García-Meilán*[1,2], A. R. Khansari [1], L. Tort [1]

[1] Department of Cell Biology, Physiology and immunology, Faculty of Biosciences, Universitat Autònoma de Barcelona, 08193, Bellaterra, Spain

E-mail: irene.garcia@ub.edu

Introduction
In aquatic ecosystems, oxygen fluctuations can lead to temporary hypoxia, being an abiotic stressor for fish. The effects of such stressor depend on the length of time spent under hypoxia, and whether it is an acute stimulus (short-term, high intensity) or a chronic one (long-term, low intensity although persistent). The overcome of the stress situation depends on the ability to modulate physiological and biochemical systems, like changes in behavior, ventilation, etc., to maintain metabolic functions and maximize O_2 extraction from water. In this sense, stressors activate the hypothalamic-pituitary-interrenal axis (HPI) resulting in the release of cortisol that triggers secondary and tertiary responses such as immunomodulatory processes. It is assumed that these responses are usually dual, first stimulatory, and later inhibitory, depending on the stressor and its persistence. The aim of the study was to determine whether and how relationships between the central systemic response and peripheral skin response are taking place in trout subjected to hypoxic stress.

Materials and methods
Rainbow trout juveniles were acclimated to AQUAB fish facilities (Universitat Autònoma de Barcelona, UAB), subjected to a 12L:12D photoperiod and 18ºC in a closed recirculation system. Fish were fed ad libitum with a commercial diet (Skretting). After the acclimation period, trout with a final body weight of 80.8 ± 3.5g, were subjected to an acute hypoxia stress challenge, for one hour, performed by reducing the oxygen levels in water from 8-9 mg/L oxygen to 2 mg/L (by removing the aeration pumps and bubbling N2 into the system). Water oxygen levels were continuously monitored during the experiment. After the challenge, 8 fish per treatment, and time-point (control: without stress, 1h, 6h and 24h post-stress) were euthanized with phenoxyethanol. Samples of blood, skin mucus and tissues were collected for further analysis. Plasma was isolated by centrifugation (5 min at 5,000g) and stored at –20°C until analysis. Plasma and skin mucus cortisol, plasma glucose and lactate and gene expression in skin were analyzed by real time quantitative PCR (RT-qPCR).

Results
Figure 1 shows selected physiological and molecular responses after the stress. All of them were significantly affected by the hypoxic stress and their interaction with time after the challenge was significant. In this sense, rainbow trout presented a significant increase in hematocrit 1 and 6 hours after suffering hypoxic acute stress (Figure 1A). Moreover, a significant rise 1 hour post-stress of plasma and skin mucus cortisol (207.5% and 786.3%, respectively) was observed. Both parameters presented a similar decrease over time, reaching control values 6h after stress (Figure 1B).

Figure 1B also shows how stress triggers glucose release from tissues. Accordingly, glucose levels in fish one hour after the hypoxic treatment were significantly higher than in control ones (67.4%). However, 6 hours after the stressor, glucose levels achieved control values. The same pattern was found for plasmatic lactate where an increase by 51.8% was detected one hour after the stress (Figure 1C).

In skin pro-inflammatory (*ilβ1 and il6)*, anti-inflammatory (*il10* and *tfg*β1), innate immunity genes (*lysozyme, caspase 3*) and stress proteins (hsp70), were analyzed by qPCR. One hour after the hypoxic challenge, gene expression of *ilβ1, il10, caspase 3* and *hsp70* showed a rising trend. In this sense, one and six hours post-hypoxia *hsp70* showed 10.7 and 5.1 times higher relative gene expression than control rainbow trout (Figure 1D). Regarding time, *il10* and *caspase 3* gene expression significantly diminished 24h post-stress versus 1h, showing *caspase 3* even less expression than in control group. No clear trends were found for *il6, tfg*β1 and *lysozyme* gene expression.

Discussion and conclusion
Data shows that one hour acute hypoxia triggers the typical physiological stress responses as expected. Moreover, our results also show that skin gene expression was also activated, directly after stress, such as for the increase of *hsp70*, and inflammatory interleukins (*ilβ1, il10)* activation. Therefore, it is suggested that the stress response appears to be triggered simultaneously at both central and peripheral levels rather than sequentially after neuroendocrine axis activation.

CRYOPRESERVATION PROTOCOLS FOR ELASMOBRANCH SPERM CRYOBANKING: NEW TOOLS FOR SHARKS AND RAYS CONSERVATION

P. García-Salinas[a,b,*], V. Gallego[a], J.F. Asturiano[a]

[a] Grupo de Acuicultura y Biodiversidad, Instituto de Ciencia y Tecnología Animal, Universitat Politècnica de València, Valencia, Spain
jfastu@dca.upv.es
[b] Associació LAMNA per a l'estudi dels elasmobranquis a la Comunitat Valenciana, Valencia, Spain

Introduction

Elasmobranchs are an ecologically diverse vertebrate group that plays a key role in the regulation of the ecosystems they inhabit (Stevens, 2000). But the life histories of sharks and rays make this group extremely sensitive to elevated mortality from fishing habitat destruction (Dulvy et al., 2014). Given this situation, the use of *ex situ* conservation breeding techniques, including artificial insemination, could be a strategy worthy of consideration in elasmobranch conservation plans. However, to perform this technique a reliable sperm supply is needed, and despite cryobanking is the most common way to guarantee the availability of viable sperm (Asturiano et al., 2017), there are not widespread protocols for elasmobranch sperm cryopreservation. In fact, information on elasmobranch sperm cryopreservation is limited to just two scientific publications, with information regarding two ray species and one shark (Daly et al., 2011; Daly and Jones, 2017). While the authors reported successful results in the cryopreservation of both rays no conclusive information was given about the shark besides the toxic effect of the cryoprotectant used on the sperm. To date there is no reported information on successful cryopreservation of shark sperm.

Material and Methods

Sperm from two species, the small-spotted catshark (*Scyliorhinus canicula*) and the rough skate (*Raja radula*) was obtained from alive animals kept in a public aquaria and from animals obtained from commercial fisheries.

An artificial elasmobranch seminal plasma extender (EE) was formulated to be similar in composition (solutes, pH, and osmolality) to the inner fluids of marine elasmobranchs: in mM; 433 Urea, 376 NaCl, 120 Trimethylamine N-oxide (TMAO), 8.4 KCl, 50 Glucose, 7 $CaCl_2$-$2H_2O$, 3.5 $NaHCO_3$, 0.08 Na_2SO_4, 1.4 $MgSO_4$; pH 6.5; Osmolality 1000 mOsm/kg). Short-term preservation of the sperm was tested by diluting (dilution ratio 1:9; sperm:EE) the small-spotted catshark sperm in EE and using sea water as a control. Samples were kept at 4 ºC. Sperm motility was assessed for a period 36 days. Only sperm samples with an initial motility higher than 60% were considered for the trials.

The cryopreservation protocols were performed by adding to the previous mixture of sperm and extender (EE) a series of different cryoprotectants: 10% methanol (MET) or 10% dimethyl sulfoxide (DMSO) or 20% fresh egg yolk. The combination of the cryoprotectants was also tested: 10% MET plus 10% fresh egg yolk, or 10% DMSO plus fresh egg yolk, or 5% MET plus 5% DMSO plus 10% fresh egg yolk. The cryopreservation mixture was used to fill 1.5 ml cryotubes and left for an equilibration period of 15 min at 4 °C to ensure the correct functioning of the cryoprotectants. Samples were frozen inside a styrofoam box partially filled with liquid nitrogen (LN). After the equilibration process, cryotubes were placed over a net metal platform floating 1 cm over the LN, for a period of 15 min. Cryotubes were completely submerged into the LN after that time, remaining there for 5-60 min. For the thawing process, cryotubes were extracted from the LN and submerged for 75 s in a water bath at 70 °C. Samples post-thawing motility was assessed using a microscope and video recording, and cells membrane integrity was checked using a fluorescence LIVE/DEAD Sperm Viability Kit with SYBR-14, which stains intact cells green, and propidium iodide (PI) that stains damaged cells red.

Results

Short-term storage trial. Sperm motility in seawater showed a significant decrease after 5 days, reaching values close to 30%, and close to 0 on day 19. In contrast, diluted samples in EE showed a significant decrease in motility values with respect to day 0 (85-90%) after the first days of storage (days 5 and 12), showing approximately 60-65% of motile cells, followed by a second significant motility decline on day 19, reaching values of 45-50%, and a progressive reduction until day 36 (<10% motility).

(Continued on next page)

Cryopreservation trials. In the rough skate the use of 10% DMSO or 10% MET rendered post-thawing motility values higher than 40%. However, the combination of 5% DMSO plus 5% MET caused a significantly lower result than the other protocols. The small volume of rays sperm samples avoided the test of egg yolk.

In the case of the shark sperm samples the best post-thawing motility values were obtained with a combination of 5% DMSO, 5% MET and 10% egg yolk, which induced mean values close to 35%. Overall, the addition of egg yolk increased the post-thawing motility values, by up to 42.1% in samples with initial motility values of 70%.

Discussion

We have formulated a specific sperm extender capable of maintaining spermatozoa motility capacity for several weeks in different elasmobranch species. Moreover, we achieved the cryopreservation of sperm supplementing the extender (EE) with different combinations of cryoprotectants. Best results were obtained with a combination of DMSO, methanol and egg yolk. Despite the setting up process was developed using sperm samples from small-spotted catshark (*Scyliorhinus canicula*) and rough skate (*Raja radula*), additional cryopreservation attempts have been carried out using other 8 species, including sharks and rays classified as Critically Endangered, such as the blue shark (*Prionace glauca*) and the bull ray (*Aetomylaeus bovinus*). In the end, the sperm of a total of 10 species of elasmobranchs have been cryopreserved for the first time, including sharks, whose cryopreservation had not previously been achieved.

These results can allow the creation of cryobanks for elasmobranch sperm, becoming new tools for their conservation, complementing *ex situ* conservation efforts developed by public aquaria worldwide. Besides gene conservation and reproductive research projects, a regular supply of frozen sperm will reduce the problems that result from the long-distance transport of specimens, inbreeding or the lack of synchronized reproductive cycles in captivity.

Introduction

The Chondrichthyes are an ecologically diverse group of vertebrates, which appeared more than 400 million years ago (Compagno, 1990). But their complex life histories make this group extremely sensitive to elevated mortality from fishing and habitat destruction, being is one of the most threatened groups of vertebrates on the planet (Dulvy et al., 2014). Given this situation, the use of *ex situ* breeding programs could be a strategy worthy of consideration for their conservation. The reproduction in captivity of some species of elasmobranchs and chimaeras has been reported, but these events have traditionally relied on natural mating instead of the use of reproductive techniques (Daly and Jones, 2017). A potentially useful technique in breeding programs is the artificial insemination of females, but to do it a reliable supply of sperm is required. Traditionally, cannulation and abdominal massage are the most common procedures to obtain it (Penfold and Wyffels, 2019). However, all these reproductive techniques should consider the morphology and location of the different reproductive structures to be truly effective because the wide diversity of morphologies in these species can hamper the processes of sperm obtention and artificial insemination.

Material and methods

Males and females of 8 chondrichthyan species (7 sharks and one chimaera) belonging to the orders Carcharhiniformes (n=35), Hexanchiformes (n=1), Squaliformes (n=5) and Chimaeriformes (n=4) were studied to observe their reproductive systems and to obtain viable sperm. On dead specimens a dissection was performed to specifically gain access to the reproductive structures, as a previous step for sperm extraction. The focus on each dissection was on i) determine how to gain easy access to the urogenital papilla, ii) observe the number and disposition of urogenital pores, iii) observe urogenital sinus morphology, iv) access to seminal vesicle/uterus and v) sperm obtention. Detailed photographs were taken with a macro lens camera throughout the dissection procedure of every species and illustrated notes were taken.

Sperm obtention procedures were tested in dead and alive males, as well as from the oviducal glands of females. On dead males the extraction was performed using abdominal massage on the ventral region, or around the urogenital papilla in the cloacal cavity. Sperm was also obtained by introducing a polyurethane cat catheter, or nasogastric tube through the appropriate pore on the urogenital papilla, with the help of a sterile lubricating jelly. Last, sperm was extracted after dissection, by stripping directly on the seminal vesicle and urogenital sinus. To obtain sperm from live animals tonic immobility was induced to minimize struggling and reduce the stress before sperm extraction through abdominal massage. On dead females, their oviducal glands were removed and split along its longitudnial axis to expose its lumen. A pearly mucus was collected over the edge of a scalpel blade after scraping over its luminal epithelium, diluted in artificial elasmobranch extender (García-Salinas et al. 2021) and observed under the microscope.

Results

The overall structure of the female reproductive system is well preserved among the different species studied. The system is composed of the ovaries (one or two depending on the species), two paired oviducts with oviducal glands, two uterus and a series of sphincters (or isthmus) that isolate the different parts of the reproductive tract. The greatest differences observed (shape and size of the cervixes, uterus and oviducal glands) are related to the different modes of reproduction.

In males, the overall structure of the reproductive system in both sharks and chimaeras is similar, although chimaeras show unique secondary sexual characters of their group, such as the presence of a frontal tenaculum and prepelvic claspers. The reproductive system is formed by the testes (one or two depending on the species) epididymis, vas deferens, Leydig gland, seminal vesicle, urogenital papilla and claspers with siphonal sacs. There are some differences between the different morphologies of the seminal vesicles and the urogenital papillae, which can be important during the processes of cannulation to extract sperm.

(Continued on next page)

All techniques used to extract sperm offered positive results. The technique that allows the obtention of a greater volume of sperm is the direct pressure on the seminal vesicle during dissection. Cannulation is a technique that causes less damage to reproductive structures and allows sperm to be obtained in a cleaner way. Samples of motile sperm has been extracted from the oviducal gland of females of different species.

Discussion

Chondrichthyan fishes have a higher intrinsic risk of extinction compared to other fish and, nowadays, are one of the most threatened groups of the planet. Public aquaria play an important role in the conservation of these animals, through *ex situ* conservation programs. However, real sustainability of these programs is still far, especially when threatened species are involved. Nowadays the maintenance of zoological collections of public aquaria still rely on captures in the wild or in the spontaneous reproduction of the animals under their care. Breeding programs using reproductive technologies, such as sperm extraction and artificial insemination, could allow the advance of public aquaria towards sustainability and can be the key to reintroduction programs in the wild for threatened species. Some shark species have never been able to reproduce in captivity or have done it anecdotally. Although more research must be done on chondrichthyan reproduction, the goal of this study was to offer an anatomical guide that could be used as a tool for the conservation of these species. Although abdominal massage is the simplest technique for obtaining sperm, it is not the most effective in animals not fully mature or if clean samples are required. Cannulation is a more complex technique, but it allows to obtain sperm in a more precise and clean way if the anatomy of the animal is known. Finally, obtaining active sperm from the oviducal gland in females opens new research opportunities that should be exploited in the future, such is the obtention of viable gametes from by-catch. Much work remains to be done on the development and application of reproductive techniques in chondrichthyans, but these first steps can be crucial for the future conservation of these animals.

Introduction

Appearing almost 400 million years ago, the chondrichthyans are an old and ecologically diverse group of vertebrates with a key role in the regulation of the ecosystems they inhabit (Compagno, 1990). The class Chondrichthyes is classically divided into the Holocephalans (chimaeras), and the Elasmobranchs, commonly named sharks and rays. This last group, the rays, and their relatives (skates, guitarfishes, saw-fishes and alike), is the most diverse group among chondrichthyan fishes. As happen with the rest of chondrichthyans, rays possess life histories that make them sensitive to elevated anthropic pressure, and nowadays are one of the most threatened vertebrated groups on the planet (Dulvy et al., 2014). The use of *ex situ* breeding programs could be a strategy worthy of consideration for their conservation. Although the reproduction in captivity of rays has been reported for some species, these events have traditionally relied on natural mating instead in the use of reproductive techniques (Daly and Jones, 2017). Artificial insemination and sperm extraction are reproductive techniques commonly used for other species, that could be useful in their breeding programs (Penfold and Wyffels, 2019). However, all these reproductive techniques should consider the morphology and location of the reproductive structures to be truly effective. The lack of knowledge on that wide diversity of morphologies of the reproductive system can hamper the processes of sperm obtention and artificial insemination.

Material and methods

Males and females belonging to 11 batoids species of the order Rajiformes (n=20), Myliobatiformes (n=14) and Torpediniformes (n=4) were studied to observe their reproductive systems and to perform sperm extractions. On dead specimens a necropsy was performed to gain access to the reproductive structures, as a previous step for sperm extraction. The focus on each necropsy was on i) determine how to gain easy access to the urogenital papilla, ii) observe the number and disposition of urogenital pores, iii) observe urogenital sinus morphology, iv) access to seminal vesicle/uterus and v) sperm obtention. Detailed photographs were taken with a macro lens camera throughout the necropsy of every species and illustrated notes were taken.

Sperm extraction was tested in dead and alive males, as well as from the oviductal glands of dead females. On dead males the extraction was performed using abdominal massage on the ventral region or around the urogenital papilla or pressing on the seminal vesicle after necropsy. Sperm was obtained also after introducing a polyurethane cat catheter or nasogastric tube through the appropriate pore on the urogenital papilla with the help of a sterile lubricating jelly. In the case of live animals tonic immobility was induced to minimize struggling and reduce the stress before sperm extraction through abdominal massage. On dead females, their oviducal glands were removed and split along its anterior-posterior axis to expose its lumen. A pearly mucus was collected over the edge of a scalpel blade after scraping over its luminal epithelium, diluted in artificial elasmobranch extender (García-Salinas et al. 2021) and observed under the microscope.

Results

The overall structure of the female reproductive system is similar among the different species studied. The reproductive tract is composed of the ovaries (one or two depending on the species), two oviducts with oviducal glands, two uterus and a series of sphincters (or isthmus) that isolate the different parts of the reproductive tract. The greatest differences observed (shape and size of the cervix, uterus and nidamental glands) are related to the different modes of reproduction among oviparous, viviparous, and ovoviviparous animals.

In males, the general structure of the reproductive system is similar in all the species observed: the testes (one or two depending on the species) epididymis, vas deferens, Leydig gland, seminal vesicle, alkaline gland, urogenital papilla, and claspers with clasper glands. Some differences can be observed in the number, shape and position of the urogenital pores leading to the reproductive ducts, as well as on the morphologies of the seminal vesicles, which can be important during the processes of cannulation. The technique that allowed the obtention of a greater volume of sperm is the direct pressure on the seminal vesicle during necropsy. Cannulation is a technique that causes less damage to reproductive structures and allows sperm to be obtained in a cleaner way. Samples of motile sperm were extracted from the oviducal gland of females of different species.

(Continued on next page)

Discussion

Among the group formed by the rays and their relatives (skates, guitarfishes, saw-fishes and alike) are some of the most endangered marine animals in the planet. Public aquaria play an important role in the conservation of these animals, through *ex situ* conservation programs, but real sustainability of these programs is still far. Nowadays the maintenance of their zoological collections still rely on captures in the wild or in the spontaneous reproduction of the animals under their care. Breeding programs using reproductive technologies, such as sperm extraction and artificial insemination, could allow the advance of public aquaria towards sustainability and can be the key to develop reintroduction programs in the wild for threatened species. Although more research must be done on the reproduction of these animals, the goal of this study was to offer an anatomical guide to perform artificial reproduction and sperm extraction as steps towards the conservation of these species. Although abdominal massage is the simplest technique for obtaining sperm, the shape and position of pectoral fins can hamper the sperm extraction procedure, as there is not an easy access to the seminal vesicles. Thus, it is not the most effective in animals with a scarce amount of sperm or if clean samples are required. Cannulation is a more complex technique, but it allows to obtain sperm in a more precise and clean way if the anatomy of the animal is known. Finally, obtaining active sperm from the oviducal gland in females opens new research opportunities that should be exploited in the future, such is the obtention of viable gametes from by-catch. Much work remains to be done on the development and application of reproductive techniques in rays and their relatives, but these first steps can be crucial for the future conservation of these animals.

Introduction
Sea urchin gonads have been increasingly demanded and marketed in Asian countries and Europe mainly due to its organoleptic features. *Paracentrotus lividus* is the most abundant species in southern Europe. To avoid an overexploitation of wild stocks echinoculture has become a sustainable solution. Baião et al. (2019) reported high gonad yield by using a formulated extruded diet for *P. lividus*, but resulted in gonads with a pale-yellow colour. Colour is the first stimuli presented to a consumer and a major marketability influencing factor; consumers prefer yellow-orange colour gonads. Echinenone is the most abundant carotenoid in the gonads and depends on availability, uptake and bioconversion of β-carotene from dietary sources (Symonds et al. 2007). The present study aimed to investigate the effectiveness of a natural source of β-carotene in producing *P. lividus* gonads with acceptable colour.

Materials and methods
A control diet (CTRL) was formulated and compared to four isonitrogeneous and isoenergetic experimental diets containing two levels of *Dunaliella salina* (0.75% or 1.5%, in diets D1 and D2, respectively) as a natural rich source of β-carotene. In two of these *Dunaliella* supplemented diets, a commercially available macroalgae mix was totally replaced by *Porphyra* (D1P and D2P). Another diet was included by supplementing the CTRL diet with 1.2% of crystal glycine (GLY). All diets were cold extruded (<30 °C) and softly dried (<45ºC); diets were distributed every 48h, during 8 weeks, to quadruplicate groups of sea urchins, placed in plastic mesh cages in a saltwater recirculation aquaculture system (RAS) with a stocking density of 3.5 kg.m^{-2}, temperature 18 ºC, salinity 35‰, and a 10h L/14h D photoperiod. At the end of the trial all sea urchins were individually weighted and measured. Gonads of 8 animals per tank were sampled for chemical composition, carotenoid characterisation by high performance liquid chromatography (HPLC), and evaluation of colour by lightness, redness, yellowness, hue angle and chroma (L*, a*, b*, C* and h* respectively) and texture.

Results
All diets were well accepted by the sea urchins, resulting in a similar SGR (0.1) among treatments. Diets were able to enhance gonad yield, that increased from 6.4 and 8.9 to 15.8 and 17.0, in males and females, respectively. Gonad yield and gonadal somatic index (GSI) were similar among diets, but varied significantly between sexes; females had higher yield and GSI than males. Final gonad composition presented significant differences between sexes and diets. Females had higher dry matter and energy, but lower protein content than males. Sea urchins fed diet D1 resulted in the highest gonadal protein content, whilst diet D2 presented the highest energy, irrespectively of the sex. Diets have significantly affected all free amino acids; urchins fed with the experimental diets presented significantly higher concentrations of arginine, valine, methionine and glycine in gonads than the urchins fed with the CTRL diet.

(Continued on next page)

The content of carotenoids in gonads did not vary significantly among dietary treatments, but significant differences were observed between sexes: males containing higher concentrations of total carotenoids, echinenone (most abundant pigment: 12.4 – 17.5 $\mu g.g^{-1}$ WW), α-carotene and β-carotene than females, but practically undetected lutein and zeaxantin. Female's most abundant pigments were lutein (3.7 – 5.3 $\mu g.g^{-1}$ WW) and echinenone (3.3. – 5.9 $\mu g.g^{-1}$ WW), followed by zeaxantin (1.9 – 3.2 $\mu g.g^{-1}$ WW). Gonad colour presented significant differences between sexes and diets. Gonads of males had higher L* and h*, but lower a*, b* and C* values than females. Sea urchins fed *Dunaliella*-diets produced gonads with lower L* and h* values, and higher a* value compared to those fed with CTRL diet. Sea urchins fed with diet D2 had firmer gonads than those fed diet D1P, but did not differ from the CTRL. L* was positively related with echinenone (0.7) and a* and b* positively correlated with lutein (0.8) and zeaxantin (0.8).

Conclusions

All tested diets were able to enhance gonad yield, with females having larger gonads than males, but without differences between diets. All *Dunaliella*-diets were able to produce redder and less luminous gonads than the CTRL diet. This indicates an improvement in gonad colour since consumers prefer gonads with lower values of L* and higher values of a* (Baião et al. 2020). Overall, diets supplemented with *Dunaliella* were able to improve the colour of sea urchin gonads in relation to the CTRL group, resulting in medium to bright orange/red gonads with high acceptance for consumers.

Acknowledgments

Introduction

Oxidative stress has been related to various skeletal pathologies altering the activity of osteoclasts and osteoblasts, affecting bone remodelling. Reactive oxygen species are key components to increase oxidative stress, increase bone resorption and inhibit bone formation. A large number of studies suggests the importance of the antioxidant system to reduce the effect of bone pathologies and promote better skeletogenesis in aquaculture produced fish.

Materials and Methods

Microdiets were prepared manually by mixing squid powder first with water-soluble components, then with fat and lipid-soluble vitamins, and finally with gelation dissolved warm water. Resveratrol (34mg/kg) and Doxorubicin (30mg/kg) were dissolved on polar molecules whereas MitoTempo was dissolved in water. *S. aurata* larvae at 30 days were randomly stocked into 18 experimental tanks at a density of 2100 larvae/tank. The larvae were fed experimental microdiets with added antioxidants and pro-oxidants, alone or in combination. The antioxidant microdiets were fed every hour from 8:00 to 20:00, whereas the pro-oxidant (doxorubicin) diet was fed only once a week and was continued with a respective combination of control or antioxidant diets. Similarly, zebrafish (5 dpf) were randomly stocked into 24 experimental tanks at a density of 100 larvae/tank for 30 days. The larvae were fed with experimental microdiets with antioxidant and pro-oxidants alone or in combination. The antioxidant supplemented microdiets were fed by standardized spatula 15mg/day and increased by 5mg/day every week. Antioxidant supplemented microdiets were fed 4 times a day, whereas the pro-oxidant diet was fed only once a week. The microdiet combinations were Control, Resveratrol (RES), MitoTempo (MT), Doxorubicin (DOX), Doxorubicin + Resveratrol and Doxorubicin + MitoTempo. The effect of antioxidant and pro-oxidant supplemented diet on skeletal formation, the incidence and distribution of skeletal deformities and the stages of bone mineralization, mineral content and molecular markers of bone were determined.

Results

At 45 dah, *S. aurata* fed microdiets supplemented with pro-oxidants increased the incidence of bone deformities, deformities charge and decreased bone mineralization. These effects were significantly reversed while co-feeding with microdiets supplemented with antioxidants. Doxorubicin significantly reduced the total length of larvae which was significantly reversed with the co-treatment with Resveratrol. Deformities charge was significantly higher on the Doxorubicin supplemented group and were significantly reduced on the groups co-feeding with antioxidants. Cluster analysis showed a distinct difference between the groups on the distribution of skeleton anomalies. The mineralization of the skeleton elements was significantly affected by Doxorubicin. However, co-feeding with Resveratrol the effect was rescued. The differences were also observed on Meristic count between the groups supplemented with antioxidants and pro-oxidants supplemented microdiets. Calcium and Phosphorus content were also decreased on Doxorubicin supplemented groups. Similarly, on the zebrafish trial, the effect of microdiets on standard length was compared with the standard Zebrafeed diet (Sparos Lda, Olhão, Portugal). Resveratrol supplementation significantly increased the length as compared to Zebrafeed and control microdiet. Survival of zebrafish larvae was significantly decreased under doxorubicin supplementation but significantly reversed upon co-feeding with antioxidants. Doxorubicin supplementation also delayed larvae development and significantly decreased total length however, this effect was significantly reversed by co-treatment with antioxidants. Calcium, Phosphorus, Sodium, Potassium and Magnesium contents were also decreased on Doxorubicin supplemented groups whereas, while in co-feeding with antioxidants, the loss of mineral content was significantly rescued.

Figure: *S. aurata* larvae at 45 dah fed with microdiets supplemented with antioxidants and pro-oxidants stained with an Acid-free double staining protocol for bone and cartilage.

Conclusion

Our results showed that antioxidant supplements effectively prevent the incidence of bone anomalies and mineralization defects induced by pro-oxidants on both models. Resveratrol and MitoTempo supplementation can reverse pro-oxidant induced effects on bone anomalies, mineralization and oxidative stress. The use of antioxidants in fish diets can be beneficial for improving the health and quality of aquaculture produced fish.

Introduction

The greater amberjack (*Seriola dumerili*, Risso 1810) is a species recently introduced in the Portuguese aquaculture and it is considered crucial for diversification of production. *Seriola Dumerili* represents a very interesting species due to its high added value and great export potential, since it is highly appreciated in international markets (like Japan). This species has a very high growth rate reaching up to 6 kg in 2.5 years (Mylonas et al 2016) and have a FCR close to 1 at 26ºC (Fernandez-Montero et al 2018). Despite the fast growth in captivity, there is very few data available about the nutritional requirements for this species regarding macronutrients, vitamins, essential fatty acids and minerals (Kotzamanis et al 2021). It has been shown that the levels of DHA and EPA must be strictly controlled, with imbalances in the optimal ratio of 1.6 leading to development of skeletal anomalies, particularly in the skull (Roo et al 2019). Also the dietary regimes followed during larval rearing can significantly influence the development of skeletal anomalies (Djellata et al 2021). In this study we have characterized the main typologies of skeletal anomalies observed in young adults of greater amberjack.

Methods

The experimental rearing was conducted in the IPMA-EPPO aquaculture Facilities (Olhão, Portugal) with the juvenile *Seriola* dumerili being placed in 18m^3 tanks with a constant supply of filtered seawater (temperature: 23-25ºC; salinity 36ppt; natural photoperiod; dissolved oxygen above 90% saturation level). A greater amberjack stock (N= 50; weighing on average 1171.79 ± 250.54 g wet weight) were maintained for 9 months and fed with a commercial diet specifically developed for *Seriola dumerili* (Sparos, Lda, Olhão, Portugal). Fish were sampled for weight and length and all the specimens presenting externally visible skeletal anomalies were euthanized with 500ppm phenoxyethanol. A total of 30 fish were examined and the typologies of skeletal anomalies analysed by digital radiography using a Kodac DSX 4000 pro soft X-Ray (Carestream).

Results and discussion

The most prevalent deformities found in the deformed group of *Seriola dumerili* were affecting the cranial structures particularly the skull bones and upper jaw (87%; Figure 1A) and the lower jaw (70%). Three of the specimens presented also deformities in the hyoid arch, significantly altering the morphology of the mouth apparatus, or even provoking a double mouth phenotype. The axial deformities were mostly present in the abdominal vertebrae (Figure 1B) with 33 % of the specimens showing deformed or fused vertebrae that in 13% of the cases caused lordosis.

Figure 1. Deformities observed in *Seriola dumerili*. A) Cranial deformity by alteration in the skull bones (black arrow) and hyoid arch (arrowhead) affecting the branchial arches. Abdominal lordosis (white arrow). B) Detail of abdominal lordosis with deformed vertebra. C) Caudal lordosis

(Continued on next page)

Deformities in the caudal vertebrae and arches affected 20% of the specimens, including vertebral fusions and deformed vertebrae involved in vertebral curvatures like lordosis with incidence of 10%. The caudal fin vertebrae region was the less affected with only 2 specimens (7%) presenting mild deformities in the vertebral bodies.

Overall our results show that cranial deformities are the most prevalent type of skeletal anomaly present, significantly altering the phenotype of the specimens. This type of deformities has been associated to inadequate dietary levels of DHA and EPA during early stages (Roo et al 2019), but also to walling behaviour induced by positive phototaxis that leads juveniles to collide with white tank walls. This walling behaviour can be partially prevented by rearing fish in low brightness tanks (Sawada et al 2020). The skeletal anomalies observed are rarely observed in nature, but in aquaculture fish they produce negative impacts by reducing product value, marketing image, but also affecting the biological behaviour and well-being of the cultured animals (Boglione et al 2012). The successful implementation of the greater amberjack as a valuable species in Europe requires research efforts towards reducing the incidence of deformities, that is crucial for producing high quality fish for the markets.

LONG LASTING EFFECTS OF EARLY TEMPERATURE EXPOSURE ON THE OTOLITH ASYMMETRY OF GILTHEAD SEABREAM LARVAE AND JUVENILES

G. Geladakis[1]*, S. Somarakis[2] and G.Koumoundouros[1]

[1] Biology Department, University of Crete, Heraklion, Greece

Introduction

Water temperature during early developmental stages often induces long lasting phenotypic plasticity in marine fish, with implications for the survival, growth and population structure of the wild stocks (Vagner *et al*. 2019, Kourkouta *et al*. 2021). Maladaptive plastic responses can arise as functional costs induced by developmental asymmetries (Gagliano et al. 2008). Otolith morphology is a very sensitive indicator of developmental errors because it is a reliable and permanent record of past growth events and is determined by the genetic and environmental interactions (Gagliano *et al*. 2008; Vignon & Morta 2010). In the present study we examined the effect of temperature during the short embryonic and yolk-sac larval period, on the otolith asymmetry levels of Gilthead seabream (*Sparus aurata*) at metamorphosis (57 days post hatching, dph) and early juvenile stage (94 dph).

Material and Methods

Nine groups of fish were subjected in triplicate to 17, 20 or 23°C, from the stage of epiboly onset to the end of yolk-sac larval stage. Subsequently, all groups were kept under identical rearing conditions and temperature (20°C) up to the end of the trial. From experimental population, a random sample of 10 fish was taken at 57 and 94 dph (30 fish per thermal regime). From each specimen, the largest pair of otoliths (sagittae) was removed and individually photographed. All otolith images were analyzed using the "ShapeR" package (Libungan & Palsson 2015). Following the extraction of the otolith contours, otolith bilateral asymmetry was assessed for ten traits; four univariate morphometric descriptors (maximum length, O_L; maximum depth, O_D; surface, O_S; perimeter, O_P) and six high-amplitude harmonics (H_2-H_7) produced by a normalized elliptic Fourier technique. All traits were tested for the type of bilateral asymmetry, i.e. fluctuating asymmetry, directional asymmetry or antisymmetry (Palmer & Strobeck 1986). The variance of the bilateral difference [index A_1=var(R-L)] was estimated for each temperature group at both sampling ages. The significance of the difference in A_1 between groups was tested by means of Bartlett test.

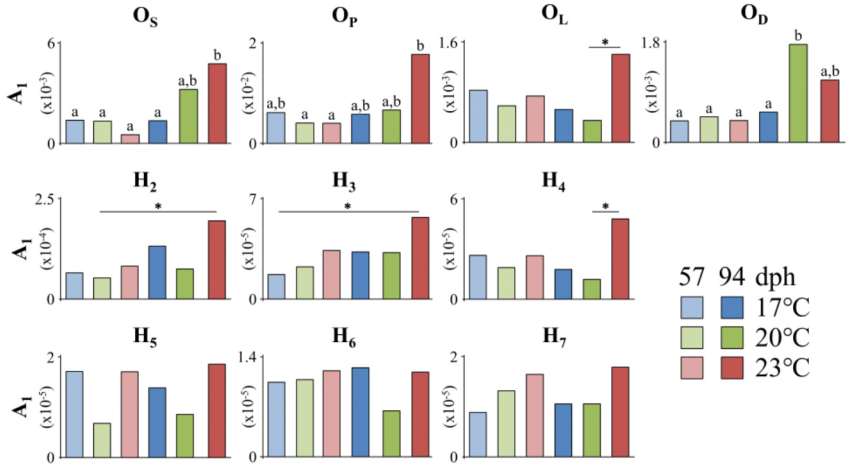

Fig. 1. Effect of developmental temperature (17, 20 and 23°C) on the otolith asymmetry (index A_1) of fish at 57 and 94 days post hatching (dph). O_L: max otolith length, O_D: max otolith depth, O_S: otolith surface area, O_P: otolith perimeter, H_2-H_7: harmonics two to seven. Values without a letter in common are statistically different ($p<0.05$). *($p<0.05$)

(Continued on next page)

Results& Discussion

Developmental temperature (DT) had a significant effect on the otolith bilateral asymmetry of Gilthead seabream. For all the univariate morphometric descriptors (O_L, O_D, O_S, O_P) and the harmonics H_2-H_4, the A_1 asymmetry index was significantly higher in the juveniles initially reared at 23°C DT (3.1±0.3 cm standard length, SL) than those reared at 17 (3.2±0.3 cm SL) and 20°C (3.2±0.3 cm SL) DT (Fig.1). Bilateral differences concerned antisymmetry for the descriptors O_S and O_P, directional asymmetry for O_L, H_3-H_4 and H_6-H_7, and fluctuating asymmetry for the O_D and H_2.

The programming of otolith asymmetry by the temperature experienced during the relatively short embryonic and yolk-sac period in fish, is supported by the findings of Lychakov *et al*. (2006) who suggested that the level of otolith asymmetry is established at the very onset of otolith growth (i.e. at the embryonic stage). Following Gagliano *et al*. (2008), individuals with higher levels of otolith asymmetry could encounter more difficulties in habitat detection during the critical settlement phase. In Gilthead seabream, in addition to its negative effects on otolith asymmetry (present study), elevated DT has been shown to induce a substantial decrease in aerobic swimming performance during the metamorphosis period (Kourkouta *et al*. 2021).

Introduction

The usefulness of ultrasonic telemetry on behavioral studies has been proven by a large number of field and laboratory studies (i.e. Abecasis et al, 2018; Schwinghamer, 2019). However, telemetry tags may have an effect on the physiological, behavioral and the performance attributes of the fish (Frank et al, 2009, McKenna et al, 2021) and could be permanent or temporal. These potential negative e□ects are still unknown for a number of species and tagging methods. Recent studies exist and focus mainly on the physiological and anatomical consequences of tag-implantation (Tsitrin, 2020; Justin et al, 2021). It is, thus, crucial to determine the behavioral attributes that are affected by the tag implantation, and the time needed for recovery. Here, we investigated the e□ect of body-implanted tags on the swimming behavior of adult European seabass (*Dicentrarchus labrax*). Three main behavioral aspects were studied, including the synchronization/polarized motion, the group cohesion and the group exploratory behavior.

Materials and methods

45 individuals were captured and transferred from sea cages to a rectangular tank (3.0x3.0x1.2m) 30 days prior to the experiment to allow for adaptation. Polyacetal (POM) cylinders (similar in size and shape with telemetry tags) were implanted into the peritoneal cavity of 20 fish following an experimental protocol that was approved by the ethical committee (Ref: 32257 09-02-2021). The remained fish were used as the control group. After the surgery, fish returned to the tanks and were being recorded from above using fixed IP cameras (HIKVISION DS-2CD1623G0-IZS) for a total period of 15 days. During this period feeding was realized once per day at 12:00. The treated fish returned to normal appetite levels four days after the surgery.

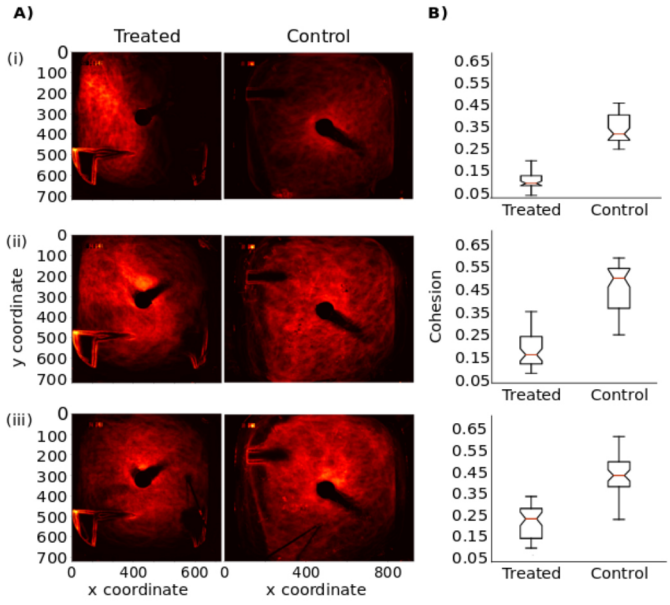

Figure 1. A) Heatmaps of the tanks showing the frequency of the exploration of the tank sites for both, the treated and the control group and for the first (i), the fifth (ii) and the last (iii) day of the experiment. The intensity of the red color indicates higher exploration of the respective tank site. B) Boxplots showing the group cohesion, expressed as the percentage of the area covered by the group, for both, the treated and the control groups and for the first (i), the fifth (ii) and the last (iii) day of the experiment. Red lines indicate median values. Lower values indicate higher cohesion.

(Continued on next page)

From the video recordings, four main variables were extracted using custom-made computer vision routines based on Python/OpenCV. Group directionality and speed were extracted using optical flow analysis. Group cohesion was determined as the normalized tank area covered by the group at each time frame. Last, the exploratory tendency showed the spatial preference of the group and was expressed as the frequency each tank site was covered by the fish.

Results

Preliminary results indicate that E. seabass exploratory behavior is temporally affected by the tag implantation but achieves recovery 10 days after surgery (figure 1A). In contrast, the group cohesion of the treated group remains high during the experiment as the group never covers more than the 40% of the tank area (figure 1B). Although the treated group becomes less cohesive as time progresses, the significant difference between the two groups remains, even 15 days after surgery. Further investigation is required to determine the time needed for recovery of this behavioural atrribute.

DOES STRUCTURAL ENRICHMENT SUPPORT THE WELFARE OF FARMED RAINBOW TROUT JUVENILES IN INDOOR FACILITIES?

Manuel Gesto* and Alfred Jokumsen

Technical University of Denmark, DTU Aqua, Section for Aquaculture, The North Sea Research Centre, DK-9850, Hirtshals, Denmark.
E-mail: mges@aqua.dtu.dk

Introduction
Many fish species show some kind of sheltering behavior. Most fishes seek for shelter, if available, as a physical protection against potential attackers or other threats and many species use shelters for other purposes, too (Kerry and Bellwood, 2017). Most fish-rearing facilities in aquaculture and fish-based research consist of barren tanks where environmental complexity is very low. This has raised concerns about the welfare of fish in captivity and different kinds of environmental enrichment have been tested as potential strategies to promote the welfare of captive fish, with different degrees of success depending on the species, enrichment type and type of welfare indicators considered (Näslund and Johnsson, 2016). In a series of experiments, we have focused on the effects of structural enrichment, in the form of simple PVC-screen shelters, on rainbow trout juveniles. In brief, growth, condition, external damage and stress resilience were monitored in the presence and absence (controls) of shelters. Furthermore, the potential effects of early-life exposure to shelters on the future performance and physiology of the fish were also evaluated.

Methods
In a first experiment, the immediate effects of exposing fish juveniles to the PVC shelters were tested. Juveniles (mean individual mass: 15.0 g; SD: 4.0 g) were reared in the presence or absence of shelters for up to nine weeks, in triplicated groups. Growth performance, condition and external damage in fins, skin, eyes, operculum and snout were monitored. Basal stress levels and the physiological responses to standardized acute and repeated stressors were also evaluated.

In a second experiment, fish were introduced to the shelters at an earlier stage (mean individual mass: 1.5 g; SE: 0.1 g) and fish groups were reared in the presence or absence of shelters for four months. The effects of shelter presence on growth, condition, external damage and stress resilience were monitored as in the previous experiment. In addition, shelters were then removed and, after some weeks of acclimation, fish juveniles grown in the presence or absence of shelters were allocated together after being PIT-tagged. The performance of the fish during co-habitation was monitored, both in normal rearing conditions and in conditions promoting competition (low density, low specific feeding rates), to evaluate the effects of the early exposure to the shelters on fish performance and coping/competitive ability.

Results and discussion
In this study, the design of the shelters was intentionally kept as simple as possible, since one of the main aims was to test the feasibility of using the shelters in the farm environment. In the presence of shelters, fish showed very marked sheltering behavior when submitted to disturbance, demonstrating a clear behavioral preference for shelter use when threatened. However, there were no major differences between sheltered and control (barren) tanks in terms of growth performance, condition factor, external tissue damage, or stress resilience, at least when fish were reared in normal conditions in terms of stocking density and feeding rations. Competitive tests showed that fish grown in the presence of shelters had an inferior ability for competition/growth when the stocking density was kept very low and feeding rations were restricted. It is at present unclear whether such an effect on competitive ability could have been prevented by increasing the time for acclimation of shelter-grown fish to the absence of shelters.

In view of the obtained results, the answer to the question posed in the title of this communication is complex. Fish had no apparent physiological- or performance-related benefits when giving the opportunity to live in a structurally enriched environment; however, they showed a clear behavioral preference for the shelters, particularly when disturbed. Regarding animal welfare, the importance of having access to preferred/wanted items and/or situations differs among the different approaches to the concept of Welfare (Maia and Volpato, 2016). Therefore, the relevance of the shelters for fish welfare in this case could be open to debate since it would depend on the considered welfare approach. It remains to be investigated whether using similar shelters in outdoor facilities, where the chances for external interference/stressors are much higher, would have stronger effects on fish performance and/or welfare.

THE EU4OCEAN COALITION FOR OCEAN LITERACY AND SUSTAINABLE FOOD FROM THE OCEAN

Iwona Gin*

Nausicaá, Centre National de la Mer, Boulevard Sainte Beuve, 62200 Boulogne sur Mer, France
iwona.gin@nausicaa.fr

Why the EU4Ocean Coalition for Ocean Literacy?
The ocean is a source of life for human beings. It gives us food, oxygen and energy. It is home to many species and acts as climate regulator. Understanding how we influence the ocean and how the ocean influences us is at the core of ocean literacy. This understanding allows us to make responsible consumer choices to better protect our ocean and to use the opportunities it offers in a sustainable manner.

The European Ocean Coalition (EU4Ocean) connects diverse organisations and people that contribute to ocean literacy and the sustainable management of the ocean. Supported by the Directorate General for Maritime Affairs and Fisheries of the European Commission, this bottom-up inclusive initiative offers a dynamic topic-oriented working environment that stimulates collaboration, exchange of practices and dialogue across the many different target groups leading to the creation of new ocean literacy partnerships and innovative actions, co-designed by organisations and the youth.

The coalition is made up of three components: an EU4Ocean Platform for organisations and individuals engaged in ocean literacy initiatives, a Youth4Ocean Forum and a Network of European Blue Schools.

They focus on particular topics: Climate and Ocean, Food from the Ocean and Healthy and Clean Ocean.

Why the Ocean Literacy about Food from the ocean
The topic of Food from the Ocean is very close to each individual because it is linked to food and nutrition, consumer choices, sustainability labels and food waste. Raising awareness of what seafood we eat, from where it comes from and what impact unsustainable fisheries have on the ocean, can bring significant results in terms of behavioural change in the times when the consumer interest in the impact of food on their health and on the planet is growing, especially among young generations.

According to the FAO, the total food demand is projected to increase by 60% by 2050 given current trends. Seafood is a crucial and growing source of nutrition for billions of people around the world. However, about 30% of fish population is overfished or even exhausted because not sustainably exploited.

Aquaculture can be a possible solution as long as it is conducted sustainably. The sector has experienced a real boom over the past years and some achievements have been made in Europe to reach sustainable methods of production. It is important now to raise awareness about these types of seafood and the importance of the sustainable aquaculture production. However, the topic is complex, as it includes cultural, economic and environmental considerations and lacks public trust in the aquaculture products. Therefore, the EU4Ocean Coalition members have started to exchange and map existing activities, stakeholders and resources for joint ocean literacy activities in relation to the topic with the aim of developing new partnerships and actions, including scaling up activities and advocacy campaigns.

How to involve younger generations of consumers?
The EU4Ocean Coalition engages younger generations in the sustainable consumption of food from the ocean through the Youth4Ocean Forum and the Network of European Blue Schools.

The Youth4Ocean Forum is a free platform for young ocean changemakers between 16 and 30 years old. Their common goal is to tackle the climate crisis, fight marine pollution, ensure food security and shape their future with a healthy ocean. Therefore, the Youth4Ocean Forum provides young people with the opportunities to speak up for their generation in front of European institutions, share their ideas and connect with like-minded young people and experts all over Europe. It empowers the youth to solve challenges facing the ocean such as e.g. food security by helping them to develop and promote their individual projects and obtain accreditation of EU Young Ocean Advocates.

(Continued on next page)

The Network of European Blue Schools brings the ocean into the classroom. The programme challenges schools to “Find the Blue,” i.e. to develop a community project that addresses a marine and societal challenge. The project consists of several complementary activities under the umbrella of one central topic. It enables pupils to gain knowledge and skills by working for an extended period of time to explore and investigate an ocean topic, question or problem and explore their connection to the ocean while creating a network across Europe. On their journey to becoming a European Blue School, teachers and pupils improve their understanding of the ocean and develop a sense of responsibility towards it. This feeling of responsibility for the ocean encourages the pupils to make ocean friendly, sustainable consumer choices and become citizens of the global ocean.

PORCINE PROTEIN HYDROLYSATES PROMOTE GROWTH AND ENHANCES SYSTEMIC IMMUNITY IN GILTHEAD SEABREAM FED LOW FISHMEAL DIETS

Introduction

Protein hydrolysates are reputed in aquafeeds for their antimicrobial, antioxidant and immunomodulatory properties beyond their nutritional value. Although fish protein hydrolysates have been extensively studied (Siddik et al., 2021), the potential use of other sources of animal and plant protein hydrolysates have not extensively evaluated in fish. Among different sources of raw materials to be used for producing protein hydrolysates, rendering by-products have been reported to have relevant nutritional and functional roles in fish nutrition. In particular, the most common evaluated blood by-product in aquafeeds is the porcine spray-dried plasma, although blood protein hydrolysates may be an untapped safe source of animal protein hydrolysates for aquafeeds. The use of rendering blood by-products is an untapped source of highly quality ingredients for aquafeeds, regardless of the change in legislation that allows the use of animal proteins of porcine and avian origin in aquafeeds.

In the present study, authors aimed to evaluate the effects of porcine protein hydrolysates (PPH) on most common key performance indicators like growth and feed efficiency parameters, as well as on its influence on gilthead seabream immunity. Particularly, the immunomodulatory effects of the dietary administration of PPH to a bacterial challenge were tested at two levels: i) by evaluating gene expression level in splenocytes exposed to a short-term *ex vivo* stimulation with lipopolysaccharide (LPS) and ii) by measuring the antibacterial activity of skin mucus when incubated with different bacterial strains.

Materials and Methods

A control diet was formulated with low levels of fishmeal (FM) (7% FM) to contain 48% crude protein, 17% crude fat, and 22 MJ kg^{-1} gross energy. Based on this basal formulation, an experimental diet was formulated, in which porcine protein hydrolysate (PPH) (PEPTEIVA®; APC Europe, SA, Spain) was incorporated at 5% at the expense of FM (final FM levels = 2%). The PPH is a hydrolysate of porcine plasma containing 76% protein (>85% of protein in form of peptides smaller than 10KDa), 2.6% crude fat and 14.5% ash. Both diets were isonitrogenous, isolipidic, and isoenergetic.

Fish were fed two experimental diets (4 replicates per diet) for 92 days under the following environmental conditions: water temperature values ranging from 22 to 27 °C, 6.1 ± 0.2 mg L^{-1} of dissolved oxygen and natural photoperiod. Feeds were distributed four times per day by automatic feeders (feeding rate of 3.3% of the stocked biomass). At the end of the trial, an *ex vivo* assay with splenocytes from both groups was performed as described in Salomón et al. (2020), and the bactericidal properties of the skin mucus were assayed against *Escherichia coli* (DSMZ423), and two pathogenic bacteria, *Vibrio anguillarum* (CECT522T) and *Pseudomonas anguilliseptica* (CECT899T) that were co-cultured with skin mucus during a 24 h-period (Sanahuja et al., 2019).

Results and Discussion

Fish fed the PPH diet were 4.6% heavier than their congeners fed the control diet with low levels of FM. No differences in length nor condition factor were found. In addition, FCR values were lower in fish fed the PPH diet (1.08 ± 0.06) in comparison to those of the control group (1.23 ± 0.04). Similar results were observed in gilthead seabream fed diets containing high FM levels (46%) (Gisbert et al., 2015). Results from the *in vitro* assay with splenocytes of fish from both dietary groups revealed that PPH enhanced the systemic immune response of gilthead seabream as gene expression markers indicated. In particular, we found an up-regulation of gene markers involved in the humoral innate response (*igM*), as well as pro- (*il-1β*, *tnfα*) and anti-inflammatory cytokines (*il-10*, *tgfβ1*), whereas no significant changes in gene expression were

found in terms of *mn-sod*, *cat* and *lys*. Considering that fish skin mucus provides a stable physical, biological, and chemical barrier against invading pathogens, knowledge of its antibacterial capacity when exposed to a pathogenic organism is of relevance. In this sense, the mucus from gilthead seabream fed the PPH showed a higher bactericidal activity than the control group along the 24 h of skin mucus co-culture with the three bacterial species considered. In this sense, skin mucus inhibited the growth of *V. anguillarum* and *P. anguilliseptica*; thus, potentially protecting fish from vibriosis and pastelleurosis when fed diets containing low levels of FM. The immunomodulatory properties of the PPH diet may be attributed to the content of plasma in immunoglobulins, albumins, growth factors and biologically active peptides, which may mediate anti-inflammatory and immunomodulatory effects (Pérez-Bosque et al., 2016).

Conclusions

This study showed that porcine protein hydrolysate obtained from blood plasma is a safe and functional ingredient, especially in those formulated with low fishmeal levels. In particular, PPH promotes somatic growth and improves feed performance, whereas at the same time it enhances the immune response of animals. Considering these beneficial properties, this ingredient can be useful for its incorporation in aquafeeds.

FORECASTING WATER TEMPERATURE IN NORTHERN ADRIATIC LAGOONS: A FUNCTIONAL DATA APPROACH

Daniel Glaser[1], Camilla Bertolini[1], Carlo Gaetan[1] and Roberto Pastres[1*]

(1) DAIS, Ca' Foscari University of Venice, 30173 Venezia, Italy
Email: pastres@unive.it

Introduction

Large-scale food production in coastal and off-shore areas represents one of the most promising ways to tackle future food security issues. Traditionally the lagoons in the Northern Adriatic have been a highly important source of fish, shellfish and game. In the last decades, shellfish farming, in particular that of the allochthonous clam *Ruditapes philippinarum*, has become the most relevant halieutic resource in that region but, in perspective, extensive fish farming in the "Valli da pesca" may also once again become profitable, as a source of sustainable, high quality fish. However, these farming activities are facing some challenges, due to the increasing climate variability related to climate change.

To avoid (sub-)lethal stress to the farmed species it is important to understand the environmental conditions necessary for successful farming, as well as being able to predict the trend and short-term fluctuations of water quality variables, such as the water temperature, dissolved oxygen and salinity. The focus of this work is to develop an innovative data driven model approach, based on functional data analysis, for 1-2 day ahead forecasting of these variables in a lagoon. Thanks to near real-time processing of the data, this tool could help farmers in mitigating the consequences of heat waves and other extreme events related to a changing climate .

Methodology

Being one of the most relevant water quality variables for aquaculture, water temperature is here used to develop and demonstrate this methodology. In order to forecast its daily pattern, an additive model was employed:

$$W_n(t) = T_n + S_n(t) + \varepsilon(t) \qquad (1)$$

in which $W_n(t)$ is the water temperature on day n, T_n represents a trend component and $S_n(t)$ a seasonal one, associated with daily oscillations. This component was modelled using a functional data analysis (FDA) approach, which can be applied to observed data which can be characterised by smooth curves. In particular, a functional autoregressive model with external predictors (FARX) was identified and estimated. In FDA, a set of observations, in this case the detrended temperature observations pertaining to one day, are fitted using a smooth function, obtained by a linear combination of suitable simple basis functions. Subsequently, standard time series analysis methodologies, i.e. ARIMA, can be applied to the weight of the basis functions, rather than to the actual values in the time domain.

In this case, a set of orthonormal functions were used as basis: 5 functions allowed us to obtain a very good fit of the original 48 daily observations. In contrast to a Fourier expansion the functional principal components are not necessarily periodic functions, which facilitates the application to signals that have little or no periodicity.

Based on the shape of the curve of the water temperature observed in previous days and that of the forecast air temperature, the FARX model predicts a curve for the water temperature development of the next day. This curve is continuous: accordingly the output forecasting frequency is adjustable at will.

For fitting the FARX model we use the R package **refund** that provides several functions for creating, handling and analysing functional data, especially for computing regression for functional data.

This methodology was applied to two Northern Adriatic lagoons, the Venice Lagoon (VL) and the Marinetta Lagoon (ML) in the Po delta, to test the model performance on real data. Water quality data was provided by the "Venezia 2021" project (VL) and the Environmental Agency of Veneto (ML), the latter also providing data on the air temperature in both locations.

For each lagoon three different time windows were selected in order to cover various seasons and extreme weather events. The included times were: July 2015 (heat wave), November 2018 (storm "Adrian") and April 2017 (as control group).

(Continued on next page)

The parameter estimation was carried out using the observations from 10 consecutive days. As external input for both modelling stages, the corresponding air temperature and salinity were regarded and their contribution to improving the model quantified using the Bayesian Information Criterion (BIC).

Results & Discussion

With this methodology we were able to successfully forecast the next-day dynamic in a detailed manner (half-hourly prediction steps) for all six cases, with overall performance being better in the more stable sets of spring and summer. Figure 1 below shows the well fitting forecast of the seasonal and combined forecast to the observed curves by the example of the July 2015 forecast in the Venice Lagoon.

Despite having different physical compositions (e.g. depth, size, openness to sea) there was no perceivable difference in the model performance between the two examined lagoons. While air temperature was identified as the most relevant external input in 5 cases out of six, salinity could be used for improving the trend forecast. This could be an indicator that tidal patterns (for which salinity is a likely marker) have a slower, more diffused effect on the water temperature than air temperature does.

Conclusion

With little computational effort, this method is able to create significant results which are also ecologically interpretable, making this a strong alternative for forecasting high resolving time series in near real-time. It can easily be adjusted to model other environmental parameters such as dissolved oxygen or salinity. While the model performance is better when the input time series is smooth, there is no restriction to use only periodic functions.

This tool can help aquaculture farmers to obtain short-term forecasts of adverse extreme events and undertake mitigation action, for example by regulating water flows in the adriatic “Valli di pesca”.

A major restriction for application is still the limited forecasting horizon (here one day), which should be extended to several days after some supplementary analysis.

Introduction

Optimal husbandry conditions, healthy animals and innovative raw materials are prerequisites for sustainable aquaculture of animal organisms, the production of quality products and profitable sales. However, although fish grow up successfully in aquaculture from a human point of view, knowledge about animal welfare itself is rudimentary and, as a result, production success is reduced. With integrated monitoring systems, the animal welfare of aquatic organisms can be measured at various stages of production from hatching to harvest weight of the animals. Furthermore, it can be used to certify rearing conditions and aquaculture facilities and thus optimize fish production processes up to the slaughter process. The partners in the project BioFiA developing integrated testing and monitoring mechanisms for fish welfare for the juvenile life stages of salmon. For this purpose, a comprehensive molecular monitoring of the fish on the level of gene expression will be performed (Rebl et al., 2020). This will be supported by blood and stress hormone analyses (Seibel et al., 2021). In parallel, rearing conditions of the fish will be recorded using physicochemical and image sensors (MonitorFish GmbH). The analyses also include detection of bacteria and parasites in the fish and in the farming system (Unger & Palm, 2016, Spieck et al., 2020). AI algorithms are used to perform Big Data analyses of the monitored data. The comprehensive sensory analytics should enable early assessment and even prediction of animal welfare in real time. Currently, the project is looking at the impact of microalgae as innovative probiotic diets (Michl et al., 2019; Microganic GmbH). In addition, an examination of the product quality as food for humans is carried out (Molkentin et al., 2015).

Introduction

The necessity for aquaculture to sustainably feed the world's growing population with a healthy protein, in a responsible manner, is well accepted and understood in government and academic circles. The Portuguese offshore has particularities that have to be taken into account and technically resolved, namely with regard to the vigorous marine swell on the West Portuguese Atlantic coast. Significant technological advances are needed in order to develop sustainable technical solutions from a structural point of view, capable of providing the national aquaculture industry with oceanic cages that allow the establishment of a stable and competitive production base on a global level.

This work intends to contribute to this effort by providing a cage prototype that, after further improvements, is expected to boost the Portuguese aquaculture sector. Many different cage designs and models have been developed and a few are commercially available. Various parameters, like site location/exposure, mooring system, environmental conditions, affect the well-being of culture fish and farm performance. Nevertheless, geometry/shape, size, construction materials and proper design are critical for cage performance, especially on rough sea conditions. High-density polyethylene (HDPE) has been widely used because of its versatility, resistance and low cost. In this work, HDPE tube was also used as main structural material, covered by a nylon net for fish stabling, and a central tube aiming to control the up and down movement of the cage on the water column.

Materials & Methods

The effect of different forces on the performance of the developed cage was assessed by using models for dimensioning the cage considering two main types of forces: static forces as self-weight and hydrostatic pressure and hydrodynamic forces as drag, current and wave forces. Wind forces were not taken into consideration since the cage is submerged.[1,2] The sizing model considers its position relative to water level, up to 30 m depth. These models were developed according with DNV[3]. The dimensioning was performed on Abaqus software.

Cage structure was manufactured using HDPE tube (200 mm of diameter) connected to a central tube made of fiberglass (500 mm of diameter) that ensures the movement of descending and ascending the cage. HDPE tubes were assembled using a standard welding processes, forming a tubular structure that is connected by steel cables to the central fiberglass tube.

Results & Discussion

The cage concept (fig. 1) was designed and developed to meet challenges identified by aquaculture, such as autonomy, maintenance and robustness. The cage incorporates a up and down movement system that allows it to be placed safely, if rough wave conditions arise, for its structural resistance and for the healthy development of the fish. The cage is characterised by an external tubular structure where the net that allows the stabling of the fish is fixed and connected to a central tube. Details regarding geometry, materials and construction methodologies used are provided.

(Continued on next page)

The external tubular structure is circular in its water plane and rounded in depth, allowing greater efficiency in the space for fish to swim in circular patterns[4]. Other reason for this type of geometry was the better resistance to stresses when installed in different locations, as often occur at Peniche (wave height of 7 m and average period of 11 sec*: IPMA, 2018*). The structure was manufactured with HDPE tubes, a material with good energy absorption capacity that makes it interesting for applications subject to fatigue conditions.

The central tube is expected to accommodate different cage functional systems for autonomous operation, such as the automatic feeder, monitoring system, batteries and the up and down movement system of the cage. This component was designed in composite material to incorporate systems that require greater robustness.

Introduction
Insect protein is a sustainable alternative to animal and plant protein and has been introduced as a core ingredient in aquafeeds. In addition, insects have a good essential amino acid (EAA) profile and are rich in vitamins, minerals, and functional compounds such as chitin, antioxidant and antimicrobial peptides. The defatted *Tenebrio molitor* larvae meal (*d*TM) is a highly digestible protein, able to meet European seabass (*Dicentrarchus labrax*) EEA requirements (Basto et al., 2020). The aim of this work was to assess the effects of partial and total replacement of fish meal (FM) by *d*TM meal in seabass gut microbiota community structure, functionality and interactions.

Material and Methods
Juvenile European seabass (55 ± 2g) were distributed over 12 tanks and were fed with practical extruded diets formulated with 45% FM (CTRL) that was gradually replaced by *d*TM at 40% (TM40), 80% (TM80) and 100% (TM100). Fish were fed for 10 weeks and starved for 24 hours prior being sacrificed. Intestines from 5 fish per tank were collected under aseptic conditions, flash frozen in liquid nitrogen and subsequently processed for microbiota analysis. DNA was extracted from intestinal mucus with the DNeasy Blood & Tissue Kit (Qiagen GmbH, Hilden, Germany) following manufacturer's instructions, and the 16S rRNA gene was amplified and sequenced in a MiSeq Illumina platform. Raw data were processed for filtering and quality control with QIIME2, taxonomic assignment was performed, and alpha and beta diversity were calculated. The modulation of the functional profile of the microbiome was predicted with PICRUST2. Correlations between taxa was assessed by SparCC and networks were built to further understand taxa interactions.

Results and Discussion
Gut microbiota community richness (Chao1 index) and diversity (Shannon index) were not affected by the FM replacement by TM. In terms of beta diversity, diets had a limited effect on the communities' composition. European seabass gut communities were composed mainly by Proteobacteria, Actinobacteria, Bacteroidetes and Firmicutes. Genera *Flavobacterium*, *Acinetobacter* and *Micrococcus* were the most abundant, regardless dietary treatment. Interestingly, a random forest analysis indicated that the most relevant taxonomical groups belonged to genera *Pseudomonas*, *Flavobacterium*, *Acinetobacter*, *Burkholderia* and *Acidovorax*, and their abundances were modulated by *d*TM inclusion, but not in a dose dependent manner. As an example, *Flavobacterium* and *Acidovorax* increased abundance in TM40 and TM80, but these same genera were significantly reduced in TM100; whilst the abundance of *Acinetobacter* was reduced in TM40 but increased in TM80 and TM100.
Microbiome functional prediction showed some upregulated pathways in TM40 microbial community when compared with CTRL. Those were mostly related with energy production and peptidoglycan biosynthesis. On TM80 community very few pathways were putatively modulated. When comparing TM40 with TM100, a major downregulation in microbiome pathways related with energy production was observed.

Correlation analysis was performed to identify potential interactions between microorganisms that hold potentially commensal, mutualistic, or competitive relationships. The genus *Acidovorax* was highly correlated with several less abundant taxa with potential beneficial effects for the host, such as *Lactobacillus*, *Burkholderia*, among others. This was not observed in all diets, since in TM100 the *Acidovorax* correlation cluster included other taxa such as *Acinetobacter* and *Limnohabitans*. Previously, Basto et al. (2021) reported the effects of FM replacement by *d*TM in European seabass and demonstrated that up to 80% substitution no negative effect on fish performance were observed. Interestingly, microbiome overall analysis indicates no major changes up to 80% FM replacement, but the total replacement by *d*TM evidenced slightly different effects on microbial community composition and function.

(Continued on next page)

Conclusion

This study provides insights on the effects of defatted *T. molitor* larvae meal as main protein source in European seabass gut microbiota and brings light to taxa interactions and functional profiles that can explain the physiological output observed in fish.

Introduction

Seaweeds are an important source of nutrients and have been part of human nutrition worldwide. Their composition includes a large set of bioactive compounds that confer the algae antioxidant, immunostimulant, antibacterial and antiviral properties among others. In aquafeeds, algae inclusion as a main ingredient has been studied mainly as a fish meal replacement protein source, but more recently other properties have been highlighted pushing their usage as fish health boosters. The macroalgae *Gracilaria gracilis* has an interesting composition that includes biologically active phytochemicals and others that confer functional properties to be used in fish nutrition. Peixoto et al (2019) showed that a 5% inclusion of *Gracilaria* sp. biomass improved seabass resistance to a pathogen due to its immunostimulatory and antioxidant capacity. However, evidence have shown that algae can act as prebiotics, modulating gut microbial communities, stimulating the production of functional metabolites in the gut, and this might be one of the origins of the observed better physiological performances in fish.

The aim of this work was to evaluate the modulation of European seabass gut microbiota when fed with diets with *Gracilaria gracilis* biomass inclusion or its extract.

Material and Methods

Experimental diets were formulated to include seaweed dry powder at 2.5% and 5%, or 0.35% of the algae extract. The control diet was the base for all the diets, and these were provided to juvenile seabass (*Dicentrarchus labrax*) (17.49 ± 6.07 g; mean ± SD) *ad libitum* for 47 days.

By the end of the feeding trial, intestines were aseptically removed and a portion of anterior and another of posterior intestine were collected and stored at -80 °C until DNA extraction. DNA was extracted from the intestine mucosa and mucus and the V3 and V4 hypervariable region of the 16S rRNA gene was sequenced in a Miseq Illumina platform. Raw reads were processed in QIIME2, and as a first step, they were filtered for quality, merged and chimeras were removed with DADA2. Rarefaction was applied for alpha and beta diversity analysis. Taxonomical assignment of the obtained ASVs (amplicon sequence variant) was performed based on greengenes database and microbial community composition in both intestinal compartments of fish fed the four experimental diets was evaluated up to genus level (or species when available). Random forest analysis was performed to highlight the most important genera in the communities, and microbiome functionality was predicted with PICRUST2.

Results and Discussion

The community richness (Chao1 index) and diversity (Shannon index) were not altered by the diets, however, diets with algae biomass (both 2.5% and 5%) showed a tendency for higher richness and diversity. Both Weighted and Unweighted unifrac distances analysis indicated differences between anterior and posterior intestinal sections, however, the same analysis did not show differences in the microbial communities of each experimental group. The most abundant phyla were Proteobacteria, followed by Actinobacteria and Firmicutes, and in the anterior intestine groups fed with algae the last two phyla had higher abundance, whereas in posterior intestine abundances were more similar. Algae inclusion in diets significantly reduced the abundance of members of genus *Photobacterium* in both intestine sections, and inclusion of 2.5% algae biomass reduced the abundance of *Staphylococcus* genus' members.

(Continued on next page)

Based in a random forest analysis, the most important genera within the communities according to abundance shifts with diet were *Photobacterium*, *Staphylococcus*, *Acinetobacter*, *Micrococcus* and *Sphingomonas,* and their abundances were reduced when fish were fed diets with algae, but not always with algae extract.

Functional prediction of the intestinal microbiomes showed that in anterior intestine several pathways are modulated whereas in posterior modulation occurred in only few. These pathways were mainly related with metabolism and biosynthesis of protective compounds such as ectoine and were upregulated in fish fed diets supplemented with algae.

Conclusions

This study highlights that feeding fish with diets with *Gracilaria gracilis* biomass up to 5% did not change the gut microbial community structure. However, it produced an effect on specific taxa that might be related to disease states, and the reduction of abundance of these microorganisms in algae groups encourages to consider a possible association with reduced mortalities observed by Passos et al (2021), after a challenge with *Photobacterium damselae* subsp. *piscicida*. Despite the few changes in community composition, function of the microbiome was putatively modulated in a beneficial manner. This study brings light to the effects of algae as functional ingredient in fish gut microbiota and will serve as base for future studies.

Introduction

Algae, either micro- or macro-algae, are sustainable natural ingredients that have been used in human nutrition due to their rich composition in high valued nutrients such as proteins and long-chain polyunsaturated fatty acids (LC-PUFAs). More recently, they have been acknowledged for their potential as a nutraceutical resource due to their enriched composition in pigments, minerals, vitamins and other bioactive compounds. In early life stages, fish are immature in their responses to the environment and their health and development can easily be compromised. Microalgae have been used to promote larvae health in larviculture, however the study of their effects in feeds as a health promoter is recent. Peixoto et al (2021) showed the potential of microalgae as larvae robustness enhancer in Senegalese sole (*Solea senegalensis*), however, considering the contents of bioactive compounds in macroalgae, their synergetic application may be a cost-efficient strategy to potentiate algae as functional ingredient in aquaculture (Batista et al 2020). The aim of this study was to evaluate the immune response of *S. senegalensis* postlarvae when fed microdiets with algae blends (*Nannochloropsis* sp. and *Gracilaria gracilis*) included as functional ingredient to boost immunocompetence and overall performance.

Material and methods

Senegalese sole post-larvae were fed the CTRL diet, or the blend at 3% or 6% inclusion (BLEND3 and BLEND6 in equal proportions of micro- and macroalgae). The trial was conducted from 34 to 63 days after hatching (DAH) and molecular and physiological immune response was evaluated at 49 and 63 DAH (12 and 29 days of feeding). Growth performance and whole-body immune response were assessed, as well as the expression of a panel of genes related with immune response. Here, the modulation of the expression of hepcidine (*HAMP*), *complement C3*, g type lysozyme (*gLys*) the cytokines *IL1b* and *IL10* and the toll like receptors *TLR1* and *TRL5* was evaluated and integrated with the observed physiological output. Data analysis was performed at univariate level and data were further integrated in a canonical discriminant analysis to infer different performances. A follow-up trial was performed to evaluate the capacity of post-larvae to cope with a *Tenacibacullum maritimum* infection inflicted by bath exposure.

Results and Discussion

Overall growth performance was enhanced in fish fed diets with algae blends, mainly BLEND3. Lysozyme and peroxidase activity was higher in both blend groups but was more evident in BLEND6 group. Interestingly, molecular analysis revealed lower expression of *gLys* in fish fed the blends at 49DAH. Expression of *HAMP*, *IL10* and *TLR5* was modulated in BLEND6 at 63DAH, and were slightly higher than in BLEND3. Multivariate analysis showed that at 49DAH groups are not separated based on the evaluated parameters, however at 63DAH both groups with blend inclusion, BLEND3 and BLEND6 were significantly discriminated from CTRL group. When fish were challenged with *T. maritimum* fish responded with a 20% increase in survival when compared with CTRL group, validating that algae blends inclusion in post-larvae microdiets improve fish robustness and resistance to diseases.

(Continued on next page)

Conclusions

Micro- and macro-algae blends inclusion in microdiets have a great potential to promote health and resistance in Senegalese sole post-larvae. Algae blend is a sustainable ingredient and supports a cost-efficient strategy for larviculture since the inclusion of macroalgae mitigate the high production costs of microalgae and provides a more diverse bioactive compounds composition to the mixture. Here we observed that overall, the BLEND3 produced similar results than BLEND6 therefore the former is a more cost-effective inclusion rate.

ALGAE AS A NUTRACEUTICAL INGREDIENT IN AQUACULTURE: UNLEASHING THEIR POTENTIAL AS GUT HEALTH MODULATORS

Introduction

Fish health management in aquaculture is a fundamental axis for the sector's performance and sustainability. Fish are frequently exposed to aggressions inherent to the culture conditions jeopardizing their homeostasis reducing growth and defensive performance. The gut and associated microbiota comprise a pivotal organ with key role in digestion, nutrient acquisition, metabolism, immune defense and also endocrine and neuronal regulation that are highly responsive to environmental changes. These changes often result in higher epithelial permeability, inflammatory responses and dysbiosis associated with reduction of functionality. Thus, gut health management is crucial for fish health and nutraceutical strategies can be applied to support gut health and function.

Algae are one of the most abundant marine resources and their nutritional properties have made them highly valued ingredients for human and animal nutrition. In addition, their diverse composition in bioactive substances such as polysaccharides (e.g. fucoidans, alginic acid, ulvans), polyphenols (e.g. phlorotannins) and pigments (e.g. fucoxanthin, zeoxanthin) makes them targets for human medicine and cosmetics due to their anti-inflammatory, antioxidant, antimicrobial properties, and their ability to stimulate cell and tissue repair. In aquaculture their potential has been highlighted as alternative protein and fatty acids source, however their prebiotic and functional properties indicate a possible relevant application in fish nutraceuticals for gut health management and performance.

The aim of this study was to assess the potential of algae biomass as gut health promoters for gilthead seabream (*Sparus aurata*), using a gut explant model.

Material and methods

Gilthead seabream (210±10 g) were used to obtain the explants cultures. Intestines were dissected in aseptic conditions, separated in anterior and posterior sections, and were cut in small portions. These small sections were open to expose the lumen and were placed in plastic plates with lumen facing up. Medium was added to the wells and tissues were rested for a short period to acclimate. Several algae biomasses were tested, and these were the macroalgae *Gracilaria gracilis*, *Fucus* sp., and *Ulva* sp., and the microalgae *Nannochloropsis* sp., *Phaeodactylum tricornutum*, *Skeletonema* sp., *Isochrysis galbana* and *Tetraselmis* sp..

Algae were used in their commercial form in dried biomass, and their protective and therapeutic effects were tested in the explants by application of suspensions in culture medium. Gut explants were stimulated with a commercial lipopolysaccharide (LPS) to promote an inflammatory response, and algae protective effect was tested with previous incubation of the tissue with an algae suspension (6h), whereas the therapeutic potential included incubation of the tissue only after LPS exposure (2h). Explant's stability was assessed by measuring the lactate dehydrogenase activity in culture medium, and tissue response was assessed by measuring the expression of a panel of genes. These included genes related with inflammatory response (e.g. *IL1b*, *COX2*), adaptive immune response (e.g. *MHCI*, *mIgM*), epithelium integrity (e.g. *OCL*, *CLD*) and antioxidant response (e.g. *CAT*, *GPx*). Multivariate integrative statistical approach was used to discriminate and rank responses to infer the potential of the different biomasses.

(Continued on next page)

Results and Discussion

Seabream explants were responsive to commercial LPS, and after 6h an engaged inflammatory response was observed with alterations in tissue epithelial integrity at molecular level. When gut tissues were incubated with algae suspensions a modest immune modulation was observed with some species (mostly microalgae). The protective effect of algae was reflected in an overall attenuated response to the LPS exposure, although not always significant. Algae suspensions homogeneity are relevant for tissue stimulation, and especially in the case of macroalgae, the biomass fragments size variability might influence gut explant response. However, when applied as therapeutic strategy after inflammatory cascade was triggered, gut response was soothed indicating a potential regulatory action exerted by algae.

This model allows a fast screening and ranking algae potential as gut performance enhancers, reducing the number of animals used and still accounting for the complexity of the intestinal multiple cell/bacteria interactions and arrangements. Algae biomass have shown a strong potential as functional ingredients for fish gut health management, and it is relevant to further explore the optimization of their functional properties by, for instance, increasing the availability of their bioactive compounds with cell disruption or other cost-efficient methods.

GENOMIC IMPUTATION BETWEEN HIGH DENSITY AFFYMETRIX ARRAYS USING HISTORIC GENOMIC DATA FROM A COMMERCIAL NORTHAMERICAN ATLANTIC SALMON (*Salmo salar*) BREEDING PROGRAM

L. Gonzalez[1]*, J.A.K. Elliott[2], F. Powell[2], M. Herlin[1]

Email: lgonzalez@cookeaqua.com

Introduction
Since 2014, the Canadian company CookeAqua Inc. (CAI) has invested in the development of high-density genomic tools to increase the selection precision in its breeding program for the North American strain of Atlantic Salmon (*Salmo salar*). Over the past seven years, two 50K and 70K Affymetrix arrays (Thermofisher Scientific Inc.) were used to genotype broodstock candidates belonging to both the nucleus and multiplier families units. With the aim to unify and improve the quality of the company's historical genomic data, the present study explored the possibility of applying genotype imputation techniques.

Materials and Methods
Real historic genomic data from CAI breeding program was used for the present imputation study. The working dataset consisted of genotypes from a group of 332 animals analyzed on both NASsa50k and SsaCooke arrays.

A total of 66,204 SNP markers, with known physical positions on the North American Atlantic salmon reference genome (S. Lien, T.M. Knutsen and F. Grammes, personal communication,) were selected based on several quality parameters including minor allele frequency (MAF), observed heterozygosity, expected heterozygosity and Hardy Weinberg equilibrium test.

To test imputation accuracy, a range of reference sample sizes (i.e. proportion of animals with complete genotypes included in the input dataset) was considered. A total of ten replicate datasets were created and subsequently imputed for each reference sample size (ranging from 30% to 90%).

Genotype accuracy was evaluated using two indicators: 1/ the concordance rate (i.e. the percentage of imputed genotypes which are matching true genotypes) and 2/ the imputation quality score (IQS) -as defined by Lin et al. in 2010- which adjusts for "chance" agreement.

Missing genotypes were imputed using Beagle v5.2 software program (Browning et al., 2018).

Results
Genotype imputation results are presented below.

It was possible to impute, with high confidance (>80%), between 10,902 and 18,995 SNP markers for each animal. A greater precision was achieved when imputing SNP markers from the NASsa50K array. In addition, the results showed that, as the SNP MAF values increased, the IQS values tended to decrease. Finally, this study permitted to define a cost-effective protocol to apply genomic imputation in the context of a commercial Atlantic salmon breeding program. For both Affymetrix arrays used in CAI program, a good precision for the imputed haplotypes was obtained when the reference sample population size was equal to 75%.

INVESTIGATING THE IMPACT OF WATER TEMPERATURE ON SEXUAL MATURATION IN ATLANTIC SALMON POST-SMOLTS

Christopher Good[1*], Curtis Crouse[1], Travis May[1], John Davidson[1], Tom Ole Nilsen[2], Åsa Maria Espmark[3]

[1]The Conservation Fund Freshwater Institute, Shepherdstown, WV 25443, USA

Email: cgood@conservationfund.org

Introduction

The onset of sexual maturation in Atlantic salmon is a highly flexible process, with numerous environmental factors capable of influencing this process. Mature salmon are undesirable for aquaculture producers for several reasons, including the reduced value of the consequently downgraded product. Recirculating aquaculture systems (RAS) are increasingly being utilized to produce smolt, post-smolt, and even harvest-sized Atlantic salmon; however, RAS environments have been associated with increased prevalence of precocious maturation in Atlantic salmon populations. Among other things, it has been speculated that the relatively higher water temperatures of RAS could provide the necessary environmental cue to induce sexual maturation. We sought to investigate this area through two experiments, (i) assessing the prevalence of maturation in post-smolt salmon raised in replicated freshwater RAS at either 12 °C or 14 °C, and (ii) determining whether there is a size threshold at which post-smolts exposed to an increase in water temperature from 12 °C or 14 °C will exhibit increased levels of sexual maturation. This presentation will discuss the findings of these studies and their ramifications for RAS production of post-smolt Atlantic salmon.

Materials and methods

Study 1. Mixed-sex diploid Atlantic salmon (approximately 50 g in weight, 243 days post-hatch in age) were stocked into six replicated RAS, three operated at 12 °C and three at 14 °C; salmon were raised at these temperatures under controlled conditions until final sampling at 489 days post-hatch (mean weight 1,323 g), at which time all fish were assessed for maturation via typical external signs, and gonadosomatic indices. Study 2. Post-smolt Atlantic salmon raised at 12 °C were stocked into 12 replicated tanks in a flow-through system, with three random tanks receiving an elevation in temperature from 12 °C to 14 °C at time points corresponding to source population mean weight reaching 100 g, 150 g, 250 g, and 350 g. All salmon were subsequently raised to a mean weight of approximately 600 g, after which maturation was assessed via gonadosomatic indices.

Preliminary Results

At the time of abstract submission (July 2021), Study 1 data are still being analysed, while Study 2 is ongoing and scheduled to conclude in August 2021. All final results will be presented and discussed in depth at Aquaculture Europe 2021. Preliminary results from Study 1 suggest that maturation was significantly ($p<0.05$) reduced in RAS operated at 12 °C vs. 14 °C, although maturation was still relatively prevalent (approximately 20% of the population) in the 12 °C treatment group. External evaluations of typical maturation signs (kype, color, ovipositor, etc.) correctly predicted maturation status, as assessed through gonadosomatic indices, >94% of the time.

EXTRUSION PROCESSING OF FISH FEED PELLETS: INFLUENCE OF SILICA AND OIL CONTENT ON THE PRODUCT PROPERTIES

*Email: maria.graefenhahn@brabender.com

Over the last several decades, aquaculture has gained importance since wild capture can no longer meet the global demand for fish. Therefore, this market has grown exponentially, and with it, the demand for fish feed. In particular feed with high amounts of fat has gained relevance, since it allows for many species (e.g., salmon, trout) the most efficient growth and, thus, farming.

Extrusion processing is often used to produce fish feed pellets. Within the heated barrel containing rotating screws, the raw materials are mixed, heated, and sheared along the extruder. The combined thermal and mechanical stresses applied to the material lead to its plasticization and cooking. Due to the temperature and pressure gradients between the melt and the room conditions, the material can expand after it leaves the die and is pelletized through a rotating knife. Although addition of oil is desired, it has a negative influence on the cooking process during extrusion, as its lubricating properties reduce the specific thermal and mechanical energy input and, consequently, the degree of cook. In general, a lower degree of cook has a negative influence on the product quality of the feed pellets, i.e., decreased water stability and hardness. Therefore, to cook the material sufficiently and to achieve the aimed product properties, manufacturers avoid adding high oil levels during extrusion. Instead, manufacturers add oil in a separate coating step post-extrusion. This additional step makes the production of aquatic feed more complicated and expensive. Additionally, if fat does not bind properly to the pellets fat leakage can occur, whereby the fat drains out of the pellet, consequently, leading to increased fat oxidation. The addition of additives, especially silica, would resolve these issues while achieving high fat levels in high quality fish feed pellets without a coating step. Since the increase of fat leads to a decrease in the matrix viscosity, the mechanical energy input is expected to decrease leading to a lower degree of cook. As silica is known for its water- and oil-binding capacity as well as for its ability to control rheology and therefore to increase viscosity, its addition is expected to counteract this effect leading to an enhanced gelatinization during the extrusion process. This strategy will be introduced and the relationship between process conditions, addition of different oil and silica concentrations and resulting product properties (among others pellet hardness, pellet abrasion and fat content) will be evaluated.

THE EFFECTS OF OXYGEN SUPPLEMENTATION ON FARMED ATLANTIC SALMON (*Salmo salar)* BEHAVIOR USING ACOUSTIC TELEMETRY

J. Grant[a*], C. L. Stockwell[a], R. Filgueira[b]

[a] Department of Oceanography, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4R2

Introduction

The solubility of oxygen in seawater is dependent on pressure, salinity, and temperature, where warmer waters decrease the solubility of oxygen. Temperature and dissolved oxygen (DO) together play a crucial role in the growth and health of farmed fish (Elliott & Elliott, 2010). When DO falls below the optimal range (~6.0 mgL^{-1} at 15°C) fish stress and mortality levels increase. In the past few years, examples of mortality event have been documented worldwide, associated with hypoxic water events interacting with stress from factors such as disease (Galea *et al*., 2018; Evans, 2020). In order to counteract the negative effects of low DO on fish health, farms have initiated oxygen supplementation including pumping of oxygen nanobubbles via diffusers placed inside sea cages. The response of fish to changes in oxygen as well as the presence of bubblers was investigated on a commercial Atlantic salmon (*Salmo salar*) farm using acoustic tags to monitor 3D fish position.

Materials and Methods

The farm study site is located in St. Margarets Bay, Nova Scotia, Canada with 6 net pens measuring 48m diameter with maximum depth of 11 m and arranged in one column running southwest to northeast. Fifteen adult salmon (60-72 cm and 4.5 kg) were surgically implanted with VEMCO acoustic tags (model V9P-180). An acoustic array was installed consisting of 8 HR2 receivers at 2 and 7m depth, used to triangulate horizontal position of each fish. Tags were programmed to transmit resulting data on 3D position every 3 seconds.

An oxygen supplementation trial was conducted in autumn 2019, during which compressed oxygen was continuously supplied to all cages on site. The study cage was supplied with 4 ring-shaped diffusers placed at 7m depth. No control cage was available due to the risk of fish mortality during low DO months. Temperature and DO data were collected using AquaMeasure wireless sensors in cage center at 2m and 7m depth.

Three fish variables were calculated using positioning data: velocity [ms^{-1}], distance from cage center [m], and turning angle [°], and depth [m]. The study was split into two periods 1) during the oxygen trial (2 Oct 2019 – 7 Nov 2019) and 2) after the trial (8-25 Nov 2019).

Results

Temperature ranged from ~8-14°C during the study, with similar values between 2 and 7m depths during the entire time series. There was a gradual temperature decrease through the autumn, then declining more steeply at the water column overturn in early November. Oxygen was always slightly higher at 2m than 7m, fluctuating over a range of 7-8.3 mg l^{-1} until the end of October when it rapidly declined to a low of 6.0 mg l^{-1}. From that minimum, oxygen showed a continual increase throughout November to 9 mg l^{-1} during the fall overturn.

Swimming velocity of the tagged population averaged 0.72 ± 0.39 ms^{-1} with higher velocities during the day than at night. Fish depth showed a daily cycle with deeper values during day than at night. The tagged population averaged 14.5 ± 5.1 m from cage center swimming in a counterclockwise direction with an average turning angle of 53.2 ± 44.1°.

During the oxygen trial, all tagged individuals displayed a slower swimming speed, negatively related to water temperature (Fig. 1), contrary to literature. Furthermore, 77% of tagged individuals showed a change towards cage edge during the trial compared to after, with 85% of tagged fish displaying straighter turning angles during the trial. During the trial, 85% of the tagged fish swam significantly shallower than after the trial.

Climate change is triggering increased sea surface temperatures and decreased dissolved oxygen, leading to more sites requiring supplemental oxygen. Our work suggests behavioural changes associated with oxygen supplementation. However the implications of these changes for feeding, growth, and fish health are not yet clarified. Continuously developing farm sensing technology associated with intervention such as oxygenation provides further scope for management options leading to improved fish welfare and more sustainable aquaculture.

Introduction

Harvesting of microalgae biomass represents a major technological and economic challenge in the overall microalgae production process (Kumaran et al., 2021; Augustine et al., 2019). Since traditional harvesting methods, such as centrifugation and filtration, significantly contribute to production costs, developing alternative methods with low energy consumption is needed to improve the economic feasibility of microalgal biomass production on an industrial scale (Perez et al., 2017; Lama et al., 2016). One low-cost strategy for addressing this challenge involves using flocculation as the initial dewatering and concentrating step (Morales et al., 1985; Matter et al., 2019). Chitosan, a natural cationic polyelectrolytic biopolymer composed of linear poly-amino-saccharide chains, is considered less toxic, biodegradable, and relatively inexpensive (Matter et al., 2019). The present work evaluated the potential of chitosan as a flocculation agent for the flocculation of the marine microalga *Picochlorum* sp. The effect of flocculant concentration and culture pH on cell flocculation were investigated.

Materials and methods

All experiments were conducted with the 26-day old culture of marine microalgae *Picochlorum* sp., which was previously isolated from the Adriatic Sea. Chitosan solution was prepared by dissolving 5 g L^{-1} in 1% acetic acid. The initial pH of the culture was adjusted to 8.0 with 1 mM sodium hydroxide. Experiments were performed in 100 mL Erlenmeyer flasks with 100 mL of culture suspension at room temperature using a magnetic stirrer. First, the effect of chitosan concentration and pH of the culture on cell flocculation was studied. Further, the minimal concentration of chitosan for cell flocculation was determined at optimal pH. Experiments were conducted as follows: (1) chitosan was added to the culture and culture was mixed at 450 rpm for 10 minutes, (2) optional step, the pH value of the culture was set to a chosen value, (3) the culture was mixed for another 10 minutes at 250 rpm and (4) flocculated cells were allowed to settle down for 30 min (without mixing). The flocculation efficiency was determined by measuring the optical density of microalgal culture before chitosan addition and after settling the flocculated cell. The optical density of the culture was measured at 540 nm. All experiments were done in triplicates.

Results

Optimal conditions for flocculation of microalga was conducted in three steps. First, the effect of chitosan dosage on biomass recovery from culture suspension was examined by applying chitosan concentrations in the range from 5 to 80 mg L^{-1}. The flocculation efficiency of 98.15% was achieved at 25 mg L^{-1} of chitosan. An increase of chitosan concentration above 25 mg L^{-1} did not significantly increase flocculation efficiency, so this concentration was applied in the following experiments. Since chitosan was dissolved in 1% acetic acid, the addition of flocculant solution decreased the pH of the microalgal culture suspension. Therefore, the effect of pH on flocculation efficiency was further investigated in the pH range between 7.5 and 9. Flocculation efficiency of the culture increased with the increase of alkalinity of the culture suspension. At pH 8.0, a high flocculation efficiency of 97.46 % was obtained with the smallest alkali volume used for the pH adjustment. Finally, the minimum concentration of chitosan required for efficient flocculation was determined at pH 8.0 in the concentration range between 12 and 25 mg L^{-1} (12,15,17,20,22 mg L^{-1}) of chitosan. Low flocculation efficiencies were obtained at chitosan concentrations below 25 mg L^{-1}, ranging from 13,54% at 15 mg L^{-1} to 19,8% at 22 mg L^{-1}, confirming the previously selected chitosan concentration of 25 mg L^{-1} as the lowest chitosan concentration needed for achieving flocculation efficiency above 95 %.

Conclusion

High flocculation efficiency of 97.46 % was obtained at chitosan concentrations above 25 mg L^{-1} in the pH range 8.0-9.0. The optimal chitosan concentration for efficient flocculation of microalga was 25 mg L^{-1} at pH 8.0, with minimal volume of alkali used for the culture pH adjustment.

josecarlos.campos@um.es.

Introduction

The inflammatory process has widely been studied in mammals, but we know very little about this mechanism in fish (Esteban, 2012). Cantharidin, a toxic vesicant terpene secreted by male blister beetles of *Meloidae* and *Oedemeridae* families has been used to study inflammation in mice and humans due to its properties to produce irritations on the dermis, rashes, and bladders (Ivetic Tkalcevic *et al*., 2012). In addition, low doses of cantharidin have been used in both folk and traditional Chinese medicine due to its anticancer, antibiotic, antiviral, and immune-regulating properties (Whitman *et al*., 2019). The main aim of the present study was to assess the related-inflammatory effects of cantharidin on gilthead seabream head-kidney leucocytes.

Material and methods

Ten specimens (403.6g ± 16.5 g, 27.3 ± 0.3cm) of gilthead seabream (*Sparus aurata*) obtained from a local farm (Murcia, Spain), and maintained in the Marine Fish Facilities at the University of Murcia (Spain), were anesthetized with clove oil (20 mg L^{-1}, Guinama®) and bled from the caudal vein. Head-kidney was dissected out by a ventral incision and leucocyte suspensions were obtained by forcing fragments of the organ through a nylon mesh (mesh size 100 μm). The cells were washed twice (400 x g 10 min) in sRPMI culture medium (Gibco), counted (Z2 Coulter Particle Counter) and adjusted to $2x10^7$ cells mL^{-1} in sRPMI (Esteban *et al*, 1998). Then, leucocytes were incubated with cantharidin at final concentrations of 5, 1.25, and 0 μg mL^{-1} (DMSO diluted in sRPMI; Control) for 3, 6 and 12 h. After incubation, samples were divided: one-half was processed according to Reynolds (1963) to determine possible morphologic alterations by transmission electron microscopy, whilst the other-half was used to analyse the gene expression of NF-κB transcription factors (*c-rel*, *nf-κb1*, *rela*, *relb* and *nf-κb2*), and inflammatory-related genes (*il-1β*, *tnf-α il-6*, *il-10* and *tgf-β*) by using the $2^{-\Delta Ct}$ method with some modifications (Cordero *et al*., 2015). Results were expressed as mean ± standard error of the mean (SEM) and data were analysed by One-way ANOVA (followed by Tukey tests) to determine differences between experimental groups and each group respect to time, respectively. The level of significance used was $p < 0.05$ for all statistical tests.

Results and discussion

Ultrastructural results obtained in the head kidney leucocytes incubated with cantharidin varied depending on the cell type analysed. Apoptotic and necrotic acidophilic granulocytes were observed after their incubation with cantharidin at 3, 6 and 12 h. Besides this, at 12 h of incubation with cantharidin, macrophages changed their rounded general morphology to a more irregular one and exhibited a high cytoplasmic vacuolisation. However, the ultrastructure of the lymphocytes was not modified as consequence of the incubation with cantharidin.

Regarding the gene expression, *c-rel* was up-regulated in leucocytes incubated for 6 and 12 h with 1.25 and 5 μg mL^{-1} of cantharidin compared to control leucocytes. Contrarily, the gene expression of *nf-κb1* was down-regulated in a time and dose-dependent manner. Both, the proinflammatory cytokines *tnf-α* and *il-1β* were up-regulated in leucocytes incubated with 5 μg mL^{-1} of cantharidin at 3 h compared to control leucocytes and those incubated with 1.25 μg mL^{-1} of cantharidin also at 3 h. Besides, although *il-1β* gene expression was also up-regulated in leucocytes incubated for 6 h with 1.25 μg mL^{-1} of cantharidin in comparison leucocytes from the control group, but not in comparison to with these incubated with 5 μg mL^{-1} of cantharidin, the gene expression of this gene was down-regulated in leucocytes incubated for 12 h with 5 μg mL^{-1} of cantharidin, in comparison with control leucocytes.

Otherwise, not significant differences were detected in the gene expression of *rela*, *relb*, *nf-κb2, il-6, il-10* and *tgf-β* of leucocytes incubated with cantharidin. Therefore, it seems that cantharidin, as a selective inhibitor of serine/threonine protein phosphatases, is able to trigger the activation of proinflammatory genes in leucocytes of gilthead seabream incubated for few hours through the activation of NF-κB signalling pathway. On the contrary, prolonged exposures of leucocytes with cantharidin leads to death cell and morphological changes of some leucocyte populations (Huang *et al*., 2011; Zhou *et al*., 2018).

(Continued on next page)

Conclusion

Present results offer a new approach of the potential properties of cantharidin as inflammation trigger in gilthead seabream, as well as its possible therapeutical use due to the fact that incubation of cells with the substance for a long time produces apoptosis.

IN VITRO HEMOLYTIC, HEMAGGLUTINATING, CYTOTOXIC AND BACTERICIDAL EFFECTS OF λ-CARRAGEENIN

J.C. Campos-Sánchez, F.A. Guardiola, M.A. Esteban*

Immunobiology for Aquaculture Group, Department of Cell Biology and Histology. Faculty of Biology, Campus Regional de Excelencia Internacional "Campus Mare Nostrum", University of Murcia, 30100, Murcia (Spain)
josecarlos.campos@um.es.

Introduction

Biological activities of seaweed polysaccharides have attracted the attention of researchers due to their medical potential. Carrageenin is a mucopolysaccharide derived from the cell walls of red algae *Chondrus crispus* which has been used in a high-extended manner for decades as a model of acute inflammation in rats and rabbits (Winter *et al*., 1962). Nonetheless, although immunostimulant properties of carrageenin have been demonstrated in teleost fish, molecular and biological properties and its action mechanism has not been studied in fish (Silva *et al*., 2010). For this reason, the aim of the present study was to evaluate the possible haemolytic, hemagglutinating, cytotoxic and bactericidal, effects of λ-carrageenin.

Material and methods

In this study, ranging concentrations from 0, 0.1, 1, 10, 100 to 1000 μg mL^{-1} of λ-carrageenin were used in all the techniques carried out. Thus, erythrocytes from gilthead seabream (*Sparus aurata*) (284,53g ± 17,21g, 26,02cm ± 0,39) obtained from a local farm (Murcia, Spain), and maintained in the Marine Fish Facilities at the University of Murcia (Spain) were isolated according to Morcillo *et al*. (2016). The hemolysis of erythrocytes after incubation with λ-carrageenin in phosphate-buffered saline (PBS, containing 0.35 % sodium chloride) with 10 mM glucose was determined by the correlation of the cell viability and the liberation of the oxyhaemoglobin to the medium at 3 and 6 h (Morcillo *et al*., 2016). Hemagglutination of erythrocytes was visualized in a 96-well microtiter plate after 6 h of incubation with λ-carrageenin at room temperature (Li et al., 2008). Otherwise, λ-carrageenin in Eagle's Minimum Essential Medium (EMEM) were used to evaluate their cytotoxic activity at 3 and 6 h in the cell line PLHC1 (ATCC® CRL2406™), hepatocellular carcinoma from *Poeciliopsis lucida,* by using the MTT assay (Berridge *et al*., 1993; Denizot *et al*., 1986). Besides, four opportunist marine pathogenic bacteria (*Vibrio harveyi, Vibrio anguillarum, Photobacterium damselae,* and *Tenacibaculum maritimum*) were used to determine the bactericidal activity of λ-carrageenin in PBS (Stevens *et al*., 1991). The results were expressed as mean ± standard error of the mean (SEM) and data were analysed by One-way ANOVA (followed by Tukey tests) to determine differences between experimental groups. The level of significance used was $p < 0.05$ for all statistical tests.

Results and discussion

Results showed an increase in the haemolytic activity of erythrocytes at both 3 and 6 h after incubation with 1000 μg mL^{-1} of λ-carrageenin in comparison to control. The increases were also statistically significant in erythrocytes incubated with 100 μg mL^{-1} of λ-carrageenin at 6 h. In addition, λ-carrageenin showed hemagglutinating activity only at doses of 1000 μg mL^{-1} in comparison to the rest of the concentrations tested. Regarding the cytotoxic assay with the PLHC1 cell line, it was detected an increase of this activity only at 6 h of incubation with all assayed doses of λ-carrageenin in comparison to control. This activity was statistically higher with the highest concentration of λ-carrageenin (1000 μg mL^{-1}). On the other hand, only a dose-dependent increase of the bactericidal activity against *Photobacterium damselae* was found when the bacteria were incubated with the two highest doses of the polysaccharide (100 and 1000 μg mL^{-1}) in comparison to lower doses of λ-carrageenin. Therefore, a high concentration of λ-carrageenin seems to have hemolytic, hemagglutinating, cytotoxic and bactericidal, biological properties that could be derived from its high molecular weight and sulphate concentration, as well as other seaweed polysaccharides (Silva *et al*., 2010).

Conclusion

The present results offer a different approach of the effect of λ-carrageenin in fish, being able to extend its use not only as a model to reproduce inflammation, but also for therapeutical purposes in the aquaculture sector due to the properties here demonstrated.

IN VITRO EFFECTS OF *Chiliadenus glutinosus* (L.) FOURR. AQUEOUS EXTRACT IN HEAD-KIDNEY LEUCOCYTES OF GILTHEAD SEABREAM (*Sparus aurata* L.)

J.C. Campos-Sánchez, F.A. Guardiola, M.A. Esteban*

Immunobiology for Aquaculture Group, Department of Cell Biology and Histology. Faculty of Biology, Campus Regional de Excelencia Internacional "Campus Mare Nostrum", University of Murcia, 30100, Murcia (Spain) josecarlos.campos@um.es.

Introduction

Nowadays, the use of extract from medicinal plants for control of fish diseases in aquaculture is a plausible alternative to drugs, antibiotics and chemicals due to their, immunostimulant and bactericidal properties (Van Hai, 2015). In this sense, *Chiliadenus glutinosus* (L.) Fourr. is an endemic species of plant used in the Spanish popular medicine as remedy to prevent and treat human diseases and to date, it has poorly been studied in fish (Las Heras Etayo *et al*., 2021). Thus, the aim of the present study was to evaluate the immunobiological effects of aqueous extracts of *C. glutinosus* on head-kidney leucocytes of gilthead seabream.

Material and methods

Six specimens (128.49g ± 3.84g, 18.11cm ± 0.25cm) of gilthead seabream (*Sparus aurata*) obtained from a local farm (Murcia, Spain), and maintained in the Marine Fish Facilities at the University of Murcia (Spain), were anesthetized with clove oil (20 mg L^{-1}, Guinama®) and bled from the caudal vein. Head-kidney was dissected out by a ventral incision and leucocytes' suspensions were obtained by forcing fragments of the organ through a nylon mesh (mesh size 100 μm) and washed twice (400 x g 10 min) in sRPMI culture medium (Gibco). Leucocytes were counted (Z2 Coulter Particle Counter) and adjusted to $2x10^7$ cells mL^{-1} in sRPMI (Esteban, 1998). Then, leucocytes were incubated with ranging concentrations from 0 (PBS diluted in sRPMI; Control) to 1 mg mL^{-1} of an aqueous extract of *C. glutinosus* for 24h. After incubation, the following parameters were analysed: viability, respiratory burst, peroxidase and phagocytic activities. The results were expressed as mean ± standard error of the mean (SEM) and data were analysed by One-way ANOVA (followed by Tukey tests) to determine differences between experimental groups and each group respect to time, respectively. The level of significance used was $p < 0.05$ for all statistical tests.

Results and discussion

Results obtained in the head kidney leucocytes showed a decrease in the viability and peroxidase activity of leucocytes incubated with 1 mg mL^{-1} of aqueous extract in comparison with leucocytes incubated with the rest of concentrations, although in the case of the peroxidase this difference was only significant compared with the doses of 0, 0.001 and 0.1 mg mL^{-1}. Respiratory burst activity was decreased in leucocytes incubated with 1 and 0.5 mg mL^{-1} of aqueous extract compared to those incubated with 0, 0.001 and 0.1 mg mL^{-1}. Otherwise, phagocytic capacity was decreased in leucocytes incubated with 0.125 mg mL^{-1} of aqueous extract in comparison with leucocytes incubated with lower doses. In addition, this capacity was decreased to a greater extent in leucocytes incubated with 1 mg mL^{-1} of aqueous extract compared to leucocytes incubated with 0.125 mg mL^{-1}. Phytochemical composition of aqueous extracts (polyphenolic compounds majorly, and terpenes) seems to be responsible for affecting the immune activities of head kidney leucocytes of gilthead seabream by modulating their redox metabolism (Amorati and Valgimigli, 2018; Rodríguez, 2003).

Conclusion

The present results offer a detailed view of the potential immunosuppressive effects of *C. glutinosus* due to soluble bioactive molecules present on this medicinal plant, from which therapeutic uses could be developed in fish of commercial interest.

EXPRESSION OF IMMUNE-RELATED GENES IN EUROPEAN EEL (*Anguilla anguilla*) AFTER BACTERIAL CHALLENGES

S. Vicente[1], A. Sridhar[2], J. Mayor-Lafuente[1], M. Cámara-Ruiz[1], M.A. Esteban[1], F.A. Guardiola[1]*

[1]Immunobiology for Aquaculture Group, Department of Cell Biology and Histology. Faculty of Biology, Campus Regional de Excelencia Internacional "Campus Mare Nostrum", University of Murcia, 30100, Murcia (Spain) *Email: faguardiola@um.es

[2]Laboratory of Aquabiotics/Nanoscience, Department of Animal Science, School of Life Sciences, Bharathidasan University, Tiruchirappalli - 620 024, Tamil Nadu, India

Introduction

In the recent decades, the great expansion of all aquaculture types has contributed to emphasizing studies on the immune system and defence mechanism of fish against diseases associated with intensive farming. In European eel (*Anguilla anguilla*), some of those diseases are caused by viruses (*e.g.*, Alloherpesvirus-1 and *Herpesvirus anguillae*), nematodes as *Anguillicoides crassus* or some genus of bacteria as *Vibrio*, *Aeromonas* or *Tenacibaculum* which can infect in all life cycle stages (Chang *et al*., 2002). However, little is known about eel's immune system and its defense mechanisms against pathogenic microorganisms. Therefore, understanding them would be important to prevent and control infections (Raida & Buchmann, 2008), providing the possibility to develop various prophylactic and therapeutic methods trying to improve the critical situation of their populations. Taking these considerations, the aim of this study was to investigate the expression of several immune-related genes in head-kidney (HK), skin and gills of European eel bath challenged with *V. anguillarum* and *V. vulnificus* after 72 h post challenge.

Material y methods

Forty eight adults specimens (110.08 ± 18.65 g weight and 39.58 ± 2.19 cm length) of European eel obtained from commercial fish market (*Comunidad de Pescadores del Palmar*, El Palmar, Valencia, Spain), and maintained in the Marine Fish Facilities at the University of Murcia (Spain) were randomly distributed into three experimental groups by duplicate [6 tanks of 50 L filled with 20 L of water, 4 fish per tank, 8 fish per group] where the following groups were established: 1) Unchallenged (control group, immersion with sterile distilled water instead of bacteria); 2) Bath challenged with *V. anguillarum* (immersion with a sub-lethal bacteria concentration of 3.0×10^8 CFU L^{-1}); 3) Challenged with *V. vulnificus* (immersion with a sub-lethal bacteria concentration of 3.0×10^8 CFU L^{-1}). For the challenges, fish were exposed separately in other tanks (6 tanks of 50 L filled with 20 L of water) for 60 min with strong aeration and returned to their respective tanks. After 72 h, fish were sacrificed by using an overdose of MS-222 (Sandoz, 1,000 mg L^{-1} water), dissected and fragments of HK, skin and gills were collected and used to analyse the expression of several immune-related genes (*c3*, *c1*, *tnfα*, *il-1β*, *il-10*, *irf7*, *irf3*, *lysc*, *tlr2*, *mhc2*, *igm* and *cd3*) by real-time qPCR. The results were expressed as mean ± standard error of the mean (SEM). Data were analysed by One-way ANOVA (followed by Tukey tests) to determine differences between experimental groups. The level of significance used was $p < 0.05$ for all statistical analysis.

Results and discussion

The expression of the immune-related genes measured in HK did not show any variations between unchallenged and challenged fish. In the case of skin, the expression of *igm*, *mhc2* and *il-1β* genes was up-regulated in fish challenged with *V. vulnificus* compared to unchallenged ones. In addition, our results showed a higher relative expression of *igm* and *mhc2* genes in fish challenged with *V. vulnificus* in comparison with the fish challenged with *V. anguillarum*. Contrarily, no significant variations were detected in the expression of *c3*, *c1*, *irf7*, *irf3* and *lysc* genes, although in the case of *lysc* gene a downward trend was observed from the highest value at unchallenged fish to lowest value at those fish challenged with *V. vulnificus*. The expression of *cd3*, *tlr2*, *tnfa* and *il-10* genes in skin was undetected in none of experimental groups. In gills, the expression of *igm* and *irf7* genes was up-regulated in challenged fish with *V. vulnificus* regarding unchallenged group. In the case of *mhc2* gene, the relative expression was up-regulated in fish challenged with *V. anguillarum* compared to unchallenged fish whilst not variations were found between challenged groups. Nevertheless, the expression of the other studied genes was not affected by challenge trial and the expression of *tnfα* gene was not detected. Interestingly, the expression of *cd3* gene was only detected in the gills although no variations were observed between experimental groups. As the principal lymphoid organ, HK is responsible for the cellular response and secretion of cytokines to the infection site as first steps of immune response (Olabuenaga, 2006). The no variations in the expression of immune-related genes in this organ may be due to early sampling time (72 h) because of the modulation of immune response has not been carried out. Contrarily, the up-regulation of some immune-related genes in skin (*igm*, *il-1β, mhc2*) and gills (*irf7*, *igm*, *mhc2*)

(Continued on next page)

after a bath challenge with *V. vulnificus* and *V. anguillarum* could be related with the important role of MALTs (Mucosal-Associated Lymphoid Tissue) as physical, biological, and chemical barrier against pathogens (Esteban, 2012) and the role of *il-1β* as the leader of the pro-inflammatory response (Adamek *et al*., 2013; Cecchini *et al*., 2013).

Conclusion

The presents results offer a new molecular view to enlarge the knowledge of the immune system of European eel in response to bath-challenge trial against two common pathogenic bacteria for this species, broadening the horizons of the knowledge on the first steps of the immune response against these pathogens. In fact, the information provided by this study could optimize culture conditions and disease preventions protocols.

Introduction

Fish skeleton is a highly conserved organ system which provide support and protection of soft parts of the body, maintaining the movement by muscles attachment and acting as mineral reserve (Witten et al., 2017). Bone tissue takes part in the regulation of calcium-phosphate metabolism since it is the major mineral storage organ in the vertebrate body. Unlike terrestrial vertebrates, fish can absorb minerals from surrounding water across the skin, oral and branchial epithelium, as consequence stressors related to water and ion homeostasis, such as starvation, have greater physiological impact on fish (Leatherland and Woo, 2010; Suarez-Bregua et al., 2018). Many fish species are exposed to starvation or restricted food intake in particular phases of their life cycles and during this period, they have to direct energy reserves from growth to the support of vital processes, which triggers metabolic changes in many tissues including bones (Suarez-Bregua et al., 2018). Therefore, this study attempts to explore the effects of starvation in the skeleton of gilthead seabream (*Sparus aurata*) subjected to 60 days fasting.

Material and Methods

Ten juvenile specimens (5 months old) of gilthead seabream (*S. aurata*) (26 ± 3 g and 12 ± 2 cm) were obtained from a local fish farm (Murcia, Spain) and kept in re-circulating seawater aquaria (250 L). Fish were allowed to acclimatize for 4 weeks in the Marine Fish Facility at the University of Murcia and were fed a commercial diet (Skretting, Spain) based on fish meal (21%). The temperature and salinity of the water were 22 ± 2°C and 28‰, respectively. The artificial photoperiod was of 12 hour (h) light: 12 h dark. Fish specimens were randomly assigned into two groups (n = 5 each) to be studied under two different conditions (fed and starved). The control group (fed fish) was fed with commercial pellets (Skretting) at a rate of 1.5% body weight day-1 and the last group was starved, both groups were kept in these conditions for 60 days. Image analysis and measurements were performed using the Carestream Molecular Imaging Albira CT system in conjunction with Pmod and Amide packages. Boxes ROIs were drawn within the density range previously determined for fish bone (from 200 Hounsfield Units) in Amide software.

Results and discussion

At 60 days, the fed group gained in body weight [26.385 ± 1.950 (Mean ± SD) to 53 ± 6.931 g] and size (12.566 ± 0.625 to 16 ± 1.00 cm) while at 60 days starved group decreased in weight and size 19.66 ± 2.200 g and 12.416 ± 1.625 cm respectively. Intensive farming of certain commercial fish species uses starvation to control several parameters that can affect health quality and produce economic losses (Caruso et al., 2011). One of the proven effects of starvation on fish body is cessation of growth (Sakyi et al., 2020). Furthermore, when we visually analyse the CT image of the skeleton of fed fish at 60 days, the structure appears normal. However, in the image of the skeleton of the starved gilthead seabream some morphological differences were notice, the abdominal region seems compressed, the orbit wider and deeper. In this sense, deficiencies of minerals, vitamins and phospholipids that can be acquired through diet have been reported to cause skeletal disorders in fish species like Atlantic salmon (*Salmo salar*), common carp (*Cyprinus carpio*), haddock (*Melanogrammus aeglefinus*) or halibut (*Hippoglossus hippoglossus*) (reviewed by Leatherland and Woo, 2010). Moreover, the skeleton of the starved fish is observed radiologically denser and small gaps are visible in the vertebrae. During migration of Atlantic salmon from estuaries to spawning areas, the compacity of bony tissues significantly decreases owing to osteoclastic resorption, resulting in significant reduction of vertebral bone mass (Kacem et al., 1998). Moreover, scales, another part of the skeleton, demineralize during the up-stream migration where maturing Atlantic salmon stop feeding (Kacem and Gustafsson, 2000).

Conclusion

This study demonstrates that starvation affects not only muscle mass and fat but also bone structure and bone density. Computed tomography have probe to be a useful tool to explore aquaculture specimens under different conditions, allowing qualitative and quantitative information of bone structure in a non-destructive way.

Introduction

Jellyfish have been commonly considered a nuisance for human activities. However, some species bear potentials for food, cosmetic, pharmaceutical and biotechnology fields. *Catostylus tagi*, a jellyfish common in the western Atlantic and Portuguese coasts, holds several biochemical properties along to be edible for human consumption (Raposo *et al*., 2018; Amaral *et al*., 2018). Its collagen and antioxidant properties showed a potential new bio-resource for the cosmetics and food sector (Calejo *et al*., 2009; Morais *et al*., 2009). While local *C. tagi* fisheries might respond to the needs of the various sectors, the ability to control its life cycle and biomass production might be the key for future sustainability in this rising new product.

Materials and methods

Catostylus tagi specimens were samples and *in vitro* fertilisation performed in different temperature, salinity and light conditions. Once the planula obtained, different trials were performed investigating the optimum conditions (temperature, salinity and food type) for planula survival and settlement, polyps development, and asexual reproduction (podocyst, strobilation and ephyra production). The life cycle of the species was also documented from the planula to the juvenile stage.

Results

Catostylus tagi displays the typical Rhizostomida metagenetic life cycle. The results showed a high tolerance of the different life stage to the wide range of salinities and temperatures. The planula settlement was significant influenced by temperature ($P < 0.001$) and salinity ($P < 0.01$), but no interaction was detected ($P = 0.31$). Polyp development was enhanced at higher temperature with an optimum of 25 °C and all salinities. Among the asexual reproduction, only the strobilation processes were significantly influenced by temperature and food type ($P < 0.01$) (Figure 1).

Discussion and conclusion

C. tagi displays a typical meta-genetic life cycle observed in Rhizostomatidae: a benthic scyphistoma phase that reproduces asexually via strobilation releases ephyrae that grow into a pelagic medusa, which reproduce sexually. The trials showed *C. tagi* high tolerance to a wide range of salinities and temperature. This plasticity reflects the species adaptation to estuaries conditions known for their highly dynamic environments, subject to rapid changes in the *in situ* conditions associated with varying freshwater flows.

While *C. tagi* appears as an euryhaline and eurytherm species, each stage (planula, polyps) and process (planula settlement, polyps development and strobilation, ephyrae production) responded distinctively to the different conditions. While the specifications of each stage need to be fulfilled to reach optimum production, the environmental plasticity makes *C. tagi*, among other jellyfish species, a good candidate for aquaculture

Introduction

Metamorphosis is a fascinating process by which a larva completely changes its morphology in order to face the new challenges of adult life. In fish, including paradigmatic species with commercial value such as flatfish, this process initiated in the brain has traditionally been considered to be a critical rearing point and despite the pioneering molecular work carried out on the metamorphosis of the Japanese flounder, Atlantic Halibut and Sole the underlying molecular basis of flatfish metamorphosis is still relatively poorly characterized. In this study we performed a brain transcriptome profiling of three key stages of turbot metamorphic remodeling process (pre-metamorphic, climax of metamorphosis and post-metamorphic) using RNA sequencing (RNA-seq). A total of 1,570 genes were differentially expressed in the three developmental stages and we found a specific pattern of gene expression at each stage. Unexpectedly, at the climax stage of metamorphosis we found highly expressed genes related to the immune response, while biological pathway enrichment analysis in pre-metamorphic and post-metamorphic were related with cell differentiation and oxygen carrier activity, respectively. In addition, our results confirm the importance of TSH, increasing its expression during metamorphosis. Based in our results we assume that inflammation events during climax of metamorphosis stage could be related to processes of larval tissue resorption and replacement as occurs in other vertebrates.

Material y métodos

Newborn turbots (*Scophthalmus maximus*) were reared under a standard commercial production cycle and supplied by the company Insuiña SL, Grupo Nueva Pescanova (Pontevedra, Spain). Brains of the three key developmental stages in turbot (Al-Maghazachi and Gibson 1984) were extracted: pre-metamorphic (15dpf), climax of metamorphosis (30dpf) and post-metamorphic (57dpf). Fish brains were dissected and fixed in RNAlater (Thermo Fisher Scientific) for 24 hours at 4 °C and preserved at -80 °C until use. Brain samples were removed from RNAlater solution and homogenized in RLT buffer (RNeasy Mini Kit (Qiagen). Total RNA was extracted and purified using the RNeasy Mini Kit (Qiagen) with on-column DNase digestion (Qiagen) according to the manufacturer´s instructions. Approximately 1 μg of total RNA was initially used for BGISEQ-500 standard library construction at BGI (Beijing Genomics Institute, China). Prepared cDNA libraries were sequenced on a BGISEQ-500 platform and single-end reads of 50 base pairs (bp) length were generated per sample. A differential expression analysis and clustering was performed between the different stages to find genes involved in each stage of interest. In addition, an enrichment of the gene ontology (GO) was carried out to know the biological processes in which the genes are involved. The results of RNA-seq were confirmed by quantitative real-time polymerase chain reaction of five genes of different pathways.

Results and discussion

We sequenced the brain transcriptome in three key developmental stages across turbot metamorphosis (pre-metamorphic, climax and post-metamorphic stages). Nine cDNA libraries (three replicates per each metamorphic stage) were sequenced and more than 180 million 50 bp single-end reads were generated. After filtering the reads were mapped to the turbot reference genome obtaining average mapping rates of 88.98%, 88.78% and 89.23% for pre-metamorphic, climax and post-metamorphic stages, respectively. To identify DEGs in the turbot brain during metamorphosis, we performed pairwise comparisons among three postembryonic developmental stages. A total of 1,570 genes were differentially expressed in the three metamorphic developmental stages. A high proportion of DEGs were found when pre-metamorphic vs climax stages (338 up and 221 down-regulated) and pre-metamorphic vs post-metamorphic stages (415 up and 487 down-regulated) were compared (Fig.1).

(Continued on next page)

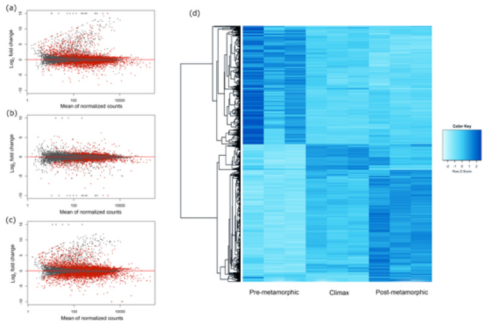

Figure 1. MA plot of all transcriptome genes from pairwise comparisons: (a) pre-metamorphic vs climax, (b) climax vs post-metamorphic and (c) pre-metamorphic vs post-metamorphic. The red dots plotted represent genes with an adjusted *p*-value < 0.1, while gray dots are those genes that do not show the established significance. (d) Heatmap displaying the genes hierarchically clustered according to the expression profiles throughout metamorphosis. Each column represents an individual triplicate from each metamorphic stage (pre-metamorphic, climax and post-metamorphic) and each row represents different genes. The colors from light blue to dark blue indicate gene expression from low to high, respectively.

However, a significantly lower number of DEGs (33 up and 76 down-regulated) were found after comparison between climax and post-metamorphic stages (Figure1). All DEGs from the three developmental stages were combined into a single set and hierarchically clustered within a heatmap in order to have an overview of the gene expression profiles across metamorphosis (Figure 1). In the heatmap, DEGs were clustered according to gene expression level. Overall, we can observe two major clusters. Most genes clustered on the top half of heatmap displayed an expression decrease throughout the metamorphosis process (Figure 1) while groups of genes on the bottom half showed an increased expression over time. Specifically, a set of tightly clustered DEGs showed a marked expression peak at the metamorphic climax while they exhibited a down-regulated gene expression at the pre- and post-metamorphic stages (Figure 1). In summary, our results show for the first time, a significant activation of the innate immune system during the metamorphosis process in flatfish, thus corroborating that metamorphosis is a time of dramatic changes in development that affects the entire organism.

Introduction

For several years, feed manufacturers are searching for new sources of proteins in order to respond to the growth of the sector and the challenges of sustainable development. At the same time, more than 30% of the world agricultural production is wasted (unsold or expired products, by-products of agri-food industries). Recommended by the Food and Agriculture Organization of the United Nations (FAO), insects make it possible to valorize food waste (bioconversion). The black soldier fly (*Hermetia illucens*) represents a particularly adapted resource to feed fish or shrimps because it is natural, safe, sustainably produced and has a good nutritional quality.

The objective of the study carried out in the facilities of IMAQUA (Merelbeke, Belgium) between March 2020 and April 2020 is to evaluate the zootechnical performances of juvenile shrimps (*Penaeus vannamei*) when a part of fishmeal is replaced by a partially defatted black soldier fly (BSF) meal at different inclusion levels in comparison to a conventional feed (CTRL).

Materials and methods

A BSF meal, produced by a French company (MUTATEC), is incorporated in pelleted feeds at different inclusion rates (6.4; 12.7 and 19.1%), as replacement material for fishmeal (respectively 33; 66 and 100% of replacement). These feeds have been used to feed 600 Pacific white shrimps from 0.24 grams to 2.74 grams (28 days of trial). The shrimps were divided per group and in triplicates (50 shrimps per tank). The feed distribution was done automatically 6 times a day. The groups of shrimps received the respective diets at the predetermined percentages of their initial mean body weight and expected daily growth. This was adjusted daily according to the expected growth, observed mortality and feed consumption per group.

Results

All results were positive. Although not significant, an increased final weight (and related weight gain) was observed in all treatments where fishmeal was replaced with insect meal. The feed conversion ratios were also better for the shrimps fed with insect meal than the CTRL group shrimps. The optimal inclusion level was 12.7% (66% of fishmeal replacement), the specific growth rate was significantly better than the CTRL for this group of shrimps. An increase in average final weight up till 16.8% for this group could be observed after 28 days of feeding. At the end of a complete culture period this would result in a substantial increase in productivity. Also, survival was slightly higher in all dietary treatments compared with the CTRL.

Conclusion

These results suggest a positive impact on growth performance in shrimp. It therefore seems possible to replace a significant portion (up to 100%) of fishmeal by BSF meal.

Other studies that used insect meal as fishmeal replacement in shrimp feeds observed the same type of results with a high palatability among diets containing BSF meal (Cummins *et al.,* 2017) and no effects on colour and firmness of the shrimp fed with different proportion of mealworm meal (Panini *et al.,* 2017b).

As BSF meal contains some antimicrobial peptides, some health effects are expected. This trial ended with a bacterial challenge which showed promising results that will be presented later.

Introduction

For several years, feed manufacturers are searching for new sources of proteins in order to respond to the growth of the sector and the challenges of sustainable development. At the same time, more than 30% of the world agricultural production is wasted (unsold or expired products, by-products of agri-food industries). Recommended by the Food and Agriculture Organization of the United Nations (FAO), insects make it possible to valorize food waste (bioconversion). The black soldier fly (*Hermetia illucens*) represents a particularly adapted resource to feed fish or shrimps because it is natural, safe, sustainably produced and has a good nutritional quality.

The objective of the study carried out between December 2018 and May 2019 is to evaluate the zootechnical performances of juvenile trouts when a part of fishmeal is replaced by a partially defatted black soldier fly (BSF) meal at different inclusion levels in comparison to a conventional feed (CTRL) and a feed containing another insect, the mealworm (TM).

Materials and methods

A BSF meal, produced by a French company (MUTATEC), is incorporated in extruded feeds of different sizes (1.2 mm; 2 mm) and at different inclusion rates (5 to 25%), as replacement material for fishmeal. These feeds have been used to feed rainbow trout (Oncorhynchus mykiss) from 7 grams to 65 grams (86 days of trial).

Results

All results were positive. After 31 days of trial, fish fed with BSF meal show significantly better growth performances than the CTRL group fish. Trouts fed with feeds containing BSF meal showed faster growth and better feed conversion ratios than the CTRL group fish, which indicates an efficient assimilation of the feed. After 64 days of trial, growth results and feed conversion ratios of all BSF groups remain better (non-significant). At equivalent fishmeal replacement rate, results with BSF meal are superior (+7% mean body weight) than results with TM meal (non-significant). Also, survival was high and similar between treatments.

Conclusion

These results suggest a positive impact of BSF meal incorporation on growth performance in trouts. It therefore seems possible to replace a significant portion (up to 60%) of the fishmeal by BSF meal.

Other trials in experimental stations and in fish farms showed that the replacement of a part of the fishmeal by a partially defatted BSF meal improves the growth performance of the rainbow trout during the growing period (120g-350g).

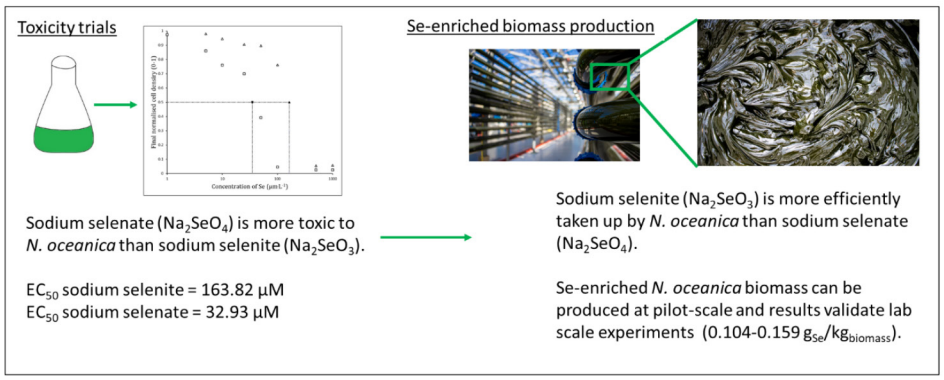
Se-enriched ingredients have recently gained interest in the aquaculture industry as feed supplements due to their positive effects on fish health, growth, and potential effects on animal welfare. This study aims to assess which inorganic selenium (Se) species is suitable to produce Se-enriched *Nannochloropsis oceanica* (*N. oceanica*) biomass for aquafeed applications. The effective concentration for 50% growth inhibition (EC_{50}) and Se bioaccumulation of the two inorganic forms of Se, sodium selenite (Na_2SeO_3) and sodium selenate (Na_2SeO_4), were assessed at different concentrations after twelve days of cultivation. Toxicity results showed that selenate, EC_{50} = 32.93 µM, had a greater negative effect on cell growth than selenite, EC_{50} = 163.82 µM. Total intracellular Se was analysed by inductively coupled plasma - optical emission spectrometry (ICP-OES) and high resolution inductively coupled plasma mass spectrometry (HR-ICP-MS), which revealed that selenite was better accumulated by *N. oceanica*. Further investigation at 30 µM of selenite in the growth medium resulted in Se bioaccumulation with a minor effect on cell growth and reached a Se intracellular content of 0.131 $g_{Se}/kg_{biomass}$ after 12 days. Thus, 30 µM of selenite was selected for batch pilot-scale cultivation in a 1500 L tubular photobioreactor. Total Se accumulated in the biomass at pilot-scale was in the same order of magnitude compared with flasks (0.104 - 0.159 $g_{Se}/kg_{biomass}$). The results from this pilot-scale study are fundamental for a proof of concept laboratory to pilot-scale production and are a critical bridging step for the potential use of Se-enriched *N. oceanica* for aquafeed.



DEVELOPMENT OF GENOMIC MARKERS ASSOCIATED TO PRODUCTION TRAITS IN LUMPFISH *(Cyclopterus lumpus)*

Introduction

Biological control of sea lice infection in Atlantic salmon cages has become an important alternative to tackle one of the most important diseases affecting salmon aquaculture. A handful of cleaner fish species have gained great importance in the control of sea lice (Barrett et al. 2020), among them, the use of lumpfish (*Cyclopterus lumpus*) has shown great promise (Imsland et al. 2018). Lumpfish is a sub-Arctic species found on both sides of the North Atlantic and commonly found along the Icelandic, Norwegian and British coastlines as well as the East coast of North America (Davenport 1985). Current lumpfish production is reliant on wild caught broodstock to meet the increasing demand. Lumpfish life cycle has been closed and hatchery reproduction is now possible.

Genomic resources are called to play a fundamental role in the improvement of selective breeding practices of aquaculture species. The development of these resources has been scarce for emerging species such as lumpfish, therefore, there is an imperative need to obtain genomic information that will support the establishment of effective and sustainable selective breeding programs. The recent release of the lumpfish genome sequence will facilitate the identification of genomic markers and the development of genomic tools. The aim of our study was to develop genomic tools and identify genomic regions linked to commercially important traits in lumpfish including gender and growth.

Materials and Methods

Fish used in this study belong to a population obtained from the Otter Ferry SeaFish farm (OFS). Ten lumpfish families from wild origin were produced in spring 2019 at OFS facilities. Four of these families were maintained in separate tanks until they reached a mean weight of 3-9g. Fin clips were obtained from all parents and from the four families including the 50 bigger, 50 smaller and 25 random fish from each family.

Two ddRAD libraries were prepared, containing all 536 samples and were sequenced on Illumina Novaseq 6000 platform. Reads were aligned against the genomic assembly *of C. lumpus* (NCBI Assembly accession GCA 009769545.1) using bwa v0.7.17 (Li & Durbin 2009) and assembled using Stack v2.41 (Rochette et al. 2019). Identified SNPs were collected from the 536 samples, and filtered according to the presence of at least two alleles, MAF >0.10, present in 75% samples and expected mendel segregation.

Genome wide association analysis was performed using the package R/SNPassoc v1.9-2 (González et al. 2007) using the “log-additive” model (except for sex, where ”co-dominant” model was used) and R/qtl2 v0.20 (Broman et al. 2019), analysing four traits, including gender, weight, condition factor and standard length.

Results and Discussion

Approximatelly 3.2 billion paired end reads were obtained as raw data from sequencing, from these, 3.2 million unique loci were detected and mapped across the available lumpish genome. After SNP calling and quality control, 10,630 informative SNPs were identified.

Association analyses were able to identify many genomic regions linked to the analyzed traits. The analysis of gender showed the highest association, identifying a single major QTL located in chromosome 13 (Figure 1A). Markers located in this region were further analyzed and a set of 16 markers was capable of accurately predict sex in all samples. Analysis of growh traits showed a polymorphic behaviour as expected, identifying significant association in many chromosomes, showing evidence of overlap in the QTL regions identified for weight and length in chromosomes 7, 12, 13, 15, 17 & 21 (Figure 1B). Of particular importance was the association between growth and gender shown in a region of chromosome 13 which could have implications in selective breeding. Moving forward, markers located in these identified QTL regions are candidates for the development of low density SNP panels that will provide a low cost alternative for producers to use genomic information in the development of selective breeding programs and improve production traits.

Introduction

In the last decades, jellyfish seem to have increased globally, significantly impacting different human activities in coastal areas (Purcell et al., 2007). Besides food purposes, these organisms have been recently evaluated as a potential resource for other industries, such as agriculture (Emadodin et al. 2020) or pharmaceutics (Leone et al. 2015). Nevertheless, little is known about the usefulness of jellyfish for feed production, probably due to their intrinsic characteristics as the high moisture level and the presence of venom in certain species. Moreover, research on the nutritional benefits of using jellyfish in aqua-feeds as raw material has been relatively unexplored.

Materials and Methods

Based on a systematic review of the literature, following the methodology recommended by Moher et al. (2009), the jellyfish nutritional composition was characterized, and the existing gaps for accurate comparability were highlighted. Furthermore, the available nutritional characterization was compared with the most used aqua-feed ingredients, critically evaluating the possible benefit and limitation of usage in the aqua-feed formulation. Data were divided into four main categories: proximate composition (Pc), amino acid (AA) and fatty acid (FA) profile, mineral (Mi) content.

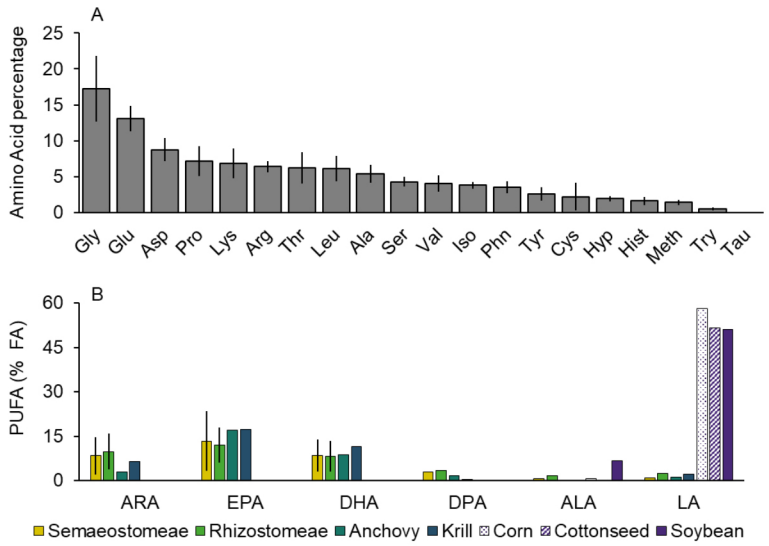

Fig. 1 Amino acid ranking in jellyfish (A) and most representative PUFA (% FA) in jellyfish and reference ingredient for aqua-feed production (B)

(Continued on next page)

Results

Of the 55 identified and validaded articles, proximate composition results showed that water ranged between 91.1 to 98 % wet weight; ash between 15.40 – 85.6 % dry weight (dw); proteins between 0.2 - 76.8% dw; lipids were 0.17 – 12.3 % dw and carbohydrates between 0.1-22.71% dw, with the proportion varying between body parts and species. Amino acid profiles were proportionally quite homogeneous and presented specific pattern; the most representative AAs were Glycine (16.6 ± 4.8 % AA), Glutamic acid (12.7 ± 1.8 % AA), Aspartic acid (8.6 ± 1.7 % AA) and Proline (7.7 ± 1.8 % AA) (Figure 1A). Although fatty acid variability was mainly associated with seasonal shift, SFAs and PUFAs were more abundant than MUFA. The most representative PUFAs were Arachidonic acid (ARA) (2.8-23.7 % FA), Eicosapentaenoic acid (EPA) (1.23-25.9% FA) and Docosahexaenoic acid (DHA) (0.8-25.9 % FA). Overall, jellyfish hold a qualitative FA profile closer to commonly used fish oil sources, such as anchovy and krill, than other oil sources currently used as fish oil replacement (soybean, corn and cottonseed) (Figure 1B). Macro elements are consistent in jellyfish and show a defined pattern for body composition. Microelements manifested more variability and were reported within the following range concentrations in mg/kg dry weight: Fe (0.59- 252) Cu (0.11 – 49.82), Zn (3.61 – 400), Si (13.01- 81.76), Mn (0.11 – 18.66).

Discussion and Conclusion

Despite quantitative differences in species and body parts, overall, the ratio between each nutritional compound was relatively homogeneous. However, the detected variability underlined in different references limited an accurate, comprehensive quantitative nutritional characterization. Factors such as seasonality, water quality, methods, and processing techniques should be further investigated for effective future jellyfish exploitation and further clarify the mechanism associated with jellyfish' apparent nutritional plasticity. With the lack of knowledge about local and temporal biomass availability, this aspect made not possible an accurate definition of jellyfish as an aqua-feed ingredient. Nevertheless, it was underlined the qualitative jellyfish raw biomass potentiality as Protein, PUFAs and Mineral sources that already at this stage can candidate them as a potential component for functional feed to be investigated.

Introduction

The deficit of fisheries resources, the increase in the world population and the growing per capita consumption of fish (20,5 kg 2020), are some of the factors that have led to greater investment in world marine fish farming. The statistics for 2019 presented a consolidated and growing Atlantic Salmon (*Salmo salar*) industry, with the highest world production (2.615.962 tons) of a species cultured in the sea. In addition to salmon, other marine fish present significant advances in technological development with productions greater than two hundred thousand tons, European seabass (*Dicentrarchus labrax*) 263.214, gilthead seabream (*Sparus aurata*) 258.753, and the large yellow croaker (*Larimichthys crocea*) 225.547 tons. These advances have encouraged interest in culturing new species in regions that have little tradition of marine aquaculture, such as Latin America. The Sciaenidae family made up of 289 species in 69 genera, presents in addition to the large yellow croaker, several species with important productions and other species with high potential for culture. This work compiles the main factors of success and problems generated in the aquaculture industry of Sciaenidae and also makes reference to the state of technological development and future perspectives of emerging species of the Sciaenidae family in Latin America.

World production

The family Sciaenidae represents one of the groups of marine fish (fully marine from egg through to adult) with the highest production in the world (340.273 tons - 2019) with a high market value of 839.569.920 U.S. dollars. Three species contribute 99,94% of the world aquaculture production of the Sciaenidae family, the large yellow croaker, *L. crocea*, cultured in China (225.549 tons), the red drum, *Sciaenops ocellatus* (77.008 tons) cultured in the USA, China, Guadeloupe, Israel, Martinique, Mauritius and Mayotte, and meagre, *Argyrosomus regius* (37.526 tons), cultured in Egypt, Spain, Greece, Turkey, Croatia, France, Saudi Arabia, Italy, Tunisia, Cyprus, Portugal, and Algeria. The remaining 0,06% (189,6 ton), was contributed by the Shi drum, *Umbrina Cirrosa* cultured in Greece and Turkey, the mi-iuy corvina, *Miichthys miiuy* cultured in the Republic of Korea, and the mulloway, *Argyrosomus japonicus* cultured in Mauritius.

Fig. 1. Species of the Sciaenidae family investigated for aquaculture in Latin America

(Continued on next page)

Success factors and problems

The three Sciaenidae species with the highest production in the world have shown high potential for aquaculture. They stand out for being euryhaline species (0-66 ppt), eurythermal (2-38 °C) and have high fecundity that allows them to produce large quantities of eggs per spawn (500-3.270.000). Red drum can spawn naturally, and reproductive dysfunctions have been overcome with hormonal therapies, for example in Red drum (GnRHa 100-160 µg + HCG 5 mg kg^{-1}), and with low doses in *L. croceus* (GnRHa 3-10 µg kg^{-1}) and in *A. regius* (GnRHa 15 µg kg^{-1}). Survival has been achieved in larval culture between 7,7 and 75% and growth rates in grow-out of 2,14 g/day^{-1}, with low feed conversion rates between 0,9 and 1,9. High larval survival rates have been correlated to the use of copepods for food in some species. Market values range between $ 7,14–14,28 U.S. dollar, which are attractive and have allowed the profitability of aquaculture production. The adaptation of Sciaenidae to technologies implemented in other species has been successful, for example, the production technologies of *A. regius* are based on knowledge and production technologies developed for the production of gilthead seabream and European seabass. A relevant aspect to consider is that these industries have developed in countries with availability of goods and services for aquaculture and where local and national governments have promoted industrial applied research, both scientifically and financially. A negative aspect to consider is the low resistance to handling, physical injuries are common after physical handling in Sciaenidae species. The little progress in the production of secondary species may be related to several factors. In the case of *U. cirrosa*, its industry is considered to be overshadowed by the good characteristics and success of the culture of *A. regius*. In *M. miiuy* and *A. japonicus*, technological problems are reported for the production of larvae and juveniles.

Emerging Species of Latin America

In Latin America there has been great interest in the development of aquaculture for the Scienidae family since the late 20th century. Research on eleven species are currently reported (Fig. 1). Two have greater technological development, the totoaba *Totoaba macdonaldi* and the corvina pampera *Cilus gilberti*. The other species are in the initial stages of technological development or have been studied sporadically.

Conclusions

The Sciaenidae family has the highest world aquaculture production of a marine species group, with biological characteristics that give high potential for aquaculture. The three consolidated species have in common that previously developed culture technologies were quickly and easily adapted for their production, allowing high larval survival rates and spawning of constant quality, using when needed established GnRHa hormonal therapies to overcome reproductive dysfunctions. Latin America has a high interest and potential to develop aquaculture with species of the Sciaenidae family. It is recommended for the Latin American region to analyse the technologies used for these established Sciaenidae to apply these technologies to native Latin American Sciaenidae to both utilise successful management aspects and avoid problems encountered.

CAN LIPIDOMICS HELP IDENTIFYING EGG QUALITY IN BALLAN WRASSE (*Labrus bergylta)*?

Introduction

What makes an egg a good egg is a long-discussed topic in many biological disciplines, but especially in aquaculture, as the fish farmer is betting that the eggs will result in a high value fish. Many different ideas have been postulated how to describe a good egg, and fertilization success, development into a normal embryo and high hatch rates are probably the most named descriptors. Brooks et al (1997) elegantly described a good egg as one that, "[…] contains all the necessary materials (both genetic and nutritive) to support the development of the subsequent embryo." This definition is certainly true and gives a good hint what to consider but does not supply a testable tool to describe egg quality.

Ballan wrasse (*Labrus bergylta*) is in the limelight of aquaculture research due to their role as cleaner fishes in salmon aquaculture. A major drawback is that the salmon industry still depends on wild caught fish as there are still many unsolved challenges in ballan wrasse aquaculture, amongst them the determination of egg quality. Eggs from wild fish are usually considered of better quality (Srivastava, Brown, 2011), and fertilization rates, hatch rates, survival and size at hatch are usually higher than in eggs produced in captivity.). To lay a knowledge foundation, we studied different egg characteristics with the potential to predict egg (and offspring) quality to provide insights into the interplay between lipidomics, fatty acids and various oocyte traits of ballan wrasse eggs.

Materials and methods

Eggs used in the current study were purchased from two commercial hatcheries in Norway. We studied 6 different egg batches, spawned and fertilized naturally on spawning mats placed in spawning tanks. One batch was spawned by an established broodstock, while five other batches were spawned by wild fish which has been in captivity 1 - 3 years. The eggs were scraped off the spawning mats and transported same day to SINTEF Sealab, Trondheim where the eggs were acclimatized and transferred into flow-through incubators. The eggs were sampled 14 times until 16 days post fertilization. We analysed several biometric measurements using microscopy and computer aided image analysis, respiration rates, egg dry weight, elemental analysis (carbon & nitrogen) and bone/cartilage development. Additionally, we performed lipidomics on these eggs to test whether their lipid profiles relate to and can be thereby used as a predictor for egg quality in fish.

Results and discussion

The potential egg quality descriptors we analysed all showed substantial variability between batches. The more conservative quality descriptors, such as larval length, egg diameter and egg weight, showed less variability than the more dynamic ones, such as the decrease in dry weight, or decrease in carbon content per egg between one- and 16-days post-fertilization. We quantified 245 different lipid species in the ballan wrasse eggs, of which 56 correlated to the 20 potential egg quality markers we used in this study (Figure 1). These markers can broadly be grouped into markers related to (a) size, (b) energy content, and (c) metabolic activity (Table 1). Those lipids which were related to the egg quality markers grouped into two main clusters: Cluster A (the lower cluster in the clustered image map Figure 1) showed a positive covariance with size related measures such as larval length at hatch, or yolk volume at 2 days post hatch, and negatively with measures related to metabolic activity, such as changes in respiration rate between fertilization and hatch or the decrease of nitrogen and carbon in the egg. This group consisted of phosphatidylcholines (PC), lysophosphatidylcholine (lysoPC), and triacylglycerides (TAG) and three different sphingomyelins (SM). Group B clustered related to the same measures, but in the opposite way with the exception that size related measures showed a weaker association. This group of lipid species contained several phosphatidylethanolamines (PE) and free fatty acids.

(Continued on next page)

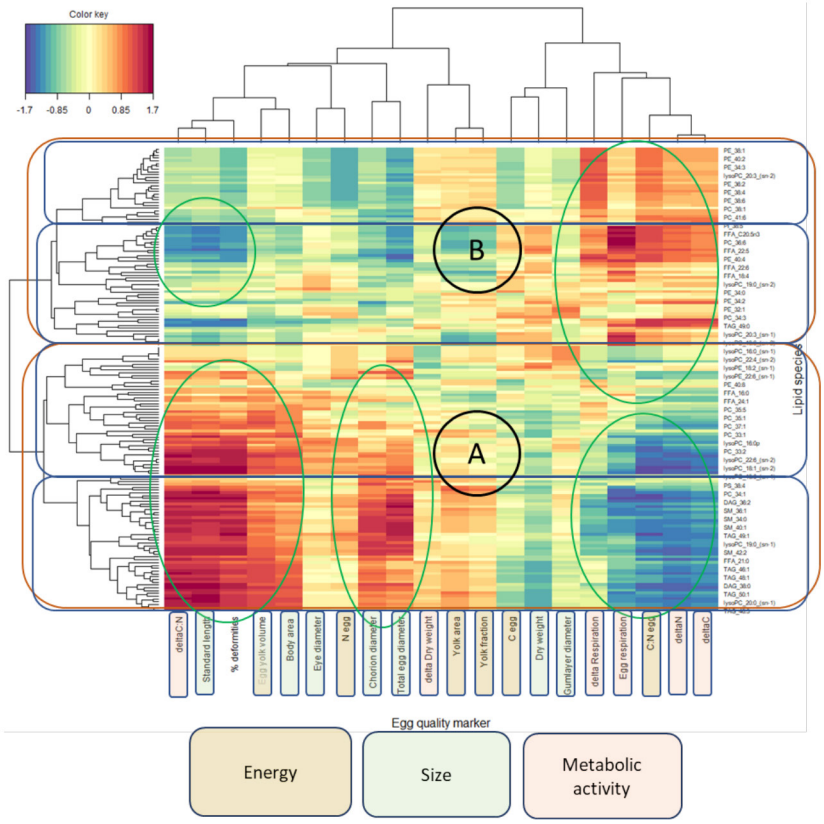

Figure 1: Clustered Image Map of the top lipid species that most contribute to the variance. (A) and (B) denotes the two main clusters.

Conclusions

The pattern of several lipid species being positively related to size and negatively to metabolic activity while another group is showing exactly the opposite deserves further investigation. To our knowledge this is the first study applying lipidomics approaches to assess its potential as an egg quality measure. This study only scratches the surface of this complex topic but can serve as a basis for further identifications of important groups of lipids. The future task would be to identify recurring patterns within species and to test to which extend these are species specific or general, and ultimately try to achieve a mechanistic understanding of the importance and the interplay of these groups

Introduction

Infectious skin diseases, such as tenacibaculosis, occur frequently in salmon production and are a major challenge compromising fish welfare, sustainability and profit[1]. Tenacibaculosis are typically associated with the presence of an external pathogen which can be isolated from the ulcers. However, when an outbreak occurs, there are often large differences in disease susceptibility and response among fish within the same tank. Here, we investigate microbial and epigenomic variation in disease response in an acute outbreak of ulcer disease in Atlantic salmon (*Salmo salar*)[2].

Materials and methods

The fish investigated in this study were one year old Atlantic salmon from a commercial hatchery recently transferred to a land facillicy in northern Norway. In this standard aquacultural setting an acute outbreak of skin ulcer disease caused by *Tenacibaculum dicentrarchi,* occurred briefly after saltwater equilibration. The gut microbiome composition of 20 fish with and 20 fish without visual indications of tenacibaculosis were characterized with bacterial 16S rRNA gene metabarcoding (Fig. 1A). Genome wide DNA Methylation patterns were characterized in 10 sick and 10 healthy fish with different microbiome compositions using whole genome bisulfite sequencing (WGBS). Lastly, we resequenced key differentially methylated regions using nanopore cas-9 targeted sequencing (nCATS), to explore the potential of targeted DNA methylation analysis as a tool for monitoring fish health[3].

Results

A) Sampling of gut tissue and microbiota in healthy and sick fish. **B)** Relative abundance of intestinal bacteria. **C)** Principal component analysis of 16 million CpG sites (i.e. epigenetic methylation markers): PC1 values shown on the y-axis, random noise on x-axis.

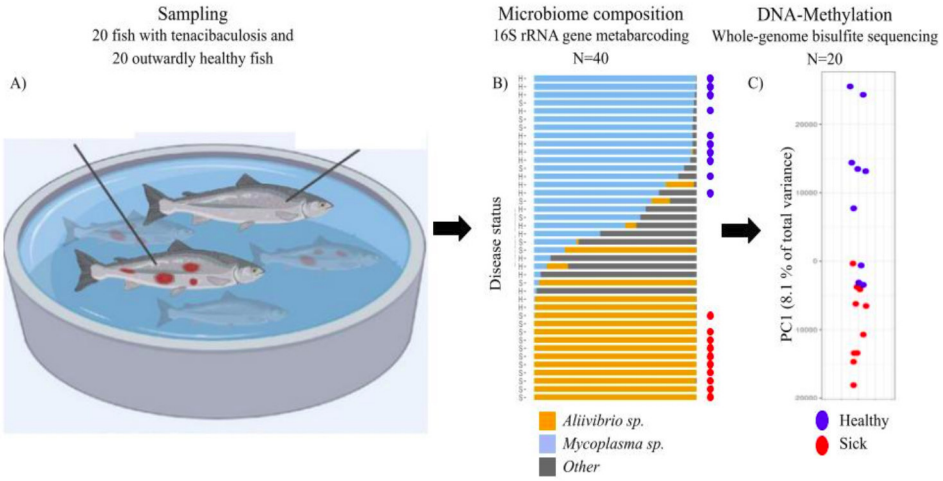

Figure 1. Summary of samples and preliminary results

The gut microbiomes were found to be dominated by two species of bacteria; *Mycoplasma sp*. and *Aliivibrio sp*. Interestingly, the sick fish were dominated by the *aliivibrio* species, while the healthy fish were dominated by the *Mycoplasma* species (Fig. 1B). Whole Genome Bisulfite Sequencing resulted in 16 million CpG sites with 5X coverage in all samples, meaning we could efficiently analyse more than a third of all the CpG sites in the salmon genome. Strikingly, the sick fish and the healthy fish showed global differences in DNA-methylation patterns (Fig. 1C), suggesting that epigenetic mechanisms were involved in the difference in tenacibaculosis susceptibility and/or response. The differences indicated large general methylation differences between the sick and healthy fish. Relative to the location of CpG sites in general, the differences between the sick and healthy fish were more often found in promoter regions and frequently multiple differences were found within the same promoter region. DNA-methylation level in promoters and other specific regions of genes is known to affect the transcription level of the gene. Therefore, investigating which genes were related to the epigenetic response of tenacibaculosis, could help to identify candidate genes involved in disease resilience. Our results suggest that especially genes involved in signaling and adhesion between cells are important for susceptibility and/or response to tenacibaculosis. In addition to presenting the analysis leading to our results, pilot results from DNA-methylation analysis of key differentially methylated nCATS regions will be presented and used to evaluate the method compared to today's golden standard method of WGBS.

Discussion

In Atlantic salmon with low genetic variation and raised in the same controlled environment, we found significant differences in microbiome composition and DNA-methylation between fish with tenacibaculosis and their more resilient healthy companions. There is increasing evidence of a symbiotic relationship between *Mycoplasma sp*. and its salmonid hosts, however the interactions between the two are still largely unexplored [4–6]. The results presented here suggest epigenomic regulation of host genes can be used to better understand interactions between the two and their influence on complex phenotypes. Exactly which mechanisms are causing the correlations and how the epigenome, microbiota, and phenotype are interconnected are still inconclusive. The results presented here, the manipulability and heritable nature of the epigenome highlights it as an interesting future target for monitoring complex phenotypes, including tenacibaculosis. On the methodological side, we hope the knowledge from our nCATS experiment can contribute to further development of strategies for analysing DNA-methylation profiles in a low cost and high throughput manner.

OPTIMIZING OFF-BOTTOM OYSTER CULTIVATION IN THE NETHERLANDS: IMPROVING YIELD WITH SITE-SPECIFIC OYSTER FARMING

Eva Hartog[1 *], Tony van der Hiele[1], Lotte Niemeijer[1], Wouter Suykerbuyk[2], Linda Tonk[2]

[2]WMR - Wageningen Marine Research, P.O. Box 77, 4400 AB Yerseke, The Netherlands

Off-bottom oyster cultivation in the Oosterschelde, the Netherlands, started in 2010. Off-bottom cultivation typically result in oysters (*Crassostrea gigas*) with faster growth and a higher meat quality in comparison with the conventional bottom oyster cultivation, due to a higher food quality and availability higher in the water column. Using triploid oysters, which invest more energy in growth, ensures a shorter cultivation process. In off-bottom cultivation oyster spat is placed at a high density (app. 5000 individual pieces) in fine-meshed bags or baskets and will be manually thinned in density during the growth process to consumption size. The starting material, oyster spat, can be of various origins and usually comes from hatcheries, as the Netherlands, Ireland and France.

Currently two different cultivation systems are being used by Dutch oyster farmers in the intertidal area in the Oosterschelde The first system consists of firm plastic bags (available in 4 different mesh sizes) which are placed on iron frames. The second system is the so-called BST system which consists of hanging baskets (available in 3 different mesh sizes) attached on longlines or on iron tables. Although these systems are widely and successfully used around the world, there seems to be quite some room to optimize this way of farming. Main issues are i) their labour intensiveness in combination with the relatively high wages in the Netherlands and ii) high losses caused by the variety wave- and flow dynamics in the Oosterschelde. It is questioned if other off-bottom cultivation systems that are also successfully deployed around the world would be a good addition and or alternative to improve efficiency and productivity of Dutch oyster cultivation.

In 2020 the European Marine and Fisheries funded project “Oyster yield improvement through knowledge transfer and monitoring” was initiated. The goal of the project is to optimize oyster farming and it should lead to efficiency improvements of sustainable oyster cultivation. In this project a comparative study between current off-bottom oyster cultivation and alternative off-bottom farming systems will be conducted. The effect of the farming systems on the performance of oyster growth, quality and shell shape will be examined for four different systems in three different off-bottom cultivation locations in the Oosterschelde. In a comparative study between the currently used systems and alternative off-bottom cultivation systems, additionally the following two methods are being tested:

1- SEAPA - hanging baskets
2- FlipFlop bags - horizontal hanging bags

For this study T15 triploid oysters, originating from the hatchery Roem van Yerseke, the Netherlands., were placed in four bags or baskets at 3 different locations in the Oosterschelde (Prinseplaat-C, Yerseke bank-74/75 and Hooge Kraaijer-46), see Table 1. The number of oysters per system is calculated according to the total volume of each individual system. All the systems and all the locations are sampled every 10 weeks for the period March 2021 till December 2021. During sampling, 1 bag or basket of all the systems (and of all three locations) will be collected. Per sample randomly 60 individual oysters are analyzed on - shell shape / growth: length, width, thickness, quality and wet fresh weight. The Condition Index (Rainer and Mann, 1992) is determined for 30 individual oysters per sample.

Monitoring and experiments are ongoing till December 2021. During the presentation the results of the study will be shown and discussed.

Table 1, Amount of oysters per system and number of treatments per location

		Location		
System	**Amount of triploid oysters**	**Prinseplaat-C**	**YB74/75**	**HK46**
Bags (current)	70 pc – T15 – 8-12 gram	* 4	* 4	* 4
BST – baskets (current)	120 pc – T15 – 8-12 gram	* 4	* 4	* 4

[4] Department of Microbiology, Faculty of Basic Sciences, Islamic Azad University, Jahrom, Iran

Introduction

Betanodavirus, the causative agent of the disease VNN (Viral Nervous Necrosis), has a substantial economic, social and environmental effect on aquaculture development in the world. Diagnostic tests, such as assays targeting the viral RNA based on reverse-transcription PCR (RT-PCR), Histopathology, diagnosis based on immunological assays, have been developed to detect the Betanodavirus in fish and for health certification purposes (Zorriehzahra et al., 2005), (Binesh et al., 2013).

Methods and Materials

In this study, a Real-time PCR assay, nested RT-PCR, immunohistochemistry (IHC) and immunochromatography (ICG) were compared in the diagnosis of Betanodavirus infection. The reverse transcription (cDNA synthesis) was carried out followed by the RNA extraction. The cDNA was screened with an SYBER Green Real-Time PCR using a pair of primers NF2/NR3and Nested RT-PCR using two pairs of primers F2/R3 and NF2/NR3 in two steps for detecting Betanodavirus infection. To visualise the location of the virus in the brain of infected fish, IHC test with rabbit polyclonal anti-Betanodavirus antibody and anti-rabbit IgG-HRP conjugate was performed. The ICG test strip was constructed using anti- Betanodavirus monoclonal antibody (mAb) labelled with colloidal gold (used as detection antibody) and the rabbit anti- Betanodavirus polyclonal antibody (PAb) (used as capture antibody), for rapid detection of Betanodavirus infection. Forty brain samples from symptomatic golden grey mullet fish and 20 brain samples from healthy golden grey mullet fish obtained from the coastal areas of the Caspian Sea. Real-time PCR was used to detect Betanodavirus in both groups. Symptomatic mullet with positive PCR were considered infected by Betanodavirus and the Real-time PCR technique was chosen as a gold standard test (An, et al.,2008), (Dai, et al., 2015)

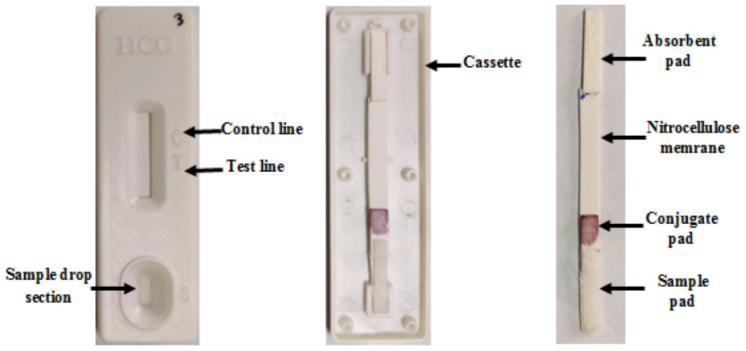

Fig.1. Most important Immunochromatography kit parts

(Continued on next page)

Result

IHC assay showed optimal diagnostic performance (100% sensitivity and specificity). ICG test identified 32 of 40 infected brain samples (80% sensitivity and 100% specificity) and 25 of 40 brain samples were positive only in nested RT-PCR (62.5% sensitivity and 95% specificity). Analysis of the results illustrate that ICG and IHC assays presented good sensitivity and specificity for diagnosing NNV; however, ICG may be more advantageous when a fast field test is required. The low overall sensitivity of nested RT-PCR may be due to high genetic variation within the T4 region occasionally leads to mismatches between primers and their targets and consequently the sensitivity (Fukuda et al.,,2009),(Dalla Valle et al.,2000)

Introduction

New sources of the very long-chain n-3 polyunsaturated fatty acids (LC-PUFA) are needed for salmon farming to grow, since the marine oils where these fatty acids are typically found, are of limited availability. High n-3 LC-PUFA canola oil has shown promise as a safe and effective source of DHA and other n-3 PUFA in small salmon (Ruyter et al., 2019). The present experiment was carried out to study the effects of long-term feeding of diets with graded levels of n-3 canola oil on performance and the fillet quality in large salmon in sea cages.

Materials and methods

A 12-months feeding experiment was carried out with Atlantic salmon growing from 0.7 to 4.7 kg in nine 5 x 5 m experimental cages. The fish were fed three diets containing graded inclusion levels of Aquaterra® omega-3 canola oil (Nuseed) resulting in levels of dietary DHA (22:5 n-3) of 4.0 % (Diet A), 6.6 % (Diet B) and 8.3 % of total fatty acids (Diet C) and total EPA + DHA of 6.4, 9.1 and 11.0 % of total fatty acids (weighted average of three pellet batches per diet). Feed intake and growth were measured, and at slaughter (4.7 kg) fish were analysed for tissue fatty acid composition and fillet quality. Fillet colour (CIE 1976 LAB color space) was measured instrumentally in 10 fish per cage using a Minolta Chroma Meter CR-400 (Konica Minolta Sensing, Inc. Japan) and the same fish were pooled for astaxanthin analyses by HPLC. Thirty fish per cage were examined for black melanin spots in the fillets using a scoring scheme (Mørkøre, 2012).

Results

There were no significant differences between diets in overall fish growth and weight at harvest, although the fish fed Diet C had lower TGC in the last part of the study, when growing from 3 to 4.7 kg. No differences were seen in feed conversion ratio (FCR).

The FA-profiles in muscle mirrored those of the diets, giving increased DHA, EPA (20:5 n-3) and ALA (18:3 n-3) with increasing inclusion level of high n-3 LC-PUFA canola oil.

Fillet redness (a*), yellowness (b*) and chroma measured instrumentally (CIE 1976 LAB color space) were higher in the fish fed Diets B and C than Diet A (Fig. 1), suggesting a positive effect of DHA on muscle pigmentation. A similar trend, although not significant, was seen for astaxanthin measured in pooled muscle samples.

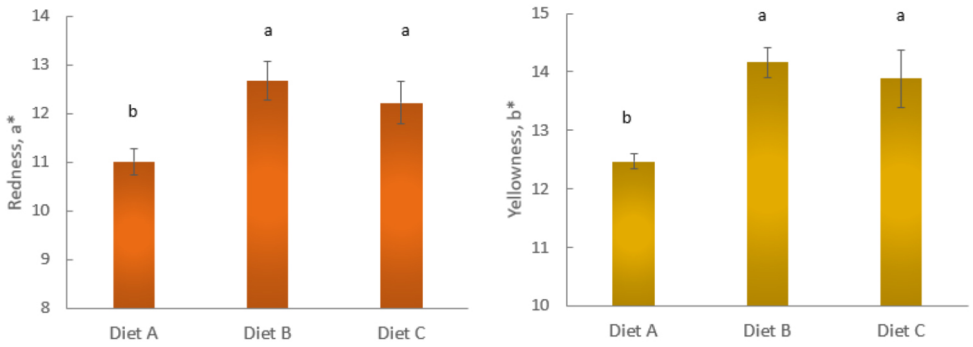

Figure 1 *Instrumentally measured redness (a*, left panel) and yellowness (b*, right panel) in fillets of salmon fed diets with graded level of DHA. Different superscripts[ab] indicate differences between diets.*

(Continued on next page)

The prevalence of dark melanin spots in the fillet was lower in fish fed Diet B than Diet A. The prevalence of more severe spots (score ≥ 2), average score and number of affected muscle segments were lower in fish fed both Diets B and C, compared to Diet A.

Conclusion

n-3 rich canola oil is an efficient source of DHA and other n-3 fatty acids for harvest-size Atlantic salmon. Increased dietary supply of DHA and other n-3 PUFA, above minimum requirement levels for DHA, improved fillet pigmentation and reduced fillet melanin spots, without compromising fish growth.

FEED EFFICIENCY IN 35 FAMILIES OF ATLANTIC SALMON – THE RELATIVE IMPORTANCE OF BODY COMPOSITION AND ENERGY EFFICIENCY

Bjarne Hatlen[1]*, G.F. Difford[1], B. Gjerde[1], A. Norris[2] and A.K. Sonesson[1]

[1]Nofima, Norwegian Institute for Food, Fisheries and Aquaculture Research, NO-9291 Tromsø, Norway

*Email: bjarne.hatlen@nofima.no

Introduction

Feed accounts for around half of the costs and 70-80% of the greenhouse gas emissions of Norwegian Atlantic salmon farming (Winther et al., 2019). Therefore, breeding more efficient animals may reduce the environmental footprint of the salmon industry and at the same time strongly increase its economic competitiveness.

Direct selection for feed efficiency (FE; gain/intake) requires measurements of feed intake in large numbers of animals. Measuring feed intake in individual fish with sufficient accuracy is difficult without interventions that may affect the measured variable. Exact feed intake measurements over time with minimal disturbance of the fish can be obtained in replicated family groups in tanks equipped for collection of the feed spill in the water outlet. However, the combination of high costs and loss of individual information prohibits the use of this method in breeding programmes.

Feed efficiency can be considered a product of i) energy efficiency and ii) weight gain per unit energy retained in the fish. Body fat and water content are inversely correlated in salmon and given similar energy efficiency lean fish (low energy density) can be predicted to have higher FE than fish with high body fat content (high energy density). Since fat content is relatively easy to measure, and may be estimated in live fish by non-destructive methods, this correlated response may be utilised for genetic selection for improved FE (e.g. Kause et al., 2016).

In order to unravel the relative importance of energy efficiency and body energy density for feed efficiency, an experiment was carried out to measure feed intake, growth, digestibility and body composition in duplicate groups of 35 Atlantic salmon families.

Materials and methods

Individually tagged and genotyped Atlantic salmon from 35 families were transported from Mowi Genetics AS (Øyerhamn, Norway) to the Nofima Research Station for Sustainable Aquaculture (Sunndalsøra, Norway) as 40 g parr. After one month of acclimation in small tanks, a random sample of 8 fish per family were taken for analyses and 25 individually weighed and length measured fish were distributed to each of two 150L experimental tanks per family. The fish were kept under continuous light and all tanks supplied with fresh water of stable temperature of 12.2 °C. The fish were then fed in excess for 7 weeks with water-stable extruded 3 mm feed pellets produced by extrusion at Nofimas Feed Technology Centre (Bergen, Norway). The feed was formulated according to commercial practices and added yttrium oxide (Y_2O_3) as an inert digestibility marker. All spill feed was collected from the water outlet and quantified daily after correction for recovery and dry matter content (Helland et al., 1996). At the end of the trial, the fish were individually weighed and length measured, and faeces collected by stripping (Austreng, 1978). The fish were then fasted for two days to empty the gut, euthanised and stored for analyses. Feces samples and initial and final samples of whole body were analysed for energy and crude protein, and their retention efficiency calculated.

Results

To the best of our knowledge this is the first report of energy and protein efficiency in families from an elite breeding population of fish. The data showed variation in mean FE among the families from 1.10 to 1.38 (Fig. 1). Digestible energy efficiency varied from 55 to 66 % and digestible crude protein efficiency from 51 to 59 %. Although mean final body energy content among families varied within the narrow range of 8.32-9.24 kJ/g (corresponding to 10.5-12.8 % crude fat), there seemed to be a negative correlation between body energy and FE, as predicted. Statistical analyses to reveal the relative effects of energy utilisation and body composition on FE are underway and will be presented.

Introduction

In domestic shrimp farming, the monitoring of important production parameters (health status, biomass, feed rates and growth success of the animals) is still largely manual, which entails an enormous amount of time and high susceptibility to errors and also causes stress and, in some cases, physical damage to the animals.

The objective is to develop a digital monitoring technology (based on imaging and acoustics data) that enables a qualitative and quantitative assessment of the condition of the entire livestock population and provides the breeder with the data on a smartphone / tablet or computer via an interface. Real time recording and immediate automated decision making in land-based breeding systems for shrimp will make catch unnecessary, reduces hence stress and risk of injury to the animals and provides the farmer with information at all times about the actual biomass of its system as well as about the condition of the animals.

Material & methods

Shrimps are stocked in experimental units at various circumstances (single housed to commercial conditions in terms of density, size, light, etc…). Cameras (model) and hydrophones (icListen – 3500 m; 24-bit Smart Hydrophone – 200 kHz, Model Sb365-ETH, Software Program Marco, Ocean Sonics Ltd.) are installed above the experimental units. Imaging and acoustic recordings will be performed at various circumstances (from acoustically insulted settings to complex acoustic commercial environments, or, at various shrimp size and location, at feeding and absence of feeding). Further data recorded manually are number of shrimps, weight and biomass, mortality, Signs of illness / stress. In addition, the standard built-in sensors continuously record the water quality.

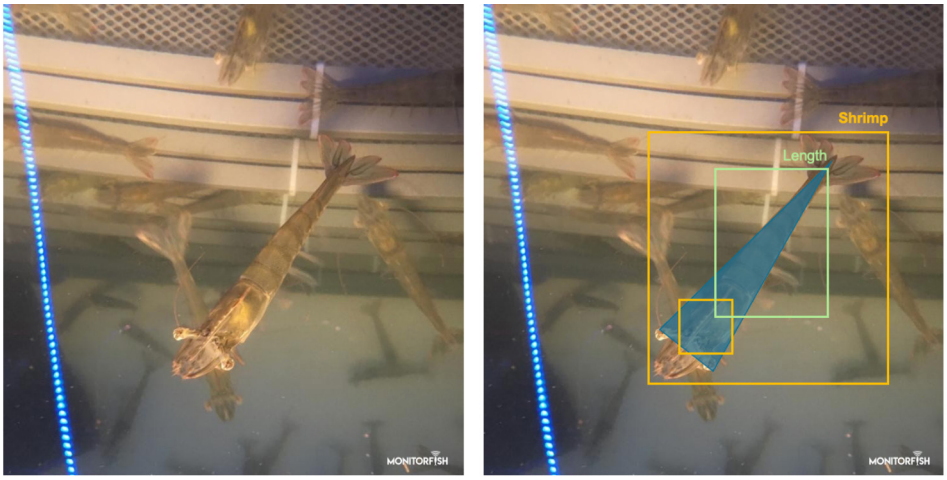
Results

At EAS 2021 preliminary results of imaging analysis and hydrophonic recordings will be presented. Experiments are currently conducted and first data will be available and analysed prior to this conference. We aim to present:

- Preliminary results of digital/automated counting the number of shrimp individual
- Preliminary results of intrinsic acoustic feeding signals from shrimp isolated in a disturbed acoustic environment

Discussion and conclusion

At EAS 2021 preliminary results on automated counting and acoustic feeding signals (considered key data for successful software development) will be presented. Reliability of first data (number of digital counts vs manual counts and acoustic feeding signal vs state of hunger) will be discussed and approaches for recognition algorithms that compares the metadata with a database on shrimp behavior will be presented.



IMPROVING PERFORMANCE OF SENEGALESE SOLE THROUGH DIET SUPPLEMENTATION WITH CURCUMIN EXTRACT

Introduction

Senegalese sole (*Solea senegalensis*) is an emerging species for Southern European aquaculture. However, sole aquaculture faces bottlenecks regarding the development of strategies to control infectious diseases and the optimization of feeding and nutrition to improve growth rates. The growth performance of sole early life stages is highly dependent on nutritionally balanced diets. Diverse plant extracts containing bioactive compounds (e.g. polyphenols) are considered promising feed additives, with high potential to improve growth performance and also disease resistance [1]. This paper presents two trials that were conducted to evaluate the effect of a plant extract (curcumin) on the growth performance, immune status and oxidative parameters of Senegalese sole juveniles.

Material and methods

Both trials used two diets: an experimental microdiet, with inclusion of curcumin extract (CC) and a commercial microdiet (WINFlat, Sparos), as Control. Automatic feeders were used to continuously supply inert diets throughout both experiments. In the first trial, microdiets were introduced in the feeding regime of Senegalese sole postlarvae at 30 days after hatching (DAH) and kept during 4 weeks (64 DAH). Sole postlarvae were reared at an initial density of 3000 fish/m^2 in triplicate flat-bottom tanks (8 L), set in a partially-closed recirculating aquaculture system. Sole were sampled at 30 DAH, 50 DAH and 64 DAH. In the second study, sole postlarvae were reared for 25 days, starting at 45 DAH. Sole postlarvae were kept in triplicate flat-bottom tanks (21 L) at a density of 3000 fish/m^2 and were sampled at 45 and 70 DAH.

Results

At the end of both trials, growth performance was improved in the groups fed CC diets. Senegalese sole fed on diets with curcumin extract presented higher (P<0.05) dry weight (Trial 1) and standard length (Trial 2) (P<0.05) when compared to sole fed the control diets (Fig. 1).

At the end of the second trial Senegalese sole fed on the diet with curcumin extract presented significantly (P<0.05) lower GST and HSP70 levels when compared to sole fed the control diet (Fig. 2).

Discussion and Conclusion

There is a growing interest in testing new feed ingredients and additives which can promote growth, and improve oxidative status and immune function in early stages of Senegalese sole and other fish species. Plant extracts such as curcumin contain phenolic compounds associated with high antioxidant capacity [2] hence posing high potential to be included as additives in fish feeds. The present results show that diets supplemented with curcumin extracts (CC) promote growth and improve oxidative status in sole postlarvae [4]. Previous studies showed that diet inclusion of curcumin improve sole growth performance through modulation in the expression of genes related to muscle growth [3]. Moreover, curcumin supplemented diets are also linked to improved growth performances and antioxidant activity in other fish species such as tilapia and trout juveniles [4, 5]. Overall results suggest that curcumin extracts at the tested levels are a viable growth promoter and can also contribute to improve oxidative status in early juveniles of Senegalese sole.

(Continued on next page)

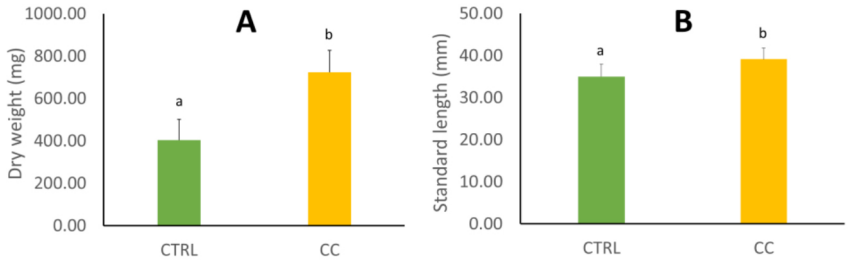

Figure 1. Dry weight of Senegalese sole juveniles fed a control (CTRL) or curcumin extract (CC) supplemented diet at: (A) 64 DAH, n=45 (Trial 1); and (B) 70 DAH, n=120 (Trial 2). Results are expressed as means ± standard deviation. Different superscript letters indicate significant differences between the dietary treatments (P<0.05).

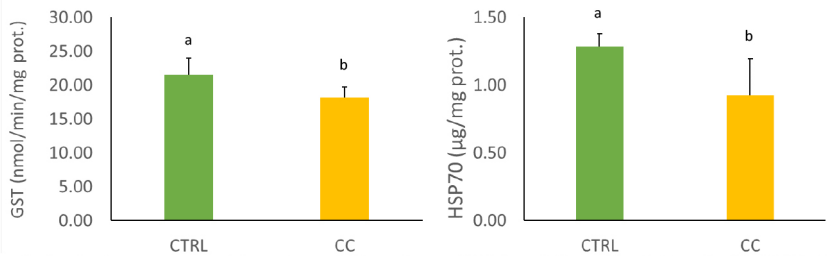

Figure 2. Antioxidant enzyme Glutathione-S-Transferase (GST) and Heat Shock Protein 70 (HSP70) levels in whole-body homogenates of Senegalese sole juveniles fed a control (CTRL) or curcumin extract (CC) supplemented diet, at the end of Trial 2. Results are expressed as means ± standard deviation. Different superscript letters indicate significant differences between the dietary treatments ($P<0.05$).

Introduction

Production of high value flatfish species including Senegalese sole (*Solea senegalensis*) has recently increased in Southern Europe. Despite the research developments on sole weaning strategies, it is paramount to further adapt microdiet formulation and physical properties to the larvae feeding behaviour, while keeping good water quality [1]. Weaning microdiets with low particle size are prone to nutrient leaching, which can lead to significant nutrient losses thus impacting on water quality and larval performance. Several ingredients have binding properties, which have the potential to stabilize feed micro pellets, and thereby contribute to minimize leaching. The present study aimed at measuring leaching in microdiets with different binding ingredients and evaluating the effects on growth performance of Senegalese sole post-larvae.

Material and methods

Four diets were used in the trial: a Control microdiet (based on a commercial formula) and three experimental microdiets (Diets A, B and C) with different inclusions of binding ingredients. Leaching tests were performed to measure total protein loss. A sample of each feed was initially submerged in seawater for 2 minutes. After going through desalination and drying processes, the protein content of each sample was analysed and total protein leaching (%) was calculated. Microdiets were introduced in the feeding regime of Senegalese sole postlarvae at 31 Days After Hatching (DAH) and kept during 4 weeks (65 DAH). Sole postlarvae were reared at an initial density of 3000 fish/m^2 in triplicate flat-bottom tanks (8 L), set in a partially-closed recirculating aquaculture system. Sole were sampled at 31 DAH, 52 DAH and 65 DAH.

Results

Leaching tests revealed that Diets A, B and C presented lower leaching level when compared to the control diet. Furthermore, diet C presented the lowest leaching level amongst the experimental diets (Fig. 1).

Discussion and Conclusion

There is scope to test alternative ingredients in microfeeds which can concomitantly contribute to minimize nutrient losses through leaching and allow keeping optimal biological performances of Senegalese sole and other fish species, reared in diverse production systems. Due to the non-proactive bottom-feeding behaviour of Senegalese sole postlarvae [2], the inclusion of ingredients with binding properties in weaning microfeeds is paramount to keep good pellet stability and minimize leaching, since lower sized feed particles are more susceptible to nutrient loss [1]. The present results indicate that diets containing different inclusions of alternative binding ingredients were linked to lower leaching levels and also promoted growth performance in sole postlarvae. Previous studies also showed that larval feeds with higher stability held more nutritional content [3]. Moreover, specific binders were also linked to higher pellet stability and improved performance of barramundi and tongue sole larvae [4, 5]. Overall, results suggest that alternative binding ingredients can reduce leaching in larval feeds which may contribute to promote growth performance in early juveniles of Senegalese sole.

Introduction

Insects are suitable fishmeal replacers in animal feeds and seven species have recently been approved for use in European aquafeeds. Another interesting insect species, the giant mealworm, *Zophobas morio*, is a large tenebrionid beetle species with a high nutritive value (Rumbos & Athanassiou, 2021) and can successfully replace fishmeal in *Sparus aurata* diets (Asimaki et al., 2020 & 2021). In addition to a valuable protein source, insects are also being considered for their antimicrobial and immunomodulatory activities (Gasco et al., 2021). These recent insights called for the present study which examined the effects of dietary partial replacement of fishmeal with *Z. morio* on some haematological and immunological parameters of Gilthead seabream, *Sparus aurata*.

Materials and Methods

Six isonitrogenous (52%) and isoenergetic (21 Mj/Kg) diets were formulated where fishmeal protein of the control diet (FM) was replaced by full-fat *Z.morio* meal (39% crude lipid) at 5% (FF5) and 10% (FF10) or low-fat *Z. morio* meal (4% crude lipid) at 10% (LF10), 20% (LF20) or 30% (LF30). Diets were given for a period of 100 days to *S. aurata* juveniles kept in triplicate tanks in a RAS. At the end of the trial, 5 fish per tank, fasted and anaesthetized, were bled through the caudal vein. Heparinised blood samples were used to assess the blood profile of the fish (hematocrit, red and white blood cell counts, differential leucocytes counts). Serum samples were assessed for their antibacterial activity against the Gram-positive *Micrococcus luteus* (lysozyme, activity) and against a luminescent strain of the Gram-negative *E. coli* (complement activity) and for their anti-protease activity, nitric oxide concentration, myeloperoxidase and ceruloplasmin activities.

Results and Discussion

Dietary *Zophobas morio* meal, either full-fat or partially defatted, showed significant effect on both the haematological and immunological status of juvenile seabream (Table 1 & Figure 1). Fish fed LF10 did not show any difference in haematological or immunological parameters when compared with fish fed FM control or with the equivalent full-fat insect meal (FF10). When compared to control fish, fish fed LF20 showed increased neutrophil percentages, fish fed LF30 showed increased serum NO, and fish fed FF5 & FF10 showed increased complement antibacterial activity while fish fed FF5 and LF20 showed significantly decreased trypsin inhibition.

Although dietary *Z. morio* clearly modulates both haematological and immunological status of *Sparus aurata*, there was no clear indication of the optimal form and dietary dose of the insect meal to be used in seabream feed. Further study involving disease and/or stress challenge may clarify this aspect.

Cooke Aquaculture Inc. (CAI) is a vertically-integrated global aquaculture corporation based in Blacks Harbour, New Brunswick (NB), Canada. The company currently manages five breeding programs worldwide: one program on North American Atlantic salmon (*Salmo salar*) in East Canada, two programs on European seabass (*Dicenthrachus labrax*) and gilthead seabream (*Sparus aurata*) in Spain and two programs on Whiteleg shrimp (*Penaeus vannamei*) in Nicaragua. Over the past six years, the company has developed strategic synergies between its breeding programs while integrating critical technical knowledge on genomic selection. In the meantime, collaborations with both private companies and International Research Institutes prompted the rapid development of customized genomic toolboxes for North American Atlantic Salmon, European seabass and Gilthead seabream. These tools were first used, back in 2016, to select salmon broodstock candidates for both improved growth and disease resistance. Five years later, the company is seeing significant increases in the annual genetic gains obtained for salmon.

These positive results have encouraged CAI to now consider applying genomic selection in both its seabass and shrimp breeding programs. The transversal approach in managing multispecies breeding programs will enable the company to rapidly bring all its breeding programs to the same technical level while seeking economies of scale for subcontracted services such as genotyping.

EFFECTS OF THE CONCENTRATION AND FEEDING PERIOD OF AMINO ACID SUPPLEMENTS ON FISH STRESS SYSTEM

Salamanca, N., Herves, M. A., Moreno, O., Herrera*, M.

IFAPA Centro Agua del Pino, El Rompido-Punta Umbria rd., 21459 Cartaya (Spain)
natalia.salamanca@juntadeandalucia.es.

It is known that some dietary amino acids can mitigate stress markers in fish. In this work, the effects of amino acid supplements on the stress response have been evaluated in order to determine amino acid concentration and feeding period for achieving the attenuation of stress response. Our findings indicate that the best feeding strategy (lesser stress indicator variations) was that containing 4% amino acid supplement and providing during 4 days.

Introduction

Stress is the most studied physiological process to assess the welfare state of farmed fish. For this reason, some experiments have aimed at reducing the stress response through the use of food additives, such as essential amino acids (Herrera et al., 2017). It seems that phenylalanine and tyrosine have mitigating effects on the stress system, probably due to their participation in the formation of catecholamine hormones (adrenaline and noradrenaline) (Herrera et al., 2017; Salamanca et al., 2020). Therefore, the objective of this work was to determine the optimal amount of phenylalanine (Phe) and tyrosine (Tyr) in the diet and the feeding time.

Material and methods

Seabreams with an average weight of 29.65±1.72g were stocked at 30 fish/tank in twelve 500 L flat-bottom circular tanks at 5 kg m^{-3}. The experimental treatments consisted of different types of feeding: control, Phe-enriched (5%, 7.5%, 10%), and Tyr-enriched (5%, 7.5%, 10%) food, for 2, 4 or 8 days each. Fish feed was provided through automatic feeders and the ration was adjusted to 3% tank biomass daily. At the end of the experiment, blood samples were taken from basal (non-stressed) fish, and 2 hours after stressing by air exposure (3 min). The samples were analyzed using commercial kits, measuring plasma cortisol, glucose, lactate, adrenaline and noradrenaline.

Results and discussion

Table I shows the p-values obtained after comparing the basal and the 2h post-stress states. The conditions whose stress indicators remained more stable (less significant differences) were the diet with a content of 5% and 10% of Phe for 4 days. In the case of the diets supplemented with Tyr, those containing 5% of the amino acid were for 2 days, for 4 days for all the amounts of Tyr in the diet and for 8 days those diets with the amount of 5% and 10% of Tyr.

Table II shows the values of the stress-related metabolites in those specimens fed the diet supplemented with Phe (5% and 10%). The adrenaline values presented significant differences between the specimens in basal state fed with 5% and 10% of the amino acid and between the specimens fed with both amounts of Phe but subjected to stress, noradrenaline only had differences in basal state.

Cortisol values in those specimens fed for 2 days with 5% Tyr were significantly lower than the rest, the minimum glucose was obtained after 4 days of feeding in the same way as in lactate and noradrenaline, adrenaline was obtained after 8 days of feeding (Table III).

In seabream, the values of plasma metabolites are modified with the addition of 5% of Phe and Tyr in the diet, in the same way it occurs in Salamanca et al., (2020) where 5% of amino acids in the diet modulate the metabolites plasmatic. The increase in epinephrine in basal state may be due to an accumulation of this hormone in plasma (Peter, 2011). Our results show that the best diet to mitigate stress is the one supplemented with 5% Phe or Tyr for 4 days of feeding.

It is known that some dietary amino acids can mitigate stress markers in fish. In this work, the effects of amino acid supplements on the stress response have been evaluated in order to determine amino acid concentration and feeding period for achieving the attenuation of stress response. Our findings indicate that the best feeding strategy (lesser stress indicator variations) was that containing 4% amino acid supplement and providing during 4 days.

Introduction

Stress is the most studied physiological process to assess the welfare state of farmed fish. For this reason, some experiments have aimed at reducing the stress response through the use of food additives, such as essential amino acids (Herrera et al., 2017). It seems that phenylalanine and tyrosine have mitigating effects on the stress system, probably due to their participation in the formation of catecholamine hormones (adrenaline and noradrenaline) (Herrera et al., 2017; Salamanca et al., 2020). Therefore, the objective of this work was to determine the optimal amount of phenylalanine (Phe) and tyrosine (Tyr) in the diet and the feeding time.

Material and methods

Seabreams with an average weight of 29.65±1.72g were stocked at 30 fish/tank in twelve 500 L flat-bottom circular tanks at 5 kg m^{-3}. The experimental treatments consisted of different types of feeding: control, Phe-enriched (5%, 7.5%, 10%), and Tyr-enriched (5%, 7.5%, 10%) food, for 2, 4 or 8 days each. Fish feed was provided through automatic feeders and the ration was adjusted to 3% tank biomass daily. At the end of the experiment, blood samples were taken from basal (non-stressed) fish, and 2 hours after stressing by air exposure (3 min). The samples were analyzed using commercial kits, measuring plasma cortisol, glucose, lactate, adrenaline and noradrenaline.

Results and discussion

Table I shows the p-values obtained after comparing the basal and the 2h post-stress states. The conditions whose stress indicators remained more stable (less significant differences) were the diet with a content of 5% and 10% of Phe for 4 days. In the case of the diets supplemented with Tyr, those containing 5% of the amino acid were for 2 days, for 4 days for all the amounts of Tyr in the diet and for 8 days those diets with the amount of 5% and 10% of Tyr.

Table II shows the values of the stress-related metabolites in those specimens fed the diet supplemented with Phe (5% and 10%). The adrenaline values presented significant differences between the specimens in basal state fed with 5% and 10% of the amino acid and between the specimens fed with both amounts of Phe but subjected to stress, noradrenaline only had differences in basal state.

Cortisol values in those specimens fed for 2 days with 5% Tyr were significantly lower than the rest, the minimum glucose was obtained after 4 days of feeding in the same way as in lactate and noradrenaline, adrenaline was obtained after 8 days of feeding (Table III).

In seabream, the values of plasma metabolites are modified with the addition of 5% of Phe and Tyr in the diet, in the same way it occurs in Salamanca et al., (2020) where 5% of amino acids in the diet modulate the metabolites plasmatic. The increase in epinephrine in basal state may be due to an accumulation of this hormone in plasma (Peter, 2011). Our results show that the best diet to mitigate stress is the one supplemented with 5% Phe or Tyr for 4 days of feeding.

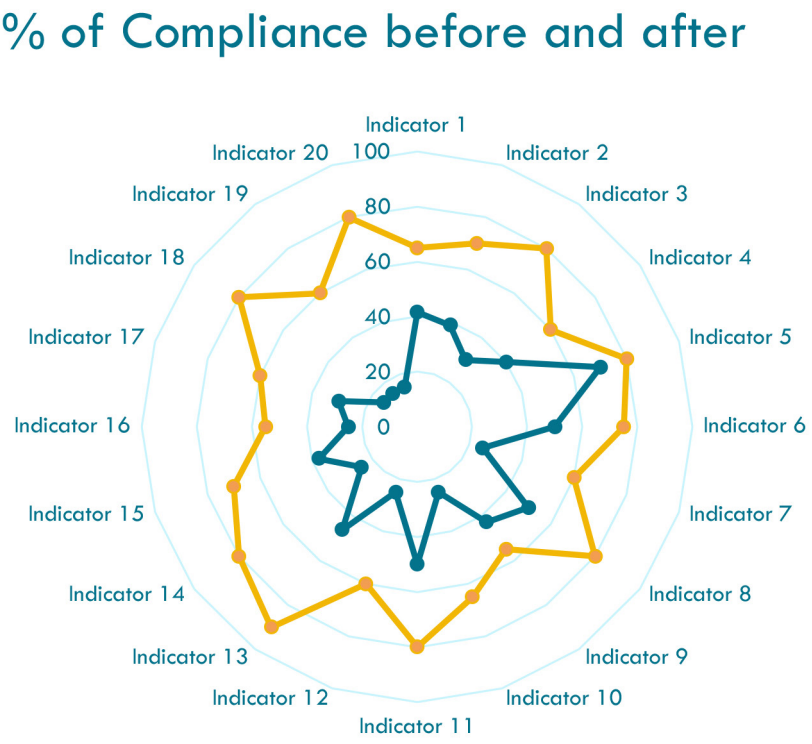
Introduction

Globally, awareness concerning poor working conditions and labour abuses on the Aquaculture Industry has significantly in the last decade. The various parts of the responsible global aquaculture system are responding with agreements, regulations, tools, frameworks, certifications and policies. The beginnings of standards to link labour on board fishing operations of marine ingredients for aquaculture are also emerging. However, a globally agreed Standard is not yet in place given the various jurisdictional, legal and operational technical challenges.

Through growing consumers and market expectations, the global communities' zero tolerance for onboard labour abuses poses significant brand and reputational risk. Key markets are demanding independent proof that seafood products are free from labour abuse and their traceability. For example, in August 2018 the Marine Stewardship Council introduced new requirements to provide transparency for labour practices at sea. All MSC certified fisheries now report publicly on the measures they are taking to address forced and child labour. In June 2021, the Aquaculture Stewardship Council launched the ASC feed standard that also include requirements for human rights and labour onboard fishing vessel

Crew members on board are also key actors to key the health of the Ocean, a tailored approach to assess the need of each fishing operation is needed to ensure that Marine Ingredients are coming from a fishery where there is not slavery, forced labour, child labour and human rights are respected.



(Continued on next page)

Methods and Materials

A unique social fingerprint tool for assessing the treatment and conditions of labor onboard fishing vessels has been developed that takes into account the major international frameworks (FFA FFC106, ILOC188, NGO criteria, Worker Voice Indicators, AENOR 195006, Responsible Fishing Scheme, the Geneva Declaration on Human Rights at Sea, SA8000, UNCLOS, UN FAO Code of Conduct for Responsible Fisheries, Aquaculture Stewardship Council, BAP, Global Gap, and BSCI).

Leading seafood sector companies have completed social labor assessments using this tool, and are developing management systems and policies and procedures to improve the conditions for labor on board.

This assessment and fingerprint tool has been trialed and developed for first time in a Tuna purse seiner fleet in Papua New Guinea in 2014 and the results were presented in 2015 at the Pacific Tuna Forum in Fiji; later in a Marine Stewardship Council certified Patagonian Toothfish fishing company (2016-2018) and further projects are underway with fishing companies operating in the Marine Stewardship Council certified Western Central Pacific tuna fishery, also the tool is able to assess fleet fishing pelagic fish for instance in Senegal and Mauritania. Building the capability within the seafood sector to manage this issue is critical.

A risk analysis, a desktop, audits on board at the port and interviews (30 crewmembers per vessel) to three toothfish multi-purpose fishing vessels and six tuna seiners fishing in the Indic, Arctic and the Pacific Ocean as well as carriers transporting frozen fish from the Western Central Pacific Ocean to Thailand, Vietnam and Philippines were assessed

Results and Conclusions

Several examples of the use of the tool, the results of the assessments in fleet fishing marine ingredients for Aquaculture, and of how capability is being built will be presented. This includes 20 criteria based on more than 150 indicators

FUNCTIONAL DIETS BASED ON ALGAE BIOMASS CAN IMPROVE GUT HEALTH IN GILTHEAD SEABREAM (*Sparus aurata*) JUVENILES

Introduction

Gilthead seabream (*Sparus aurata*) is a crucial species for Mediterranean countries' aquaculture. Seabream, like most farmed fish, faces stress and pathogens during its life, linked to the rearing conditions. One of the strategies to ensure animal welfare, is the diet, crucial to improve animal's performance and immune status. Special feeds in which selected ingredients are added, that trigger the immune system are important in certain periods of fish farming (e.g. high densities, grading, reproduction, transfer, transportation, vaccination), so their resilience against pathogens or other stressors is enhanced, diminishing the impact of disease outbreaks, mortality, and overuse of chemicals to restore the stock. Macroalgae and microalgae have been included in diets for farmed aquatic animals as sources of bioactive compounds, since they possess a high quantity of antioxidant molecules, and present high-quality protein content, promoting optimal animal growth, and overall health. In fish, like in most animals, the status of health of an animal is deeply connected with the health of its gastrointestinal tract, the gut can be used as a target tissue to evaluate the immune status of animals, as a mirror of overall health. In the present work, the synergistic effects of including a blend of *Gracillaria* sp. and *Nannochloropsis* sp. were tested on immune and oxidative stress status in the gut, and overall performance of gilthead seabream juveniles.

Materials and methods

Gilthead seabream juveniles with an initial body weight of around 1g, were randomly distributed over 12 fiberglass circular tanks (300L) in a flow-through seawater system with daily monitorization of abiotic parameters (salinity, temperature, and oxygen saturation) at IPMA/EPPO facilities (Olhão). Tanks were randomly attributed one of the four isonitrogenous and isolipidic diets to be tested in triplicate: CTRL1 (a control commercial-type formula), CTRL2 (an improved formula with no algae biomass), BLEND3 (a formula with 3% algae biomass inclusion: 1.5% *Nannochloropsis* sp.+ 1.5 % *Gracillaria* sp.) and BLEND6 (a formula with 6% algae biomass inclusion: 3% *Nannochloropsis* sp.+ 3 % *Gracillaria* sp.). Microalgae biomass was obtained from Allmicroalgae whereas macroalgae biomass was produced by Algaplus. All diets were formulated and manufactured by SPAROS. The experimental diets were supplied *ad libitum* to the fish through 4 daily meals, for 8 weeks. Sampling took place after 4 weeks (early sampling) and at the end of week 8 (final sampling). At each sampling time, fish were anesthetized with phenoxyethanol, growth was evaluated by weight, gut tissue was collected to evaluate immune and antioxidant response. Samples were stored at -80ºC for immune and biomarkers assays, and samples for gene expression were kept in RNAlater at -20ºC.

Homogenates of the gut were prepared to assay oxidative stress biomarkers (i.e. reduced glutathione: oxidized glutathione ratio, catalase, lipid peroxidation, glutathione S-transferase) and immune (immunoglobulins, and peroxidase) related parameters. A fragment of the anterior intestine was used for gene expression analysis (i.e. *il1β*, *il10*, *il34*, *hep*, *hspt70*, *igm*, *csfr1*, *tnfα*, *sod* (Mn), *gsp2*, *cd8α*, *muc*, *vim*, *occl*, and *tub*), *18s* worked as reference gene. Data analysis was performed using SPSS statistics 26 (IBM).

Results and discussion

Survival and relative growth rate were not altered by the dietary treatments, all fish developed well, presenting similar output to commercial and improved formula.

Oxidative stress biomarkers at early sampling showed no significant differences, only a slight increase, mainly in fish fed the BLEND6 diet. At final sampling, a significant reduction of total glutathione was detected, in all diets in comparison to CTRL1, more evident in BLEND6 treatment.

(Continued on next page)

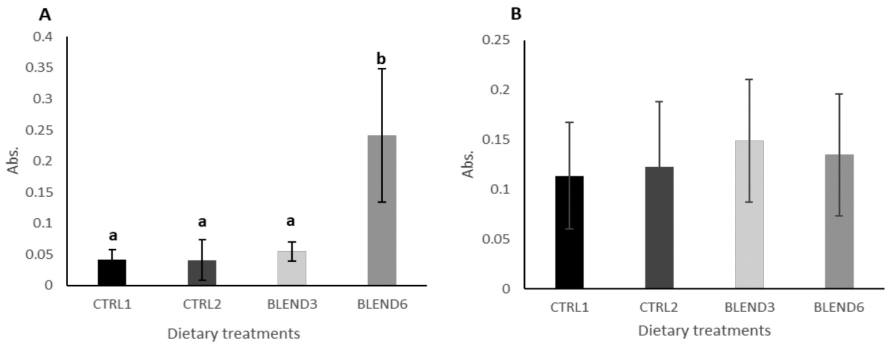

Fig.1 – Quantification of IgM levels on the gut of *Sparus aurata* juveniles fed dietary treatments: A – early sampling, B- final sampling, OD 450nm. Values are presented as means ± SD (n = 12). P-values from ANOVA one way, followed by Tukey's post-hoc test ($p \leq 0.05$). Different lowercase letters stand for significant differences among treatments.

The gut immune status recorded an increase in immunoglobulins (IgM) after 4 weeks in the diets with algae inclusion, mainly the BLEND6 (Figure 1). No significant changes were observed in total peroxidase levels. The mRNA expression levels of immune-related genes suggested that no inflammatory response was triggered. Most genes did not differ significantly between treatments; however, the BLEND3 diet promoted an increase of expression of intestinal mucins, linked to gut permeability.

Conclusion

Data from this study support the already consensus idea that algae have enormous potential as functional ingredients in fish diets. Small percentages of inclusion of microalgae and macroalgae can be crucial in terms of antioxidant capacity and growth promotion, which translates into good welfare of farmed fish. Overall, gilthead seabream juveniles fed diets supplemented with algae blends presented normal ranges for growth performance and survival. Gut oxidative stress biomarkers and immune parameters revealed that the blends improved the antioxidant system and have an immunomodulatory effect. *Nannochloropsis* sp. is known to have an immunostimulant effect, improving the innate defense mechanisms in the fish, while *Gracillaria* sp. may work as a prophylactic agent against chemotherapeutics compounds and also as an immune enhancer. According to these results, these algae biomasses combined seem to be promising candidates for inclusion in diets for gilthead seabream juveniles, mainly for stressful periods.

Introduction

Despite efforts to reduce the need for plastics, the worldwide production and use of plastic products is enormous. In addition to their ability to mechanically damage the digestive system of aquatic invertebrates and vertebrates, another major risk of plastic particles is their capability to disintegrate into smaller particles, so-called microparticles, which are commonly defined as particles <5 mm in size. Some authors have already described the ability of these microparticles to further disintegrate in the digestive tract and penetrate the tissues of the various organisms. One of the main tasks of our study was whether plastic particles in microsizes can cause inflammatory changes in the body organs and possible disruption of the immune system.

Materials and Methods

We performed a test in accordance with OECD 215 methodology (Fish Juvenile Growth Test) in which polyethylene (PE) particles (size 40–48 μm) were incorporated into rainbow trout's commercial feed pellets. A total of 80 individuals were divided into control and three experimental groups fed by 0.5%, 2% and 5% PE concentration from their feed ratio / day. The experiment lasted six weeks and ended by taking the biometric data, blood and samples of tissues for subsequent laboratory analyses. The aim was to evaluate the changes in haematological and biochemical profile, changes in markers of oxidative stress and selected genes via their mRNA expression and to support obtained result with histological and electron microscopy images. All methodological and statistical procedures of samples and data processing are referred in detail by Hodkovicova et al. (2021).

Results and discussion

One of the most interesting findings of this experiment was the presence of numerous skin lesions on the body surface of exposed groups. Disruption of the skin barrier can have a serious impact on an individual's innate immunity. These findings were also confirmed by histological images in which an increased presence of mucinous cells was observed in response to innate-immunity stimulation. Oral intake of the PE particles also disrupted the intestinal mucosa, on which visible cracks and an increased amount of mucus were detected by electron microscopy in an attempt to prevent mechanical damage to the intestine integrity. However, the most affected organs by PE were gills, liver and kidneys, i.e. organs important for metabolic and detoxification processes.

Inflammatory lesions and extensive structure alterations were observed in gills of all PE exposed groups; this could negatively affect oxygen exchange with the external environment. In liver, wide hepatodystrophies were observed histologically for all PE groups and the pro-inflammatory cytokines, tumour necrosis factor alpha (*tnfa*) and interleukin 8 (*il8*), had increased mRNA amounts in 2% PE. Same cytokines were also increased in cranial kidneys (5% PE) together with the multiple pigment deposits and hyalinosis of tubules observed histologically in all PE exposed groups. Hyaline droplets are considered to be a marker of degeneration process, tubular necrosis, functional disorders or even neoplasia. Both *tnfa* and *il8* are related to a positive immune response that suggest that the diet supplementation with PE may cause tissue inflammation. Moreover, pathological processes found in gills, liver and kidney together resulted in reactive oxygen species release which was confirmed by the significantly increased antioxidant capacity of plasma in 2% PE indicated by the ferric reducing ability of plasma, i.e. FRAP marker.

A leukocyte amount decreased with the increasing PE concentration which could be a result of leukocyte migration to the site of the inflammatory process. This was supported also by increased mRNA amounts of *tnfa* and *il8* in organs which are responsible, among other, for regulation of leukocyte migration and phagocytosis. Given all the results obtained during experiment, authors can state that there was a significant disruption of the immune system caused by PE, especially in higher tested concentrations.

(Continued on next page)

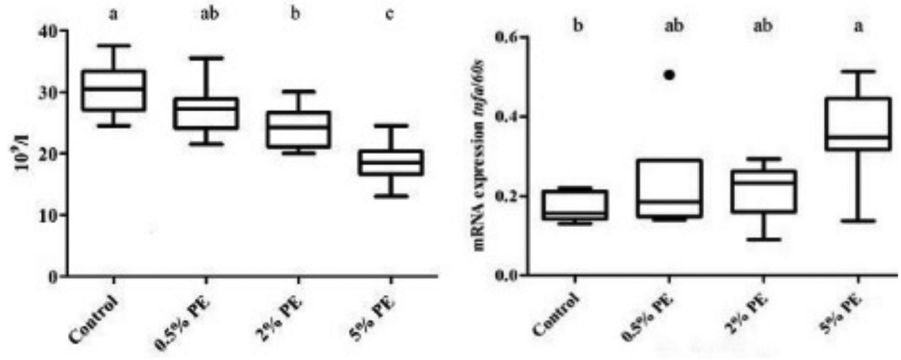

Figure 1. The decrease of total leukocyte count in plasma (left) and the increase of mRNA amount of *tnfa* in cranial kidneys (right) after oral exposure to polyethylene (PE) microparticles: 0.5%, 2% and 5%. Data are given as mean ± SD (n = 8); significance is stated as means with different letters of superscript (a, b).

Introduction

The use of single-use packaging materials has increased dramatically in recent decades in parallel with increasing trends in convenience and fast-food. Most of these packaging materials are made of non-biodegradable, petroleum-based polymers that have degradative impacts on the environment and contribute to the global plastic pollution crisis. Finding alternative packaging materials is an important step towards building a bio-based circular economy. Sustainable land-based macroalgae cultivation can provide a solution, as it eliminates land-use pressure on coastal areas, doesn't interfere with recreational activities or agriculture, reduces seasonal limitations, allows for complete control over product quality, and ensures consistent quality and traceability. Here, we present the success story of land-based macroalgae production for sustainable packaging solutions in the food industry via the Mak-Pak and Mak-Pak Scale-Up projects.

Materials and Methods

An initial screening of local macroalgae species was conducted based on detailed knowledge of growth rates, seasonality, geographic range, edibility, iodine content, biochemical properties, bioactivity, robustness and ease of cultivation. Different combinations of selected macroalgae were tested to develop a biodegradable, edible packaging prototype that was rated by consumer tests. In a follow-up project, we are focusing on eliminating the biggest bottleneck: scaling-up biomass production. We have partnered with a local, innovative farmer to sustainably scale-up and optimize biomass production for our sustainable, biodegradable macroalgae-based packaging material for the food industry.

Results

Several species of suitable macroalgae were selected based on the screening protocol and a method for using different combinations of selected species is described in a patent application for the packaging prototype. The packaging prototype was positively reviewed in consumer tests, where the consumers were pleasantly surprised by the neutral taste and smell. We could also show that certain components of the macroalgae that are important for packaging functionality (e.g. antioxidant activity) could be optimized during land-based production in artificial seawater. Currently we are in the early stages of scaling-up production and selecting strains to optimize growth rates and robustness, where we can complete the life cycle of one selected species from single cells to mature gametophytes within 6 weeks. With controlled induction of reproduction, we can continually provide material for transplantation to large-scale systems.

Discussion

The Mak-Pak and Mak-Pak Scale-Up projects have been featured in numerous news articles, exhibitions, and podcasts throughout Germany, Europe and even New Zealand. Our experience has shown that there is a lot of public interest in macroalgae-based packaging solutions. Consumers have become aware of the plastic pollution crisis and are open to alternatives to plastic packaging. Consequently, we have recently seen rapid changes in packaging trends in the cosmetic and food industries. Here we show that it is possible to produce a biodegradable, edible packaging from macroalgae biomass for the food-industry. Not only is this a success story for sustainable aquaculture, but also for macroalgae cultivation in general. This project has increased public awareness of macroalgae and contributed to a dialogue about the diversity of products and services that macroalgae can provide as we strive towards a sustainable, circular economy. However, optimization of the raw material production as well as the packaging itself is still underway. Furthermore, limitations in the food-industry require that our raw material meets high quality standards. In other industries where the quality of the raw material is not a limiting factor, there is enormous potential for macroalgae-based packaging solutions.

THE EFFECT OF ORAL APPLICATION OF POLYSTYRENE MICROPARTICLES ON RAINBOW TROUT'S (*Oncorhynchus mykiss*) HEALTH PARAMETERS

Introduction

Plastic pollution is a global problem caused by an excessive use of this material, its high resistance in the environment and poor waste management. In the environment, larger-sized plastic particles may be transformed into smaller particles, so-called microplastics (< 5 mm), which have been discovered in the bodies of various organisms, across all trophic levels of the aquatic environment. The oral intake of plastic pollutants may cause mechanical damage of digestive tract; moreover, smaller particles are able to permeate the intestinal wall and transport to other tissues and organs (Provencher et al., 2017).

Materials and methods

The experiment was performed in accordance with Fish Juvenile Growth Test (OECD 215). The polystyrene microparticles (52.5 ± 11.5 μm) were incorporated into commercial feed pellets of experimental groups and their effects were compared to the control group (without microplastics). A total of 128 rainbow trout individuals were tested, divided into control and three experimental groups as follows – polystyrene microplastics in concentration of 0.5%, 2% and 5% of daily feed intake. The whole experiment lasted 8 weeks including 14-day long period of acclimatization and 6 weeks of experimental phase. At the end of the experiment, all fish were stunned with a blow to the head and killed by spinal transection. During the autopsy, samples of the liver tissue and gills (n = 8 per one concentration) were taken for the real-time quantitative polymerase chain reaction (qRT-PCR). The methodology of the qRT-PCR was adopted according to Hodkovicova et al. (2021) likewise as the primer sequences of genes of interest – interleukin 1β (*il1β*) and 8 (*il8*), thyroid hormone receptor α (*thrα*), tumour necrosis factor α (*tnfα*) and reference gene (*60S*). The difference was considered as statistically significant and highly significant if $p < 0.05$ and $p < 0.01$. Box plot graphs were constructed using median with whiskers of maximum 1.5 interquartile range and outliers denoted as points.

Results and discussion

During the experiment lasting, the expression of genes *il8* ($p < 0.01$), *thrα* and *tnfα* ($p < 0.05$) increased in the group exposed to the highest PS concentration (5%) in the liver tissue. In gills, the expression of *il1β* ($p < 0.05$) increased as well in 5% PS. The results are expressed in Figure 1.

The results of our experiment showed that PS microparticles may negatively affect the immune system of the rainbow trout. The increased expression of the pro-inflammatory cytokines, *il1β*, *il8* and *tnfα*, may cause some severe chronic diseases and could lead to changes in leukocyte migration ability, altered neutrophil activation and phagocytosis. Increase in *thrα* expression could negatively affect cell proliferation and differentiation. Altered function on thyroid hormones could result in angiogenesis and proliferation on cancer cells (Gionfra et al., 2019). The inflammation discovered in liver and gills by gene expression analysis will be further verified by histopathological examination. As the liver and gills are main detoxifying, metabolic and osmotic organs, their prolonged weakening can cause severe homeostatic and immunity changes with consequent susceptibility to infectious diseases and increased fish mortality (Hodkovicova et al., 2021).

(Continued on next page)

DOES SPERM CONCENTRATION MATTER IN CARP SPERM CRYOPRESERVATION?

Á. Horváth*, B. Pataki, G. Mészáros, Z. Marinović, N. Kitanović, B. Urbányi

Institute of Aquaculture and Environmental Safety, Hungarian University of Agriculture and Life Sciences, 2100 Gödöllő, Hungary
E-mail: Horvath.Akos@uni-mate.hu

Introduction
Sperm cryopreservation has been recognized as an important tool in preservation of genetic resources in aquaculture as well as species conservation. Prior to freezing, sperm is typically diluted with an extender containing the cryoprotectants. In aquatic species dilution is generally done to a given ratio (e.g. 10×), while the importance of dilution to a given sperm concentration has been emphasized in several studies (Dong et al., 2007; Nynca et al., 2017; Judycka et al., 2018). Sperm concentration can be determined using several techniques: hemocytometers, absorbance measurement, computer-assisted sperm analysis (CASA) systems.

In this study we investigated whether absorbance or CASA systems give a better prediction of sperm concentration as opposed to cell counting in a hemocytometer and if standardization of sperm concentration has an effect on post-thaw motility and fertilizing capacity of common carp (*Cyprinus carpio*) sperm.

Materials and methods
Carp sperm was collected following hormonal stimulation of spermiation. Sperm concentration was determined at 1000× dilution using a Bürker-Türk type hemocytometer or using an AndroVision CASA system at 100× dilution. Absorbance of the same samples was determined either with a cuvette or a plate spectrophotometer at 100× dilution. Linear regression was used to determine the relationship of sperm concentration calculated following counting in a hemocytometer to that calculated by the CASA system as well as the absorbance measured by the two types of spectrophotometer.

Carp sperm was cryopreserved according to the protocol developed previously for that of the grayling (Horváth et al., 2012). Prior to freezing, sperm was diluted to the final concentration of 0.5; 1; 2; 4×10^9 spermatozoa per ml as well as in a 10× ratio. Following thawing, sperm motility parameters were determined using CASA. Fertilization tests were carried out using cryopreserved sperm and the fertilization percentage of eggs was determined.

Results
A significant negative linear relationship was detected between absorbance measured with cuvette spectrophotometer and sperm concentration (p=0.0002, r^2=0.7072, y=-3.416 $\times 10^{11} x - 6.658 \times 10^9$). A significant positive linear relationship was observed between absorbance measured in the plate spectrophotometer and sperm concentration (p=0.0022, r^2=0.7602, y=1.363×10^{11}x+1.576×10^9). The concentration values measured with CASA showed a significant linear relationship (p<0.0001, r^2=0.8559, y=0.7317x+8.555×10^8) with sperm concentration counted in a hemocytometer.

No significant main effect of sperm concentration was found on any of the parameters measured by CASA with the exception of LIN (p = 0.0112) where the post-hoc test found a significant difference (p = 0.0056) between linearity value for the sperm concentration of 0.5×10^9 spermatozoa mL^{-1} (0.86±0.03) and that for the 10× dilution ratio (0.74±0.08). A significant main effect (p = 0.0156) of cell concentration on the fertilizing capacity of cryopreserved common carp sperm was found with a significant difference (p = 0.0121) between the fertilization percentage of batches fertilized with sperm frozen at a cell concentration of 4×10^9 spermatozoa mL^{-1} (66 ± 6%) and the positive control (sperm diluted at a 10× ratio, 49 ± 5%).

Discussion
Results of this study demonstrated that in case of common carp sperm, CASA systems provide a reliable alternative for the determination of sperm concentration to the slow and cumbersome counting of sperm in a hemocytometer. Spectrophotometry was found also to be a good predictor of sperm concentration when CASA systems are not available. Sperm concentration, however, had little influence on the post-thaw motility an fertilizing capacity of carp sperm.

Introduction

The only currently accepted methods of producing sterile salmon for human consumption in Europe is triploidy (Benfey, 2016). Whilst research into the use of triploid salmon in aquaculture extends as far back as the mid-1980's (Benfey & Sutterlin, 1984), triploids are yet to be accepted as a viable alternative to diploids. Much of this stems from the fact that triploids are historically believed to be inferior to diploids (Leclercq et al., 2011; Benfey, 2016), however new knowledge on triploid biology has led to improved husbandry and nutrition and subsequently performance of triploid stocks (Fraser et al., 2013; Taylor et al., 2013). Triploids require lower egg incubation temperatures than diploids for optimal bone health (Fraser et al., 2015; Clarkson et al., 2020) and they are more sensitive to higher temperatures later in life (Atkins & Benfey, 2008; Hansen et al., 2015). This study aimed to study the impact of acute thermal shocks during egg incubation and explore how these impact egg dropout, growth and survival, immune response, and tolerance to a thermal challenge later in life (possible thermal programming and memory). Increasing the understanding of how early life history impacts phenotypes will support the industry in the development of ploidy specific husbandry for triploid Atlantic salmon.

Material and Methods

A total of 7,200 Atlantic salmon eggs were stripped from a single female (Aquagen) and split into 2 batches. After fertilisation by a single male, 1 batch was triploidised using hydrostatic pressure (9500 psi for 6.25 min at 8°C, 37.5 min post-fertilisation) both batches were incubated at 4 °C until eyeing (357 °/days) at which point they were transferred to the Institute of Aquaculture (IoA), University of Stirling, Scotland. Eggs were split into 24 tanks (300 eggs per tank) and after 24hr acclimation at 6 °C, three thermal shock treatments consisting in either 1 hr, 6 hr or 1 hr daily for 5 consecutive days at 10 °C were applied in triplicate with a control (egg handling but no thermal shock). During the thermal shock the eggs were subjected to an acute temperature shock from 6 to 10 °C and then back down to 6 °C. After the shocks, eggs were taken back to the tank, the temperature remained at 6 °C until just before first feeding at which point it was raised to 12 °C (1 °C/day). Fish were grown out for 7 more months. To test for the impact of the early temperature shock (thermal programming and memory), fish were challenged to an increase temperature of 16 °C (1°C/day) for three weeks. Feed intake was recorded daily in each tank throughout the experiment. Finally, to test for fish immune response, a PAMPS challenge (I.P. injection of 5 µg/g of Poly I:C, n=3, 6 fish per treatment with an additional 6 control fish injected with PBS) was performed.

Growth performances were analysed and X-rays were taken from 48 fish per tank for deformity analysis. Blood samples were taken before and after the thermal challenge for stress biomarker analysis. Head kidney samples were taken before and after (24 hrs) Poly I:C injection for qPCR analysis of immune related genes.

Results

The repeated shock treated diploids exhibited significantly more premature hatching (<430 **°/days)** than the control (*P*=<.001). Thermal treatment did not affect radiological vertebral deformities. In the triploid groups total feed intake and final weight were higher in the 6 hr and 1 hr treated fish but not significantly. Total specific growth rate was highest for the 6 hr treatments of both ploidies at both temperatures but not significantly. Biological FCR (bFCR) was lower in the 6 hr treatment than the control for diploids at both temperatures while in triploids, bFCR appeared to be lowest in the control at 12°C but lowest for the 6 hr treatment at 16°C.

Triploids suffered more pins and runts and weighed less at 1st feeding. Triploids also hatched earlier, with all tanks reaching 90% hatch 2 days earlier than any diploid tank. At both 12 °C and 16 °C triploids ate more than diploids overall, although this difference disappeared at 16 °C. At the end of the experiment triploids weighed significantly more than diploids. Radiological vertebral deformities were relatively low but were significantly higher in triploids than diploids. No cases of aplasia of the septum transversum, previously reported in the literature, were observed despite the thermal treatments. qPCR (PAMPS challenge) analyses are underway and results will be presented at the conference.

(Continued on next page)

Discussion

The thermal shocks had a limited negative impact on the performance of both ploidies. With the exception of higher premature hatch in the repeatedly shocked diploids and higher egg drop out in triploids, no differences between treatments in terms of deformity or later mortalities were observed. Given the known sensitivity of triploids to higher incubation temperatures (Clarkson et al., 2020), this result is promising and suggests that triploids are reasonably tolerant to short term acute changes from optimal incubation temperatures after eyeing. Whilst there was a significantly higher level of radiological vertebral deformities in triploids, this was considerably lower than seen in previous studies (Fraser et al., 2015), this is likely due to the fact that eggs were incubated at 4 °*C until eyeing.* Overall triploids growth and performance did not appear to be significantly impacted by the thermal shocks, and whilst there was a higher level of pin fry, survival between ploidies was comparable. Some evidence of thermal programming was apparent with the triploid 6 hr group final weight being on average 6.5 % higher than the control, the diploid 6 hr group having the lower average bFCR than the control at both temperatures and the triploid 6 hr group having a lower average bFCR than the control at the higher temperature. Ongoing qPCR analysis of the PAMPS challenge will shed more light onto the impact of the thermal shocks to immune response.

Introduction

Triploidy remains the only accepted method of producing sterile salmon for human consumption in Europe (Benfey, 2016). Triploids are historically believed to be inferior to diploids (Leclercq et al., 2011; Benfey, 2016), however new knowledge on triploid biology led to improved husbandry and nutrition and subsequently performance of triploid stocks (Fraser et al., 2013; Taylor et al., 2013). Triploids require lower egg incubation temperatures than diploids for optimal bone health (Fraser et al., 2015; Clarkson et al., 2020) and they are more sensitive to higher temperatures later in life (Atkins & Benfey, 2008; Hansen et al., 2015). This study aimed to study the impact of acute thermal shocks during egg incubation and explore how these impact the transcriptome, epigenome, and performance later in life. Such new fundamental knowledge will contribute to understanding how early life history may impact on long term phenotypes and support the development of ploidy specific husbandry in triploid salmon produced commercially.

Material and Methods

A total of 7,200 Atlantic salmon eggs were stripped from a single female (Aquagen) and split into 2 batches. After fertilisation by a single male, 1 batch was triploidised using hydrostatic pressure (9500 psi for 6.25 min at 8°C, 37.5 min post-fertilisation) and the other was handled similarly but not triploidised. Both batches were incubated at 4 °C until eyeing (357 °/days) at which point they were transferred to the Institute of Aquaculture (IoA), University of Stirling, Scotland. Eggs were split into 24 tanks (300 eggs per tank) and after 24hr acclimation at 6 °C, three thermal shock treatments consisting in either 1 hr, 6 hr or 1 hr daily for 5 consecutive days at 10 °C were applied in triplicate with a control (egg handling but no thermal shock). During the thermal shock the eggs were subjected to an acute temperature shock from 6 to 10 °C and then back down to 6 °C. After the shocks, eggs were taken back to the tank, the temperature remained at 6 °C until just before first feeding at which point it was raised to 12 °C (1 °C/day). Fish were grown out for 7 more months. To test for the impact of the early temperature shock (thermal programming and memory), fish were challenged to an increase temperature of 16 °C (1°C/day increase) for three weeks. Feed intake was recorded daily in each tank throughout the experiment. Finally, to test for fish immune response, a PAMPS challenge (I.P. injection of 5 µg/g of Poly I:C, n=3, 6 fish per treatment with an additional 6 control fish injected with PBS) was performed.

Samples (eggs) were taken before and after shocks (7 days) for Reduced representation bisulfite sequencing (RRBS) and RNA-seq analysis to analyse the effects of the thermal treatments on both genome-wide methylation and transcriptomic profiles. Growth performances were analysed and X-rays were taken from 48 fish per tank for deformity analysis. Blood samples were taken before and after the thermal challenge for stress biomarker analysis. Liver samples were taken before and after thermal challenge for RNA-seq. Head kidney samples were taken before and after (24 hrs) Poly I:C injection for qPCR analysis of immune related genes.

Results

Diploids exposed to the repeated thermal shock treatment exhibited significantly more premature hatching (<430 °/**days)** than the control (*P*=<.001). Thermal treatment did not affect radiological vertebral deformities. In the triploid groups, total feed intake and final weight were higher in the 6 hr and 1 hr treated fish but not significantly so. Total specific growth rate was highest for the 6 hr treatments of both ploidies at both temperatures but not significantly.

Triploids suffered more pins and runts and weighed less at 1st feeding. Triploids also hatched earlier, with all tanks reaching 90% hatch 2 days earlier than any diploid tank. At both 12 °C and 16 °C, triploids ate more than diploids overall, although this difference disappeared at 16 °C. At the end of the experiment triploids weighed significantly more than diploids. Radiological vertebral deformities were relatively low but were significantly higher in the triploid than the diploids. No cases of aplasia of the septum transversum were observed despite the thermal treatments.

qPCR (PAMPS challenge), RRBS (egg temperature treatments) and RNA-seq (high temperature challenge) analyses are underway and results will be presented at the conference.

THE IMPACTS OF DIETARY PHOSPHORUS ON WATER QUALITY IN RECIRCULATING AQUACULTURE SYSTEMS

Xiaoyu Huang*, Anne Johanne Dalsgaard, Sanni-Leea Aalto, Per Bovbjerg Pedersen

Technical University of Denmark, DTU Aqua, Section for Aquaculture, The North Sea Research Centre, P.O. Box 101, DK-9850 Hirtshals, Denmark.
E-mail: xiahu@aqua.dtu.dk

Introduction

The objective of this study was to investigate the impacts of dietary phosphorus on water quality in recirculating aquaculture systems (RAS).

Dietary phosphorus (P) requirement for rainbow trout (*Oncorhynchus mykiss*) is around 0.6–0.7% (Coloso et al., 2003; Dalsgaard et al., 2009). However, limitations in digestibility and body retention rate will drive up the P inclusion in feeds and consequently increase phosphate excretion (Coloso et al., 2003). High phosphate contents generally do not threat fish welfare, thus there is no internal treatment deployed in RAS to remove phosphate. Nevertheless, as a eutrophication contributor, phosphorus in aquaculture wastewater is highly regulated. On the other hand, as an essential element for cellular growth, high P concentrations may also contribute to internal eutrophication and promote microbial growth in RAS. Alteration in microbial water quality can reduce nitrification rates, introduce opportunistic pathogens, and increase fish stress (Rojas-Tirado et al., 2018). Some researchers have studied the mechanisms of phosphate excretion and its relation to dietary P in flow-through systems (Coloso et al., 2003; Sugiura et al., 2006). However, to the best of our knowledge, no study has investigated the performance of dietary P in RAS, especially with the focuses on micro particles and microbial water quality.

Materials and methods

Three type of feeds were formulated to provide 46% crude protein and 25% crude fat. High P group (HP) contained 55% fishmeal from trimmings, while medium P (MP) and low P (LP) groups replaced it with processed fish trimming meal (by further removing carcass remnants) at 10% and 20% of dietary protein, resulting in different dietary P contents (1.43%, 1.16%, and 0.90% respectively). The trial was conducted in triplicate using 9 pilot RAS situated at DTU Aqua, Hirtshals, Denmark. Each system consisted of a 500 L tank stocked with 7.84±0.02 kg of juvenile rainbow trout (*Oncorhynchus mykiss*), a moving bed biofilter (75 L), and a sump (140 L). Following 3 weeks of acclimation, experimental feeds were given to fish for 5 weeks at a fixed daily feeding rate of 100 g/tank, and daily water exchange was fixed at 60 L/system. Water samples were collected on a weekly basis from the sump for water quality analysis, including free-living bacteria abundance (represented by flow cytometry), microbial activity (represented by H_2O_2 degradation rate), and accumulated quantity and surface area (reflecting particle-associated bacteria abundance) of micro particles (1-100 μm). All statistical significance levels were set at 0.05.

Table 1. Summary of feed conversation rates (FCR) (n=3) and average water quality from the last three weeks (n=9) (mean ± standard deviation). Lowercase letters indicate statistical difference with other treatment groups.

Parameters	HP	MP	LP	Units
FCR	0.98±0.03	0.93±0.02	0.94±0.02	-
Total ammonia nitrogen	0.10±0.01^{a}	0.10±0.02^{ab}	0.12±0.02^{b}	mg N/L
Nitrite	0.09±0.02	0.09±0.01	0.09±0.02	mg N/L
Nitrate	57.29±1.77	56.12±1.59	58.31±1.69	mg N/L
Phosphate	4.32±0.17^{a}	2.65±0.07^{b}	1.39±0.30^{c}	mg P/L
UV transmittance	46.18±2.51^{a}	48.27±2.46^{a}	50.96±1.54^{b}	%
Free-living bacteria	43.29±32.35	33.51±22.84	21.12±6.08	million/mL
Microbial activity	0.70±0.44	0.65±0.31	0.46±0.10	1/h
Particle quantity	1.56±1.06	1.28±0.82	0.86±0.67	million/mL
Particle surface area	19.06±5.85	19.55±4.72	17.42±5.16	mm^2/mL

(Continued on next page)

Results and discussion

Dietary treatments had significant impacts on accumulated phosphate concentrations in RAS (Table 1), which were positively correlated with dietary P inclusions. The result was in line with the correlations between phosphate excretion and dietary P discovered by Coloso et al. (2003) and Sugiura et al. (2006) in flow-through systems. In the last three weeks, LP group had an approximately 78% reduction in phosphate content and 10% enhancement in UV transmittance when compared to HP group. Meanwhile, feed conversion rates (FCR) and nitrogenous water quality were little affected (Table 1). In general, all treatment groups experienced big variation in micro-particle quantity and microbial water quality. Even though no difference between treatment groups was detected by the end of the trial, there was a tendency for microbial activity and free-living bacteria abundance to decrease with the reduction in available phosphate (Table 1).

This study also found a strong linear correlation between microbial activity and free-living bacteria (R^2=0.769), but no correlation between microbial activity and micro particle surface area, indicating that free-living bacteria had higher microbial activity than particle-associated bacteria in intensive RAS. The findings also supported the presumption made by Pedersen et al. (2017) that in pilot RAS free-living bacteria might cause the cessation of linear correlation between microbial activity and micro particle surface area found in semi-intensive model trout farms.

Conclusion

This study showed that in rainbow trout RAS reducing dietary P from 1.43% to 0.90% could successfully minimize phosphate accumulation and cause a tendency for microbial activity and free-living bacteria abundance to decrease, with little affected FCRs and nitrogenous water quality. The result also suggested that free-living bacteria had higher microbial activity than particle-associated bacteria in intensive RAS. However, to further minimize the phosphate accumulation and confirm its impact on microbes in RAS, further reduction in dietary P should be studied.

SIMPLE FIELD STORAGE OF FISH SAMPLES FOR MEASUREMENT OF DNA CONTENT BY FLOW CYTOMETRY

Martin Hubálek*, Martin Flajšhans

University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters; South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Zátiší 728/II, 389 25, Vodňany, Czech Republic
Email: mhubalek@frov.jcu.cz

Flow cytometry is an effective and widely used tool for determination of ploidy in fish, but it is not always possible to access the fresh samples for analysis. We investigated the potential for extended storage of fish tissue with sterlet and tench as representative species of Chondrostei and Teleostei, using blood and fin of subadult/adult specimens and tail of larvae. Thirteen procedures for extending storage, selected for rapidity and simplicity in both field and laboratory conditions, were tested for each tissue sample. Flow cytometry was applied to fresh tissue immediately after sampling and to tissue subjected to experimental protocols, always along with species-specific standard, after 1, 5, and 10 days storage at 0–4°C or freezing at -80°C. The fluorochrome 4′,6-diamidine-2′-phenylindole dihydrochloride was used with excitation/emission maximum 358/461 nm. Based on the measurability of stored samples, evaluation of directly measured coefficients of variation of their DNA peaks and the changes in fluorescence intensity compared to fresh tissue, optimal procedures for extended storage of the selected tissue types of the model species are suggested.

FOODLAND: AQUACULTURE RESEARCH TO IMPROVE SUSTAINABLE FISH PRODUCTION IN AFRICA

F. Robinson, S. Hunter*, K. Hoevenaars T. Bardócz and M. Setti

*AquaBioTech Ltd, Central complex, Naggar Street,Targa Gap, Mosta, Malta
Email: fmr@aquabt.com

FOODLAND aims at enhancing the diversity of food production and consumption in six African countries displaying different stages of the nutrition transition. To this end, FOODLAND will create a network of 14 local Food Hubs that will aggregate relevant actors and serve as injection points for the introduction of innovations. FOODLAND has identified specific objectives addressing the organizational, technological, and nutritional needs of the local African food systems: 1. To detect behaviour and preferences of consumers and producers, in order to customize innovations to local sensitivities; 2. To develop and implement organizational innovations, aimed at boosting coordination among food operators; 3. To develop, test, and validate (open) technological innovations in the laboratory and in the field; 4. To disseminate knowledge of solutions towards malnutrition reduction and innovations.

The aquaculture research and validation activities of the project will ensure a solid knowledge base for overcoming the main problems in the development of aquaculture in Sub-Saharan Africa and will provide new methods and technologies for other countries in Africa. By developing aquaculture technologies for urban and peri-urban areas, the production is brought closer to the markets resulting in a shorter distribution chain that can be more competitive with imported products. The aquaculture Food Hubs to be developed in the project will therefore be less dependent on cold chain product distribution. New fish species will be valorised, and new fish processing methods tested to increase shelf life and value of the products and ensure a competitive advantage for the aquaculture sector. The project will focus on the research and development of the most efficient aquaculture technologies by applying the most advanced production methods in various systems while observing the local environment and low investment models. The possibilities of exploiting the integration of different aquaculture and agriculture systems will enable the reduction of production costs and use of imported fish feed. The specific RAS developed in this project will provide a system with low operational costs to ensure the supply of high-quality fingerling with affordable prices to small-scale fish farmers.

FOODLAND will empower smallholder farmers and food operators, foster nutrition-responsive and sustainable agro-biodiversity, reinforce the productivity and resilience of food supply chains, and will create new market opportunities at both the local and global scales, thereby encouraging the flourishing of rural communities. These achievements will benefit both African and European consumers by providing them with traditional-based, healthy, nutritious foods, while encouraging the diffusion of African diets and aiding the fight against malnutrition, particularly in women and children.

FISH WELFARE IMPLICATIONS OF PROLONGED FASTING PERIODS IN ATLANTIC SALMON

Malthe Hvas*, Ole Folkedal, Frode Oppedal, Lars Helge Stien

Animal Welfare Research Group, Institute of Marine Research, 5984 Matre, Norway
E-mail: malthe.hvas@imr.no

Feed withdrawal is a widespread practice in Atlantic salmon (*Salmo salar*) aquaculture to empty the gut prior to major farming operations. Moreover, emerging production practises such as RAS and offshore farm sites may also occasionally subject fish to prolonged fasting periods. However, such extended fasting periods may conflict with ethical and legal obligations to farm animals. Presently, science-based recommendations on responsible fasting times that consider fish welfare are lacking for Atlantic salmon as well as for other finfish aquaculture species.

We have investigated some of the physiological, behavioural, growth, and welfare related effects of fasting periods in a series of three studies on growing Atlantic salmon post-smolts in seawater. The purpose of this work was do define useable welfare guidelines for allowable fasting periods in Atlantic salmon aquaculture by identifying thresholds for significant impairments in performance traits.

In the first study, we measured metabolic rates in responses to increasing fasting periods of up to 4-weeks and after 1-week of subsequent refeeding in fish of ~575 g and ~38 cm at 12°C. The standard metabolic rate decreased stepwise after 1 and 3 weeks, showing that Atlantic salmon gradually adapt a mode of energy saving when resources are limited. The increase in metabolic rates following acute stress was slightly reduced after 4-weeks, indicating that stress responses first become impaired at this point. Following refeeding metabolic rate traits reverted to control levels, showing that metabolic adjustments to prolonged fasting were rapidly reversed when regaining access to feed.

In the second study, we measured the critical swimming speed in fish of ~250 g and ~29 cm at 12°C that had been fasting for up to 4-weeks. In addition, we also measured blood parameters before, at fatigue, and after 3 and 24 hours of recovery from the swim test. The 4-week fasting period reduced condition factors from 1.03 to 0.89. However, the critical swimming speed remained statistically unaffected at ~3.5 body lengths s^{-1}. Exhaustive exercise caused large osmotic and ionic disturbances, and large increases in plasma lactate and cortisol. During subsequent recovery, the changes in osmolality and plasma ions took the longest to correct, suggesting that these parameters may be considered the most challenging stressors during strenuous exercise in seawater. However, only minor effects of fasting period on blood parameters in relation to the swim challenge were detected which included a repressed response in red blood cell recruitment and reduced cortisol response at fatigue. Nevertheless, Atlantic salmon maintained their full swimming capacity and their ability to respond and recover adequately to acute challenges following extended periods of food deprivation.

In the third study, Atlantic salmon of ~1200 g and ~46 cm were fasted for 8 weeks at 12°C and subsequently refed for 5 weeks, whereafter they were transferred to triplicate sea cages in a common garden setup with a control group until harvest size of ~6100 g and ~73 cm. At the end of the fasting period fish had lost 7.3% mass and the condition factor had decreased from 1.2 to 1.0. Furthermore, fasted fish were 544 g lighter and 3.8 cm shorter than fed controls, corresponding to a size difference of 50%. Following periods of refeeding, fasted fish eventually showed compensatory growth and at harvest weight and length were statistically like controls. At harvest, males were larger than females, and immature fish were larger than maturing fish. The proportion of maturing fish was 25% higher in the continuously fed control treatments. After the 8-week fasting period, fish welfare was scored based on the salmon welfare index model. Only minor deviations were found and at similar regularities between fasted and control fish, showing that prolonged fasting did not cause detrimental welfare conditions. To assess potential long-term impacts on welfare status, vertebral deformities in the spinal column were quantified with radiology after harvest. Frequency of skeletal deformities were low and similar between treatments. Hence, Atlantic salmon are highly flexible with regards to growth patterns in response to food availability, and a prolonged fasting period neither caused reduced welfare in the short or in the long term.

Based on these three studies we conclude that farmed Atlantic salmon are well adapted to cope with prolonged fasting periods without suffering poor welfare or other detrimental and persisting consequences to physiological and growth performances. When poor welfare is observed in fish that have been fasting for long periods, the underlying cause will most likely instead by suboptimal environmental conditions or infectious diseases, not fasting on its own. As such, formulating welfare guidelines for allowable fasting periods for farmed Atlantic salmon may therefore ultimately be redundant since the required time to initiate severe starvation takes much longer than any realistically encountered fasting period in modern aquaculture practices.

WHY TO BET ON DIETARY LYSO-PHOSPHOLIPIDS: DEEP ANALYSIS OF WAYS-OF-ACTION IN SALMON VIA INTESTINE AND LIVER INTERACTOMES

A. Ibarz*[1], W. Nuez-Ortín[2], I. Sanahuja[1], L. Fernández-Alacid[1]

Introduction

Lipid supplies energy and acts as a structural component of cell membranes, and may spare protein in diets for aquatic animals. The inclusion of intact phospholipids in the diet could improve culture performance of various freshwater and marine fish species (Tocher et al., 2008). The primary beneficial effect was improved growth in both larvae and early juveniles, but also increased survival rates and decreased incidence of malformation in larvae, and perhaps increased stress resistance. Lyso-phospholipids or lyso-lecithin are produced from phospholipids by enzymatic hydrolysis. Lyso-phospholipids contain only one fatty acid tail. This structure makes them more hydrophilic than phospholipids, which translates into better emulsifying capacity. While lyso-phospholipid supplementation in animal feed mainly aims at improving fat emulsification, additional metabolic effects in fish have not been explored. The present study aimed to gain understanding of the mechanisms underlying the growth promoting effect of lyso-phospholipid supplementation (AQUALYSO®, Adisseo). Atlantic salmon was used as model species with intestine and liver as targets tissues.

Material and Methods

Middle intestine and liver (n =15) were dissected from adult Atlantic salmon fed a control and lyso-phospholipid (0.1% AQUALYSO®, Adisseo) supplemented feed for 12 weeks. Tissue protein purification was performed as described in Ibarz et al. (2010) with slightly modifications for the salmon tissue samples. Protein identification and quantitation were performed, via "shotgun analyses" from by nanoLC-MS/MS and the raw data were processed using the Proteome Discoverer 2.5.0.400 software (Thermo Scientific, Bremen, Germany). The complete map of interactions (interactome) was obtained from the differentially expressed proteins: DEPs (proteinteractome). For this purpose, the Search Tool for the Retrieval of Interacting Genes (via STRING program) public repository version 10.0 (https://string-db.org) was used. Protein-protein interaction (PPI) network for the differentially expressed proteins (DEPs) was conducted with a high-confidence interaction score. Gene ontology (GO) pathway enrichment analysis (Biological Processes; Reactome Pathways and Post-Translational Modifications) was also performed for the DEPs by STRING program.

Results and Discussion

Liver and mid intestine proteome were deep analysed to determine the main "ways-of-action" of the dietary lyso-phospholipid supplementation. The numbers of DEPs detected in each tissue were similar but differed in terms of the proportion of up-regulation and down-regulation (Fig. 1A). The most relevant interactomes were the up-regulated DEPs in liver and the down-regulated DEPs in intestine (Fig. 1B). They resulted from the STRING analyses and they were analysed by their significant clusters on Biological Processes and Protein Reactomes.

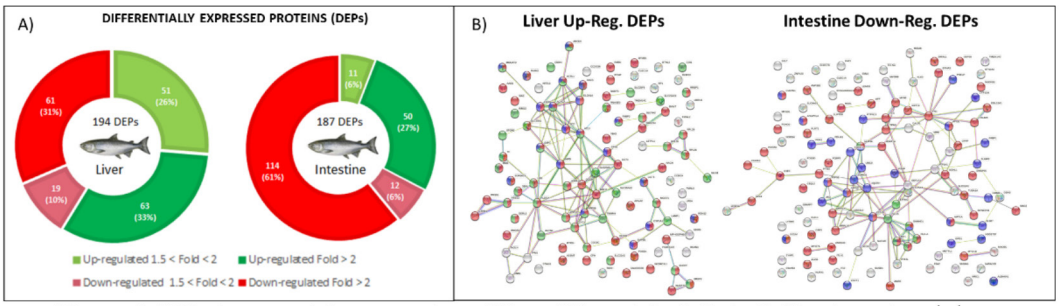

Figure 1. Effects on protein expression of Lyso-PL-enriched diet. A) Up- (green) and down- (red) regulated expressed protein distribution. B) Proteinteractome maps of liver up-regulated DEPs and intestine down-regulated DEPs.

(Continued on next page)

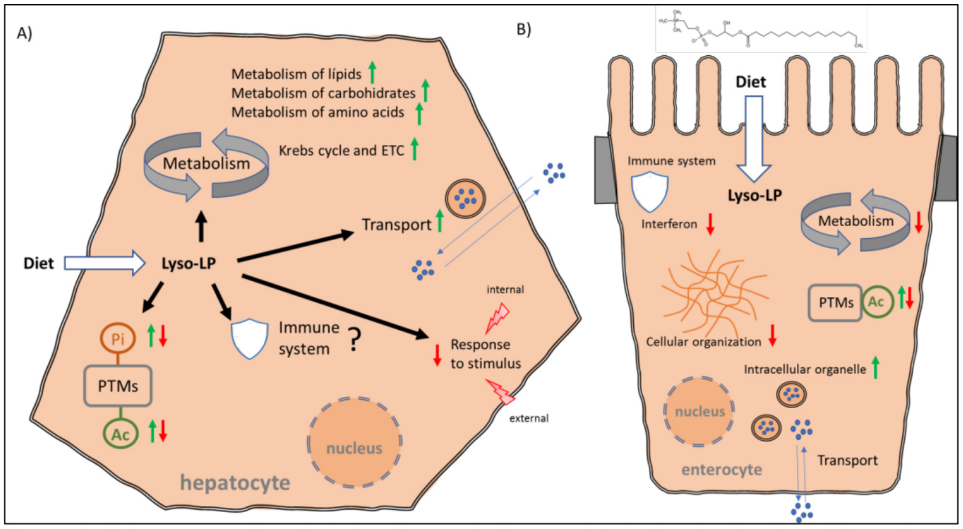

Figure 2. Scheme of main affected pathways in liver and intestine by the Lyso-LP-enriched diet. Green arrows indicated upregulation and red arrows indicated downregulation. PTMs (Post-Translational Modifications: Pi-phosphorylated, Ac-acetylated).

In liver (Fig. 2A), the Biological Processes enhanced by dietary lyso-phospholipids were related to the "metabolism" and specifically lipid, carbohydrates and amino acids metabolism together with mitochondrial activity. Moreover, intracellular "transport" was stimulated and the "response to stimulus" was downregulated. In intestine (Fig. 2B), the main effects were associated to an improvement of vesicle trafficking, whereas the "stress response" and the "interferon signalling" were downregulated. Interestingly, a vast number of DEPs in both tissues were significantly grouped in a PPI-enrichment of Post-Translational Modifications, mainly as acetylated or phosphorylated proteins. This could indicate a specific way-of-action of lyso-phospholipids also on important protein modification pathways following its biosynthesis.

In conclusion, shotgun proteomics points towards enhanced functionality of intestine and liver in fish following lyso-phospolipid supplementation.

Introduction

Anaesthesia plays a necessary role in fish manipulation in both aquaculture and research conditions. In order to maintain fish welfare during several common procedures, a wide range of anaesthetic agents has been described and used. Since its introduction, Tricaine methane-sulfonate (MS-222) has become the most used anaesthetic and its properties and physiological effects have been exhaustively reviewed (Topic Popovic et al., 2012). Being very hazardous in case of inhalation and skin contact, personnel using MS-222 must follow some safety practices, less guaranteed and controlled in large-scale production. Also, due to its toxicity and potential contamination of near ecosystems, in some European countries, such as Spain, France and Greece, MS-222 use is not licensed for food fish production while others apply very specific limitations ang lengthy withdrawal periods. Therefore, experimental studies carried in European fish farms should take regional legislation into account before administrating MS-222, widely established in laboratories. In this regard, the aim of the present study is to assess the use of clove oil, less persistent and authorized in most European countries, as a suitable alternative to MS-222 for research studies in farmed rainbow trout (*Oncorhynchus mykiss*). For this purpose, potential differences in plasma and skin mucus biomarkers and antibacterial activity were evaluated for individuals anaesthetized with MS-222 or with clove oil.

Materials and methods

Forty-eight rainbow trout individuals (343,55 ± 13,46 g) were randomly sampled from three different cages of a local fish farm (Viveros del Segre, Peramola, Spain) and anaesthetized with MS-222 (100 mg/L) (Sigma-Aldrich, Madrid, Spain) or clove oil (10 mg/L) (Sigma-Aldrich, Madrid, Spain) in two supplementary tanks of 40L in consecutives caught of 4 fish each time. Once fish were sedated, skin mucus was collected from all fishes by gently sliding sterile glass slides along both sides of the fish in a front to caudal direction and stored in sterile tubes (2mL). Blood samples were obtained from 12 fishes per condition from the caudal vein using syringes impregnated with EDTA-Li as the anticoagulant. The other 12 fishes per condition were directly recovered in two 40L additional tanks with oxygenated water, in order to evaluate the recovery capacity from both anaesthetics. The main stress and physiological biomarkers analysed in mucus and plasma were soluble protein, glucose, lactate and cortisol levels and were measured according to Fernández-Alacid et al. (2018, 2019). Additionally, antibacterial activity of plasma and mucus were measured against *E. coli*, *A. hydrophila*, and *A. salmonicida* adapting the protocol described in Sanahuja et al (2019). Statistical analysis was performed using Student's *t*-test of SPSS software Version 22.0 (IBM Corp, Armonk, NY, USA).

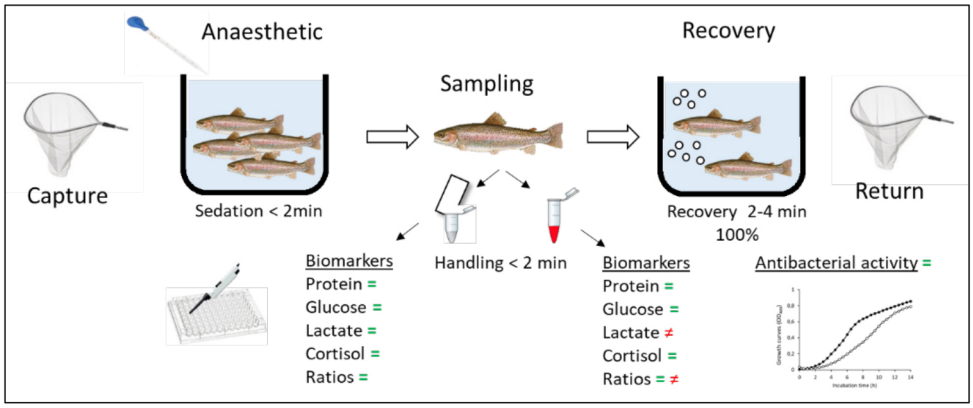

Figure 1. Schemetic representation of the whole process of anaesthesia, sampling and recovery of farmed rainbow trout. No significant differences (t-test) were observed in main biomarkers analysed (= symbol) except for plasma lactate (≠ symbol)

(Continued on next page)

Results and Discussion

In recent years, growing interest has been shown in the use of minimally-invasive methods to assess fish physiological status and welfare, such as fish skin mucus analysis. The use of MS-222 in fish research studies are not applicable to monitor farmed fish due to its hazardous. Clove oil, as an organic substance, does not require any withdrawal period in contrast to MS-222 (Topic Popovic et al., 2012). In this preliminary study we compared the main biomarkers of mucus and plasma when fish were anaesthetised with MS-222 or with clove oil (Figure 1).

Using the reported anaesthetic concentration, no differences were observed among the time for fish sedation (< 2 min) to be adequately handling and recovery (2-4 min for the 100% of returned fish). The stress-related biomarkers analysed, cortisol, glucose and lactate did not modify among clove or MS-222 for both mucus and plasma samples. Only plasma lactate was significantly higher (20%) in fish anesthetized with clove oil, which allow us to improve the time used to sampling the animals and avoid anaerobic metabolism. No significant differences of plasma antibacterial activity between anaesthetics were found for any of the bacterial strains tested (E. coli, A. hydrophila and A. salmonicida). Several previous studies suggested that the physiology of fish can be affected by changes in the haematology and biochemistry of exposed fish to clove oil. Current results have shown great promise for the use of epidermal mucus as a study and monitoring tool for trout culture.

In conclusion clove oil appears to be a strong alternative for farm aquaculture studies, specially using the mucus monitorization where sampled fish could be returned to farm in a remarkable short time (less than 10m).

Introduction

In the current scenario, global climate change is a reality that impacts all living species, including fish. The aquatic ecosystem, since it is the largest sink for global warming and high temperatures, is the most affected system and affects all types of aquatic life.

Materials and methods

Fish were fed on diets supplemented with vitamin C (0.40%) and E (0.35%), propolis (0.45%), phycocyanin (0.30%), and β-glucan (0.30%) along with a control diet for 56 days, followed by 18 days of extreme warm exposure. Growth performance, individual fitness, metabolic activities, nutrient assimilation capacity, and molecular stress responses were evaluated to understand dietary manipulation impacts.

Results

Final weight gain, weight gain, specific growth, and protein efficiency were higher in fish fed with propolis followed by phycocyanin, vitamin C & E, and β-glucan compared to the control diet. Besides, viscera somatic index, intestine somatic index, and hepatosomatic index values were higher in the control diet compared to tested diets. Significantly higher Na+ and Cl- levels were measured ($p<0.05$) in fish fed to control diet followed by vitamin C & E, propolis, phycocyanin, and β-glucan. While K+ ion level was found significantly lower ($p<0.05$) in fish fed with control and β-glucan supplemented diets during heatwave stress. Cholesterol and triglycerides levels were found significantly lower ($p<0.05$) in fish fed on vitamin C & E, propolis, and β-glucan supplemented diets compared to fish fed on the control diet. Blood urea nitrogen, creatine, and cortisol content were significantly lower ($p<0.05$) in fish fed with vitamin C & E, propolis, and phycocyanin supplemented diets compared to fish fed on the control diet. AST, ALT, and LDH contents were found higher in fish fed on Vitamin C & E supplementation followed by propolis, control, phycocyanin, and β-glucan supplemented diets. Transcriptomics result also supports the better health and physiological conditions in fish fed on vitamin C & E, propolis, and phycocyanin supplemented diets.

Discussion and conclusion

Diets with the increased dosage of Vitamins C and E, propolis extract, and phycocyanin were found to be beneficial for European seabass, *Dicentrarchus labrax* during extreme warm exposure. Diets containing high levels of either vitamin E (4.0 g kg-1) together with high levels of vitamin C (3.5 g kg-1), or propolis (4.5 g kg-1), or phycocyanin (0.30 g kg-1) were able to counteract the adverse effects of stress responses during extreme warm exposure. To some extent, these ingredients were found to improve fish growth, antioxidant capacity, and immune functions. In contrast, the inclusion of dietary β-glucan was found to be less functional in supporting fish growth, physiology, and metabolism.

SEASONAL SUCCESSION OF PLANKTON IN HYPERTROPHIC PONDS IS CONSTRAINED BY FISH DENSITY AND AVAILABLE PHOSPHORUS

Human-induced input of nutrients to waters further increases eutrophication, resulting in hypertrophy. To understand the processes of plankton succession in hypertrophic water bodies, we analysed data from six hypertrophic fishponds in Czech Republic, 2008 – 2016. The significant source of total phosphorus was supplemental fish feed giving an overall mean of 0.15 mg L^{-1} in fishpond water. Carbon in zooplankton biomass ranged from 0.004 to 5.9 mg L^{-1} reaching maximum in late spring. Fish biomass of 300–900 kg ha^{-1} disrupted the plankton food web by top-down elimination of zooplankton. Carbon in phytoplankton biomass ranged from 0.1 to 12.3 mg L^{-1} and peaked in late summer. The phytoplankton was dominated by cyanobacteria, closely reflecting the total phosphorus concentration in water. Algae grew until they had consumed available nitrogen, whereas cyanobacteria continued to grow due to the fixation of dissolved nitrogen. The top-down forcing plays a more significant role than was previously expected. Fish biomass lower than 300 kg ha^{-1} increase phosphorus transfer from phytoplankton to fish via zooplankton, and potentially improve water quality. Such seasonal plankton succession caused both by high phosphorus concentration, and high fish density has not been described by previous ecological studies.

DIFFERENTIATION AND INNOVATION IN NORWEGIAN SALMON AQUACULTURE: BARRIERS AND OPPORTUNITIES

A. Cojocaru, A. Iversen*, O. Bergesen and R. Tveterås

Nofima, Postboks, 6122, Langnes 9291, Tromsø, Norway.

E-mail: Audun.iversen@nofima.no

Introduction

The level of control over the farming process in salmon aquaculture makes it possible, in principle, for farmed Atlantic salmon to be tailored on a number of dimensions to meet requirements from different customer groups at different stages of the value chain. However, production, harvesting and primary processing of salmon have resulted in largely homogeneous products being exported from Norway. Around 85% of Norwegian salmon is exported as whole, gutted salmon (Norwegian Seafood Council, 2019). Primary processing in Norway focuses on fresh whole salmon with few of the farming companies also selling processed salmon, mostly as fresh or frozen fillets, and a few making portions and "ready-to-eat" products. As so much of the salmon is sold whole, and with fillets being of very similar quality, products can mainly be considered commodities, with standardized specifications and sold in markets where the price is driven by supply and demand (Asche, Bremnes, and Wessells, 1999; Asche and Bjørndal, 2011). Innovation tends to be focused on efficiency, and less on product development. Differentiated products are thus relatively few and associated volumes are small (Asche, Cojocaru, and Roth, 2018). Cojocaru, Iversen, & Tveterås (2020) discuss to what extent salmon is differentiated, how the differentiation strategies answer customers' quality demands, and the degree to which various attributes offer competitive benefits, leading to advantages or price premiums. However, while having identified general barriers to differentiation, we also found that differentiation is understood and approached differently across industry players depending on where in the value chain they operate or what customers they are serving.

This paper identifies five major routes of differentiation for salmon, including the strategies for differentiation as understood from the points in the supply chain where they are executed today. The paper then discusses specific barriers for each route of differentiation, including opportunities for achieving differentiation in each of them. To obtain information with respect to differentiation strategies for salmon, we conducted in-person interviews with a range of Norwegian producers, the majority of them also operating internationally.

Results

"It´s not the Norwegians who have done a good job, it´s all the customers." This quote from one of our informants illustrates the fact that differentiation of salmon products has taken place at different stages in the value chain, and not with the producers themselves. It implies different relations between sellers and buyers, with varying power balance and opportunities for differentiation. The value chain for Atlantic salmon, sketched in Figure 1, resembles that of other (intensive) food production systems such as pork and poultry (Asche, 2008; Asche, Cojocaru, and Roth, 2018), There is also an increasing tendency towards vertical integration (Kvaløy and Tveterås, 2008; Asche et al., 2013), with producers responsible for all stages from smolt production to export, but with little to no activities past the stage of primary processing.

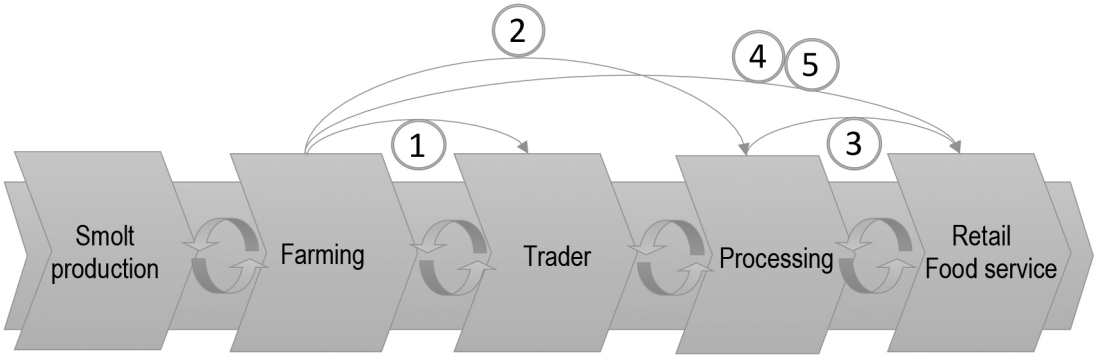

Figure 1. Simple representation of the Atlantic salmon value chain: with intermediate markets (or feedback loops) indicated between each stage. Numbered above: **Five different routes of differentiation** identified within the salmon value chain.

(Continued on next page)

The identification of differentiation routes throughout the value chain allowed for a classification of the differentiation strategies used. Figure 1 shows the five main routes of differentiation identified based on the interviews we conducted.

The first we termed *1) The commodity producer*, as most Norwegian salmon producers are large-scale producers of highly perishable products, implying a focus on low production costs and efficient production and logistics, with little differentiation. Slightly more differentiated products are sold by the *2) The industrial supplier*, supplying processors closer to the destination market, either in low-cost countries like Poland, or in the destination country. Processors, that either have their own brand or cater to private labels for retail chains, rarely ask for differentiated products, as they do their own differentiation, but choose suppliers based on industrial relations, where quality as supplier is as prominent as quality of products. *3) The marketing company*. Some traders make an effort to move away from trading the salmon as a commodity, towards marketing the salmon as something more distinctive. They move from sales to marketing. *4) The long-range producer* typically works with retail chains, contributing to a greater range and variety of products, which might be sold both under the producer´s own label or the chain´s label. *5) The branded producer*. A few of the largest salmon producers have launched their own brands, but only one has set off to create a global one. Brands are most prominent in the home market, or markets close to Norway, but are also slowly spreading to some of the major markets.

The routes identified above place an array of requirements on the firms, require different resources, or the firm's position in the value chain may lead to different probabilities of success. In practice, these differentiation route archetypes can vary from firm to firm. Some companies may also choose to pursue a number of routes in parallel, depending on the customer segments they serve. While (Cojocaru et al., 2020) identified general barriers for differentiation, this paper points to barriers for each of the identified routes of differentiation, and identifies responses to overcome these barriers.

The paper also discusses to what degree this categorization will be stable over time. Recent developments in new production techniques, with widespread innovation in new production processes (land-based farming, closed or semi-closed containment at sea, off-shore aquaculture, etc), might increase the focus on differentiation, and the share of production being marketed as differentiated products, as marketing of benefits with new production technologies, aiming to obtain premium prices, is meant to offset cost disadvantages and high investment cost in new concepts.

Table 1: Barriers and suggested responses for the defined routes of differentiation

Route of differentiation		Barrier(s)	Opportunities
1	**The Commodity Producer**	- Difficult and expensive to produce many varieties as production focuses on scale, efficiency and costs	- Origin and storytelling - Ecolabels - Shelf-life and value-added products
2	**The Industrial Supplier**	- Lacking demand for differentiated products (processing firms want to differentiate for themselves/their own products)	- Intrinsic qualities achieved through feed mix varieties - Service-oriented differentiation
3	**The Marketing Company**	- Little to no control over intrinsic properties	- Service- and concept-oriented differentiation
4	**The Long-Range Producer**	- Label-owners want to control differentiation - Supermarket chains interested in growing own private labels	- Growing category, room for more varieties, labels and certification - Intrinsic qualities achieved through feed mix varieties
5	**The Branded Producer**	- Costly, time-consuming, knowledge-intensive strategy	- Growing category, room for more varieties, value-added products, high-end products, brands, feed mixes

DESCRIPTION OF FIRST ESCAPE OF GREATER AMBERJACK (*Seriola Dumerili*, Risso 1810) IN THE MEDITERRANEAN SEA BY MEANS OF GENETICS, GEOMETRIC MORPHOMETRICS AND SOCIAL MEDIA

D. Izquierdo-Gomez[1]*, I. Talijančić[2], I. Žužul[2], T. Segvić-Bubić[2] Tanja decides the order

Introduction

The farming of the greater amberjack (*Seriola dumerili*, Risso 1810) in the Mediterranean Sea started in the 1980s in a capture-based fashion (FAO 2016-2021). Nowadays, as a result of the industrial diversification of marine fish in Mediterranean aquaculture, the rearing cycle of *S. dumerili* is fully carried out in captivity. However, it was not until 2017, when the industrial production and commercialization started, with Spain and Greece as the main producers (FishSTAT), and more recently Croatia in 2019 (No data available in FishSTAT; pers.obs Segvic-Bubic). Reared fish escaping from farms have a number of potential socio-economic and ecological implications, and some of them have been explored for *Sparus aurata*, *Dicentrarchus labrax* and *Argyrosomus regius* (Arechavala-Lopez et al., 2018).

This research describes the first escape of *S.dumerili* in the Mediterranean and aims i) to develop the identification techniques of the escaped individuals of *S. dumerili,* ii) to help understanding the potential influences of the escape events at a genetic and fisheries levels and, iii) to improve the aquaculture genetic management of the species.

Material and Methods

In the current research, captures of unusual individuals of *S.dumerili* were detected via pictures posted in Facebook groups with fisheries interest. Data on commercial fisheries landings of the artisanal fleet based on the marina of Santa Pola (38º11'12''N; 0º33'33''W, Alicante, Spain), was explored to identify abnormal captures of the *S. dumerili* at a temporal level. Local Ecological Knowledge of fishermen was obtained via personal interviews on Facebook messenger, to better understand the behavior and dispersion of the escaped fish.

Following a simplified mammalian DNA isolation procedure, a total of 492 individuals were successfully genotyped with 15 microsatellite markers developed for *S. dumerili* (Renshaw et al. 2006, 2007) from 10 populations sampled in both, the Adriatic and Balearic Seas, covering different fish origins (wild, farmed and escaped). Genetic diversity, differentiation and structure for each population were calculated and assessed by using FSTAT 2.9.3, Arlequin v.3., FreeNA, Structure 2.3 and Adegenet package in R.

A photo of the left side of each fish was taken at 1m (orthogonal distance), with a photo camera set at 50mm focal length. A 50 cm ruler was included in each picture for body length measurement in ImageJ software. Quantification and visualization of fish shapes were conducted by means of geometric morphometrics, using a total of 21 landmarks (TpsDig 2 and MorphoJ software and geomorph R package). Eventually, differences between fish groups of different origins were explored with canonical analysis.

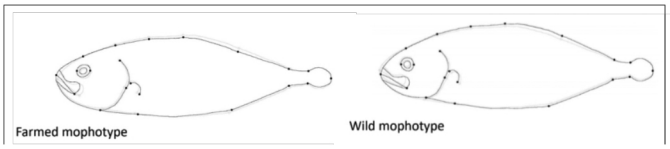

Figure 1. Farmed and wild *Seriola dumerili* morphotypes

(Continued on next page)

Results and conclusion

Arising from social media pictures and conversations/commentaries of fishermen, the escaped fish was darker than wild ones and some fish presented deformities and/or wounds. Approximately two months after the escape event, the presence of escaped *S. dumerili* still could be observed in the escape area. The maximum dispersion attained up to 100 km to the south and 90 km to the north from the potential escape locations, namely San Pedro del Pinatar (Murcia) and Calpe (Alicante), both in the SE of Spain. The captures of commercial and recreational fisheries were influenced by escaped fish. Significant genetic differentiation between farmed and wild fish groups were observed where farmed fish were characterised with reduced number of alleles, allelic richness and expected heterozygosity. Minimum estimates of effective population size, which may serve as a conservative estimate for wildlife management, were for two order of magnitude smaller in farmed (~ 3) than in wild (~ 300) populations, implicating urgent need for genetic improvement of broodstock menagment

Morphological differences between wild and reared fish existed, with a striking difference in the mouth position, which showed upwards-oriented in reared fish, compared to a more horizontal position of wild fish.

In first term, fish escapes should be managed from a prevention perspective followed by mitigation and monitoring programs. The development of a tool-kit to identify escaped individuals is suggested. The behaviour of escaped *S. dumerili* should be studied from a spatio-temporal, ecological, fisheries and management perspectives. In terms of aquaculture management, to increase the broodstock size it is suggested, in order to minimize inbreeding risks and potential genetic influences for the populations of wild counterparts.

Introduction

High density of fish in intensive aquaculture systems (recirculation system or cages) is permissive to growth of bacterial and non-bacterial pathogens. Bacterial infections are usually prevented and treated by utilization of chemical disinfectants and antibiotics, respectively, which pose a huge threat to environment and human health. Therefore, alternative strategies must be developed to improve fish health and to prevent fish diseases. For this purpose, the use of feed additives such as immunostimulant is considered to be a promising area in aquaculture. There is a great potential for freshwater algae to become feed components in intensive fish farming. In order to be used in aquaculture, a microalgae strain has to meet various criteria. It has to be easily cultured and non-toxic. It also needs to have high nutritional quality and digestible cell wall to make nutrients available. This study aimed to evaluate the suitability of new microalgae strains isolated from Hungarian water bodies in diets for sterlet (*Acipenser ruthenus*) juveniles.

Materials and Methods

The strains were selected based on their growth capacity and content of potential immunostimulant agents (like PUFA, carotenoids, beta glucan, etc.) against diseases specific to early-stage fish cultures. The immunostimulant potential of the algae strains were tested *in vivo* in juveniles of sterlet (initial weight 56.1g). The feeding experiment with different inclusion levels of algae biomass (1, 2 and 4% dry weight basis) were performed in intensive recirculation fish rearing system. The enrichment of the basal diet with algae suspension was done using simple kitchenware technique (Table 1.). The fish growth was recorded at the end of trial, on the 28th day. Blood samples were taken weekly from 2 individuals/tank in order to determine the non-specific immunological parameters as lysozyme, total protein and immunoglobulin levels. Beside these parameters the production parameters and nutrient utilization of the feeds were evaluated. At the end of the trial ten fish from each tank were transported to the infection recirculation system of the institute where bacterial infection with *Aeromonas hydrophila* was implemented and the mortalities were recorded during five consecutive days.

Results and Discussion

The determined growth parameters after feeding trial such as final weight, weight gain and specific growth rate ranged between 82-89g, 50-57% and 1.36-1.68 %/day, respectively, without significant differences between groups. However, the highest values were recorded in the group of fish with 4% of algae inclusion in all investigated parameters. Similar tendency was observed in the nutrient and protein utilization parameters (FCR and PER). Based on this we could conclude that the new algae isolate has favorable impact to the growth and nutrient utilization of juvenile sterlet.

The investigated non-specific immune parameters (Table 2.) revealed a slightly positive effect to the immune status of the fish fed with algae enriched feed compared to the control. Meantime significant increase was found in the parameters during the feeding period compared to the values measured before feeding. After infection the recorded mortalities were not significantly differing between groups but higher mortality rate was observed in the fish fed without algae inclusion.

Introduction

Several feeding experiments with insects were carried out on many aquaculture species in the last ten years, and the results so far are encouraging for their industrial production (Gasco et al, 2020). However the available nutritional characteristics of the insects are well investigated, knowledge on their digestibility in different fish species is limited. Together with chemical analysis, digestibility of the nutrients and energy may allow a more thorough estimation of the nutritive value of a particular protein source in a complete feed for fish. Scarce information exists on its utilization as feed ingredient in nutrition for intensively reared African catfish, an important and dominant aquaculture species in Hungary. Meals from insects such as the shea caterpillar (*Cirina butyrospermi*), housefly (*Musca domestica*) variegated grasshopper (*Zonocerus variegatus* L.) and black solider fly (*Helmetia illucens*) have been included in the diets of African catfish as alternate protein sources. The aim of our study was to study the digestibility of black soldier fly (BSL), yellow mealworm (*Tenebrio molitor*) (MW) and blue bottle fly (*Calliphora vicina*) (BBF) meals for African catfish juveniles.

Materials and Methods

The digestibility trial was conducted with African catfish hybrid (*Clarias gariepinus x Heterobranchus longifilis*) juveniles when we aimed to determine the apparent digestibility coefficients (ADC) for dry matter, protein, lipid, phosphorus, fatty acids and amino acids, chitin and gross energy. The feeds were formulated by using a control feed in 70% mixed with tested ingredients in 30% (as is). The control feed was prepared to be a high fish meal diet in order to be easyily digestible for fish. Nine hundred African catfish juveniles (average weight, 217.4 ± 9.5 g) were distributed in recirculation water system equipped with twelve 1m^3 fiberglass tanks. During feeding period, the fish were hand-fed to apparent satiation. At the end of feeding period 15 pc from the fish stock per tank were sacrificed in order to collect faeces from intestine. From each treatment the faecal samples were pooled, freeze dried and stored in exicator until analysis. The chemical compositions of test ingredients, feeds and faeces were analysed using standard analytical methods. The apparent digestibility coefficients for the test ingredients and diets were calculated as follows:

$$ADC_{diet} = [1 - (\{Y_{diet} / Y_{faeces}\} \times \{D_{faeces} / D_{diet}\})] \times 100$$

Where, Y_{diet} is the dietary yttrium level, Y_{faeces} is the faeces yttrium level, D_{diet} is the dietary nutrient level and D_{faeces} is the faeces nutrient level.
The apparent digestibility coefficients of the test ingredient (BSL, MW, BBF) were calculated as follows:

$$ADC_{ingredient} = ADC_{test\ diet} + [(ADC_{test\ diet} - ADC_{reference\ diet}) \times (0.7 \times D_{ref} / 0.3\ D_{ingredient}]$$

Where, D_{ref} is the % nutrient (or kJ g^{-1}) of reference diet (dry matter basis) and D_{ingr} is the % nutrient (or kJ g^{-1}) of insect ingredient (dry matter basis).

(Continued on next page)

Results and Discussion

The ADC of the test ingredients are presented in Figure 1. The protein digestibility of the BSL is in line with data presented for hybrid grouper (*Epinephelus fuscoguttatus* ♀ *x Epinephelus lanceolatus* ♂) (81-88%) (Mohamed-Zulkifli et al, 2019), higher than for turbot *Psetta maximus* (63.1%) (Kroeckel et al, 2012) and less than for Atlantic salmon (*Salmo salar*) (89%), but regarding MW our data are much lower compared to tilapia (Fontes, 2019) (85.4%). The chitin digestibility is relatively high for BSL (96%), and significantly differing from others. The ADC data on chitin in our study reflect that African catfish is able to digest the chitin from the investigated insects in different ratio, moreover these data are comparable with ADC_{chitin} data obtained in tilapia (Fontes et al, 2019). It was assumed that $ADC_{Protein}$ negatively correlate with chitin and acid detergent fibre (ADF) content of the feed (Marono et al, 2015). Chitin content of MW diet in our study is 2.64 % (as fed) and ADF level is high (10.1% as fed) compared to the control feed (2.13% as fed). The ADF content of TM used in this trial was much higher (27.7 % dry matter) than data reported in other studies (7-11% d.m Marono et al, 2015; 7.2% Piccolo et al, 2017). The chitinase activity was not measured in our case and there are no available data for African catfish as well, therefore explanation of the reduced digestibility could not be proven either with chitinase activity of the fish or with chitin content of the diet.

Comparing these ADCProtein data with other feed ingredients it surely could be stated that insects' meals are better digested than the plant feedstuffs.

Introduction

In aquaculture, loss of nutrients in the surrounding environment is an important concern. The benefits of associating aquatic organisms to use nutrients released from fish farming is well reported in the literature[1], but in general the documented applications at a commercial scale remain scarse. In the same time, Fish oil and fishmeal included in feed are also pointed out to contribute to the depletion of natural resources and to be in competition with direct human consumption[2]. Hence, to maximize the use efficiency of nutrients, the system presented was designed to associate three different organisms of commercial interest and differing from seabream (*Sparus aurata*) for their trophic level, while using only local vegetal raw materials in the formulated fish feed. In addition, fresh discarded mussels, were directly supplied to the fish to balance their micronutrient and fatty acids needs. Thus, the aim of this study was to assess the performances of this system, by monitoring the water quality and the growth performances of the different organisms reared.

Materials and methods

The system was tested from 9th June to 7th October 2020. It was composed of 4 ponds, connected in cascade, to circulate the water by gravity, according to the following order (Figure 1): (i) in pond 7, seabreams were stocked at a mean weight of 210 g; (ii) in ponds 6 and 5, oysters (*Crassostrea gigas*) and shrimps (*Penaeus japonicus*) were stocked at a mean weight of 47.5 g and 0.52 g, respectively; (iii) in pond 4, clams (*Ruditapes decussatus*) and shrimps were stocked at a mean weight of 3.4 g and 0.52 g, respectively. From the pond 4, water was pumped back to the pond 7. Since salinity remained at an appropriate level in the system during the experiment, water was added from the inlet conduct (connected to the open sea) only to compensate evapotranspiration, avoiding discharge water toward the surrounding environment. During the experiment, the fish, shrimp and bivalves were weighed to estimate the growth. The water quality was weekly recorded to control temperature, oxygen, pH, turbidity and salinity. Once a month, water was sampled in each pond for concentrations in phytoplankton, nitrogen compounds and phosphorus compounds.

Results

The mean concentration in oxygen for the entire period of experiment was significantly ($p<0.05$) lower in the pond 7 (6.5 ± 1.8 mg/l, n=13) than in the ponds 5 (9.5 ± 2.6 mg/l, n=13) and 4 (9.8 ± 2.8 mg/l, n=13), and in the inlet water conduct (8.7 ± 1.4 mg/l, n=9). An increase of the concentration in total chlorophyll was observed in the system during the cycle of production (from 2.5 µg/l in June to 60.6 µg/l in October) contrary to that in the inlet water conduct, in which the concentration remained quite constant (between 5.1 µg/l in June and 11.0 µg/l in October). No significant differences were observed ($p<0.05$) between compartments, in the mean concentrations in N (N total, NH4, NO2 and NO3) and P (P total and PO4). Nevertheless, the level of the N total in the ponds of the system was higher compared to the inlet water channel, in which the N total remained almost stable along the production cycle time. The mean values of P-PO4, were significantly lower ($p<0.05$) in all the ponds of the system than that in the inlet water conduct. Despite a period of adaptation due to changes in feed and environmental conditions, seabreams grew well according to the expected performances. Thus, 1 169 seabream were harvested at a mean weight of 352.4 g, with a survival rate of 86.6%, and a corrected FCR of 1.9. At the harvest, the mean weight of the shrimps from the pond 4 was significantly ($p<0.01$) higher (35.2 ± 10.0 g, n=120) than that from the pond 5. Unfortunately, the week before the harvest, a storm event depleted the oxygen in the water and all shrimps in the pond 6 died. The rearing performances of oyster were higher than expected. Despite a summer mortality syndrome observed in the area, the survival rate of oysters observed was 91% for the pond 4 and 87% for the pond 5. At the harvest, the mean weight of the oysters was significantly ($p<0.01$) better in the pond 5 (88.4 ± 20.6 g, n=89) than in the pond 6 (71.2 ± 10.4 g, n=89), as well as the mean filling ratio (21.5 ± 3.3 %, n= 50 and 18.8 ± 2.5 %, n=50, respectively). The number of clams harvested was estimated to 8 102, representing a survival rate of 69%, for a mean weight of 11.4 ± 3.3 g (n=100). Harvested clams had a filling ration of 20.0 ± 3.6% (n=50) which was significantly ($p<0.01$) higher than that measured in June (16.1 ± 3.0%, n=20).

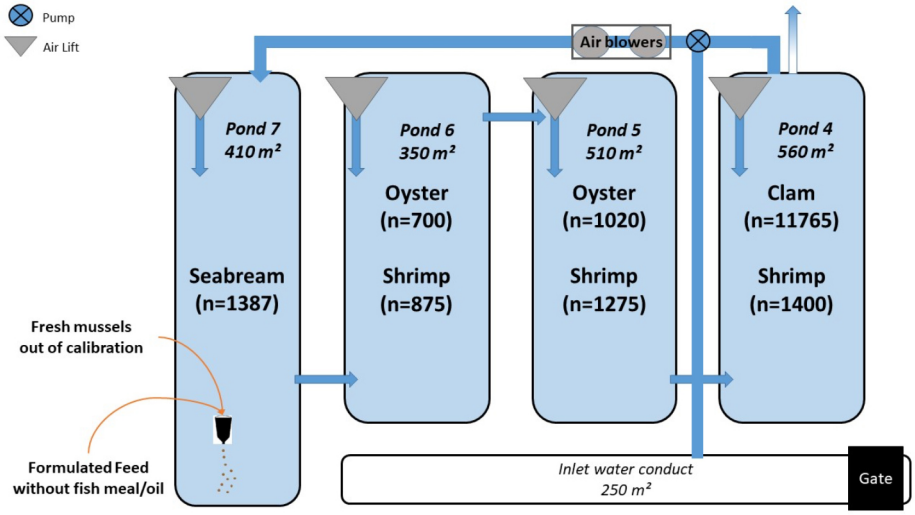

Figure 1: representation of the experimental design with the number (n) of individuals at the beginning

Discussion-Conclusion

The water concentration in oxygen was a key parameter of the system. In the fishpond, oxygen was at low levels in the morning despite the air adduction, so a special attention was paid to that in postponing the feeding time to the afternoon. The different concentrations in N and P, and physical indicators in water, like oxygen concentration, observed in the pond 4, reflected the ability of the system to improve the quality of the water released from the fishpond. Moreover, no water was discharged from the system along the rearing period, resulting in the save of water and in the preservation of the surrounding environment. In the system tested, good results were obtained for fish growth and feed conversion ratio, despite the lack of fishmeal and fish oil in the feed. Without additional specific source of nutrients in the system, except than the feed supplied to the sea bream, the body growth of the others organisms reared were similar and even higher (filling ratio and survival rate of the molluscs) compared to their usual monoculture in ponds (based on expert experience). Variations in the performances of the different species among the ponds give interesting perspectives in the improvement of this IMTA system, especially on optimization of animal densities and in adding a compartment dedicated to seaweed cultivation.

IMPAQT UNDERWATER ACOUSTIC TELEMETRY PLATFORM: RECEIVER DESIGN

Hamed Jafarzadeh, Marco Belcastro, Brendan O'Flynn

Tyndall National Institute, University College Cork, Cork, Ireland.
E-mail: hamed.jafarzadeh@tyndall.ie

Introduction

By 2050 world population will reach approximately 10 billion people, and it will requires more food production [1]. Seafood is one of the main sources of nutrition and consequently, its production should be increased to support the demand. Integrated multi-trophic aquaculture (IMTA) refers to the co-culture of the aquatic species including the extractive species that use the waste or feed leftovers of other species [2]. IMTA is gaining popularity as a sustainable aquaculture method that also minimizes environmental impacts and provides economical benefits. To maximize IMTA benefits, farmers need to gain a good insight on water quality parameters and chemical substances which can be done using manual sampling of the water or using off-the-shelf sensors.

As part of the European IMPAQT project, we are developing a universal telemetry platform that can be integrated with external sensors to collect the sensory information and transmit them wirelessly underwater to the receiver gateway, which will save the collected information for manual downloading or can transmit to an inland station using Long Range (LoRa) radios. The proposed telemetry platform enables the farmers to have relatively better and almost instant insight over the IMTA sites.

Platform

Our proposed platform, shown in Figure 1, consists of several miniaturized transmitter nodes and a receiver node that collects the sensory information of attached sensors. IMPAQT ultrasonic transmitters are designed in a miniaturized form factor that will run on a battery and they can be connected to external sensors using Serial Peripheral Interface (SPI) protocol or Universal asynchronous receiver-transmitter (UART) protocol to collect their information and transmit it in real-time to the receiver gateway. Transmitter design has been discussed in [3].

The receiver gateway is running on a battery, and it can be attached to a buoy with a connected hydrophone immersed into the water, and it receives information from the transmitter nodes. The received information can be collected on a SD Card and it also can be transferred to an inland receiver station for monitoring or further processing.

The receiver board has 3 main stages which is shown in Figure 2.

The signal reception stage receives the hydrophone signal, pre-amplifies the signal, and then drives the hydrophone signal for the filter stage. There is also a variable gain amplifier that is controlled via Inter-Integrated Circuit (I2C) protocol [4] by STM32 microcontroller to amplify the signal to the required level before feeding into the digitalization stage. We chose the On-Off keying (OOK) modulation technique as it is the most favourable to the battery life of the miniaturized transmitters and there is a relevant OOK demodulator on the receiver side to demodulate the received signal.

Results

The transmitter and receiver boards are manufactured, and tests were successful. We managed to connect external sensors to the platform and transmit the sensor's data underwater and receive it using the receiver board. We initially managed to achieve 40 bit per second bitrate at 42KHz carrier frequency. The battery life, bitrate, and deployment results will be presented in the oral presentation.

Future Work

Future work involves increasing the carrier frequency to shorten the active transmission period to increase the overall battery life and also increase the bitrate. It would be also interesting to evaluate binary-phase-shift keying modulation and compare the results with OOK demodulation regarding battery life and signal noise ratio between two. Also, there is an opportunity to perform edge-processing on the receiver board, to inform emergency events, for instance, early detection of excessive number of toxic substances in the sites.

IMPACT OF TRANSPORT ON SUBSEQUENT ROE ENHANCEMENT OF THE SEA URCHINS *Stronylocentrotus droebachiensis* AND *Paracentrotus lividus*

P. James*, T. Evensen, C. Hannon, L. Gutiérrez

*Nofima, 9-13 Muninbakken, Tromsø, Norway
Email: philip.james@nofima.no

Introduction

There is growing interest in Europe and worldwide in the capture and roe enhancement of various sea urchin species. There has been a significant amount of research focused on feed development and protocols for sea urchin roe enhancement. Less focus has been directed on the protocols for, and the impact of, transport on subsequent survival, and roe enhancement of sea urchins. This is a crucial step in the value chain as sea urchins need to be transported from the point of harvest to enhancement facilities as well as onwards to markets (sometimes via live holding hubs). This study describes some of the research being undertaken to understand what the stressors are for sea urchins during transport, particularly when this is followed by roe enhancement.

Materials and methods

A series of experiments were run to determine the optimal transport methods for *Strongylocentrotus droebachiensis,* in terms of both 'in water' (road and sea) and 'out of water' (road and air) transportation. This presentation will focus on a simulated transport trial followed by a roe enhancement trial to measure the effect of transport stress on subsequent roe enhancement. Sea urchins were held in simulated transport (static seawater tanks with aeration) for 0 days, 7 days and 14 days at 2 different densities. They were then transferred to a roe enhancement system and enhanced for 8 weeks. At the conclusion of that period the increase in sea urchin gonad index (GI) and the biochemical quality of the roe was measured. Additional trials have been conducted on *Paracentrotus lividus* to see how they compare in terms of sensitivity to transport stress. This presentation will focus on the former species but will discuss possible implications for the latter.

Results and Discussion

Overall, sea urchins held in simulated transport (static seawater tanks with aeration) for 0 days, 7 days and 14 days showed no significant differences in GI after the enhancement period (Figure 1). There was also no significant difference in the final GI of sea urchins held at low (4kg) or high (8kg) densities during the transport or between sea urchins transported for 7 days or for 14 days prior to enhancement (Figure 1).

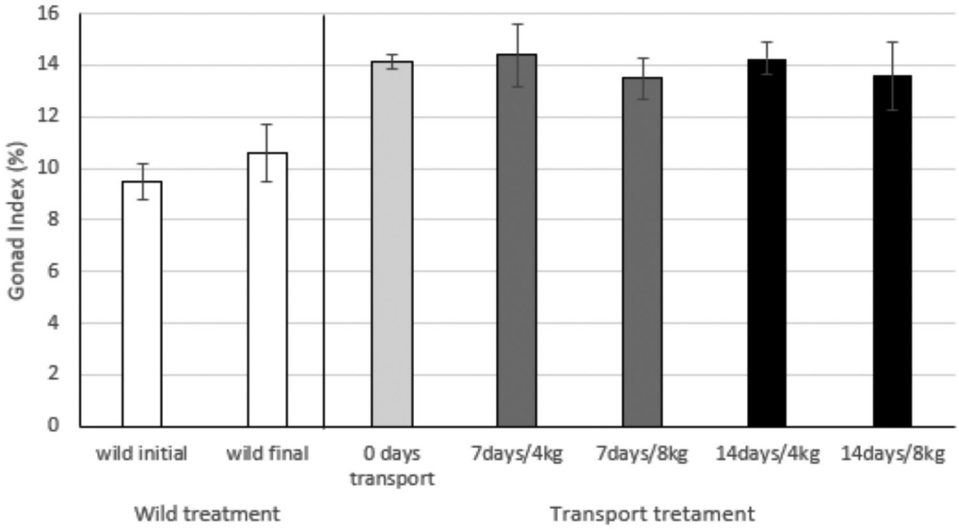

Figure1: The final GI of sea urchins collected from the wild compared to those held for 0, 7 and 10 days simulated transport followed by an 8 week enhancement period.

(Continued on next page)

Table 1: The % mortality of sea urchins held for 0, 7 and 10 days simulated transport followed by an 8 week enhancement period.

Treatment	Mortality (%)
0 days transport	2.0
7 days / 4kg	10.4
7 days / 8kg	8.3
14 days / 4kg	14.5
14 days / 8kg	10.41

However, there were differences in sea urchin mortality between sea urchins transported 0 days vs all simulated transport treatments. There was also higher mortality in sea urchins transported for 14 days compared to 7 days (Table 1). The biochemical results will also be presented (not yet available).

Preliminary testing on *P. lividus* suggest this species is much more sensitive to transport stress than *S. droebachiensis*. All the results from this and a series of studies will be discussed in terms of the future development of a sea urchin roe enhancement industry and what role transport plays in this.

EFFECTS OF BLUE MUSSEL MEALS WITH VARYING ASH LEVELS ON TROUT PERFORMANCE

J. Jaxion-Harm*

TripleNine Group, Trafikhavnskaj 9, 6700 Esbjerg, Denmark
E-mail: jjh@999.dk

Introduction

Mussels are an important fishery industry that has primarily focused on harvesting for human consumption. Undersized mussels are generally discarded or restocked for further growth. A special case of undersized mussel production has been used to reduce the effects of eutrophication, and this "mitigation mussel" culture is expanding. Nutrients leading to eutrophication is recaptured in the mussel tissue and can be used as a valuable source of protein, lipids, and other nutrients. There are limited studies testing the effects of blue mussel on aquaculture fish, and most replace fishmeal in high fishmeal diets (17%-50% of diet, e.g. Berg and Austreng 1989; Larsen et al. 2015). The present study aimed to uncover the effects that replacing fishmeal with blue mussel meal would have on commercially relevant (low fishmeal) trout diets. Furthermore, the study investigates two types of mussel meal- one with shell completely removed and one with shell only reduced.

Materials and Methods

Rainbow trout (starting weight 50g +-) were fed low fishmeal (10%) diets with 5% protein and 25% fat. Fishmeal was replaced with either 50% or 75% mussel meal. Two types of mussel meals were tested- mussel meal with shell removed before cooking (MM, ash =) and a whole mussel meal with sieving to reduce shell content after drying (SMM). The last diet was supplemented with fish-sourced phospholipids to the control diet level.

Rainbow trout (9kg/tank) were distributed in three 1.17x1.17x 0.9 m tanks per diet, and mean water temperature was 16ºC during the experiment. Diets were randomly distributed amongst tanks. Fish were sampled after 30 days and 60 days via individual weighing, while number of dead fish was recorded daily. At the start and the termination of the trial, HSI was also measured from 7 fish per tank.

Results and Discussion

Overall survival of rainbow trout in the present study was high (more than 98%) and was not affected by diet. However, growth was affected by diet: SGR of fish fed MM5% tended to be higher than the fishmeal control and was significantly higher than for fish fed MM7.5% and SMM7.5%. FCR of rainbow trout was similar with fish fed MM5% having the lowest FCR. Because of differences in ash content amongst diets, there was a slight variation of digestible energy. When FCRe was calculated (i.e. based on digestible feed intake, no significant differences were observed.

Previous research shows that effects of mussel meal replacement of fishmeal are dependent ash content of mussel meal. Replacement of fishmeal in high fishmeal diets of rainbow trout with whole mussel meal (with shell) resulted in decreased growth due to low digestibile energy of the feed from high ash content (Berg and Austreng 1989). However, full replacement of fishmeal with de-shelled mussel meal resulted in no differences in growth of rainbow trout fed ad-libitum (Larsen et al. 2015). Poor performance of trout fed SMM corroborates the need to reduce the ash content of mussel meal by removing shells as part of production is essential to improving the energy content of the ingredient.

Berg and Austreng (1989) found that fish fed whole mussel meal (high ash) resulted in increased liver size which was hypothesized to be due to physiological stress. However, the present study did not find any differences in hepatosomatic index (HSI) amongst diets.

The results verify that Blue Mussel meal can be used to replace fishmeal up to 50%, even in low fishmeal diets. With a growing aquaculture market needed to sustain the nutritional security of an increasing population, the need for sustainable marine ingredients is strong.

Introduction

The current protocol for the induced maturation of female European eel consists of long-term weekly injections with carp or salmon pituitary extract (C/S PE) to induce oocyte growth, a single booster PE injection and a single 17α,20β-dihydroxy-4-pregnen-3-one (DHP) injection to induce oocyte maturation and ovulation. However, egg quality is often poor and when larvae are produced they die before exogenous feeding. This study describes the third *in vivo* experiment in a series of ongoing experiments in our lab aiming to replace PE treatment by highly stable eel-specific recombinant gonadotropins (Peñaranda et al, 2018) in order to improve gamete quality and reproductive success. In an earlier study, we have been able to fully mature European eel and strip good quality eggs by treatment with recombinant gonadotropins but no larvae hatched (Palstra et al., 2019). In this third *in vivo* experiment, we have stimulated the sexual maturation by treatment with (i) CPE, (ii) recombinant FSH (recFSH) followed by CPE, and (iii) recFSH followed by recombinant LH (recLH), and compared the effects on reproductive success. Additionally, to focus the study on dose and effects of recombinant LH in boosting oocyte maturation, we have set-up an *in vitro* system and compared recLH with CPE as control.

Materials and methods

For the *in vivo* trial, experimental eels were feminised, subjected to simulated migration (Mes et al., 2016) and treated with a steroid implant (Thomson-Laing et al., 2019) containing 17-methyltestosterone and E2. Thirty eels were then divided over three groups and treated as described in Table 1. Oocyte maturation was boostered by injecting CPE or by injecting recLH (Table 1). Ovulation for eels in all groups was induced by injecting DHP (2 mg kg^{-1}). Eels were stripped for eggs which were fertilised and reared.

For the *in vitro* trial, experimental eels were feminised, subjected to simulated migration and treated with a steroid implant. Ten females were weekly injected with CPE to induce oocyte growth. Just before the CPE booster, ovarian tissue (~5g) was retrieved and kept on ice-cold culture medium. After the oocytes had been dispersed by pipetting the ovarian pieces, approximately 60 oocytes were placed per well in triplicate per treatment in a 24-well culture containing 1mL of hormone-free media and 1mL medium supplemented with the treatment (CPE: 1.25, 12.5 and 125 ug/mL; RecLh: 10, 100, 1000 ng/mL). Just before incubating, oocytes were sampled for microscopy, histology, RTPCR and medium analysis for DHP measurements. Culture plates were then incubated at 16°C for 12 and 18h. After incubation, oocytes were sampled for the same purposes.

Table 1. The three groups and the weekly injections they received. CPE= carp pituitary treatment. recFSH= recombinant follicle stimulating hormone. recLH= recombinant luteinising hormone.

Group	weeks	recFSH (µg)	recLH (µg)	CPE (mg kg^{-1})
1	1-12			20
	13-15			20
	16-18			20
	>18			20
	Booster			20
2	1-12	12		
	13-15	12		10
	16-18	6		20
	>18			20
	Booster			20
3	1-12	12	10	
	13-15	12	20	
	16-18	6	20	
	>18		20	
	Booster		20

Table 2. Reproductive success of eels from the three treatment groups (CPE, recFSH-CPE and recFSH-recLH) with the number of eels that started the treatment, died during the treatment, matured, died after DHP, gave eggs, embryos and larvae. Larval longevity (i.e. the number of days post hatch that larvae survived - dph) was daily recorded.

Treatment	Start	Died	Mature	Died DHP	Eggs	Embryos	Larvae	Longevity (dph)
CPE	10	1	9	5	4	2	2	6, 18
recFSH-CPE	10	4	6	4	2	1	1	2
recFSH-recLH	10	3	7	4	3	1	1	2

From the *in vitro* trial, analyses are currently being executed but results will be presented.

Results and discussion

Of the ten eels that were treated with CPE *in vivo*, one eel died during treatment, seven matured after 7-9 weeks, two matured after 12-13 weeks. Four of these eels could be stripped and two eels gave larvae that survived up to 6 and 18 days post hatch (Table 2). Of the ten eels that were treated with recFSH and CPE, four eels died during treatment, others matured much later after 15-22 weeks. Two of these eels could be stripped and one eel gave larvae (Table 2). Of the ten eels that were treated with recFSH and recLH, three eels died during maturation, others also matured after 15-22 weeks. Three eels could be stripped and one eel gave larvae (Table 2). Three eels that had been treated with recFSH died after DHP injection with GSI values of 75, 77 and 80 which are enormous in comparison with the regular average values of 40-50 after CPE treatment.

From the *in vitro* trial, analyses are currently being executed but results will be presented.

Introduction

The production of halophyte plants for human consumption, such as *Salicornia ramosissima,* is increasing as they have the ability to grow in saline soils or be irrigated with seawater allowing the utilization of unexploited cultivation areas. Their richness in bioactive secondary metabolites, which can have health promoting effects for the consumer, is a distinctive quality of these plants. The tenderest stems of Salicornia can be directed for human nutrition and the remaining parts of the plant, which can be considered as a residual co-product, have great potential for animal nutrition. Valorization of such co-products is paramount to develop a sustainable aquaculture feeds following principles of circular economy. Although fairly low in protein (9-10%), this Salicornia co-product may potentially serve as a source of carbohydrates in fish feeds, allowing for a reduction on the use of cereal eatable crops like wheat. European sea bass (*Dicentrarchus labrax*) is one of the most representative species from the aquaculture industry and therefore, the present study aimed to evaluate the potential of aerial *S. ramosissima* biomass to integrate aquafeed formulations for juveniles of this species. The sea bass growth performance, survival, body composition and nutrient digestibility were evaluated during this work.

Methods

Four experimental diets were tested in triplicate: a commercial like diet (CTRL) and three experimental diets containing *S. ramosissima* biomass at 2.5%, 5% and 10% inclusion levels (SL2.5, SL5 and SL10, respectively), at the expenses of wheat. European sea bass juveniles (initial mean wet weight 7.3 g) were kept at around 22 ºC and fed *ad libitum* for 62 days. At the end of the trial, fish were weighed and counted for growth performance and survival determination. Additionally, a digestibility trial was conducted and feces collected daily according to the Guelph system (each tank provided with a feces settling column). Fish were fed *ad libitum* 7 days a week, and temperature maintained at 22ºC.

Results and discussion

No significant differences in growth performances, feeding and survival were observed among treatments (Table 1), suggesting that the inclusion of *S. ramosissima* biomasses in the levels tested did not compromise the nutritional adequacy of the diets. The SL2.5 and SL5 diets revealed only some significant differences to control diet regarding some indexes of whole-body composition and digestibility coefficients (see Table 2 and 3, respectively). The SL10 did not show any significant differences for control diet regarding whole body composition and digestibility coefficients. The above-mentioned results suggest that it is viable to incorporate values up to 10% of Salicornia biomass in European sea bass juvenile diets, without any jeopardy for the species and producer.

Conclusion

Data from this study indicates that *S. ramosissima* biomass can be included in diets for juvenile European sea bass up to 10% of their composition, with no detrimental effects to growth performances, survival, whole body composition and digestibility coefficients. The valorization of Salicornia as biomass to incorporate aquafeed diets is of utmost importance, especially if it is produced under principles of sustainability and circular economy.

DEVELOPING AN IMTA VALUE CHAIN: SEA-BASED FARMING OF MACROALGAE AND MUSSEL IN SALDANHA BAY, SOUTH AFRICA

C.L.W. Jones*[1], A. Wu[1] and D. Weich[2]

[1]Department of Ichthyology and Fisheries Science, Rhodes University, South Africa; [2]Marifeed (Pty) Ltd, South Africa
Email: c.jones@ru.ac.za

Introduction

Commercial-scale mussel farming is well established in Saldanha Bay, South Africa. The strong winds along the Atlantic coastline of the country, coupled with the upwelling of cold, nutrient-rich water provides the ideal condition for mussel production, within the confines of a sheltered bay. Numerous farms produce mussel in the bay, where the bivalves are seeded onto vertical twisted ropes, attached to rafts and left to filter-feed on the plankton in the bay for approximately eight months. There is already a well-established and complete value-chain for this monoculture production system.

The environmental conditions that are conducive to the filter-feeding production of mussel are also conducive to the production of various species of macroalgae; yet they are not being farmed in Saldanha Bay. The potential of culturing macroalgae, using a sea-based integrated multitrophic aquaculture (IMTA), on the existing mussel rafts had not been investigated prior to this study.

The macroalgae take up dissolved nutrients from the water column, so they do not compete for food with the mussels, but sequester the dissolved metabolic waste of the mussel. Furthermore, the production of macroalgae on the mussel rafts would result in the more efficient utilization of the existing aquaculture facilities, making this a first attempt at sea-based IMTA-produced macroalgae and mussel in South Africa.

Materials and methods

Three rafts in Saldanha Bay, that were already fully stocked with mussel, were loaded with additional twisted ropes that had been seeded with *Gracilaria gracilis* at 15 g/site along a 3.0 m rope at 40 cm intervals. The twisted ropes were placed below the rafts, either horizontally or vertically in the water column, and were positioned in the current on either the south (i.e., facing the oncoming current) or north side of the raft (i.e., with its back to the current). After three months (September 2020) and after six months (November 2020), the ropes were lifted out of the water and approximately 80 % of the tufts of Gracilaria were removed and weighed. The remaining tufts of algae were left in their original position and the ropes were returned to the sea.

Results

The position of the twisted ropes on the raft, in relation to the oncoming current had a significant effect on the mean weight of the seaweed, and this was the same after three and six months of growth (Figure 1). In both instances, algae on the south-side of the raft (i.e., algae that was placed in the oncoming current) was significantly larger than that on the leeward side of the raft.

There was also a significant interaction between the depth that the *Gracilaria* were seeded and the vertical/horizontal position of the ropes in the water column (Figure 2). *Gracilaria* that was seeded just below the surface of the water grew similarly on ropes that were placed vertically and horizontally at both sampling times (Figure 2); while there was significantly more Gracilaria on the vertical ropes than that on ropes that were placed horizontal in the water column at 3.0 m below the water surface (Figure 2).

Discussion

There are currently no commercial-scale, sea-based IMTA operations in South Africa. As part of the AquaVitae (AV) project (European Union, Horizon 2020, Research Innovation Action BG2019), partners lead by Marifeed (Pty) Ltd with support from Blue Ocean Mussels (Pty) Ltd and Rhodes University, have been developing technology for the IMTA production of mussel and macroalgae in Saldanha Bay, South Africa. In this presentation, we will show the audience how we have used these data to develop this technology and we will also show how this research initiative fits into a larger program that aims to develop IMTA value chains that span the Atlantic Ocean.

This presentation will take the audience on a journey through numerous preliminary trials in which the industry and researchers together developed technology to simultaneously produce macroalgae (*Gracilaria* sp.) and mussels on the rafts that were originally designed for mussel production only. We will discuss what worked and where improvements were needed, and we will demonstrate how these preliminary results have been used to design a final, commercial-scale test of this IMTA system, that is currently ongoing.

Introduction

Cleaner fish are now used as a biological control for sea lice on farmed salmon in Europe and Canada (Treasurer 2018). As lumpfish, *Cyclopterus lumpus,* tolerate lower temperatures than wrasse species, their implementation and use has increased dramatically in recent years (> 42 m in Norway in 2019, Norwegian Directorate of Fisheries (NDF) 2019). Given the intensive use of lumpfish along the coast of Norway it is imperative that their use is done with the aim of minimizing possible genetic translocation with local populations. The prerequisite is to have reliable baseline information about the population genetic structure of lumpfish. The present study is a follow up study of the Jónsdóttir et al. (2018) study and aims to fill a knowledge gap by re-examining genetic diversity and population structure of the Norwegian lumpfish using genotypic data derived from using expressed sequence tag-short tandem repeats (EST-STRs) markers.

Material and methods

Sampling areas and protocols

A total of 291 specimens were collected at six fishing grounds from Mandal (58°N) in south Norway along the Norwegian cost up to 69°N in the north, with additional 18 samples of first-generation reared fish from a lumpfish fish farm.

DNA was isolated from all samples using the DNeasy Blood and Tissue Kit following the manufacturer's instructions (Qiagen). A total of seventeen EST microsatellite loci were genotyped. Five multiplexes PCR reactions were performed in a 10 μl volume containing 1 μl DNA, 0.8 µl of dNTP, 0.75 U Taq polymerase, 1 μl of 10x Standard Buffer, 0.08-0.3 μl of a 50:50 ratio of fluorescent dye labelled forward (100 μM) and reverse (100 μM) primer tagged on the 5'-end with a GTTTCTT PIG-tail to enhance PCR amplification. PCR reactions were performed on a Tetrad2 Peltier thermal cycler. Samples were analyzed on an ABI PRISM 3730 sequencer using the GeneScan-500 LIZ size standard and genotyped with GeneMapper v4.1.

Statistical analyses

To assess the potential numbers of genetic clusters a Bayesian cluster analysis was performed in STRUCTURE (Pritchard et al. 2000). The relative importance of geographical distance (isolation-by-distance) and genetic distance was examined using the Mantel test implemented in library ape v5.4-1 in R (Paradis and Schliep 2019).

Results

Test for population structure using both location of samples and not using the location of samples show that there is no population structure in lumpfish along the Norwegian coast (Fig. 1). In accordance with low values of differentiation observed using different statistical tests, there was no correlation between geographical and genetic distance ($R^2 = 0.0015$, $P = 0.89$) and thus no indication of Isolation-by-distance. (Fig. 2).

Discussion and conclusion

In the present study the same sampling material was analysed using functional genetic markers (EST-STRs) giving more or less the same results as found for non-functional genetic markers (g-STRs, Jónsdóttir et al. 2018). Based on the results for both g-STRs and EST-STRs analyses, the former advise of non-negative genetic effect of translocation of farmed juvenile lumpfish along the Norwegian coast is, therefore, still valid, given that wild lumpfish are used for juvenile production to prevent possible inbreeding.

(Continued on next page)

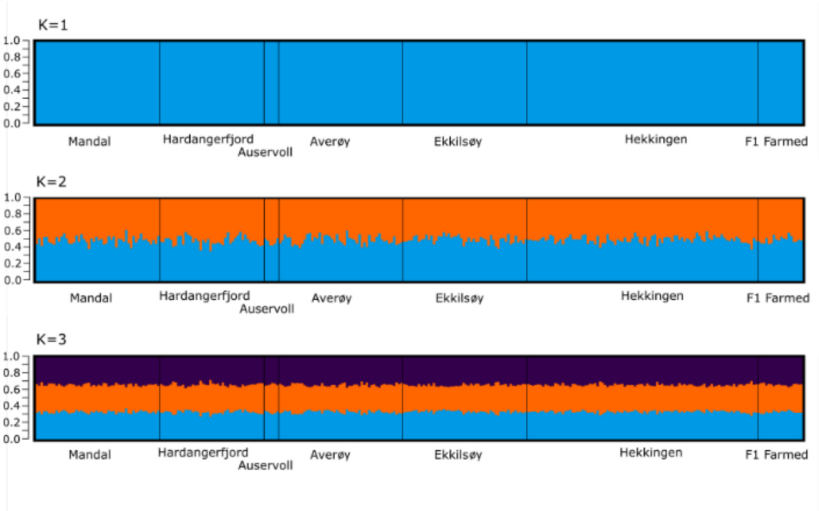

Fig. 1. Bayesian cluster analysis conducted in STRUCTURE. Shown are clustering for K = 1 to 3 for seven samples of lumpfish collected in costal Norway. Within each plot, vertical bars represent individuals while colours indicate the different clusters detected. K = 1 was the most likely number of populations.

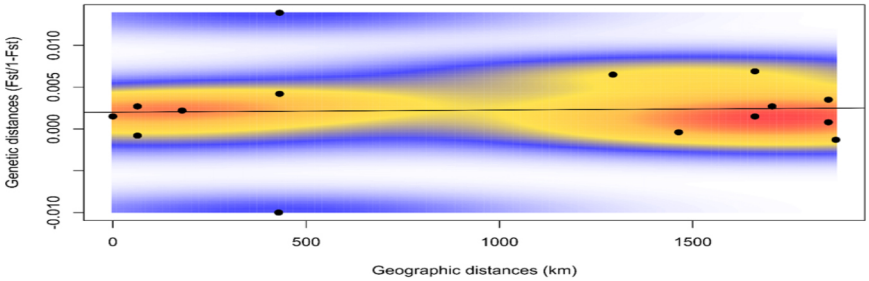

Fig. 2. Relationship between geographical (km shortest waterway) and genetic distance (estimated as $F_{ST}/(1-F_{ST})$) among pairs of lumpfish samples along the Norwegian coastline.

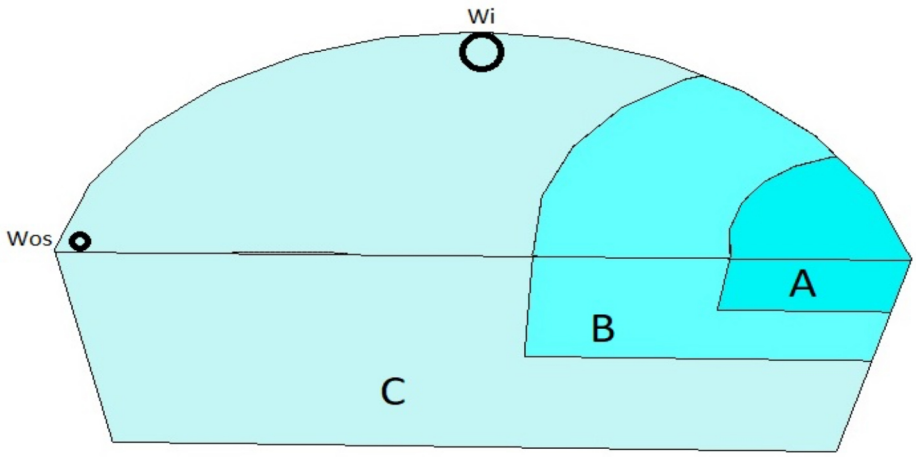
Introduction

The growth of the aquaculture industry was achieved with the improvement and development of larval rearing methodologies, as well as with the increase of the number of production facilities (Giménez and Estévez 2008). Mesocosm semi intensive methodologies has provided juveniles of high quality of well-known species, as well as being a methodology that is suited for the culture of "new" species, contributing for aquaculture diversification (Andrade, Nascimento et al. 2013). Mesocosm methodologies make use of large rearing tanks, with volumes between 30 and 100 m^3, and rearing densities between 2 and 8 individuals per litter. Most research on "new" species using this system focus on the ontogenetic development of larvae and their diet needs. Considering the size of the rearing tanks and the dramatic changes occurring during larval stages, the monitoring of larvae and water quality are difficult tasks and time consuming, which may eventually compromise the overall performance of the larvae and the rearing system (Andrade et al. 2012). In this presentation we propose a new approach to describe the spatial and temporal evolution of environmental parameters and larvae performance in mesocosm using sea bream (*Sparus aurata*) larvae as model species

Methods

Approximately 374 000 *S aurata* eggs where placed in a 40 m^3 rearing tank to hatch and rearing. Larvae were reared using standard procedures for the species and new methods are tested to evaluate daily mortality at surface and bottom of the tank. Behaviour analysis was recorded by observation of the observer standing at the edge of the tank for 5 minutes. Distribution of larvae on the surface and water column was regarding the majority of individuals as well as the first time a larvae was observed at that depth. Biotic parameters were analysed through the rearing period.



Lateral profile of the distribution of larvae in the rearing tank, regarding depth and occupation of surface through time . **A** – 0 to 20 Days after hatch (DAH), **B-** 21 to 32 DAH, **C -** 32 to 49 DAH. Wi- Water inlet; WOS – Water outlet at surface

(Continued on next page)

Results and Discussion

Sparus aurata hatching rate was high (98 ± 0.1%), and the larvae presented a high rate of swim bladder inflation (>90%). Larvae allocation patterns at the surface and different depth in the tank are described as well seven patterns of behaviour during the rearing period to reaching post-larvae stage. Mortality rates and larvae sampling were efficiently accomplished. Abiotic parameters (temperature, dissolve oxygen, light, pH and salinity) show high variability in time and space denoting changes in diet, stocking density and daily water management.

The improved methods followed in the present work provided a better understanding of the rearing tank environmental parameters, as well as of larvae behaviour, useful to enhance production quality and quantity and a baseline work for larval research on "new" species reared in mesocosm od semi-intensive methodologies.

Introduction

The barbel is a rheophyl fish species (Pintér K. 2002; Valló L. 2016) with great economic importance. It is a highly regarded sport fish in Europe (Pintér K. 1975). Areas required for reproduction have been greatly reduced (Szabó T. 2001; Fürész et al. 2006). Fish propagation and habitat conservation may support barbel population of natural waters (Pintér K. 1975). Several methods have been developed for the artificial propagation of barbel (Szabó 2000). Gametes can be collected during the spawning season at the spawning sites. Eggs and sperm can also be obtained after hormonal treatment. Fertilized eggs can be incubated in hatcheries. Due to the reophilic nature of the species, the offspring of the barbel cannot be effectively reared in paddy ponds typical of the Hungarian aquaculture (Pintér 1975). However, fry could be effectively raered in tanks in intensive systems.

Materials and methods

Barbus larvae required for the experiment obtained from artificial propagation of fish caught from the river Ipoly during the spawning season. Fertilization was carried out on the river-bank. The fertilized eggs were incubated at the Department of Aquaculture of the Hungarian University of Agriculture and Life Sciences in Gödöllő. The experiment was started from the day of the hatching time. The fry were reared for 21 days at a temperature of 22,4±0,5 °C and a dissolved oxigen 6,6±0,4 mg / L in Recirculating Aquacultural System (RAS). The lighting period was 12 h/day. Fish were stocked in tanks with the capacity of 12 L. The effects of two different stocking ratios (50, 100 individual/L) was examined in three repetition. The fish were fed ad libitum in three times a day. The fish were fed for the first 7 days with newly hatched Artemia larvae (*Artemia salina*). On days 8-9. fish were fed with Artemia and complete fish feed. On days 10-21. only complete fish feed was used. Wet body weight (20 individual/group; accuracy: ±0,1 mg) and total body length (25-25 individual /group, accuracy ± 0,1 mm) were measured in both group on the 0^{th} and 21^{th} days. Fish were anesthetized with 2-phenoxyethanol in dosage 0,4 ml/L before examinations. At the end of the experiment, the survival rate was also determined.

Results

On the first day of the experiment, mean body weight of the fry was 11,0±1,77 mg (*N*=20). At the end of the experiment, the mean body weights were 654±149 mg and 605±171 mg in the 50 larvae / L density group and the 100 larvae /L density group, respectively (*N*=60). The mean body weight from the three repetitions of the two treatments was 629,3±161,6 mg (*N*=120). No significant difference was observed between the two different stocking ratios.

On day 0^{th} of the experiment, total length of the fry was 13,1±0,99 mm (*N*=25). At the end of the experiment, significantly higher body length was measured in tha case of the 50 individual / L group (20±2,1 mm) compared to the 100 individual /L group (18,8±2,46 mm) (*N*=75). The body length from the three repetitions of the two treatments was 19,43±2,35 mm (*N*=150). High survival rate was recorded for the two groups (above 95%) without significant difference.

Discussion and conclusion

Pre-nursing of barbel in intensive system on three-four weeks resulted perfectly developed offspring with extremely low mortality. At the end of the experiment, body weight did not differ significantly between the two groups, but body weight was significantly lower in 50 individual / L compared to the 100 individual / L group.

E-mail: anajuan@ctnaval.com

Improving the efficiency of the feeding process remains one of the major challenges for the aquaculture sector. The lack of control over the fish feeding process, the considerable associated costs and the related environmental impacts are one of the main obstacles to overcome. The Marine Technological Centre (CTN) deployed its cost-effective Smart System for Feeding Control (SICA) in several offshore sea cage farms to validate this real time monitoring technology. The results obtained during these performances in salmon, Gilthead Seabream and Seabass cultures demonstrate that the SICA technology is able to detect different behaviours of fish during feeding process, anticipating human decisions and thus optimizing the feeding process. The potential contribution of SICA technology to reduce feed waste and improve the efficiency of fish production have been demonstrated.

Introduction

The control of the feeding process in aquaculture farms has traditionally been carried out by means of qualified stuff and observations of behavioural cues that indicate fish appetite while feeding (Li *et al*., 2020). Currently, although computer vision technology and camera-based systems are increasingly in use, they are limited by their dependency on illumination, water conditions, that define visibility, and their inability to monitor the entire population of fish in a net pen. Therefore, alternatives based on acoustic observation of fish behaviour have been examined.

According to different studies (Maniva, 1976; Samueloff, 2000), during the feeding process, fish make different sounds due to their own movement in the water or the splash on the surface to catch the food. In this context, SICA system (Smart System for Feeding Control), uses passive acoustics to distinguish the different sounds produced during the feeding process, without masking problems. For this, the device is based on decision-making through machine learning, a particular approach to Artificial Intelligence (AI). This makes possible to differentiate the moment when fish stop eating and thus indicate when the supply should be stopped.

The aim of this study was to validate the use of SICA technology in offshore sea cages in real production scenarios. First approaches were performed at high commercial interest species in Europe: Gilthead Seabream and Seabass (*Dicentrarchus labrax*) in Mediterranean fish farms and Salmon (*Salmo salar)* in Norwegian fish farm.

Material and methodology

SICA prototype is composed of two modules: Data Logger (DL) and Control Unit (CU). First module is deployed in the sea cage by using a mooring system, this DL acquires the signal through a hydrophone and transmits it to the CU trough wireless connection. Once the signal is received by the second module it is stored, then the acoustic records are processed and analysed automatically.

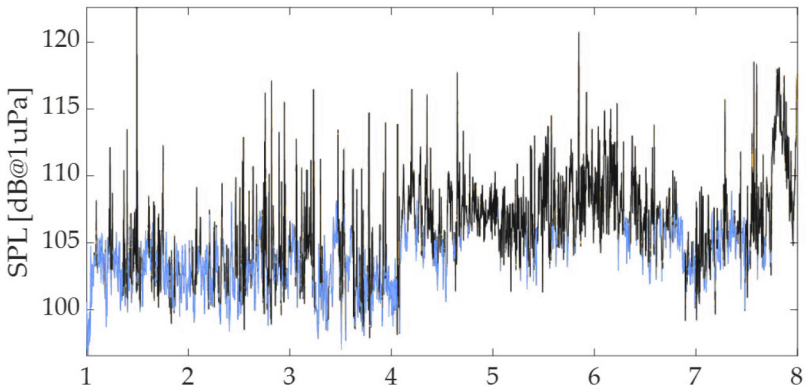

Figure 1. Sound pressure variations during one Salmon feeding register. Low feed intake events (blue colour) are differenced from the rest of feeding events (black colour).

(Continued on next page)

Information related to fish behaviour was collected during feeding process conducted according to industry standard. Appetite and feed management was registered by CTN researchers and fish farm technicians by means of underwater video camera registers and water surface fish observations.
Using acquired data by the SICA, the information collected during feeding process and a machine learning process, validation test is performed.

Results and discussion

In contrast to the traditional methodology undertaken with underwater video cameras the SICA system was found to be more efficient in detecting unusual fish behaviour since it was able to make earlier predictions during the feeding process. The accuracy in low feed intake detection was of over 84% in Seabream and Seabass cultures. In salmon cultures we find an accuracy 95% due to differences in feeding methodology and technology, an example of salmon feeding acoustic recordings are shown in Figure 1.

The SICA technology results a cost-effective and non-invasive solution in early detection of different fish behaviours during feeding process. Its ability in real time acquisition, data processing and anticipating decisions-making provides great potential to reduce the associated costs and minimizing the impact of the waste on the seabed.

Introduction

In vertebrates, feed intake is controlled by the synergic actions of central and peripheral signals which stimulate ingestion in relation to the nutritional status of the animal. In the brain, the hypothalamus plays a pivotal role in the regulation of appetite and feeding. In mammals, the hypothalamic neuronal network comprising major distinct cell populations that express the orexigenic neuropeptides agouti-related protein (AGRP) and neuropeptide Y (NPY) and the anorexigenic peptides proopiomelanocortin (POMC) and cocaine and amphetamine-regulated transcript (CART) have been described, and constitute the melanocortin system (reviewed in Lanfray and Richard, 2017). These neuropeptides act on the melanocortin-4 receptor (MC4R) in higher order neurons that control both food intake and energy expenditure. This system seems to be relatively well-conserved among vertebrates, including teleost species. However, in Atlantic salmon (*Salmo salar* L.), the salmonid-specific fourth round whole-genome duplication led to the presence of several paralog genes which may have resulted in divergent functions of the duplicated genes (Lien et al., 2016)Ss4R. In the current study, we have updated the *agrp, npy, pomc, cart* and *mc4r* gene repertoire information, including an assessment of their role in controlling appetite in Atlantic salmon. This includes their distribution in the brain regions olfactory bulb (OB), telencephalon (TEL), mid brain (MB), cerebellum (CE), hypothalamus (HYP), saccus vasculosus (SV), pituitary (PT) and brainstem (BS).

Materials and Method

In silico searches were performed to retrieve the *agrp*, *npy, pomc, cart* and *mc4r* paralogs from GenBank and Ensembl. Sequence comparisons and phylogenetic analysis were performed to confirm the identity of the newly identified sequences and qPCR assays were developed using gene specific primers. Atlantic salmon post smolt (weight ca. 200g and 250g) from two experiments each (n = 6) were randomly selected, and euthanized using an overdose of MS222, before the brain was collected and immediately transferred to RNAlater. The 8 brain regions (**Figure 1**) OB, TEL, MB, CE, HYP, SV, PT and BS were dissected using a stereo dissecting microscope and used for the gene expression analysis.

Results

In silico analysis have confirmed the presence of **2 *agrp*** (*agrp1&2*), **3 *npy*** (*npya1*, *a*2 & *b*), **3 *pomc*** (*pomca1*, *a2* & *b*), **10 *cart*** (*cart1a*, *1b1*, *1b2*, *2a*, *2b1*, *2b2*, *3a1*, *3a2*, *3b* and *4*) and **4 *mc4r*** (*mc4ra1*, *a2*, *b1* & *b2*) genes in the Atlantic salmon genome database. The Atlantic salmon Npy mature peptide shared 78-86% and Pomcs 27–37% identity with the human homologues whereas, the amino acid full length sequence of Carts shared 14-50% and Mc4rs 63-68% of identity with human homologue sequences. Brain region distribution analysis using qPCR showed a wide distribution pattern with varying range for all genes analyzed. *agrp1*, *pomca1* and *pomca2* were highly expressed in HYP while *agrp2* was high in TEL and *pomcb* in PT. The *npya1* (most abundant among *npy*), and *b* were highly expressed in TEL and *npya2* in HYP. All ten *cart* paralogs were analyzed with 7 pairs of primers for qPCR. *cart2b* is the most abundant *cart* paralog, followed by *cart3b*, *3a*, *1b*, *2a*, *4* and *cart1a*. The *cart2b* was abundant in OB and TEL; *cart3b* in BS and MB; *cart3a* in TEL, MB, and BS; *cart2a* was predominantly expressed in MB and HYP whilst *cart4* in HYP and TEL. The *cart1a* and *1b* were quite similar with major expression in MB. Among all neuropeptides *agrp1*, *pomca1*, *pomca2*, *cart2a, 2b, 3a, 3b, 4* and *npya2* showed considerable expression in HYP. The *mc4rb1* was the most abundant *mc4r* paralog, and *mc4ra1*, *a2* and *b1* showed higher expression in HYP and TEL whilst *mc4rb2* was high in HYP. (**Figure 1**).

(Continued on next page)

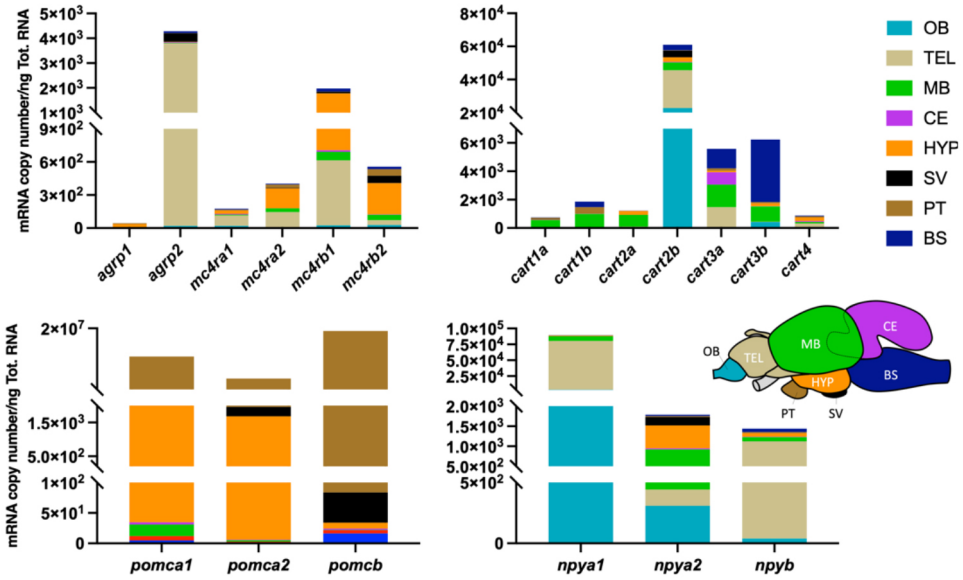

Figure 1. The mRNA expression of *agrp*, *mc4r*, *cart, pomc* and *npy* paralogs in eight brain regions (Insert: illustration of brain dissection) in Atlantic salmon. The genes were grouped according to their expression level to fit in the graphs.

Discussion

The present study updates the current knowledge of the agrp, npy, pomc, cart and mc4r gene paralogs in Atlantic salmon and shows their distribution profile and abundance in 8 brain regions. The gene expression distribution suggests that, in addition to HYP, brain regions, such as TEL, MB, BS, and PT may contribute to control of appetite, feeding and energy homeostasis. However, a remarkably diverse array of physiological functions has been reported in correlation to the site of gene expression in the teleost's brain. A recent functional analysis in grass carp (Ctenopharyngodon idellus) suggested that HYP and TEL might be involved in feeding and reproduction process, OB in immune response and reproduction, optic tectum in vision and feeding, PT in energy metabolism and medulla oblongata in auditory functions (Ye et al., 2020). Unraveling the physiological roles of these neuropeptides will provide more insight into the appetite regulation in Atlantic salmon, a global key commercial aquaculture species.

COMPOSITIONAL CHANGES IN LOW TROPHIC SPECIES GROWN AT A PILOT SCALE INTEGRATED MULTI-TROPHIC AQUACULTURE SITE

Joanne Casserly* [1], Frank Kane[1]

[1] Marine Institute, Rinville, Oranmore, Co. Galway, Ireland. H91 R673
Email: joanne.casserly@marine.ie

Introduction

The EU is the world's largest importer of fisheries and aquaculture products, importing 70% of the EU consumption (EUMOFA, 2018). Change in consumer attitudes has seen a parallel demand in low trophic products such as invertebrates and seaweeds (Barbier, 2019). Aquaculture continues to be a key pillar of future food production systems and there is a drive in aquaculture for sustainability and more circular economies. Strategies such as the European Green Deal, World Ocean Initiative and Sustainable Development of Aquaculture Strategy, also focuses on innovation, integration and the adoption of a multi-sectoral approach, to maximize ecosystem services while providing social and economic benefits.

Integrated Multi Trophic Aquaculture (IMTA) is acknowledged as a promising solution for sustainable development of aquaculture. Recapturing nutrients from aquaculture and the environment by extractive species, such as shellfish, seaweeds and invertebrates, re-circulates the wastes and by-products from fed species into feed, fertiliser and energy for others (Chopin, 2013). For this reason, culture of extractive species with fed species in the same aquaculture sites is encouraged, and this practice is shown to remove waste materials from fed species and lower the nutrient load in the water (FAO,2018). However, it is also critical to understand the value of extractive and low trophic species for the vital ecosystem services they provide in addition to their biomass as food goods (Chopin, 2013).

Methodology

IMPAQT aims to promote the eco-intensification of aquaculture by demonstrating the eco-efficiency and minimization of environmental impacts, enabling socio-economic benefits and ecosystem services, and promoting the transition towards a circular economy business model. Biometric and abiotic data from this pilot site contributed to multiple case studies to examine potential yields, crop quality, circularity, socioeconomic impacts and the interaction of farm components with the environment on the scale of an ecosystem. This study focused on monitoring of the different crop/species throughout the growing season to ascertain whether the molecular structure of the extractive species vary with enough significance to warrant a change in farming practices such as planting and harvesting, or emphasis on extractive species as environmental remediators.

Results

This IMTA implementation saw the application of two low trophic species, *Alaria esculenta* and *Pecten maximus* to a monoculture finfish facility producing Atlantic salmon. The increase in production from the site is discussed using data on biomass accumulation and crop yields to provide expected nutrient uptake rates, compositional make up and value of additional products to the site. To further understand the 'value' of these species, comparison of samples taken throughout the growing seasons is presented to examine the interaction of the species with the site over time and the potential benefits for planning decisions by both farmers and regulators.

IMPAQT – AN INTELLEGIENT MANAGEMENT SYSTEM FOR INTEGRATED MULTI-TROPHIC AQUACULTURE

Frank Kane* [1], Panagiotis Vlacheas[2]

[1] Marine Institute, Rinville, Oranmore, Co. Galway, Ireland. H91 R673
[1] WINGS ICT SOLUTIONS PC, 189 Siggrou Avenue, 17121 Nea Smirni, Greece
Email: frank.kane@marine.ie

Introduction
IMTA is well recognised as a promising advancement for sustainable development of aquaculture, offering a method to increase productivity while, at the same time, reducing environmental impacts. The concept of IMTA is to farm species of different trophic levels, complementary to each other, so that the wastes and by-products of one species become the feed, fertiliser and energy source for another. This practice is shown to remove waste materials from fed species and lower the nutrient load in the water. IMTA is in its infancy in Europe and commercial level IMTA is rare. Understanding the validity of the IMTA approach, the interaction of the trophic levels and. the management of IMTA in large-scale areas, remains a challenge.

Methodology
The H2020 IMPAQT project (https://impaqtproject.eu/) worked to promote the eco-intensification of aquaculture by demonstrating the eco-efficiency and minimisation of environmental impacts, the socio-economic benefits and ecosystem services, and promoting the transition towards a circular economy business model. IMPAQT has developed an intelligent management platform which featured an autonomous data acquisition and communication system, an advanced IMTA model and an intelligent management system to achieve a holistic approach addressing this complete system view.

Results
Outputs from the IMPAQT project will be presented. Technologies developed and deployed include novel sensors, data acquisition and communication systems. These data aggregators and power management tools have been developed as an integrated management platform, feeding into an intelligent management system (IMS), operating at the scale of an IMTA farm. This system comprises analysis and decision support functionalities, utilising data from various sensors, remote data and crowd sourced data. The data is used to determine environmental quality, stock welfare and assist with farm management to monitor and manage IMTA production and enable enhanced operational decisions for animal welfare, production optimisation, environmental protection and food-quality assessment. The Impaqt platform and IMTA set-ups have been validate in six pilot sites across Europe, Turkey and China.

Supporting this, an IMTA model has been utilised to show the responses and interactions between IMTA farm components and their footprint on the environment in different nutrient environments, and identified controlling processes for incorporation in future models to improve their predictive value.

The Impaqt pilot site outputs provided data to demonstrate the circularity, sustainability and eco-efficiency from IMTA as well as the socioeconomic benefits, cost effectiveness, and the ecosystem services provided by IMTA. An overview of the project out puts will be presented.

Acknowledgments
This work is part of the IMPAQT project, funded by the EU H2020 research and innovation programme under Grant Agreement No 774109.

INTRODUCING DRY FEED FROM MOUTH OPENING IN RED SEABREAM *Pagrus major* LARVAE PROMOTES LARVAE AND POST-LARVAE PERFORMANCE

Introduction

Marine larval feed technology is a fast changing field with great progress in manufacture technology. Many of the fish larval feed industries provide small enough feed particles that cover the nutritional needs of newly hatched larvae and have high acceptability and palatability, water stability and low nutrient leaching (Hardy and Barrows, 2002). In the hatchery practice of red seabream *Pagrus major*, dry feed is progressively introduced to fish larvae not earlier than 20-22 days post hatching (dph) with the concomitant use of live feeds (rotifers, *Artemia*) until weaning. However, compared to live feed, dry feeds appropriately manufactured (i.e. physical and nutritional properties) are expected to better provide for all nutritional needs of altricial fish species, such as red seabream. Although the exclusive use of dry feeds is still inefficient, it is widely accepted that the longer the co-feeding period of live and dry feeds, the better the larvae performance at weaning (e.g. Cañavate and Fernández-Díaz, 1999; Khoa et al., 2020). The aim of the present study was to investigate the introduction of dry feed as early as on mouth opening (3 dph) on growth and functional development of the digestive system of red seabream larvae, as well as to monitor post-larvae growth performance and deformities.

Materials and methods

The experimental trial was conducted in two stages: Stage 1, Hatchery rearing (Hr), was performed in a commercial marine fish hatchery. Four tanks of 9 m^3 were stocked with eggs of the same broodstock. In two of the tanks a commercial dry feed (Larviva Prostart, Biomar) was introduced on 3 dph (DF3), while in the other two tanks the dry feed was introduced on 22 dph (DF22) according to a common hatchery protocol. In all experimental tanks, the larvae were fed with rotifers from 3 dph up to 21 dph and with *Artemia* nauplii/metanauplii from 16 dph up to 35 dph. From 36 dph larvae were fed dry feed only. Larvae samples were observed under microscope to confirm food consumption. During larval rearing, water quality was monitored daily and larvae were sampled daily from 2 to 10 dph, and at 6-days intervals up to 40 dph to estimate larvae length and digestive function (i.e. lipase, amylase, trypsin, chymotrypsin, pepsin specific activities). On 53 dph larvae of each duplicated tank were graded to two size classes (Big, Small). Data obtained were used to calculate survival and performance. Stage 2, Laboratory rearing (Lr), was performed in a recirculating seawater system. On 43 dph ungraded larvae of each duplicated tank were transferred to laboratory installations. On 50 dph, six hundred fish from each duplicated Hr tank were group weighed and randomly distributed in pentaplicated tanks (120 fish per tank). Fish growth (i.e. body mass, survival, specific growth rate-SGR, thermal growth coefficient-TGC, mass variation) was monitored for six (6) weeks. All fish were fed the same commercial diet *ad libitum*. Water quality was monitored daily and fish were group weighed (app. 15-20 fish per group) every 15 days, while at the end of rearing fish were individually weighed. Phenotypic deformities were also individually recorded. During the last 15 days of rearing, food consumption was recorded to estimate feed efficiency (food conversion ratio-FCR).

Results

Stage 1, Hatchery rearing (Hr): After 10 dph and up to 40 dph, larvae length was significantly higher in DF3 larvae. Survival and length variability were not affected by experimental treatments, while DF3 produced a much greater percentage of Big fish (61%) than DF22 (9%). Furthermore, both the Big and Small fish of DF3 were significantly larger than those of DF22. Trypsin and chymptrypsin specific activities were higher in 3-5 dph and 16-28 dph DF3 larvae. Pepsin was firstly detected in both treatments on 22 dph, peaked on 28 dph and remained at higher levels in DF3 larvae. Amylase activity was higher on 4 dph DF3 larvae while lipase pattern was similar in both DF3 and DF22 larvae. Stage 2, Laboratory rearing (Lr): After 6 weeks of pre-growing (up to 95 dph) fish of the DF3 treatment were significantly larger than DF22 (6.7 *vs* 6.0 g respectively) with higher daily weight gain. Body weight frequency distribution were different between treatments; fish larger than 6 g consisted the 63% of DF3 fish and the 48% of DF22 fish. No differences were observed for coefficient of weight variation and survival. Furthermore, spinal cord malformations of DF3 fish were significantly lower than those observed for DF22 fish (3.8 *vs* 11.7 % respectively).

(Continued on next page)

Discussion and conclusion

Present results showed that the introduction of dry feed from mouth opening (on 3 dph), was more efficient for larvae and post-larvae performance compared to a more commonly used protocol (dry feed on 22 dph). The functional development of the digestive system was not compromised and it was similar to previously reported results for red seabream (e.g. Waqalevu et al., 2019; Khoa et al., 2020). Besides, digestive enzymes differences observed indicate an increasing number of actively feeding larvae in DF3 treatment. Present beneficial effects gained from the early introduction of dry feed are probably related to a better acclimation of larvae to dry feed particles, which once ingested offer a diet of higher nutritional value able to support the higher demands of faster larvae growth. Growth benefits obtained during larviculture were maintained during further rearing up to 95 dph. In accordance to our previous similar work on gilthead seabream larvae (Karakatsouli et al., 2019), the present markedly lower spinal cord deformities recorded at the end of the pre-growing period support the hypothesis that the ingestion and digestion of an appropriate dry feed may provide larvae with the necessary nutrients to form a healthy skeletal system at the sensitive stages of skeleton ontogenesis. Overall, the introduction of dry feed as early as on mouth opening is considered safe and feasible for red seabream providing advantages for both larval and post-larval production stages.

Methods of induction of uniparental inheritance have been developed for model organisms as well as for species of commercial interest to fix sex-specific traits in breeding programs or to restore breeds or lines from cryopreserved sperm in aquaculture important species.

Androgenesis in common carp (*Cyprinus carpio*) has been successfully induced by egg nucleus inactivation with **γ-**, X- or UV-ray irradiation but these techniques are not widely applicable for laboratory or commercial use on practical, financial and safety grounds.

In the past decade a promising low-cost, low-tech cold-shock approach for successfully inducing androgenesis has been demonstrated for loach, Japanese flounder and zebrafish.

The aim of the current study was to develop a cold shock methodology for application in common carp, a freshwater species of high commercial interest and a widely used model species. Gametes were collected from wild-type females (dominant green phenotype) and Koi males (recessive blonde phenotype) to enable easy identification of successful induction of androgenetic haploid progeny. A combination of different temperature treatments (0, 2, 4, 6, 8 ˚C) and different cold-shock durations (15, 30, 45, 60, 75 min.) applied shortly after gamete activation (3 s after fertilization) were initially trialed.

Optimal condition for egg nucleus elimination was a cold-shock at 2 ˚C for 60 min duration where hatching rate of haploid progeny reached 35.6% and 26.26±10.19% across two attempts. Double haploid induction was then attempted with replicate 300g egg masses: a 2 ˚C cold-shock, 60 min. duration, followed by arresting first mitotic cleavage by heat shock (40 ˚C) applied 40 min after transfer to the environment of normal egg incubation temperature (20 ˚C).

These combined treatments resulted in reduced fertilization and hatching rates for all replicates and low yield of progeny (1.09-1.28% in experimental incubation, <1% in hatchery incubation*)*. A genome wide SNP analysis of a subset of progeny confirmed that they were double haploids. Cold-shock androgenesis was found to be effective in common carp, providing a new possibility of uniparental inheritance induction for isogenic line production.

POTENTIAL APPLICATION OF INDIRECT COLD ATMOSPHERIC PLASMA NOVEL TECHNOLOGY FOR THE SHELF-LIFE EXTENSION OF AQUACULTURE PRODUCTS: CASE STUDY ON SEA BREAM FILLETS

Introduction

The Dietary Guidelines encourages citizens to increase the seafood consumption to improve the health of their diets. On the other hand, the seafood availability (overfishing and ocean pollution etc.) along with the growing global population will result in increased demands and constraints of seafood supplies. Seafood loss and waste reduction is prerequisite for supporting increased seafood consumption without further stressing aquatic resources.

Fish fillets are among the most consumed aquaculture products but with a very limited shelf-life due to contamination during the filleting process operations (washing, cutting and skinning) or due to mishandling during transportation and storage. These may lead to increased microbiological load, degraded quality characteristics including undesirable odors and off-flavors as well as modified texture, thus reducing their shelf life and the consumers' acceptability, contributing to seafood waste. Many strategies have been proposed for seafood waste minimization, some of them targeting to shelf-life extension applying conventional or novel non-thermal technologies (where applicable without affecting seafood freshness and quality).

Cold atmospheric plasma (CAP) has raised overwhelming attention for various food products since it can improve food products shelf-life. It could be applied either directly (plasma zone is in direct contact with the food to be treated), semi-directly (plasma generated Reactive-Oxygen-Nitrogen-Species are able to reach the food surface as the food product is positioned remotely with respect to the active plasma region) or indirectly (two-step process where a gas plasma is applied to water until enough concentration of secondary RONS is produced and then food products are treated with Activated Water in order to induce decontamination). Plasma activated water (PAW) has been proved to be a disinfection media since it is capable of inactivating microorganisms while simultaneously maintaining the quality characteristics of the treated products.

The aim of this study was to investigate the application of PAW as innovative immersion agent for the extension of shelf life of fish fillets by evaluating their microbial and quality characteristics during storage.

Materials and Methods
