WELCOME MESSAGE

Welcome to Aquaculture Europe 2022 on the Italian Adriatic coast in Rimini.

The theme of the conference "Innovative Solutions in a Changing World" reflects the need for addressing the many challenges facing the sector in the coming decades. Most in land, coastal and marine water bodies will undoubtedly be impacted directly or indirectly by climate change and urbanisation, from sea acidification and warming, sea-level rise, coastal erosion, flooding, eutrophication and pollution. These will represent important sustainability challenges for current and future European aquaculture. AE2022 will provide a great opportunity for discussing new and innovative ideas to address these challenges but also identify strategies for implementing and up scaling already proven concepts and solutions.

Since moving recently from academia to industry, I can testify on the importance of capturing and translating new research into industry protocols and solutions for the benefit of the sector. What makes EAS annual events unique is bringing together scientists, industry leaders and entrepreneurs, governmental bodies and regulators from all over Europe and sharing the same passion for aquaculture. AE2022 will include a wide range of scientific sessions (32 over 3 days) and a trade show with close to 180 booths. In addition, several workshops and special events will take place; including the AE2022 Industry Forum and the AE2022 Innovation Forum - organised by The European Aquaculture Technology and Innovation Platform, the European Commission and EAS.

This year we are expecting more than 2000 attendees with more than 600 scientific abstracts received and these have been reviewed by the session chairs and integrated into an impressive programme by Maria Letizia Fioravanti and Daniel Żarski as Program co-chairs. Thank you for your hard work! I'd like also to thank our Steering and Local Organising Committees who gave their time and efforts to make AE2022 possible as for my colleagues on the Board of the EAS with several newly appointed directors. A big thanks also to our Gold Sponsors Biomar, Silver Sponsors U.S. Soybean Export Council, Session Sponsor Lallemand and Conference Support from the Italian National and Regional Governments.

This is the end of my two-year term as President. It has been a challenging period for all, but I am delighted to see the great resilience of EAS thanks to our collective efforts and welcome to our new president, Bente Torstensen. I hope you enjoy the event, the people and the science.

Herve Migaud
EAS President 2020-2022

THE EFFECT OF FOAM FRACTIONATION AND OZONATION TO WATER QUALITY AND MICROBIAL COMMUNITIES IN RAS

Introduction

Microbes inhabit all the compartments of recirculating aquaculture systems (RAS), being suspended in water phase and forming biofilms on the surfaces. The majority of these microbes is considered to be harmless for the fish, and some of them are even beneficial, having an important role in the nitrifying biofilters. However, uncontrolled growth of microbial biomass can promote the abundance of harmful microbes, and increases the need for aeration and degassing. To maintain sufficient water quality and to hinder microbial blooms, water treatment methods to remove microbes and other organic matter are currently searched and developed for RAS. Two potential methods are foam fractionation and ozonation, the first removing organic matter, while the latter destroys and inactivates microbes directly. In this study, we examined the effect of foam fractionation and/or ozonation on water quality and on microbial communities in water and biofilter biofilms in replicated freshwater RAS with rainbow trout.

Materials and methods

The experiment was conducted in 12 replicated, 0.8 m^3 pilot-scale freshwater RAS stocked with 8.05 ± 0.03 kg juvenile rainbow trout (*Oncorhynchus mykiss*) and with final feed loading of 1.66 kg feed m^{-3} make-up water. Four treatments were applied in triplicate: 1) three control RAS, 2) three RAS with foam fractionator (ff), 3) three RAS with ozone (oz), 4) and three RAS with ozone and foam fractionator (oz + ff). The trial lasted eight weeks. Water quality characteristics, and microbial activity and abundance were measured every week. The composition of microbial communities in water was analysed at beginning of the experiment (week 0) and at weeks 1, 3, and 7 and the composition of communities in biofilter biofilms at week 7 using next generation sequencing with IonTorrent PGM targeted on 16S rRNA gene V4 region. The detailed description of the experimental setup and sample analysis is given in de Jesus Gregersen et al. (2021) and Aalto et al. (2022)”ISSN”:”00448486”,”abstract”:”Efficient water treatment is required to maintain high water quality and control microbial growth in recirculating aquaculture systems (RAS.

Results and discussion

Both ozonation and foam fractionation improved the system water quality by decreasing the biological and chemical oxygen demand and the amount of microparticles in water (Table 1), and this effect was pronounced when these two water treatments were combined. The same trend was observed with microbial activity, which decreased by 10-fold when applying both ozonation and foam fractionation as compared to the control systems. However, foam fractionation affected neither the microbial community composition (Fig. 1A) nor the abundance of microbes (data not shown), suggesting that the lower microbial activity observed under foam fractionation was due to the lower amount of organic matter being available for heterotrophic microbes. In constrast, ozone posed a strong selection pressure by attacking the microbes directly, having a significant effect on the microbial community composition already one week after application (Fig. 1). Moreover, the microbial abundance was significant lower in ozonated units (oz, oz + ff) than in foam fractionation or control units (data not shown). While the biofilter biofilm communities were more resistant to the water treatment than the communities suspended in the system water, we found comammox *Nitrospira*, carrying out the complete nitrification (Daims et al., 2015), to be more abundant in the foam fractionation unit biofilters. This together with the significantly lower nitrite concentration found in the foam fractionation treatment (Table 1) suggests that by removing organic matter, foam fractionation promotes more stable nitrification in the biofilters by decreasing the activity of heterotrophs, which allows a higher abundance of nitrite oxidizers but also a shift in the nitrifying community from canonical two-step process into the complete nitrification. Altogether, the results indicate that although these two water treatment methods have similar outcomes on physico-chemical water quality and microbial activity, their underlying mechanisms are different, potentially leading to different outcomes under the long-term application.

Abstract

Due to the risks associated with using synthetic chemicals in producing all-male tilapia seed, plant-based products are presently considered as safe nature-based alternatives. In the present study, pine pollen (PP) was utilized to sex inverse Nile tilapia (*Oreochromis niloticus*), since it contains phytoandrogens that have potential to alter the process of sex differentiation in fish. However, there is no available data describing the molecular mechanism involved in PP-induced sex inversion of Nile tilapia. To understand the role of PP, the study examined its effect on the expression of sex-related genes: cyp19a1a, foxl2, dmrt1 and amh, in all-female (XX) individuals, which were fed a basal diet supplemented with 1.28 g PP kg^{-1}. This was compared to the expression patterns obtained from fish fed: 1) only a basal diet (CT treatment) and 2) a basal diet supplemented with 0.06 g 17α-methyltestosterone (MT) kg^{-1}. Generally, the expression levels of all genes were altered. In the fish treated with PP and MT, significant up-regulation of dmrt1 and amh was observed, but were repressed in the CT treatment ($P < 0.001$). At the same time, cyp19a1a and foxl2 were markedly down-regulated in the PP and MT treatments, and up-regulated in the CT group ($P < 0.001$). While dmrt1 and amh were activated in the PP-treated fish, higher expression was observed in the MT group. This expression pattern was consistent with masculinization levels in the PP and MT treatments. A significantly higher proportion of male individuals (97.8 ± 1.1 %) was obtained in the MT treatment compared to 77.8 ± 2.9 % in the PP group ($P = 0.003$). However, all the female fish in the CT group remained un-masculinized. Therefore, cyp19a1a and foxl2 were female-biased while dmrt1 and amh were mainly associated with maleness, confirming their role in female and male sex development respectively. These findings suggest that PP induces sex masculinization of Nile tilapia by activating the expression of both dmrt1 and amh accompanied by attenuation of foxl2 and cyp19a1a.

EFFECT OF A MIXTURE OF *Yucca schidigera* EXTRACT AND *Bacillus subtilis* ON THE AMMONIA REDUCTION IN EFFLUENT AND ANTIOXIDANT ACTIVITY OF NILE TILAPIA (*Oreochromis niloticus*)

Heba M. Abdel Ghany*, Amr M. Helal, Mohamed El-S. Salem, Doaa M. Elsisy

*National Institute of Oceanography and Fisheries (NIOF), Cairo, Egypt
heba_elshamy85@yahoo.com

Tilapia (*Oreochromis niloticus*) farming effluents contain high level of ammonia, which poses a significant threat to fish and the surrounding environment. *Yucca schidigera* extract (YE) has been found to reduce ammonia pollution resulting from fish farming. On the other hand, dietary supplementation of *Bacillus subtilis* was found to improve anti-oxidation activity, and water ammonia level for fish. Therefore, the aim of the present study was to assess an inclusion of *Yucca schidigera* extract and *Bacillus subtilis* separately or in combination on anti-oxidation activity and ammonia reduction in the effluent of Nile tilapia fingerlings.

Fish were divided into 4 groups and fed for 60 days with four experimental diets which supplemented with 0.2 gkg^{-1}diet of YE and 2 g kg^{-1}diet of *Bacillus subtilis* (B) separately or in combination (YEB) and the control diet was left without addition (CON).

Results revealed the positive role of YE and B on total ammonia nitrogen (TAN) reduction (Table 1); however combination of both YE and B had less efficiency. The addition of YE or B in tilapia diets reduced TAN removing by 50% compared with the control. Superoxide dismutase (SOD) showed the best activity in YEB treatment followed by YE and B treatments while the lowest activity was recorded in the control group. Fig. 1 illustrates the effect of YE and B on anti-oxidative activity of Nile tilapia.

The highest activity of Malondialdehyde (MDA) was reported in the control group while the lowest value was found in YEB group followed by YE and then B group. Glutathione peroxidase (GPx) and total antioxidant capacity (TAC) showed the highest activity in YEB followed by B treatment, while the lowest activity was recorded in YE and CON. It could be concluded that Yucca extract and bacillus can efficiently reduce ammonia in Nile tilapia effluent and boost their antioxidative activity.

Table 1. Effects of experimental diets on antioxidant activity of Nile tilapia

Treatment	SOD	MDA	GPx	TAC
CON	16.63±0.55^{c}	4.07 ±0.15^{a}	0.23±0.03^{c}	0.25±0.04^{d}

Background

During 2021 the GLORiA project (Global Change Resilience in Aquaculture) identified socioeconomic impacts and interactions of escapees with the surrounding environment and studied de frecuency, magnitude and causes to anticipate future scenarios derived from global change. GLORiA increased the knowledge of the origin of escaped fish at fish markets, wholesale and retailers established and made it possible to establish the scientific criteria to be taken into account when establishing a contingency plan.

GLORiA^2 is an extension of the research carried out in GLORiA. During the implementation of this project, a series of needs were raised by the stakeholders (aquaculture companies, fishing sector, other scientific bodies, regional and national administrations) which require to continuously develop actions to improve our knowledge about the impacts of escapes both in the environment and in the value chain; from the moment the cages suffer a technical failure to that moment when the fish is purchased by the final consumer (Fig.1).

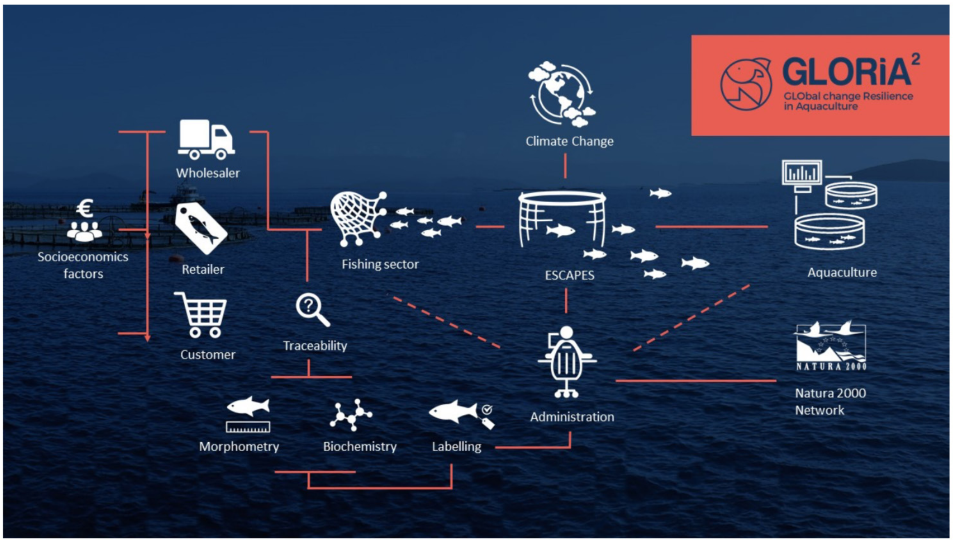

Figure 1. Conceptual framework from GLORiA 2 project

(Continued on next page)

GLORiA² project goals

- Encourage participatory management through the creation of working groups at regional and national levels.
- Use state-of-the-art computer vision and analysis technologies to improve the identification of escaped fish at the fish market and therefore their traceability.
- Improve, through morphometric and physiological biomarkers, the traceability of escaped fish entering value chains in order to ensure food safety for consumers.
- Analyse the level of fraud in products shared by aquaculture and extractive fishing, proposing measures related to labelling in order to allow correct identification.
- Predicting future incidence of fish escape events and their interactions with marine coastal ecosystems.
- Analyse social preferences about escaped fish management measures and their implications for fresh fish market prices, improving food security and environmental sustainability.

Acknowledgements

GLORiA 2 is developed with the collaboration of the Biodiversity Foundation (Spanish Ministry for Ecological Transition and the Demographic Challenge), through the Pleamar Program, co-financed by the European Maritime and Fisheries Fund (EMFF).

NORMALIZING DATA MODELS FOR INTEROPERABILITY IN AQUACULTURE

Introduction

Smart feeding systems are emerging in aquaculture. They are expected to bring improvement and optimization of feeding practices by digitizing real-time biological and environmental information, integrated with core biological knowledge, new technologies and machine learning to maximize profit while minimizing environmental footprint and maintaining fish welfare.

This digitization requires the automation of data collection, exchange, and decision support. In such a process, sensor data are collected, combined with other important data such as fish behaviour, feeding patterns, weather conditions, and finally processed by Artificial Intelligence (AI) algorithms to provide recommendations and management decisions, such as feeding management strategies and optimal harvest times.

The issue if that the offers are multiplying to provide vertically integrated solutions with limited capabilities for the end user to share data from one application to one another. This creates several drawbacks including the risk of vendor lock-in, the limited innovation capabilities or having a sub-optimal system not allowing data reuse.

This could be achieved by collecting and validating data from heterogeneous sources and organise it in an interoperable way so it can be used over several applications spanning over different domains. In this paper and following our previous work in [1], we will introduce our work toward the normalization of Aquaculture Data model for smart fish feeding support using standardised cross-domain specifications.

Data Platform

For managing data in a fish farming system, the proposed core data platform is based on NGSI-LD[1]. The NGSI-LD specification is produced by ETSI and made open-source within the FIWARE ecosystem[2]. From a technical perspective, FIWARE brings a curated framework of open-source software components which can be assembled and combined with other third-party platform components to build platforms easing the development of smart solutions and smart organizations.

In a nutshell, the NGSI-LD specification is based on data model and API. The NGSI-LD data model is an entity-based data model. An NGSI-LD Entity is an informational representation that is supposed to exist physically or conceptually. Relationships in NGSI-LD capture possible links between a subject which maybe an entity, a property, or another relationship on the one hand, and an object, which is an entity, on the other hand. NGSI-LD Property is a description instance, which associates a main characteristic to either an Entity, a Relationship, or another Property. Based on its cross-domain ontology, NGSI-LD covers several generic domains such as Mobility, Location, Temporal, System Structure and Behavioural Systems. The NGSI-LD API relies on this data model. It provides a set of operations on entities covering entity creation, update, deletion, retrieval, and subscription. The API also proposes operations that include temporal operations.

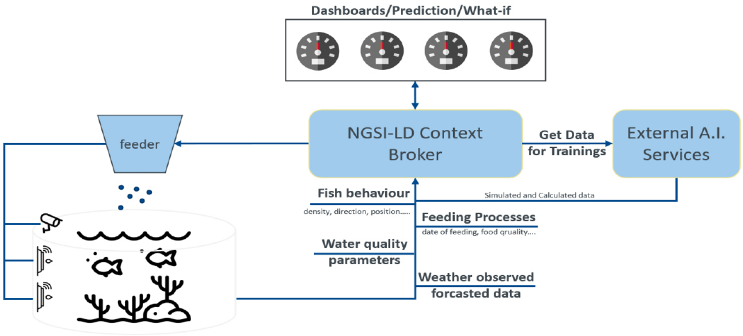

Figure 1: Overall schematic of Data Management in a fish farming system.

(Continued on next page)

A simplified overall schematic of Data management in a fish farming system is depicted in Figure 1. The main NGSI-LD entity in this fish farming system is the Fish Containment: Fish Cage, or Tank, are the equivalent concept for it. Data may be devised in different categories: Fish Behaviour, Feeding Processes, Water Quality and Weather. Weather Parameters (temperature, wind, cloud, waves height, etc.) will be added as a property to Weather Observed Entity. Water Parameters (pH, redox, dissolved Oxygen…) are added as properties to the Fish Containment entity.

We analysed a number of existing data models and ontologies including Agrovoc[3], WORMS[4], dbpedia; FOODI[5], Aquacloud[6], SmartdataModels[7] to identify terms relevant for the aquaculture applications, list equivalence among the models and select a definition leading to the least unambiguous description of the term. This term is then mapped over the NGSI-LD interface so data exchanges can occur across the systems. The table below illustrates the discussion for one NGSI-LD entity and one NGSI-LD property. The complete property graph will be described in detail during the presentation.

Examples of mapped concepts

Examples of mapped concepts

attributes	NGSI-LD type	Links In External Knowledges	Equivalent Terms
feedingOperation	Entity	http://aims.fao.org/aos/agrovoc/c_2922	Feeding procedure,
Feeder	Entity-	http://aims.fao.org/aos/agrovoc/c_29bc6f3f	Feeding equipment, Fish feeder, Feed dispenser

Conclusion and Discussion

The NGSI-LD fish farming system is published in the smart data models repository[8]. In this data model we have tried to normalize data from different sources and types in one common NGSI-LD model. We have also tried to link and map almost data model attributes to external knowledge and known thesaurus for interoperability issue.

EFFECT OF SHADED AND NON-SHADED CULTURE CONDITIONS ON GROWTH PERFORMANCE AND FEED CONVERSION RATIO OF JUVENILE AND PRE-ADULT GILTHEAD SEABREAM (*Sparus aurata*)

Introduction

The effect of light intensity on the growth performance, feed utilization and stress response have been studied in different fish species, including gilthead seabream (Sparus aurata), and European seabass (Dicentrachus labrax) (Tandler and Mason 1983; Cuvier-Peres et al., 2001). High light intensity can contribute to fish stress, which increase the energy expenditure and reduce growth rates and feeding efficiency (Karakatsouli & Chiras 2005). There is a paucity of research in evaluating the growth performance and feed utilization of gilthead seabream fed different diets under shaded and non-shaded conditions. Therefore, in this study we compared the effects of shaded and non-shaded culture condition on the growth performance of gilthead seabream juvenile fed with commercial diet and in-house formulated improved diets.

Materials and Methods

Four test diets, improved diet (ID) and commercial diet (CD) for juvenile gilthead seabream, similarly, improved diet (ID) and commercial diet (CD) for pre-adult gilthead seabream were used in this experiment. In experiment 1, eighteen juvenile gilthead seabream (average weight of 55.23 ± 1.08 g and total length of 14.07 ± 0.16 cm) were stocked in triplicates in each tank at density 4 kg m-3. In experiment 2, forty three pre-adult gilthead seabream (average weight of 234.40 ± 2.57 g and total length of 23.35 ± 0.07 cm). In each experiment, the four different treatments were carried out for juvenile and pre-adult stage of gilthead seabream 1) shaded condition, fish fed improved diet (SID); 2) Non-shaded condition, fish fed improved diet (NID) 3) shaded condition, fish fed commercial diet (SCD) 4) non-shaded condition, fish fed commercial diet (NCD). For the shaded treatment, the tanks were covered by 90% green shade net to cut off the natural light intensity. For the non-shaded treatment, the tanks were exposed to the natural light. The light intensity in all the treatments (shaded and non-shaded) were measured by Lux meter and the unit was expressed in lux (lx). Fish were hand-fed at apparent satiation daily twice a day (9:00 - 15:00), except the days of sampling when the fish were kept under starvation. Pellets were released slowly to allow fish to easily chase the food and to evenly eat. Feed intake was recorded daily and uneaten pellets remained in the tanks were removed and air-dried, and pellets were weighed to calculate daily fish feed intake. The experiment lasted for 74 days. The proximate composition of the commercial diets and fish samples were estimated following the standard methods (AOAC). All data was analyzed using ANOVA followed by Fisher Least Significant Difference (LSD) test.

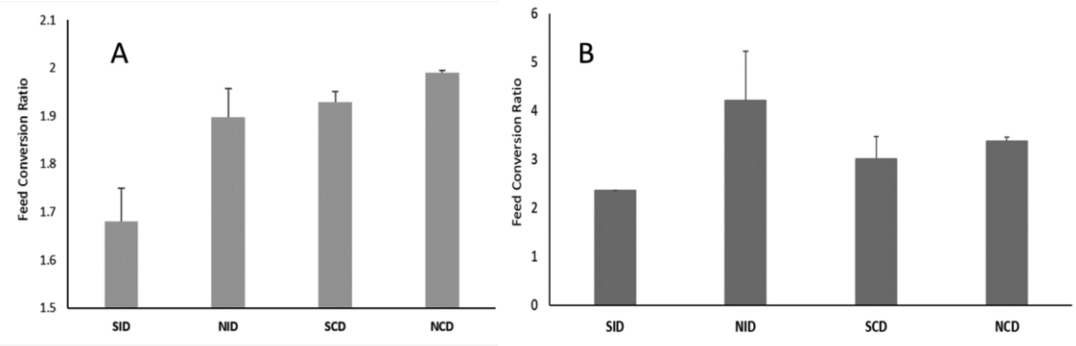

Figure 1: Feed conversion ratio of A: juvenile gilthead seabream B: pre-adult gilthead seabream reared under different conditions like shaded with improved diet (SID), non-shaded with improved diet (NID), shaded with commercial diet (SCD) and non-shaded with commercial diet (NCD).

(Continued on next page)

Results

The survival of the juvenile gilthead seabream fed improved diet under shaded condition was high (100%). The growth of the juvenile gilthead seabream has increased 2.2 - 2.4 times from its initial size after 74 days of culture. The final weight gain of juvenile fish showed significant difference ($P < 0.05$) among the different treatments. The FCR of juvenile gilthead seabream was significantly lower ($P = 0.002$) under the shaded condition where fish fed with improved diet. The SGR of the shaded treatment fed with improved diet showed significantly higher when compared to the non-shaded treatments. In pre-adult gilthead seabream, the feed conversion ratio was lower (2.36) in shaded treatment fed with improved diet (SID) as compared to other treatments. One way ANOVA analysis revealed that survival, final body weight gain and SGR are significantly higher in shaded condition where fish fed improved diet.

Discussion

In this present study, our results showed that juvenile and pre-adult gilthead seabream attained high survival rate (100%) when fed with improved diets under shaded conditions. However, the survival rate of juvenile gilthead seabream is not statistically significant between shaded and non-shaded conditions. Similar results were observed on juvenile catfish Clarias gariepinus and Epinephelus coioides, where the light intensity did not influence the survival rate (Tao et al., 2013). Alvarez-Verde et al., (2015) reported that Brazilian flounder *Paralichthys orbignyanus* prefer low light intensity for better growth. Similarly, in the present study, the final weight gain of fish, feed conversion ratio and specific growth rate of juvenile and pre-adult gilthead seabream were influenced significantly in shaded condition where fish fed with improved diet.

Conclusions

In conclusion, survival and growth performance of the juvenile and pre-adult gilthead seabream cultured under shaded conditions with improved diets were comparable to previous studies conducted in low intensity light. Among the improved diets tested the performance of the juvenile and pre-adult gilthead seabream in terms of FCR and SGR were better in shaded conditions. Based on the final weight gain, FCR and SGR in juvenile and pre-adult gilthead seabream the formulated improved diets were performed well at low light intensity.

Introduction

Cryptic Female Choice (CFC) is a form of sexual selection operated by the female through chemical and physical mechanisms [1]. In some fish species, CFC has been associated to the Major Histocompatibility Complex (MHC). In the Atlantic salmon (*Salmo salar*), the presence of specific MHC alleles has been associated with a higher survival of the offspring [2]. In the rainbow trout (*Oncorhynchus mykiss*), the CFC phenomenon has not yet been demonstrated but there are indirect pieces of evidence for this process [3]. The present study aims to investigate the CFC phenomenon associated with the MHC-IIB gene in the rainbow trout by evaluating the reproductive performance of specific matings.

Materials and Methods

The selective matings and evaluation of physiological parameters were carried out at the "Azienda Agricola Canali Cavour" fish farm (Centallo, Italy). One hundred rainbow trout were selected based on their MHC-IIB gene haplotypes, obtained through amplification and direct sequencing[4]. Haplotypes were inferred through Bayesian statistics, considering 23 Single Nucleotide Polymorphisms (SNPs), using the software PHASE V.2.1.1. The rainbow trout were monitored to assess the reproductive status and to perform artificial reproductions. A total of 15 females (4 individuals with a haplotype 2/2, 4 with a 2/x and 6 with a haplotype x/y) and 12 males (4 per haplotype) were selected for the reproduction. Morpho-physiological parameters were recorded for each female: body weight and length, weight of the eggs produced, volume, density, and pH of the ovarian fluid. Matings were performed selecting individuals based on the three haplotypes according to a full-factorial design. The success of fertilization can be used to estimate the quality of a gamete. However, fertilization does not directly involve embryonic survival, since this should be assessed in different specific embryonic steps, such as the eyed stage, the hatching, and the yolk-sac resorption stage [5]. Therefore, reproductive performance rates were calculated following the literature [6]. Finally, from the data collected during the incubation period, the overall survival rates were estimated. For the collected parameters, the presence of differences among haplotypes was assessed with ANOVA or Kruskal-Wallis test. The Pairwise Wilcoxon Rank Sum Tests with Bonferroni correction was adopted as a post-hoc test. A generalized linear model was used for modelling the survival rates.

Table 1. Results of the GLM analysis on the survival rate.

Variables	β	Standard error	t-value	p-value
F 2/2 + M 2/x	0,04	0,09	0,46	0,65
F 2/2 + M x/y	0,01	0,09	1,14	0,26
F 2/x + M 2/2	-0,23	0,09	-2,51	< 0,05
F 2/x + M 2/x	-0,25	0,09	-2,75	< 0,01
F x/y + M 2/2	-0,050	0,09	-0,55	0,59
F x/y + M 2/x	-0,11	0,089	-1,24	0,22
F x/y + M x/y	-0,29	0,11	-2,68	< 0,01
Time	-0,09	0,02	-6,31	< 0,001
Single egg weight	5,53	3,42	1,62	0,11

(Continued on next page)

Results

Morpho-physiological parameters of the females did not differ significantly, except for the single egg weight and the relative fecundity. The value of the single egg weight was different between the haplotype 2/2 and the haplotype x/y ($p<0.05$). The parameters related to the matings (eggs and larvae) did not differ significantly, except for the deformed larvae rate ($p<0.01$) and the healthy larvae rate at the end of incubation ($p<0.05$). However, in both cases, the post-hoc test was not able to detect differences between groups, probably because of the low number of samples. From the GLM analysis on the trend of the survival rates it emerges that the type of mating and the time are the variables that significantly affect the survival (Tab. 1). The weight of the single egg is not significant and consequently has no effect on the survival rate.

Discussion

The lower egg weight did not affect negatively the reproduction performance of the female 2/2, since the mating with the 2/2 females showed, in average, higher reproductive rates compared with other matings. On the other side, some differences were noted in the larvae deformity rate ($p<0.01$) and in the rate of healthy larvae ($p<0.05$), however these differences were not confirmed by the post-hoc test due to a restrained sample size per category. The GLM analysis on the trend of the survival rates highlight that the type of mating and the time are the variables that significantly affect the survival. A significant effect emerges for the matings F 2/x + M 2/2, F 2/x + M 2/x and F x/y + M x/y, which compared with the mating F 2/2 + M 2/2 shows a lower survival. A lower survival rate is also observed for the F x/y + M 2/2 and F x/y + M 2/x matings, which however are not significant, as well as the F 2/2 + M 2/x and F 2/2 + M x/y which have a slight positive effect on survival.

Conclusions

This study aimed to evaluate the reproductive performance of rainbow trout associated with the MHC-IIB gene in relation to the CFC. Taken together, the results of the reproductive performance indicate a better output for the matings performed with 2/2 females. Furthermore, the GLM results indicate a greater survival during the incubation phase for the mating F 2/2 + M 2/2 if compared with other matings. Despite these encouraging findings, the results of this study are not able to confirm the presence of CFC in the rainbow trout (*O. mykiss*) associated with the mating among similar haplotypes (F 2/2 + M 2/2).

Introduction

The COST (Cooperation in Science and Technology) Action CA 20106 – known as SeaWheat- aims to exploit seaweeds’ potential in Europe. Building on the successes of previous EU and pan-European algae projects, and thanks to the unique characteristics of the genus *Ulva* (Linnaeus, 1753), the Action identified these green algae as the most suitable organisms for biomass production and innovative blue biotech industries in European mariculture. *Ulva* (class Ulvophyceae) belongs to a genus inhabiting shallow marine and brackish waters and its species are ubiquitous throughout the world’s oceans, where they constitute an important primary producer.

Much of the knowledge on *Ulva,* generated in diverse scientific disciplines and communities, are not easily comparable, nor is it shared among scientists, stakeholders, end users and the public. This COST Action proposes an innovative conceptual pathway to address these issues, significantly improving knowledge on the biology of the most promising *Ulva* spp., capitalising on their economic potential, and exploring commercial applications in human nutrition, livestock nutrition, pharmaceutical industries and ecosystem services.

With seven different Working Groups (WGs), the Action has created a network of 190 participants belonging to 31 COST member states, including 20 SMEs (Small and Medium-sized Enterprises). The Action combines interdisciplinary approaches to the sustainable use of marine resources, encompassing all the facets of *Ulva* biology, ecology, aquaculture, engineering, economic and social sciences. In addition, it fulfils the current ‘Societal Challenges Priorities’ of European Horizon 2020 strategy for food security, and its application will contribute to the UN Sustainable Development Goals 14 (UNSDG) to conserve and sustainably exploit natural resources.

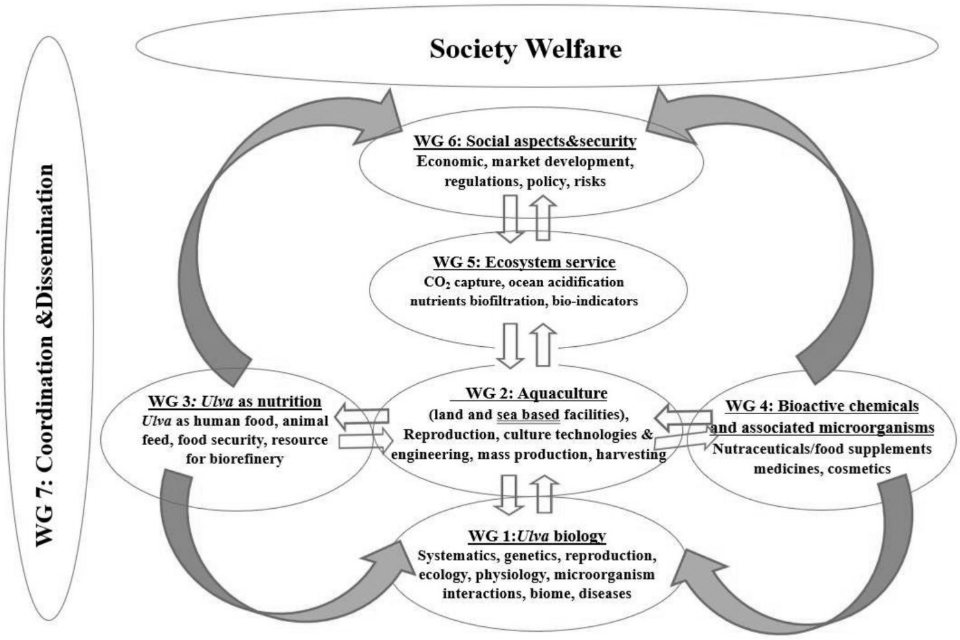

Fig. 1; Scheme of the Working Groups (WGs) in the COST Action and their interactions.

(Continued on next page)

Main Challenges

The main aim of the COST Action is to make a step-change towards a green economy based on *Ulva* mass production and utilisation within the European community and beyond. The ultimate goal is the development of *Ulva*-based blue-biotech industries and the utilisation of *Ulva* as a model organism in European algaculture.

Through the *Ulva* COST Action, the traditional European diet and taste will become acquainted with *Ulva* as a new, sustainable, and safe food item. Furthermore, thanks to its nutritional quality, the Action will promote *Ulva* inclusion in the European human diet and animal nutrition. Indeed, as an aquafeed ingredient, *Ulva* can facilitate a sustainable European aquaculture expansion. A high potential market also exists for new bioactive molecules that may provide innovative products in the nutraceutical and biomedical industries. Furthermore, *Ulva's* ecosystem services (provisioning, supporting, regulatory and economic), particularly nutrient recycling and removal and carbon fixation, will ensure environmental sustainability. However, large-scale production of *Ulva* is a prerequisite for making *Ulva*-derived compounds market-competitive.

The Action will bridge the scientific, regulatory and social practical knowledge gaps still existing in *Ulva,* paving the way to the commercial production of this seaweed in the blue-biotech industries.

Introduction

In the framework of the COASTAL project, two regions, the Charente (France) and the Danube Delta (Romania), are evaluating their aquaculture activities and opportunities with regard to their role in their further development. The EU is indicating the pathway towards a sustainable aquaculture with their Strategic guidelines for a more sustainable and competitive EU aquaculture for the period 2021 to 2030[1], for which sustainability of these activities should be assessable. For this, the EU has initiated the Blue Economy Sustainability Framework with Sustainability indicators for the Blue Economy (SIBE)[2], including aquaculture.

These indicators are covering the four dimensions of sustainability (economic, environmental, social and governance). For each dimension, a number of sustainable criteria were listed and different indicators established. There are 44 common indicators as well as 104 sector-specific indicators, divided over 12 subsectors. The SIBE wants indeed to obtain a cross-sectoral approach to the blue economy with flexibility for an application at different scales, levels and geographic zones. As the COASTAL project has an aquaculture focus in some of the project case studies, it could be of interest to cross-check the sustainable criteria listed by the SIBE with the in- and output generated through stakeholders interactions, dynamic models and their indicators and policy guidelines. The SIBE lists, aside the common indicators, three different subsectors of interest for aquaculture, namely “fish and shellfish harvesting”, “fish and shellfish processing” and “aquaculture”. While the French Charente region is looking to assure the production as well as the regional heritage of shellfish farming, the Romanian region is aiming to intensify its aquaculture (pondfarming and marine cagefarming) in the Danube Delta Biosphere reserve and its marine waters (Black Sea). Both region will have to deal with different challenges, but their further development should have to be sustainable. In that respect, indicators for assessing their negative impacts as well as their benefits in the different dimensions, have to be stipulated. This review will compare the different aspects of these aquaculture activities with the SIBE and help improve the sustainability indicators for aquaculture.

INNOVATION IN THE NORWEGIAN AQUACULTURE INUSTRY

S. Afewerki*, F. Asche, B. Misund, T. Thorvaldsen, R. Tveterås

SINTEF Ocean, Department of aquaculture, NO-7465, Trondheim, Norway

Email: samson.afewerki@sintef.no

Introduction

Global aquaculture production has grown very rapidly in recent decades. This is largely due to a number of innovations that has increased the control with the production process and competitiveness. These innovations come in a number of forms from radical new concepts to knowledge adaption from the terrestrial food production system. While there exist a number of studies investigating the impact of specific innovations, there are few studies that takes a larger perspective on how innovations over time impacts an aquaculture industry or the innovation system that support these innovations.

Materials and methods

Based on secondary data gathered from media, industry and government reports, as well as previous research, in this paper we review the innovation process in Norwegian salmon aquaculture industry from its infancy in 1970 until present. Of particular interest is the increasing complexity of the industry, and how most innovations are conducted by suppliers and not the aquaculture producers themselves.

Results

The success of the Norwegian salmon aquaculture industry over the last decades has largely resulted from innovations across the aquaculture value chain such as genetics (breeding), fish feed, feeding equipment, vaccines, information technology and cages. Innovations have contributed greatly to increased growth rates for salmon, lower mortality, higher product quality and lower production costs (Asche et al., 2013).

As in most aquaculture industries, the original Norwegian salmon farmer was an entrepreneur, who was also a "Jack of All Trades" in that the farmer had to do everything involved from building the farm, raise the fingerlings, mix the feed and harvest the fish. As the industry grew, there has been a dynamic process of innovations that has enhanced productivity and increased the control with the production process. This has largely been conducted by new supplier industries, where the specialized suppliers identified the growing industry as a market, and competition between suppliers lead to innovations giving better inputs at a lower cost (Tveteras and Heshmati, 2002; Asche, 2008). Today, there are specialized suppliers for a wide range of equipment such as (but not limited to) sensors and control systems as well services such as veterinary tests, net cleaning and research. As such, an increasing part of the employment associated with the industry is in different types of suppliers.

A common thread is that the size of everything has increased in salmon aquaculture, the production, the fish, the pens, the farms, the feed barges, the well-boats, the processing plants and the firms. This suggest that innovations are also important for creating and allowing economies of scale to be exploited. Innovations have generally been scale-biased or scale-increasing, and through the value chain from smolt production via sea transportation and grow-out farming to primary processing the optimal economic scale has increased. Not unexpectedly, many of the most radical innovations occurred early in the history of the industry, and later innovations are mostly smaller process or product innovations which in sum provides a powerful gradual process. However, there still occur radical innovation as exemplified by offshore and land-based farming. It is also interesting that public incentives in combination with the regulatory system is facilitating such innovations.

The innovations provide more technological opportunities for salmon aquaculture than we have ever seen before. Innovations in open and closed production systems from land-based or onshore to offshore ocean allow for several new value chain configurations. These new production technologies have the potential to both reduce firms' internal production costs, as well as reduce the external costs of environmental emissions, diseases and Salmon lice. As of now, no-one knows what is going to be the production concepts used in salmon farming in the future, or even whether there will be one dominating one or several parallel concepts used. However, it is highly interesting that the basic production technology, open sea pens, are being challenged, and that all the new concepts increase the control with the production process and thereby the potential for further innovation.

(Continued on next page)

Conclusion

Although our research is focused on innovations in the Norwegian aquaculture industry, the insights are also of general interest in global aquaculture as salmon is among the species with the most advanced production technologies, but also a species where innovations are adapted to other species also in very different production systems. Furthermore, in this paper, we have solely focused on the production part of the supply chain. However, as consumers in general only care about the price they are paying, innovations in the supply chain are equally important for the competitiveness of any industry. Previous research has shown that the supply chain for salmon is highly competitive in relation to most other seafood species (see Asche and Smith 2018). Compared to other more advanced (especially terrestrial) production systems such as poultry (e.g., chicken) however, the supply chains for salmon is still lagging behind in many dimensions (Asche et al., 2018). Hence, there is still significant scope for innovations also down-streams in the supply chain. This includes not only logistics and product development, but also perceptions of the species. This is particularly important for salmon since there is a number of issues with respect to its environmental sustainability that can at least partly be addressed by certification (Osmundsen et al., 2020).

Introduction

Several pathogenic agents can cause lesions and diseases in bivalve molluscs both in wild and in production areas. *Ostreid herpesvirus* (OsHV-1 and OsHV -1 *μ*var) has been the cause of important mortalities in Japanese oyster (Crassostrea gigas), in several countries, including in Portugal since 2012. The lesions are not pathognomic of that virus and include, namely, discoloration of the digestive gland, presence of vacuoles in the cytoplasm of epithelia of the digestive gland diverticula and necrotic lesions in several tissues, mainly in gills epithelium and connective tissue. Furthermore, hemocitosis and intracytoplasmatic inclusion bodies can be observed in most affected tissues.

Materials and Methods

The presence of OsHV-1 and OsHV-1 *μ*var in Portuguese oyster and Japanese oyster were surveyed from January 2021 until May 2022. Oysters (adults) were sampled from three different sites of the Portuguese coast (water temperature: 18-20ºC; salinity: 30-34 ppm). Portuguese oyster from Sado estuary (n=74) and Japanese oyster from Formosa lagoon (n=63) and Aveiro lagoon (n=136).

For the detection of this pathogen we followed, since the first time thepathogen was detected in Portuguese waters (2011), the protocol set out in COMMISSION REGULATION (EU) No 175/2010 of 2 March 2010, Part B of Annex I for the DNA extraction method and PCR analysis. The tissue samples for histopatholgy were fixed in Davidson's fixative for 48h,dehydration, embedding in paraffin and cutting with a microtome in sections with3-5 *μ*m thick, than stained with Hematoxylin and Eosin (H&E).

Results

The histopathological examination of both oysters species revealed the presence of *Trichodina sp*. ciliates in gills and mantle epithelium and *Ancistrocoma sp*. in the digestive gland tubules and in the connective tissue, both with a moderate prevalence. The copepod *Mytilicola sp*. was observed in the intestine lumen of both oyster species. In both populations, hemocytosis was observed in connective tissue, edema and metaplasia in digestive gland and tissues necrosis. In the population from Mira estuary the prevalence of these lesions was slightly higher, except for individuals with metaplasia.

The lesions observed in the epithelium of the diverticula of the digestive gland, the hemocytic infiltration and necrosis can be related with different pathogenic agents.

In all populations analyzed in this study the presence of the virus was not identified.

Discussion and conclusion

The first mortality outbreak observed in Portugal, occurred in populations of Pacific oyster, *Crassostrea gigas*, related with the presence of a herpes-like virus,*Ostreid Herpsvirus* (OsHV-1), reported during the summer of 2012 in an offshore long line culture systems, settled near S. Vicente Cape, in south coast of Portugal.Associated with high mortality rates, was detected for the first time in 2011, the presence of the µvar genotype of OsHV-1 in *C. angulata* produced from a broodstock collected in Sado River and then transferred to the Formosa Lagoon (Batista et al., 2015). This disease reached the highest impact in oyster production during 2017, when mortalities rates between 60 and 100% where registered in Alvor (Algarve) and Aveiro lagoons. Since then, reports of massive mortalities have been declining.

(Continued on next page)

Environmental factors, as well as managing culture practices, namely hight densities in oyster tables, and intensive handling of the animals during critical environmental conditions, can contribute to increase the pathogenicity and the spread capacity of this pathogenic and of those that are opportunistic. However, biosecurity measures are fundamental to prevent the spread of the disease, namely control of the transport of the animals and of the equipment from different countries and regions and quarantine. Also, regular laboratory control, the identification and the characterization of pathologic processes in oysters are important measures for sanitary control. All together, these measures and the collaboration of the producers have been contributing to the control and spread of *Ostreid Herpsvirus* in Portugal.

Introduction

The demand of farmed oysters in Italy is increasing since 2010 (Lopes *et al.*, 2020), due to better quality of shape and organoleptic quality of meat compared to wild specimens. The research of new cultivation areas and farming systems are fundamental to answer the request.

Although the Pacific cupped oyster (*Magallana gigas*) is the most widely cultured species, the European flat oyster (*Ostrea edulis*) could also represent a good chance of development especially in areas where the parasites *Bonamia ostreae* and *Marteilia refringens* are not endemic.

The aim of this study is to introduce the "off-bottom" oyster cultivation method in Valli di Comacchio (Northern Italy), that are brackish basins mainly dedicated to fish farming. The channels linking the basins to the Adriatic Sea are highly productive and well established in the cultivation of Manila clams (*Ruditapes philippinarum*) and they also hold large benches of *M. gigas*, while *O. edulis* represents an occasional catch.

Methodology

The study was conducted in Valle Sottolido, a basin of 60 ha and mean depth of 1.5m. The sea water arrives to the basin through a 4,2 km channel and the water flow is influenced by tides. Water characteristics were investigated using data loggers (temperature, dissolved oxygen, salinity), while the chlorophyll-a concentration was measured weekly by spectrophotometry after extraction with acetone (Lorenzen, 1967), during the period January – July 2022.

O. edulis and triploid *M. gigas* spat were placed into floating cages of FlipFarm™ system, stocked at 100 individuals cage^{-1} and they were nested within two daily immersion time: 18h and 24h, in order to test also the effect of immersion time on survival, growth, shell composition and meat quality.

To evaluate differences in chemical and bromatological composition between *O. edulis* and *M. gigas*, also related to both farming techniques, the oysters were opened, and the soft body was removed from the shell. The soft body was homogenized and lyophilized for lipids, proteins, ashes, and carbohydrates determination. The element composition of shells (previously grounded) of both species, was determined by Inductively Coupled Plasma - Optical Emission Spectroscopy (ICP-OES). The concentration of elements Ca, Sr, Fe, Mg, Si, Al and S was calculated.

Results

M. gigas farmed with 24h of daily immersion time grew till an early marketable size in 180 days. Oysters of the same species but farmed with 18h of daily immersion time had a slower growth. Both treatments resulted in survival above 90%. *O. edulis* showed a slower growth than *M. gigas* and more mortality, in particular on the 18h immersion time treated batch.

The higher growth rate was found during the month of April 2022, when average day temperature ranged from 13,9°C and 21,3°C and Chl-a concentration was not low than 2,314μg/l.

Bromatological composition of *O. edulis* and *M. gigas*, did not show any quantitative nor qualitative differences within the two cultivation methods. However, a higher percentage of total lipids was detected in *M.gigas* compared to *O.edulis*. In detail, *M. gigas* showed a higher percentage of Eicosapentaenoic acid (EPA) and Docosahexaenoic acid (DHA) for both cultivation methods. The elements concentrations of the shells, obtained by ICP-OES, differed between the two cultivation methods and between the species. In particular, the shells of animals grown for 24h immersion contained higher concentration of each element compared to oysters grown for 18h immersion, except for Ca, that did not show any differences.

Introduction

Coastal fish farming plants can have a significant environmental impact due to the release of catabolites by farmed organisms and feed residues, causing an overall increase in organic matter and potentially pathogenic or antibiotic resistant bacterial load in the water body. In this sense, Integrated MultiTrophic Aquaculture (IMTA), the practice that combines the cultivation of fed aquaculture species with other organisms able to extract organic and/or inorganic substances from seawater, represents an eco-friendly alternative to the monoculture. IMTAs allow water quality improvement, promise high economic return and social suitability also implying an improvement in human welfare and in the quality of ecosystem services provided by the marine environment. Among extractive organisms, filter-feeders and particularly Porifera seem the most promising although they are still little known or underexploited in these activities. Their environmental and economic potential and thus the interest in these organisms is increasing as new sustainable and profitable applications for the biomass obtained from these systems are developed.

Bioremediation, the basis of sponge production

One of the main advantages of filter-feeding organisms such as Porifera is precisely that their energy source is obtained by highly efficient filtration of organic particles between 0.1-50 μm, such as dissolved and particulate organic particles, heterotrophic bacteria and eukaryotes, phytoplankton and even viruses (Simpson, 1984; Riisgård & Larsen, 1995; Hadas et al., 2006), so that their mere growth leads to bioremediation of the surrounding environment. Similarly, being filter-feeding organisms, they are constantly exposed to contamination of the water column, which makes them target organisms as bioremediators or bioindicators due to their (and their microsymbionts') ability to accumulate metallic and organic pollutants (e.g. Bauvais et al., 2015; Gentric et al., 2015).

Past and present concern

The trade of sea sponges dates back hundreds of years, when they were collected for cosmetic use known as "bath sponges"; today, in the Mediterranean basin countries such as Italy, Greece, Croatia, Cyprus or Tunisia still maintain this economic sector (e.g. Spugnificio Incorvaia, Italy; Spuga2, Croatia). However, the unregulated overexploitation of this resource in the past has caused the cultivation of sponges to attract increasing attention over the years, in addition to the shift in commercial interest in their production from rearing of bath sponges to their cultivation for the production of secondary metabolites (Biertwirth et al., 2022).

A marine bioactive compound factory

The first marine origin drugs to reach clinical trials were extracted from a Caribbean sponge around seven decades ago (Bergmann & Feeney, 1951); since then, the number of these compounds has only increased and together with cnidarians, they are the most prominent organisms for their discovery, exceeding 200 per year (Carroll et al., 2019). These compounds are synthesized not only by sponges, but also by their symbiont microorganisms (Proksch et al., 2002). They have a wide range of applications: from anti-tumour, antiviral and antimicrobial in human medicine up to antimicrobial and antifouling activities in the aquaculture industry or biomaterial production in different sectors (Rotter et al., 2021; Varijakzhan et al., 2021). However, obtaining the needed biomass involves a considerable challenge, as natural populations are unable to supply this market in a sustainable manner. Therefore, co-culture strategies such as IMTA appear as a possible solution, as the natural environment provides the optimal conditions (even for endosymbiont microorganisms) that *ex-situ* can be costly and difficult to maintain.

From the sea to the tank

Another economic potential of marine sponges is their sale for recreational aquaria, where, due to their diverse colours and shapes, they are particularly attractive. There are companies dedicated to their trade (mainly in the US), and their prices vary from tens to hundreds of euros per individual depending on species and size (e.g. RUSALTY, US). In addition, there is a growing interest in the sponge specimens supplies as food for certain spongivorous fishes. In this sense, facilities such as IMTA systems could provide a suitable environment for the growth and sustainable production of local species.

(Continued on next page)

The challenge in marine sponges' restoration

Combining production for human consumption with restorative aspects is a recent and arising approach (Giangrande et al., 2021). Wisely planned IMTA could be reasonably proposed for environmental restoration and conservation purposes. Such plants combine bioremediation with biodiversity increase. In the case of sponges, the biomass obtained can be valorized for transplantation or restocking of threatened or vulnerable species up to benthic habitat restoration.

Conclusions

The production of biomass from non-edible species in properly designed IMTAs such as marine sponges with important profitable applications implies the use of new resources that promotes a blue circular economy. In this sense, Remedia Life IMTA system represents an eco-friendly sponge biomass supply not only for economic interests such as green extraction of bioactive molecules and aquariology (ornamental species, food or shelter for fishes) but also for environmental welfare as bioremediators or restoration purposes that increase ecosystem biodiversity.

CO-PRODUCTION OF KNOWLEDGE FOR A DECISION SUPPORT TOOL FOR AQUACULTURE AND COASTAL MANAGEMENT DEVELOPMENT IN NORWAY

A. V. Strand*, I. Ahlquist, R. Tiller, T. Thorvaldsen, and A. Misund

SINTEF Ocean, Postboks 4762 Torgarden, NO-7465 Trondheim, Norway
E-mail: andrea.v.strand@sintef.no

Introduction

There are several challenges currently limiting the production growth of conventional aquaculture in open net cages in Norway including sea lice, emissions, and escaped salmon. New production systems may allow for growth though, by allowing for production at more exposed localities, in land-based farms and even in semi-closed or closed floating cages. These systems can battle some of the challenges faced by conventional aquaculture still though, and each also have other challenges connected to their respective systems, both on the technical and on the regulatory and management side.

For the purposes of this study, we co-develop a decision support tool in close collaboration with stakeholders, based on conceptual mental models created with Fuzzy Cognitive mapping (FCM) in the software Mental Modeler (Gray; Kosko, 1986). Groups of experts and stakeholders within a given area decided on relevant variables and their connections within a specific field, which formed the basis of the mental models. The decision support tool allowed us to develop stakeholder driven future scenarios aimed at countering the identified sustainability issues by testing a broad range of management options, to assess trade-offs and establish mitigation and adaptations needs. These scenarios can theoretically verify if impacts of different measures implemented work as intended or to identify where and which measures are needed to regulate or manage a change in a system. It is therefore the aim that the tool can aid policy makers, industry, stakeholders, and researchers alike with stakeholder driven data that give legitimacy when making critical choices in terms of what to prioritize given different weighing of SDGs for example.

We have included two case studies to test the decision support tool. These are mental models on the new aquaculture production systems in Norway, and on coastal-rural interaction due to the land-sea utilization of different industries along the coastline in Norway. The aim is to make a generic tool that can run scenarios with different datasets from diverse socio-ecological settings using Fuzzy Cognitive Mapping.

Methods

The input dataset referred to as the mental model, was created with FCM in Mental Modeler. Several representatives and experts for the aquaculture industry have collectively participated and agreed on which variables and their connections are important for the specific case study. These variables include amongst others “Optimal feeding”, “Oxygen levels”, “Regulations, “Acceptance of local communities” and more. The variables are connected to the other variables that they directly influence. These connections have been quantified on a scale between 0 and ±1. A negative value indicates that if one variable increases, the “negative” connection decreases, or opposite with a positive value, then an increase would lead to an increase. These values have been determined and later validated by the expert panel from the stakeholder groups.

The decision support tool has been created in R (R Core Team, 2020), which is a free software and programming language specialized for statistical computing, data mining and graphics. We are using the existing functionality in R related to FCM, such as the FCM package (Dikopoulou & Papageorgiou, 2017) for model simulations.

The scenarios are visualized in the decision support tool, where each variable is presented in the same figure. In this figure, the value of each variable changes over the iterations of the model, until the model has reached one of the three following states: 1) Equilibrium, 2) A cycle behaviour or 3) Chaotic behaviour. These states are presented by the function as “convergence” since they become fixed points. These graphs represent the storylines of the scenarios, that are determined by the initial value of variables set by the user, and the mental model defined by the experts. Therefore, these scenarios are modelled based on the stakeholders’ perception of the system if there is a change to the current system. The decision support tool will be verified and calibrated further by the experts from the specific case studies.

(Continued on next page)

Results & Discussion

The decision support tool allows the user to change the values of one or several variables at the time. The tool then models a scenario based on the choice of the user. The results are visualized graphically where the user can see the development of each variable over the iterations.

To illustrate the area of use and possibility the decision support tool gives, we have selected some examples. If, in the new aquaculture production system's case, "Acceptance of local communities to a new production system" was increased to 1 (the highest possible value, representing "complete acceptance"), the decision support system would see a similar increase in production. This, however, would also trigger a demand for a larger workforce, which could again affect the initial "Acceptance" variable. Another example from the coastal-rural interaction is that if "Infrastructure" improved in the North of Norway, "Transportation" would increase, which would lead to increased "Production" from the industry in the municipalities. On the other hand, improved "Infrastructure" would also lead to increased "Emissions".

The scenarios are heavily dependent on the mental model used, which again is based on the inputs of the participants. The scenarios can identify policy options, business strategies and practices for policy makers, industry actors and other stakeholders that support the sustainability of the aquaculture sector. The power of the decision support tool is that it can uncover connections and repercussions that are not apparent. Another benefit is that it is co-produced with the stakeholders themselves, who know the system in ways that scientists in isolation may not be able to represent. The tool does allow the users to create scenarios and predict how the rest of the system reacts, providing crucial inputs for both production planning, policy making and resource management.

TWO-PHASE FLOW MODELING VIA COMPUTATIONAL FLUID DYNAMICS (CFD) STUDIES ON A CASE STUDY: MOVING BED BIOMEDIA REACTOR (MBBR) 1000

Manolya Akdemir Çolpan[*1]
[*]MAT Filtration Technologies
e-mail: manolya.colpan@matglobal.tech

Total Ammonia Nitrogen (TAN), which occurs due to various reasons especially fish defecation and death, is crucial for life and bring about death of living creatures. Therefore, it is very important to reduce the amount of TAN in water and it is called as Nitrification process.

In order to carry out the nitrification process in the best way, the bacteria must be optimally provided in the environmental conditions of the habitat. The parameters that ensure these are: 1) biomedia surface, 2) pH of water in unit, 3) amount of oxygen in the air, and 4) optimum two-phase flow of water-air flow. There are two ways to remove TAN in fish farming and industrial aquariums. One of them is Trickle filter and the other is Moving Bed Biomedia Reactor (MBBR). It can be said for these two systems that provide advantages over each other, but to sum up; the MBBR is more user-friendly and more advantageous in that it provides higher removal rate of TAN in the same size. By giving the air taken from the blower into the water, a double phase flow will be provided inside the MBBR unit. Modeling this is important in terms of the accuracy of the intermediate and main parameters.

The aim of this study is to structure the project according to the parameters that need to be optimized above. The methods used consist of mathematical modeling according to the amount of TAN determined on a project basis, MBBR unit sizing, biomedia diversity and mixing ratio determination, and finite element analysis with ANSYS CFX® to model two-phase flow.

REDUCING RISK IN OPERATION OF EXPOSED HIGH VOLUME, ADVANCED FISH FARMS - HOW TO MAINTAIN SAFETY OF ASSET, PERSONNEL, MAINTAIN FISH WELFARE AND PREVENT FISH ESCAPE FOR OFFSHORE FISH FARMS

Mr. Aland, PA

DNV – Det Norske Veritas
Veritasveien 1, 1363 Høvik, NORWAY
e-mail: per.arild.aland@dnv.com

INTRODUCTION

It is a growing trend that fish farms are moved out of sheltered, near-shore areas and moved to locations further offshore. There are several advantages applying this solution, Better fish welfare, less conflicts with interests in the ocean space as well as possibility to scale up output volume without compromising environmental sustainability are some of them. As the world's population grows, the options for producing enough food are becoming limited. The oceans offer a vast opportunity to meet this demand with sustainable, safe and efficient offshore fish farming.

Adding safety to offshore fish farming projects is mainly ensured by providing uniformity, transparency, and predictability and thereby reducing project risk. We need to be ensure that facilities for aquaculture can handle harsh environment and still contain the fish safely.

MAIN APPROACH

The main areas of concern when it comes to ensuring safe and reliable offshore fish farming units may be categories into: Asset integrity, personnel safety, fish welfare and prevention of fish escape.

Asset integrity includes structural strength, stability, mooring, technical arrangement, and solutions on board together with reliability of essential equipment installed.

Personnel safety is mainly addressing arrangement for emergency escape and fire safety. This included lifesaving appliances, launching equipment and similar as well as fire detection and -extinguishing. It is common to apply well know maritime codes as acceptance criteria for personnel safety. SOLAS is a good example followed by local flag- or shelf states interpretation of requirements embedded in this maritime code.

Fish welfare and requirements related to this varies depending on local authorities. It is essential to verify the reliability of technology utilized to monitor environment of the fish. Instrumentation indicating oxygen level, temperature, salinity, turbidity is subject for special attention. Maximum acceptable level of biomass is also a crucial parameter that needs to be monitored.

Fish control or prevention of escape is the main function of a fish farming unit. Structural integrity of net system and ropes together with capability of fish transfer systems are crucial items in fish control. Flexible net systems utilized in rigid high volume steel fish farming installation has proven to be exposed to fatigue and need to be attended to in particular. Wear and tear of net due to cleaning and handling is also a concern. Several of reported incidents related to fish escape happens while handling of fish – for example crowding due to de-licing or transfer. Equipment contributing to these operations needs to be specially attended to.

The four different items are considered equally important for safe and sustainable fish farming offshore. These elements are also closely interconnected where integrity of on may support several others.

CONCLUSION

There is a significant potential to utilize competence from traditional offshore and maritime industry to help operators of exposed fish farming units to identify operational risks by applying technical rules and requirements from classification. As opposed to the offshore oil and gas industry, classification may not be obligatory in aquaculture, but it turns out that many developers and operators nonetheless choose to follow class requirements and recommendations.

Combining the well-known classification concept from maritime industry with balanced aquaculture-based requirements provides a robust and cost-efficient solutions to reducing risk in operation of offshore fish farming installations.

BY-PRODUCTS FROM CRAB SHELLS INCREASE FEED INTAKE, GROWTH, SKIN QUALITY AND HEALTH IN ATLANTIC SALMON *Salmo salar* SMOLT AFTER SEAWATER TRANSFER

Sissel Albrektsen[1]*, Aleksei Krasnov[1], Tina Olaussen[2], Elisabeth Ytteborg[1]

[1] Nofima AS, P.O. 6122, N-9291 Tromsø, Norway
E-mail: Sissel.Albrektsen@nofima.no
[2] Nutrishell AS, P.O. 1212, N-7010 Trondheim, Norway

Introduction and aim

In the first period after seawater transfer it is essential to use high quality feed ingredients that can stimulate appetite and growth of salmon and thereby improve quality and robustness of fish. High production losses of salmon are annually reported in the period after seawater transfer due to development of wounds and injuries that makes the fish prone to infections and fungal attacks. Some of the free amino acids in fish protein hydrolysates are known to affect smell and taste perception in fish, and hydrolysates produced from marine by-products have demonstrated effective feed attractant properties in salmon. The aim of this project was to document impacts of crab hydrolysate and crab meal ingredients produced from crab shells on feed intake, growth and skin quality in Atlantic salmon when supplied as an additive in salmon feed after seawater transfer.

Material and Methods

The crab products were added at 2 dietary levels (1.5%, 3.0%), mainly by replacing crab protein with fishmeal protein, but also with small corrections with plant proteins. The crab hydrolysate contained 39% protein and replaced 0.9 and 1.8% of the protein, respectively, while crab meal contained 16% protein and replaced 0.35 and 0.69% protein. Both crab products were added by top-coating on extruded feeds. A feeding trial with Atlantic salmon in the first 6 weeks period after transfer was performed. Results with respect to feed intake, growth and dietary impacts on skin quality was recorded by visual and histological analyses and by transcriptional profiling and compared to results obtained by feeding a similar formulated control diet without crab products.

Results

Crab hydrolysate used as an additive in feed for salmon and fed for 6 weeks after seawater transfer, stimulated feed intake and growth more effectively than crab meal added at the same dietary levels, and improved feed intake and growth significantly as compared to control fish ($P < 0.05$). A linear relation between feed intake and growth was found, indicative of efficient nutrient utilization in all dietary groups, as confirmed by no or small differences in nutrient digestibility. Feed intake responses equivalent to 3 % of fish biomass was recorded after 5 and 10 days in fish fed crab hydrolysate and crab meal diets (only Crab M1), respectively, and after 15 days of feeding in fish fed the control diet. The variable time of onset of feeding after seawater transfer explain most of the variation in fish growth. Feed intake responses equivalent to 3 % of initial biomass was recorded after 5, 10 and 15 days of feeding in fish fed crab hydrolysate, crab meal (Crab M1) and control diets, respectively.

Salmon fed crab hydrolysates gained 78 - 83 % of their initial weight and showed efficient growth rates; mean SGR = 1.44 ± 0.09 % during 6 weeks of feeding after transfer, which is significantly higher than in fish fed the control diet; mean SGR = 0.95 ± 0.06 % ($P < 0,05$). Salmon fed crab meals gained 59 - 60 % of their initial weight, and the growth in this group was not significantly different from control fish ($P > 0.05$).

Histological examination of the dorsal skin (Aiforia) showed thicker skin in the dermal layer, and increased area and number of mucus-producing cells in the epidermal layer. Significantly lower dark pigmentation was found in the skin of fish fed crab hydrolysate diet compared to fish fed the control diet ($P <0.05$). Dark skin pigmentation is regarded a non-specific reaction typically found in fish exposed to frequent handling, stress, and diseases.

A visual assessment of the dorsal skin quality (FishWell Operational Welfare Indicator scores) that included fish shell losses, wounds, and bleeding, confirmed better skin quality in fish fed with crab hydrolysate. At the same time, anti-inflammatory properties were detected in the skin of salmon fed with crab hydrolysate, where several well-known genetic markers (serum amyloid A-5 protein, matrix metalloproteinase 13-2, 9-1, 9-2) and other less described follow up markers of acute inflammation were significantly lower expressed as compared to fish fed the control diet without hydrolysate ($P <0.05$). Histopathological changes in the upper skin layer (oedema, altered morphology) consistent with early infectious stages of *Moritella viscosa*, a fish pathogen associated with wounds and mortality in salmon farming, was observed. The significance of the anti-inflammatory action of crab hydrolysate shown during the early infectious stage in fish, is not entirely understood and warrants confirmation.

(Continued on next page)

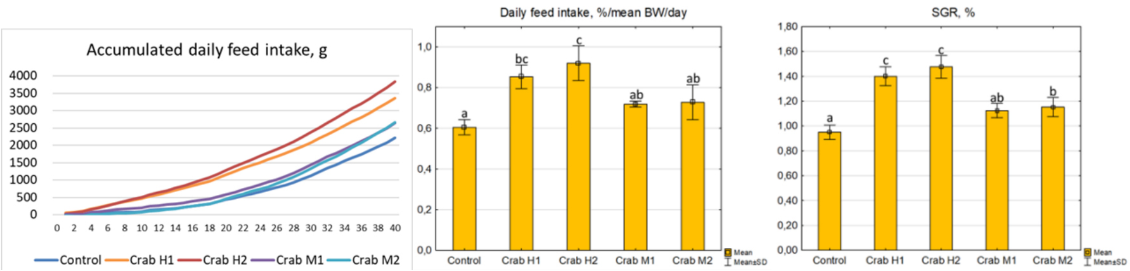

Figure 1 Accumulated (g) and daily (%/mean bodyweight (BW)/day) feed intakes and daily specific growth rates (SGR, %) in Atlantic salmon after 6 weeks of feeding post transfer. Mean values ± STD(x) are given. D1: Control; D2: Crab hydrolysate (H1); D3: Crab hydrolysate (H2); D4: Crab meal (M1), D5: Crab meal (M2)

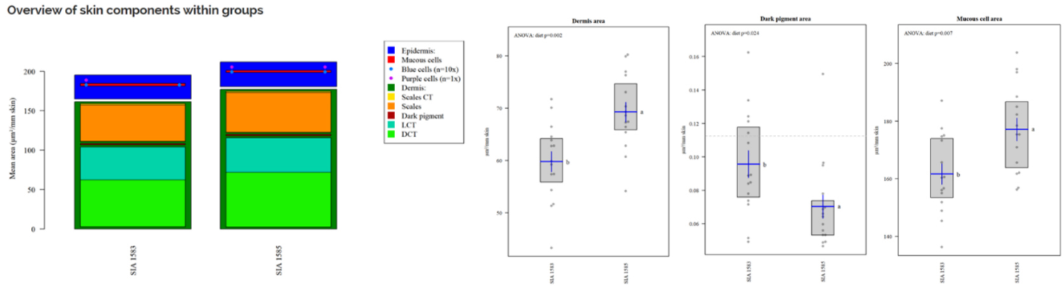

Figure 3 Overview of variable skin components of fish fed control diet (SIA 1583) and Crab hydrolysate H2 diet (SIA 1585). Dermis area was significantly higher, dark pigment area significant lower, and mucous *cell area and number of N cells per mm skin in fish significant higher in fish fed Crab H2 compared to control fish.*

Figure 1 Transcriptional profiling of genetic markers strongly associated with fish health. Data are presented as test group (Crab hydrolysate H2) relative to control folds (CL).

Conclusions

The improved feed intake and growth-stimulating properties of the crab products, in particular the crab hydrolysate, is mainly explained by effective release of appetite-stimulating water-soluble compounds into the seawater. The results suggest positive impacts of the crab hydrolysate on skin quality, and strong anti-inflammatory properties of significance for quality, health, and robustness of salmon. The collagen rich dermal skin layer in salmon grows in line with fish growth, and the thicker dermal skin layer observed may be explained by higher body weight of fish fed the crab hydrolysate. The positive impacts on mucus producing cells and the strong anti-inflammatory properties measured in fish fed the crab hydrolysate, however, appear to be of dietary origin. Overall results suggest positive quality and health promoting impacts of crab hydrolysate produced from crab by-products, that may contribute to increase the utilization of available resources. The crab meal was less efficient as feed attractant in salmon but has previously been reported as a valuable high ash, growth stimulating ingredient in cod feed, that may also contribute to sustainable aquaculture production.

THE EFFECTS OF MELATONIN IN PRESERVING GILTHEAD SEABREAM (*Sparus aurata*) SPERMATOZOA: PRELIMINARY RESULTS

Introduction

Many species of fish can be benefited from the use of cryopreservation as a tool for artificial reproduction in genetic development programmes (Cabrita et al., 2010; Magnotti et al., 2018; Martínez-Páramo et al., 2017). During cryopreservation, the quality and viability of the sperm shows significant decline , mainly due to the significant increase in the production of reactive oxygen species (ROS) and the oxidative metabolism alteration during the freezing -thawing process (Marques et al., 2019). Besides its several well-known physiologic roles, melatonin has a significant antioxidant potential through free radical scavenging properties (Meng et al., 2017). Melatonin and its metabolites, shows protective action based on their direct and indirect antioxidant properties (Reiter et al., 2017). The main aim of this experiment was to examine the protective role of melatonin, tested on gilthead seabream spermatozoa during in vitro storage at 4°C and -196°C (liquid nitrogen) respectively.

Materials and Methods

The current experiment was carried out during the reproductive period of gilthead seabream (November to May in Greece). A total of 4 samplings were carried out and in each one 2 pools of four individuals were formed. The sperm collection was done individually for each fish and for the formation of the pools only sperm with a total motility >80% were used. Samples were diluted 1:3 in the extender 1% NaCl w/v (300 mOsm/kg) plus 1% BSA w/v. In the control group was added 5% DMSO v/v. In the treatment groups were tested 0.5mM, 1mM, 1.5mM and 2mM melatonin concentrations. Motility parameters were assessed with CASA (Computer Assisted Sperm Analysis) Hamilton Thorne CEROS 14.0 Version analyzer, under a Zeiss-Scope A1 contrast phase optical microscope, using an objective lens with 10× magnification. Specifically, were determined Total Motility (%) and Progressive Motility (%), Path Velocity (VAP, μm/s), Straight Line Velocity (VSL, μm/s), Curvilinear Velocity (VCL, μm/s), Straightness (STR, %) and Linearity (LIN, %) and the Velocity Distribution (Rapid, Medium, Slow and Static spermatozoa, %). In the experiment during short-term cold storage at 4°C the previous parameters were evaluated at 24h, 48h and 72h post dilution. The kinematic parameters of the spermatozoa were statistically analyzed with the methodological framework of General Linear Models Anova (GLM: General Linear Models) for all sperm collections as a whole and for each separate one, using the static program Minitab 17, USA. The significance level was set at 5% ($P<0.05$) for all parameters.

Results

In the experiment during freezing storage at -196°C, there were no significant differences between melatonin treatments and control group. The fresh sperm presented the best values of total motility and velocity parameters. In the experiment cooling storage at 4°C, there were significant differences between melatonin treatment groups and control and fresh sperm group in Total Motility (%), Static cells (%) and Path Velocity (VAP, μm/s) at all three times of evaluation (24h, 48h and 72h). Treatment with melatonin presented the best values of these parameters.

Discussion

From the above results, we can conclude that during the short-term cold storage of gilthead seabream sperm at 4°C, the supplementation of melatonin into the cooling extender, significantly improves the quality of sperm in terms of total motility. Spermatozoa remains motile for a longer period of storage compared to the fresh sperm and the control group. In contrast, during freezing sperm storage in liquid nitrogen no statistically significant differences were observed in any of the four melatonin concentrations tested, compared to fresh sperm and the control group. Further research is needed to find out the beneficial melatonin concentration into the freezing extenders during storage of *Sparus aurata* sperm at -196°C (Alevra et al., 2022).

Introduction

The fish farming industry needs instruments that can monitor in real time fish health and welfare objectively, without disturbing the fish or interfering with the daily management. In this context, precision livestock farming is gaining increased attention to enhance animal welfare, but also to enhance production and environmental sustainability (Halachmi et al., 2019; Brijs et al., 2021). In this study, we monitored European sea bass (*Dicentrarchus labrax*) implanted with acoustic transmitter which is measuring fish depth and swimming activity, a proxy of energy expenditure at the KEFISH farm at Argostoli (Greece) over ~4 months. In addition, environmental sensors were deployed in the farm cages to monitor environmental variables (temperature, oxygen concentration, salinity and turbidity). The aim of this work was to investigate the possibility to model key performances indicators (KPIs; i.e., growth performance and fish mortality) of sea bass using the physiological and environmental parameters recorded using a wireless sensors system, and so to investigate if the use of such sensors may help management procedure, enhance fish welfare and production.

Materials and methods

The environmental and physiological sensors were deployed in the KEFISH farm for a monitoring period of 134 days (from the 09.20.2021 to 01.31.2022). Over the experiment duration, morphometrics measurements were carried out by the farmer when fishing (n=7 sampling times) allowing the estimation of the weight gained by fish per day over the trial. Mortality events (count of dead fish) were also recorded by the farmer every day. Physiological sensors used in the study were acoustic accelerometer tags with 'tailbeat mode' algorithm, allowing to measure fish acceleration (m s^{-2}), which is a proxy of energy expenditure (Alfonso et al., 2021). Five environmental sensors were installed in the cage (Figure 1). Among the five sensors, we installed three dissolved oxygen (DO) sensors, one turbidity sensor and one salinity sensor. In this trial, we unfortunately faced issues with the outputs of both turbidity and salinity sensors. Thus, being not satisfied of the outputs of these parameters, they have been not included in any of the model presented below. Receiver linked to a HUB continuously received acoustic signals from both environmental and physiological sensors acoustically at frequency of 69kHz. The Hub was installed at a radius of ~200 m of the cage and was connected to WIFI of the farm to send data to the cloud and to display data in real time to live dashboard.

Growth performance and mortality data gathered over the trial were modelled using generalized linear models depending on environmental and physiological parameters recorded by different sensors. Selection of parameters to fit the best models has been carried out and only the best model for each variable is presented below.

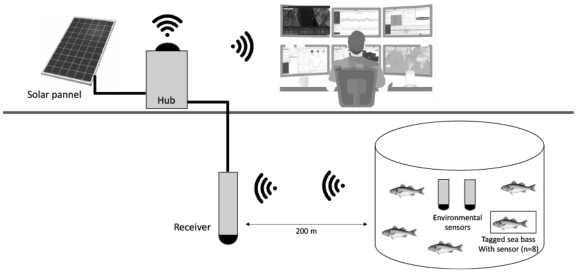

Fig. 1. Schematic of sensors deployment in the cage and connection of the sensors with the hub for transmitting environmental and fish physiological data farmer

(Continued on next page)

Results and discussion

Growth performance (i.e., weight gained by fish per day) was found to be significantly affected by both temperature and DO; the fish grew better with higher temperature and lower DO. It could appear surprising that fish grew better at lower DO but this can be explained first by the fact that the low DO values are overall associated to higher temperature occurring at the beginning of the trial (i.e. September), and so fish grew better. Also, even is the DO is overall low in this period (lowest measured at 40 % in some moments) and known to affect swimming and metabolism, this value is not significantly affecting critically the sea bass physiology. We also found a tendency for significant effects of both swimming activity and fish depth (p=0.054 and p=0.064 respectively). In more details, the growth performance tends to be enhanced when swimming activity recorded is greater, and fish is located near the water surface. This appears relevant because greater fish swimming activities are generally recorded when temperature is high. Overall, greater swimming activity is related to greater energy expenditure (Alfonso et al., 2021). However, greater energy consumed at higher temperature may be compensated by greater environmental conditions, overall favorizing better growth performances.

Also, we found that mortality is significantly affected by both temperature and the DO recorded. In more details, higher mortality is linked to low temperature and high DO levels. Oppositely to what has been observed for growth performance, the mortality did occur when the water temperature was cold. This is not very surprising but it is important to empathize that high temperature are also known to lead to such mortality events (Genin et al., 2020)kelp forests, and rocky shores. In this study, however, we found that the rate of onset (Ronset, but since we started the trial at the end of September, we did not face any huge warm vague triggering such mortality events, generally occurring during summer. In addition, the swimming activity and fish depth recorded by the physiological sensors implanted in fish were interestingly found to predict the mortality. High mortality over the experimental duration has been linked to greater swimming activity and fish located deeper in the cage. Therefore, here, contrary to what has been observed for growth performance, greater energy consumed could be linked to a response to acute stress event occurred in the sea cage which resulted in mortality events. Interestingly, location of fish at the bottom is known as thigmotaxis behaviour and indicative of stress in fish, including in sea bass (Sadoul et al., 2021), and could explain why mortality event are occurring in these moments.

In conclusion, predicting growth performance and mortality of sea bass using physiological and environment parameters of interest gathered by wireless sensors is very promising for the future, especially in the framework of precision livestock farming. It is, however, important to note that models and predictions have to be enhanced by including more parameters such as, species, salinity, turbidity, water current, stocking density, mass.

Introduction

Salmon aquaculture loses c.20% of annual production as a result of gill disease triggered by plankton organisms, including jellyfish and harmful algal blooms - as such, health challenges from the plankton threaten the sustainability of the European salmonid aquaculture industry. Current methods of plankton monitoring lack sensitivity and specificity, can be time consuming, and require taxonomic expertise. For these reasons, data generated fail to provide actionable and timely information to aquaculture managers. We have previously provided proof-of-principle that environmental DNA (eDNA) metabarcoding may be deployed to identify and quantify multiple planktonic threats of salmon farms. In the current study we present a seven-month longitudinal planktonic survey of salmon aquaculture on the west coast of Scotland (UK), covering both spring and autumn blooms when the periods of highest mortalities in the farms typically occur. This dataset allowed us to assess biodiversity and abundance from DNA-based data in comparison with plankton morphological identification, and to identify planktonic threats for salmon health.

Materials & Methods

Metabarcoding, plankton morphology and fish health were readily combined to identify key drivers of salmon gill health. Two sea cage sites (Site A (exposed), Site B (sheltered)) were monitored for c. 200 days (March - October 2021) by daily eDNA, phyto- and zooplankton samplings. Prior to both morphological and molecular analyses, a hit list of species of interest was compiled based on previously published literature and personal communications with the farms in order to record target planktonic taxa causing salmon gill disease. This list would allow us to inform our industrial partners of our preliminary findings in case of a bloom, and to perform quality control on our species database for metabarcoding analyses. Using GLMs and morphological species data, we have so far been able to investigate potential effects of species abundances on the incidence of AGD and PGD scores and mortality. We first tested these relationships assuming no temporal lag between species dynamics and fish mortalities, as well as assuming that mortality lagged 1, 2 and 3 and 7 days behind species dynamics. Preliminary eDNA data indicate that the method is sensitive to detect both phyto- and zooplankton species of interest and that some species might have been misclassified via the microscopy method. Next steps using the full eDNA dataset will aim to benchmark the molecular method against the microscopy data and, combined with abiotic variables (e.g., temperature, salinity, turbidity), to assay their ability to predict salmon mortality and gill disease (AGD, PGD).

Preliminary results

Up to 96 phytoplankton and 74 zooplankton taxa were recorded after morphological identification analyses, including most of the target species from our hit list. The dynamics of the hit species as well as of the most abundant plankton groups are shown in Fig 1, where abundance of taxa is represented in a logarithmic scale. Regarding phytoplankton, the two sites presented similar species dynamics; the HAB genus *Pseudo-nitzschia* was present on both sites and was abundant from April onwards whereas a March *Skeletonema* bloom was only observed in site B. Regarding zooplankton, total abundances, as well as bivalves and ophiura larvae were higher in site B. The most abundant hydromedusae species from our target list were *Obelia* sp. and *Lizzia blondina*. The latter showed higher abundances during late summer, same as for doliolids (only for Site A) and *Oikopleura.dioica* (more clearly observed in Site B).

Preliminary data (Table 1) shows the potential of eDNA metabarcoding in detecting planktonic organisms at the species level when morphological analyses is only reaching to genus level. Moreover, our eDNA analyses will detect benthic life stages from meroplanktonic target species, allowing for a thorough analysis of the potential threats for salmon health that are in the water off the pens. We expect that our upcoming sequencing data will include many more taxa than those recorded by microscopy, hence improving our initial hit list. Lagged statistical modelling will enable the detection of species that have a significant immediate, delayed and cumulative impacts on fish health

Outcome

Our project will augment our proof-of-principle that environmental DNA monitoring can be used to detect planktonic threats (algae, jellyfish, amoebozoans) to salmonid aquaculture and potentially translate this into a low-cost on-site quantitative test for key drivers of Complex Gill Disease (CGD). Rapid and early identification of the planktonic threats will thus enable salmon farmers to take effective, timely steps to mitigate their impact on finfish. We hope our technology will provide a step change in mitigating losses caused by planktonic threats, improving both the sustainability and productivity of the salmonid aquaculture industry.

HYDROGEN SULPHIDE (H_2S) REGULATES THE MUCOSAL IMMUNE DEFENCES OF ATLANTIC SALMON (*Salmo salar*)

Introduction

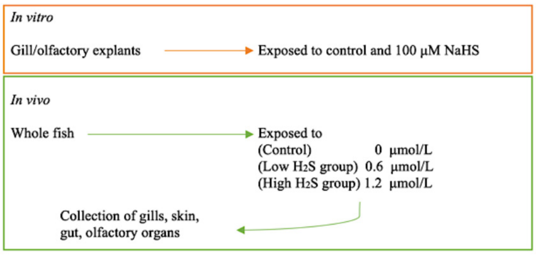
Fish are exposed to several chemical stressors and toxicants during their lifetime, which may cause damage and adverse effects on their physiological functions. Hydrogen sulphide (H_2S), a flammable gas characterised by the odour of "rotten eggs", is one of these chemical stressors. The gas is mainly produced by sulphate-reducing bacteria (SRB) by using sulphate (SO42-) as a terminal electron acceptor in the degradation of organic matter and directly reducing it to bisulphide (HS−) to produce H_2S under anaerobic conditions. H_2S has been a problem in land-based Atlantic salmon production particularly in recirculating aquaculture systems (RAS). Marine water contains more sulphates than freshwater, hence issues on H_2S toxicity are often encountered in saline production systems. High levels of H_2S may affect the fish health and robustness, and in worst case, can result to mass mortalities. Significant research studies have been done to explain its formation in the system, however, physiological and immunological studies designed to understand the mechanism of H_2S are scarce.

This problem is particularly relevant for mucosal organs that are exposed to this chemical stressor. Fish mucosal organs such as the gills, gut, skin, and the recently described immune organ of the nasal mucosa (olfactory organs), are considered the first line of defence against external threats and have a direct role in fish innate and adaptive immune responses. To further contribute to the understanding of the physiological impacts of H_2S in fish, the present study utilised mucosal tissues of Atlantic salmon.

Materials and methods

The study performed *in vitro* and *in vivo* exposure trials to investigate the biological functions of exogenously produced H_2S on the mucosal organs of Atlantic salmon. The *in vitro* trial explored the culture of gills and olfactory explants from Atlantic salmon smolts and exposed them to a sulphide donor, sodium hydrosulphide (NaHS). The *in vitro* trial further explored how mucus participated in H_2S-mucosa interaction and this was achieved by pharmacological treatment of the explants either to stimulate or inhibit mucus production, prior to NaHS exposure.

In another trial, Atlantic salmon smolts were transiently exposed to group of H_2S treatments for an hour followed by a 24 hr recovery period. The mucosal organs were collected for gene expression analysis and histology.



(Continued on next page)

Results and Discussion

The results from *in vitro* trial discovered the regulation of two important immune-related genes. The genes for sulphide-detoxification were found to be responsive in both mucosal explants which may likely suggest a stimulated toxicity reduction of H_2S and can be perceived as a protective mechanism of the mucosal organs from the toxic threats brought by H_2S. The sulphide donor NaHS also inhibited the expression of genes responsible for mucin secretion in olfactory organ explants suggesting a possible adverse effect to the integrity of the nasal mucosa and may likely provide less protection from the sulphide toxicity. The presence of a mucus stimulant causes differential modulation of mucin expression, which could potentially provide a sufficient protection in the olfactory mucosa from a subsequent dose of NaHS.

In vivo transient exposure trial showed that H_2S-induced stress provoked molecular and histo-structural changes in the four mucosal organs. Acute H_2S exposure influenced several immune-related genes encoding for mucins, cytokines, sulphide-detoxification enzymes, antioxidants, and apoptotic enzymes. While gut remained unaffected, gills and skin predominantly exhibited gene upregulation, whereas olfactory organ displayed a down-modulation. These distinct responses imply a diverse and probably a tissue-specific response exhibited by the mucosal organs as an adaptation and recovery strategy from H_2S exposure. The study also provided evidence that a synergy between pro- inflammatory cytokines and oxidative stress occurred in the induction of inflammatory response following an acute H_2S exposure, particularly in the olfactory organ and skin. In terms of histo-structural alterations, gills, gut and olfactory organs were moderately affected. Overall, H_2S possesses both stimulatory and inhibitory effects which interferes with Atlantic salmon mucosal immune responses.

Conclusion

The results reveal that exogenous source of H_2S regulates the mucosal organs of Atlantic salmon. Acute exposure to H_2S could alter both molecular and morphological immune defences of gills, skin, gut and olfactory organs.

A well-known challenge

European fish farmers have to face a competitive market where environmental concerns are now at the center of consumer choices. The feed distributed to fish is at core of sustainable development of aquaculture. On the one hand, feed is the first item of expenditure, and can represent up to 70% of the costs of producers (Besson et al., 2016)fish farming faces an increasing demand in fish products, but also various environmental challenges. Genetic improvement in growth rate and feed conversion ratio is known to be an efficient way to increase production and increase efficiency in fish farming. The environmental consequences of genetic improvement in growth rate and feed conversion ratio, however, are unknown. In this study, we investigated the environmental consequences of genetic improvement in growth rate and feed conversion ratio in an African catfish farm, using Recirculating Aquaculture System (RAS. On the other hand, feeds contribute to the exploitation of fishery resources and to degrading the environment around the farms, and are the main contributor to the global environmental impact of aquaculture in Life Cycle Analyses. The sustainable development of fish farming therefore depends on its ability to use less feed. One of the key levers to meet this objective is to improve the feed conversion ratio (FCR) of farmed fish through selective breeding (de Verdal et al., 2018). FCR represents the ability of fish to convert the feed distributed into fish biomass.

The killer question

Including feed efficiency as a trait in fish breeding programs, an accessible grail or a wonderful myth? We will review the latest results obtained on European sea bass (Besson et al., 2019, Rodde et al., 2021), gilthead seabream (Besson et al., 2022), rainbow trout, and Nile tilapia (de Verdal et al., 2022), in order to identify successes and remaining issues in the genetic improvement of feed efficiency, and to identify future directions.

The present strategies

During the past two decades, a huge effort has been deployed to tackle a simple but very hard problem: how to accurately measure feed intake of individual fish? Individual phenotypes are indeed the key for efficient genetic improvement of feed efficiency.

We will see how this question was either targeted (radio-opaque glass beads, isolated fish feed intake, chemical markers, video recording) or circumvented (screening of putative correlated indirect traits, including growth rates, fasting-tolerance, metabolic rate, behaviour) in different projects. Genetic variation, putative efficacy of pedigree and genomic-based selective breeding for feed efficiency through these strategies will be compared and discussed.

Which future opportunities ?

Prospects of improvement of feed efficiency with alternative methods to estimate feed intake including stable-isotopes strategies, or artificial intelligence-based feeding behaviour tracking (including fish recognition and pellets detection), will be exposed and discussed.

SUBSTRATE CONSUMPTION PREFERENCE OF POTENTIAL BACTERIAL PATHOGENS ISOLATED FROM BIVALVES

A.R. Almeida[1]*, C.F. Lourenço[1] and C.R. Marques*

Centre for Environmental and Marine Studies (CESAM) & Department of Biology, University of Aveiro, Campus Universitário de Santiago, 3810-193 Aveiro, Portugal

[1] First authorship shared; Correspondence e-mail:
*crmarques@ua.pt
rita.almeida@ua.pt

Introduction

Bivalves are widely distributed around the European coastline, at intertidal and subtidal zones (Bridge, 2012), being responsible for several ecosystem services (e.g., carbon storage and nutrient cycling) and representing an important nutritional and economic source for humans (Olivier et al., 2020). Due to its filtration characteristics, bivalves are highly exposed to pollution sources, concentrating contaminants from water, including potential pathogenic microorganisms that can cause several infectious diseases to humans (Olivier et al., 2020; Pereira et al., 2015). Therefore, since, traditionally, bivalves are consumed low or raw cooked, it may represent an important via of pathogen contamination to humans (Anacleto et al., 2014). Although depuration process is a useful method to eliminate or decrease the number of some microorganisms (e.g., *E. coli*), for others it may not be efficient (Martínez et al., 2009). Hence, there is the need of new efficient and rapid strategies to detect potential pathogenic microorganisms in bivalves. Thus, the main objective of our work is to characterize the substrate consumption preference of four potential pathogenic bacteria isolated from bivalves for human consumption.

Materials and methods

This study focused on the characterization of substrate consumption preference of 4 potential bacterial pathogens isolated from bivalves collected in Ria de Aveiro, Aveiro, Portugal. Namely, were tested the species *Pseudomonas aeruginosa* (*P. aeruginosa*), *Pseudomonas knachmussii* (*P. knachmussii*), *Vibrio pacinii* (*V. pacinii*), *Vibrio diabolicus* (*V. diabolicus*) and *Escherichia coli* (*E. coli*). The metabolic profile of each bacterium was analyzed using the BIOLOG® GEN III Microplates™ (Biolog, Hayward, CA, USA). Briefly, fresh grown bacteria were suspended in inoculum fluid with the recommended turbidity, followed by its inoculation in the microplates and incubation at 33ºC for 6 hours. The optical density (λ = 590 nm and 750 nm) was analyzed immediately (t= 0) and after each hour of incubation in the Biolog MicroStation device. The metabolic profile was estimated through the average well color development (AWCD) as described by Zhao et al. (2022).

Results and discussion

In Fig. 1 is represented the substrate consumption of each isolate tested during 6 h of incubation. It was possible to notice that *Pseudomonas*, has a high substrate consumption rate while *Vibrio* species seemed to take more time to consume the different substrates (Fig. 1 and Fig. 2). In fact, *Pseudomonas* genus is considered a ubiquitous microorganism mainly due to its metabolic versatility which may explain this result. Overall, among the substrates tested, the carboxylic acids, esters and fatty acids seem to be preferably consumed followed by sugars (Fig. 2). Nevertheless, worth to note that that each bacteria species seems to have a consumption pattern preference.

Concerning antibiotic tolerance, several antibiotic classes are incorporated in the BIOLOG plate GEN III. Hence, through the analysis it was observed that *P. aeruginosa* grow well in the presence of most of the antibiotics tested. On the other hand, *Vibrio* species showed lower growth rates.

(Continued on next page)

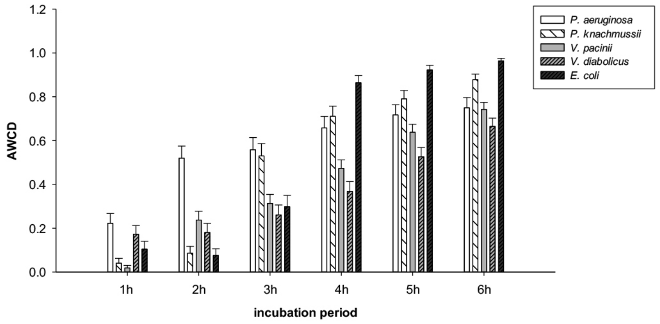

Fig. 1 – Substrate consumption estimated through average well color development (AWCD) for each bacterial strain tested: *Pseudomonas aeruginosa (P. aeruginosa), Pseudomonas knachmussii (P. knachmussii), Vibrio pacinii (V. pacinii), Vibrio diabolicus (V. diabolicus) and Escherichia coli (E. coli)*. Bars represent mean ± standard error.

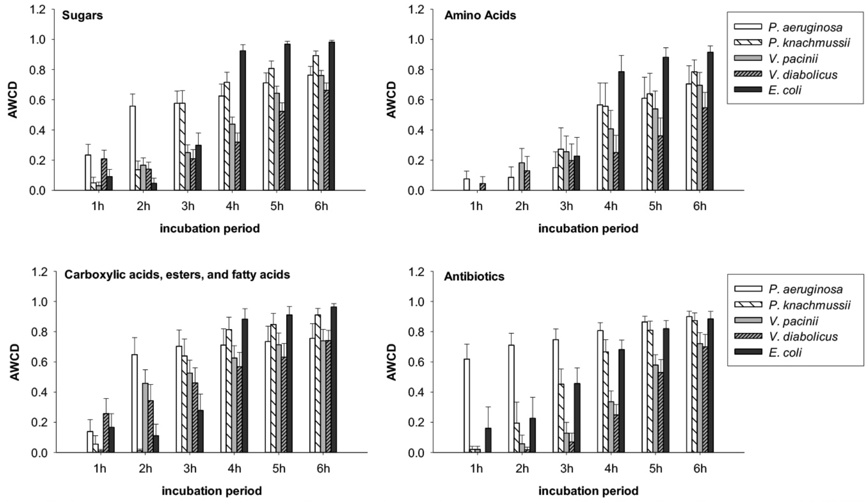

Fig. 2 – Substrate consumption estimated through average well color development (AWCD) for each type of substrate tested: sugars, amino acids, carboxylic acids, esters and fatty acids and antibiotics and for each bacterial strain tested: *Pseudomonas aeruginosa (P. aeruginosa), Pseudomonas knachmussii (P. knachmussii), Vibrio pacinii (V. pacinii), Vibrio diabolicus (V. diabolicus) and Escherichia coli (E. coli)*. Bars represent mean ± standard error.

Background:

Infections in farmed fish are commonplace, often resulting in considerable fish production constraints. *Philasterides dicentrarchi* is a ciliate protozoa responsible for scuticociliatosis outbreaks in turbot aquaculture, and high mortality rates, resulting in significant economic losses (Iglesias *et al*., 2001)the causative agent is not always accurately identified. In this study, we identified two isolates of scuticociliates from an outbreak in cultured fine flounder Paralichthys adspersus. Scuticociliate identification was based on morphological data, examination of life stages and the use of molecular approaches. The isolates were compared with a strain of Philasterides dicentrachi from turbot Scophthalmus maximus and with a strain deposited in the American Type Culture Collection as Miamiensis avidus ATCC® 50180™ . The use of morphological, biological and molecular methods enabled us to identify the isolates from the fine flouder as P. dicentrarchi. Comparison of P. dicentrachi isolates and M. avidus revealed some differences in the buccal apparatus. Unlike P. dicentrarchi, M. avidus has a life cycle with three forms: Macrostomes (capable of feeding on P. dicentrarchi. Implementing safe and effective strategies to eliminate this organism has proven difficult so far (Shin *et al*., 2014), as pharmaceutical drugs effective against such infections have been shown to be detrimental to fish and the environment, putting fish and human health at risk (Dai *et al*., 2008; Ahilan *et al*., 2010). Comparatively to synthetic drugs, plant extracts have lower associated costs, are more biodegradable, induce lower environmental impact, and minimal side effects, making them an interesting alternative to explore (Ahilan *et al*., 2010; Shankar Murthy and Kiran, 2013)besides serving as a source of employment. Application of medicinal herbs in aquaculture is gaining success. Recently use of medicinal plant is considered as an alternative to antibiotics in fish health management The present investigation was designed to study the influence of two herbal additives viz., Phyllanthus niruri and Aloe vera on the growth and disease resistance in goldfish, Carassius auratus. The experiment was conducted with the adult fishes for a period of 60 days. After the 60 days of experiment, fish of each treatment were challenged by pathogenic Aeromonas hydrophila which was given by intraperitoneal injection and kept under observation for 10 days to record clinical signs and the daily mortality rates. Phyllanthus, at 1.5 per cent concentration yielded highest mean weight gain (1.769 g. There is little research on protozoan virulence factors, however, it is known that *P. dicentrarchi* secretes proteolytic enzymes to invade and disseminate within its host cells and tissues, representing one of its main pathogenicity characteristics (Paramá *et al*., 2004; Shin *et al*., 2014).

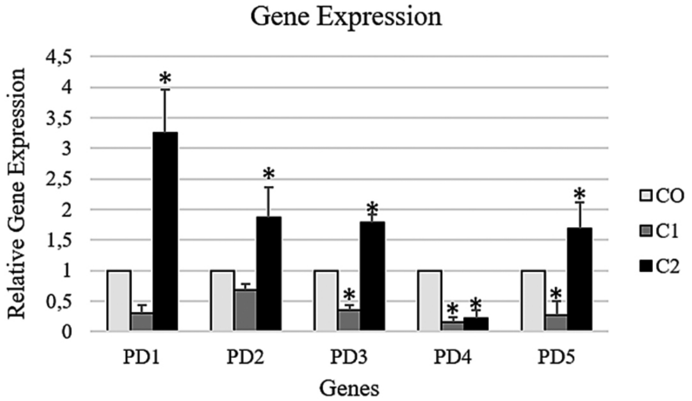

Figure 1 – Graphical representation of the effect of a plant extract on *P. dicentrarchi* at the expression level of virulence genes. Results were normalized using β-tubulin as a reference gene, and are expressed relatively to the negative control, which is thereby valued as 1. Bars represent relative gene expression ± standard deviation. PD1, PD2, PD3, PD4, PD5 represent the five assessed genes. CO – Control; C1 – 0.09 mg mL^{-1}; C2 – 0.83 mg mL^{-1}; * Significantly different from control ($p < 0.05$).

(Continued on next page)

Aim:

Evaluate the effect of a plant extract on the expression of virulence genes of *P. dicentrarchi*, to verify the potentiality towards the integration of plant-based strategies for disease control in aquaculture.

Methods:

The plant extract was obtained through the immersion of dried and grinded leaves in ethanol, incubation under orbital shaking, centrifugation, and solvent evaporation in a rotavapor to obtain the crude extract. *P. dicentrarchi* was exposed to two concentrations of the plant crude extract (C1 – 0.09 mg mL^{-1}; C2 – 0.83 mg mL^{-1}) plus the negative control (CO – 0 mg mL^{-1}) for 4h. The exposure period was then followed by RNA extraction, cDNA synthesis and RT-PCR (reverse-transcriptase PCR). Five relevant genes (PD1 to PD5) encoding proteases associated with *P. dicentrarchi* virulence were targeted for comparative analysis. Data was normalized with a reference gene, the β-tubulin gene, and expressed relatively to the negative control. Statistical analysis was performed via one-way ANOVA followed by the *post-hoc* multicomparison Dunnett's test ($\alpha = 0.05$).

Results and Discussion:

Exposure of *P. dicentrarchi* to a plant extract affected the expression of the five assessed genes (Figure 1). PD1 and PD4 expression was significantly increased at C2, however, PD3 and PD5 significantly decreased at C1 and increased at C2, while PD4 relative gene expression significantly decreased at both concentrations.

Our findings show that exposure to the plant extract induced a significant inhibitory effect on the expression of PD4 gene, although this trend had only occurred to the other genes under the lowest concentration of the plant extract. Nevertheless, these results evidence the potential feasibility of using this plant extract as a prevention strategy against *P. dicentrarchi* infections in aquaculture, representing an alternative to the application of antibiotics or other therapeutics, hence providing a safer option with lower environmental, economic, and health impacts on both farmed fish and the consumers (Voon et al., 2012).

CONSUMER AWARENESS ABOUT AQUACULTURE IN EUROPE: A COMMUNICATION CAMPAIGN IN THE FUTUREEUAQUA PROJECT

T. Altintzoglou* and P. Honkanen

Nofima, Muninbakken 9-13, 9291 Tromsø, Norway
themis.altintzoglou@nofima.no

Introduction

Stakeholders believe that consumers play an important role in the promotion of aquaculture, especially regarding organic production (Lembo et al., 2018). Scholars have identified a general low awareness concerning aquaculture (Zander et al., 2018), which varies according to the species (Garza-Gil et al., 2016) and location (Froehlich et al, 2017). This low awareness persists despite media exposure (Papacek, 2018). However, consumers report some concern and awareness about general issues associated with seafood production, such as how it effects the environment (Jacobs et al., 2015a), its impact on the sustainability of fish populations (Bacher, 2016) and its influence on people's health (Jacobs et al., 2015b). Yet, there is lack of awareness about specific production methods, such as integrated multi-trophic aquaculture (IMTA) (Alexander et al., 2016) and labels associated with sustainable production in general (Feucht & Zander, 2015). The main objective of this study was to develop recommendations for social media communication strategies for increasing consumer awareness, perception and acceptance of European aquaculture. The recommendations were based on scientific literature, evaluations of the effectiveness of previous and current communication campaigns, the consumer survey results in previous stages of the FutureEUaqua project and experimental testing of the types of messages in social media that are preferred by consumers. The FutureEUAqua project focuses on social media as the preferred communication channel to influence consumers. Social media is considered to be the most appropriate channel to reach young consumers, who are a challenging group with falling seafood consumption levels.

Methods

After the evaluation of already available insights, a total sample of 2500 participants was recruited in the UK, France, Germany, Spain and Italy that were at least 50% responsible for the purchase and preparation of seafood in their household. They participated in an experimental survey and were randomly assigned to balanced groups that were exposed to one of five experimental social media posts that varied in tone (factual vs emotional) and visual representation (text vs text and image). Participants were then asked to evaluate the posts on comprehension, liking and willingness to repost. Participants also responded to explanatory topics, such as open-ended questions and consumer characteristics in terms of global innovativeness, attitudes towards nature, food technology neophobia, health concerns, as well as seafood purchasing and consumption behaviour. The last part of the survey focused on social and demographic characteristics, including region and country, coastal and inland location, occupation, education, household situation, gender, age and income.

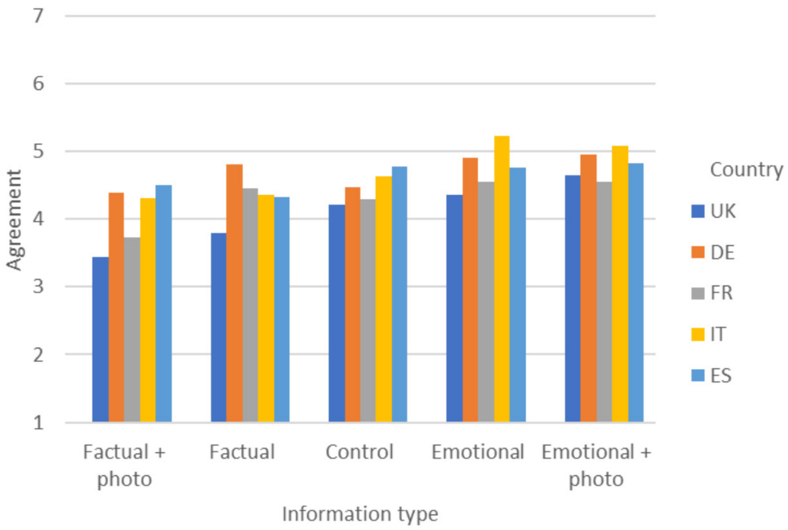

Figure 1 Country differences for liking of the five social media posts

(Continued on next page)

Results

The main results from the experiment showed a clear consumer preference for emotional content in social media posts (figure 1). Female participants seemed to report higher scores in general in this study. Age did not seem to have a major effect on the experiment. However, younger participants in the study seemed to like the control message less than other age groups, while they preferred the emotional message without a picture the most.

Conclusion

Based on the results, the FutureEUAqua communication strategy will use short, visually attractive and emotionally engaging social media posts to improve perceptions and increase awareness of and acceptance for aquaculture in Europe.

ULTRAVIOLET B RADIATION EXPOSURE INDUCES TRANSCRIPTIONAL CHANGES IN GILTHEAD SEABREAM (*Sparus aurata*) REARED IN CAGES ON THE RED SEA COAST OF SAUDI ARABIA

Ricardo N. Alves[1]*, Susana Agustí[1]

[1]Red Sea Research Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia
E-mail: ricardo.alves@kaust.edu.sa

Introduction

Ultraviolet B (UVB) radiation has been recognized as a significant stressor for marine fish, particularly those confined to aquaculture cages. Gilthead seabream (*Sparus aurata*) has a high economic value, and it has been increasingly reared in offshore aquaculture systems in the oligotrophic and highly transparent Red Sea waters, which shows elevated underwater UVB levels. We recently reported that exposure to UVB daily doses from 3 to 12 kJ m^{-2} d^{-1} resulted in increased mortality, growth reduction, and typical sunburn, epidermal sloughing, and necrosis in the skin of *S. aurata*. Moreover, we also demonstrated that UVB induced changes in behavior, metabolism, physiology, immune system, and increased oxidative stress (Alves et al., 2020, 2021). With the aim to understand whether the responses and tissue damage previously reported in this species towards exposure to UVB are accompanied by overall transcriptional changes, the present study addressed the global gene expression profiles in the skin and immune organs after exposure to natural underwater UVB levels.

Material and methods

Juveniles (32.03 ± 4.17 g) were exposed for 43 days to two experimental groups: 1) UVB (daily dose, 6 kJ m^{-2}; representing levels between 5 and 7 m depth); 2) Unirradiated treatment, used as a control. Skin and immune organs (head kidney, spleen) were collected for RNA sequencing and for histopathology. Differentially gene expression analysis was performed in both skin and immune organs between control and UVB treatments. Lists of differentially expressed genes (DEGs) were subsequently used to perform gene ontology and pathways enrichment analyses. UVB-induced damage was also confirmed through histopathological examination.

Results

We described for the first time the transcriptional changes occurring in the skin and immune organs of *S. aurata* after long-term exposure to UVB. In the skin, 580 genes were up-regulated in the fish exposed to UVB, while 365 genes were down-regulated. In the immune organs, 34 genes were up-regulated in fish exposed to UVB, while 56 genes were down-regulated (Figure 1).

We identified several candidate genes in both tissues in response to UVB exposure, and several enriched GO terms and pathways were annotated in the skin after enrichment analysis. In the skin, enriched pathways in UVB-exposed fish were related to cell cycle, immune system and inflammatory response, proteasome, proteolysis, and oxidative stress response. UVB exposure up-regulated several key genes involved in cell cycle regulation, proteolysis, immune system and inflammation response, and antioxidant components. In contrast, UVB exposure inhibited the expression of several genes related to growth factor activity, cell growth and differentiation, and pigmentation (Figure 2).

We also demonstrated that UVB induced morphological changes in both tissues. Several UVB-induced lesions were identified in the skin, particularly an infiltration of immune-related cells resulted from an inflammatory response.

In the head kidney, we observed that UVB exposure induced a loss of tissue aggregation and impairment of intercellular integrity, accompanied by a down-regulation of several claudins and keratins genes, suggesting a disturbed tight junction function. UVB exposure also down-regulated genes related to angiogenesis.

This study provides noteworthy insights about the molecular changes in fish with long-term exposure to UVB. Our data can be used in the future to identify potential biomarkers and explore the mechanisms underlying the molecular changes occurring in fish reared in offshore aquaculture systems in oligotrophic and highly transparent waters.

(Continued on next page)

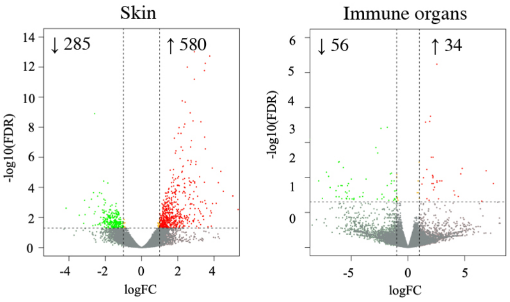

Figure 1. Volcano plot of DEGs identified in the skin and immune organs of *S. aurata* exposed to UVB. Each dot represents one gene. Red dots represent up-regulated genes (FDR < 0.05 and log2 fold change ≥ 1), and green dots represent down-regulated genes (FDR < 0.05 log2 fold change ≤ -1) in UVB-exposed fish.

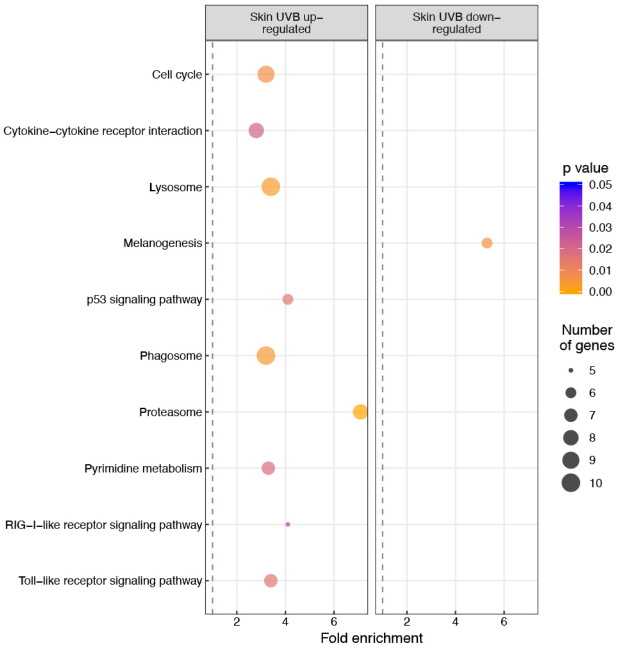

Figure 2. Dot plot showing the enriched KEGG pathways ($p < 0.05$) of DEGs (left, up-regulated; right, down-regulated) in *S. aurata* skin after UVB exposure. The vertical axis represents the enriched pathways, and the horizontal axis represents the rich factor of the enriched pathways. The size and color of dots represent the gene number and the range of p-values, respectively. Fold enrichment is the ratio of differentially expressed gene number enriched in the pathway to the total gene number in a particular pathway.

Email: luciana.a.musialak@ntnu.no

Introduction

Atlantic salmon (*Salmo salar*) aquaculture is of great importance to Norway, which is the global leader producer of this species (Ernst & Young AS, 2019). Egg and hatchery production is a crucial step in salmon aquaculture, as is it essential to provide good quality fishes throughout the whole production cycle (Blaxter, 1988). Although the Atlantic salmon is a well- established industry, little has been reported about early stages of development in relation to time, and sensitivity to mechanical stress (handling routines) during the embryonic period. Facing these research gaps, this study aimed to provide a detailed description of *Salmo salar* embryonic development in relation to time in degree days (dd) and to identify the sensitive stages from fertilization to hatching.

Materials and methods

Approximately 15000 eggs, pooled from three females, were fertilized with milt from one male and incubated at 8°C. From fertilization to hatching the embryonic development was recorded through pictures. To test sensitivity, a mechanical shock device that allowed to drop the eggs from predetermined heights, adapted from Jensen & Alderdice (1983), was used. Four different heights were used for dropping the eggs: 25 cm, 50 cm, 100 cm and 125 cm, and a control where the eggs were only handled as the others, but not dropped. The eggs were incubated for 7 days after they were mechanically stressed, and mortality was then recorded. LD10 and LD50 were estimated, which are the heights causing 10 and 50 % mortality, respectively.

Results

The embryonic development timing found in this study was, to some extent, similar to what was previously described by Gorodilov (1996). Discrepancies might be due to genetic variation and adaptation. This study provided a more practical embryonic development in relation to time in degree days, which is the main unit used by commercial hatcheries to follow development.

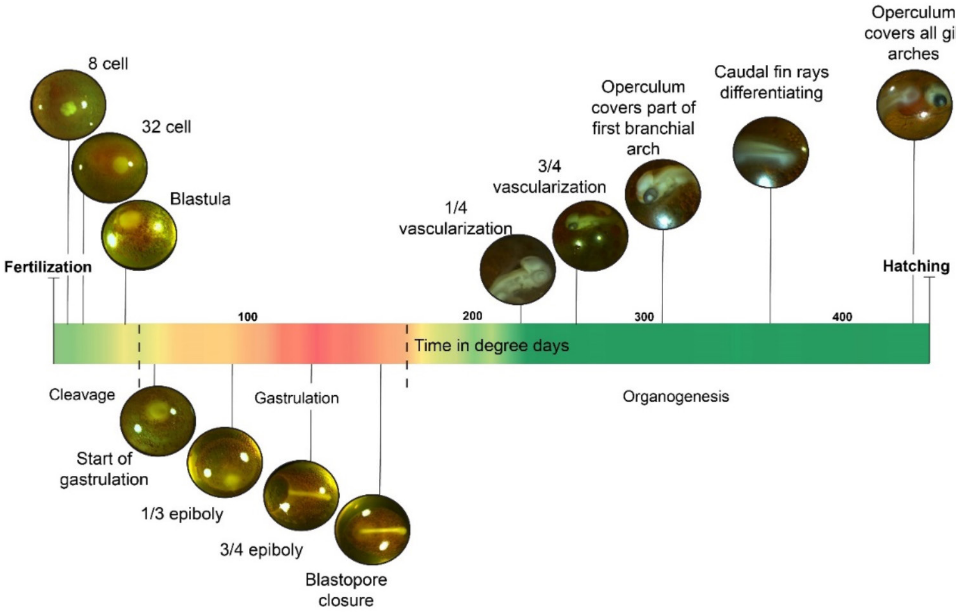

Figure 1. Timeline in degree days (dd) showing sensitivity to mechanical shock in the different stages and phases of embryonic development. Sensitivity is indicated by the color gradient. where green is less sensitive, and red is more sensitive. Different stages are demonstrated by the pictures, and the embryonic development phase are divided in cleavage, gastrulation, and organogenesis.

(Continued on next page)

Sensitivity observed during the embryonic development is illustrated on Figure 1. Embryos presented low sensitivity (LD50 > 100 cm) during the first 32 dd after fertilization. A steep increase in sensitivity was observed during gastrulation, where maximum sensitivity was reached, and the embryos were extremely sensitive (LD50 < 10 cm). Thereafter, at blastopore closure, sensitivity decreased, and it was very low until hatching. The results indicate that the window that the embryos were not sensitive to mechanical shock was wider than what was anticipated by commercial hatcheries. The study provided an overview of sensitive stages during the embryonic development of *Salmo salar*, but as the results in this experiment only accounted for mortality after 7 days from mechanical shock exposure, more studies are needed to determine other possible detrimental effects that do not result in mortality.

Introduction

Aquaculture is considered the fastest growing animal food-producing sector. If this expansion of aquaculture production is carried out with current practices it is destined to become unsustainable and contribute even further to the climate emergency, which is a growing challenge to the industry itself due to irregular weather patterns and abnormal environmental water parameters that may reduce fish performance, welfare and increase the risks of diseases outbreaks [1]. Aquaculture has relied on the incorporation of fish meal into aquafeed but due to ethical and environmental concerns and an inability to expand production [2], it is necessary that this ingredient be gradually phased out of aquafeed production, thus creating a need for novel ingredients. Multiple industries generate plant-based by-products with high amounts of indigestible carbohydrates and fiber, lower protein content and an unbalanced amino acid profile, which may limit their application in aquaculture feed. In a bid to improve these by-products, ingredients may be subjected to solid state fermentation (**SSF**), resulting in higher protein concentrations [3], higher bioavailability of nutrients [4] and bioactive compounds [5], thus providing better feed digestibility and higher bioavailability of bioactive compounds with health benefits that may increase animal resilience to stress caused by oscillating water conditions. This study aimed to evaluate the effects of dietary inclusion of fermented plant-based ingredients on physiological responses of European seabass subjected to different rearing temperatures under salinity oscillations.

Materials and Methods

Experimental diets consisted of one control diet with a 20% inclusion level of non-fermented plant-based ingredients mixture (Mix), and a test diet with 20% inclusion levels of same mixture fermented by *Aspergillus niger* in SSF conditions (Mix-SSF). Plant-based ingredients mixture consisted of soybean, rice bran, sunflower seed, and rapeseed meal (25% each). Both diets were isolipidic (18%) and isoproteic (42%).

In an environmental stress trial, seabass juveniles (22.4 ± 4.2g) were distributed into 24 experimental units. The trial occurred, simultaneously, in two recirculating aquaculture systems (RAS_1 and RAS_2). In $RAS_{1,}$ fish were kept in triplicate units at 3 temperatures (17°C, 21°C and 26°C) and fed the 2 experimental diets (control Mix and Mix fermented), in a 3 × 2 factorial design (total of 18 units). In Ras_2 fish were kept at a fixed temperature (21°C) and fed the two experimental diets (n= 3 repetitions/treatment, total of 6 tanks). During the six-week feeding trial, salinity was altered weekly in RAS1 whereas in RAS_2, salinity was kept constant (33 ppt). Growth performance, digestive enzymes, oxidative stress and innate immunity parameters were analysed at the end of the trial.

Results

An overall reduction in growth performance, regardless of environmental conditions, was observed in seabass fed the experimental fermented diet (Mix-SSF), which in part can be explained by a higher feed conversion ratio and a reduced feed intake due to an apparent reduction of dietary palatability.

Diet formulation did not have an effect on digestive enzymes activities. However rearing temperature and especially salinity oscillation significantly effected digestive enzyme activities. When comparing the two groups reared at 21ºC, fish exposed to different salinity conditions, showed a significant decrease in digestive enzymes activities when compared to fish kept at fixed salinity.

(Continued on next page)

Oxidative stress indicators were significantly affected by experimental diets and temperature and salinity conditions. Catalase and glutathione peroxidase activities showed an interactive effect, where fish reared at 21ºC showed higher enzymatic activity when fed the Mix-SSF. In contrast, fish reared at 17ºC and 26ºC showed higher enzymatic activity when fed the control diet (Mix). When comparing fish reared at 21ºC but exposed to different salinity conditions, fish subjected to salinity oscillation showed a reduction in redox status. Interestingly, the Mix-SSF diet reduced the effect of salinity stress.

Innate immunity parameters analysed were affected by rearing conditions with experimental diets having a significant effect on the alternative complement pathway (ACP). Fish fed the Mix-SSF diet showed higher ACP activity than those fed the Mix diet.

Conclusions

Despite the improvement of some antioxidant mechanisms and innate immunity parameters, the fermentation process of plant-based ingredients using *Aspergillus niger*, as carried out in this work, was unable to provide a more efficient ingredient for European seabass juveniles, leading to an overall decrease in growth performance.

Introduction

For the last decades, the aquaculture industry has grown at a stable rate and currently, due to stagnant capture fisheries, is the sector responsible for seafood production growth [1]. Aquaculture has heavily relied on fish meal for feed production but this practice has raised sustainability concerns due to its environmental impact and an inability to expand production [2]. If aquaculture feed production continues with current practices, it will become unsustainable and potentially hinder aquiculture expansion. The supply of novel feed ingredients is essential to prevent aquafeed quality and availability from becoming limiting factors for the sector. Multiple industries generate plant-based by-products with high amounts of indigestible carbohydrates and fiber, lower protein content and an unbalanced amino acid profile, which may limit their application in feed production. These potential ingredients may be upgraded by biotechnological processes such as solid state fermentation (**SSF**), resulting in higher protein concentrations [3] and higher bioavailability of nutrients [4], thus potentially providing better feed digestibility.

This study assessed the *in vivo* digestibility of diets, including fermented plant-based ingredients, and the effect on digestive enzyme activity in European seabass, *Dicentrarchus labrax*, juveniles.

Materials and Methods

Experimental diets consisted of two control diets with 20% and 40% inclusion levels of non-fermented plant-based ingredients mixture (20Mix and 40Mix), and two test diets with 20% and 40% inclusion levels of same mixture fermented by *Aspergillus niger* in SSF conditions (20Mix-SSF and 40Mix-SSF). Plant-based ingredients mixture consisted of soybean, rice bran, sunflower seed, and rapeseed meal (25% each). All diets were isolipidic (18%) and isoproteic (42%).

The *in vivo* digestibility trial was performed in a RAS system consisting of twelve tanks with individual faeces sedimentation columns (Guelph system). Twelve homogenous groups of European seabass juveniles (initial body weight, 70.9 ± 0.3g) were hand-fed each experimental diet, in triplicate, *ad libitum* twice a day, for 6 days a week during the faeces collection period. At the end of the digestibility trial, fish intestine (with pyloric caeca) were sampled. Apparent digestion coefficients of experimental diets were calculated and digestive enzymes activity were analysed.

Results

A clear trend emeged regarding apparent digestion coefficients (ADC) of experimental diets, where an interactive effect between ingredient treatment and inclusion level of ingredients was observed. More precisely, solid-state fermentation of plant-based mixture improved ADC of dietary crude protein, energy and dry matter when plant-based ingredients mixture was included at a 20% level. In diets where plant-based ingredients mixture were included at a 40% level, solid-state fermentation of this mixture significantly reduced the ADCs of dietary crude protein, energy, and dry matter. ADC of crude lipids was not affected by plant-based ingredients mixture SSF and inclusion level of ingredients.

Regarding digestive enzymes activity, α-amylase activity was significantly higher in diets where plant-based ingredients mixture was included at a 40% level, regardless of the SSF of the mixture. Solid-state fermentation of plant-based ingredients led to significantly higher lipase activity, while the opposite was observed for trypsin activity.

Conclusion

This works shows that solid-state fermented plant-based ingredients are well digested by European seabass juveniles, increasing protein, dry matter and energy digestibility, as long as dietary supplementation was kept at a 20% level. This work also demonstrates the potential of this biotransformation process to contribute to the replacement of fish meal in the aquaculture industry.

Introduction

As consumers become increasingly aware of the importance of eating habits on their health and wellbeing, the demand for natural and functional foods is growing fast to meet the specific consumer requirements. Fish are generally regarded as a healthy food because they provide valuable nutrients as the omega-3 long-chain polyunsaturated fatty acids (LC-PUFAs), EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid), that have been unequivocally associated with a protective role against a number of human diseases (e.g. cardiovascular diseases, diabetes and obesity).

Driven by sustainability and economic issues, feeds for farmed fish suffered in the past decades a shift in diet formulation from fishery-derived resources (fish meal and fish oil (FO)) towards terrestrial agriculture ingredients. Such dietary modification has been promoting a marked reduction on omega-3 LC-PUFA contents of diets and farmed fish, which is undesirable from the consumer point of view. Hence, aquaculture industry needs to find new fortification strategies to tailor aquaculture products with such health promoting nutrients.

Omegapeixe project aims to bring to the market omega-3 LC-PUFA- fortified fish products produced with sustainable and cost-effective diets. For this purpose, new biofortified finishing feeds will be developed to maximize deposition of omega-3 LC-PUFAs on fillet of two important European aquaculture species, turbot (*Scophthalmus maximus*) and European sea bass (*Dicentrarchus labrax)*. Efficacy of dietary fortifications aiming to raise omega-3 LC-PUFAs in fish fillet will be dependent on the optimization of the relative proportion of dietary omega-3 LC-PUFA and careful selection of best sources to replace the unsustainable fishery-derived resources (e.g FO). In this context, the present study aimed to screen the fatty acid (FA) profile of different omega-3 rich ingredients available on the market and to assess their potential application in turbot and sea bass feed formulations.

Materials and methods

The FA profile of a high quality FO, the conventional source of omega-3 LC-PUFA in aquafeeds, and three commercially available LC-PUFA-enriched ingredients (salmon oil, a byproduct from the salmon industry; algae oil; and a blend of microalgae and macroalgae (Algablend)) was determined by Gas Chromatography(GC) with flame-ionization detection. Fatty acid methyl esters (FAME) contained in these ingredients were obtained through transesterification by acidic methylation. FAME were identified by comparison with known standard mixtures and quantified using the software GCsolution for GC systems. Each FAME was expressed as % of total FAME. The amount of FA expressed in % of dry matter (DM), were calculated using an internal standard (C23:0) as a reference.

Results

Among the four ingredients, FO exhibited the highest content of EPA (% tFA and %DM) (Table 1). On the other hand, the algae oil was characterized by high levels of DHA, resulting in higher EPA+DHA levels. Salmon oil and algablend) had the lowest concentration of DHA and EPA (% tFA and %DM), respectively.

Final remarks

The FA characterization revealed that algae oil due to its high content of omega-3 LC-PUFA, particularly DHA, is the most promising ingredient to be included in omega-3 LC-PUFA- fortified feeds. Although with a lower content of omega-3 LC-PUFA than algae oil or FO, the use of salmon oil in fortified diets is also appealing from an economic and a circular economy point of views. In vivo trials conducted with both species demonstrated that combination of these ingredients in feeds might be an effective fortification strategy to enhance omega-3 LC-PUFA content in turbot and sea bass fillets (please check the results in Monteiro et al., 2022 and Marques et al., 2022).

Introduction

Marine heatwaves (MHWs) are extreme events featuring abnormally high water temperature for a prolongued period (from days to months) (Holbrook et al., 2019). This phenomen is expected to increase in frequency, duration and severity over the century (IPCC, 2021). MHW can have particularly significant impacts on marine habitats and ecosystems, deeply affecting organisms' physiology, namely their metabolism, growth and feed intake, thus compromising their energy budget (i.e. the energy intake and expenditure within the whole organism) and, consequently, their fitness and survival rates (Jobling, 1994). Even though the effects of ocean warming on the energy budget (EB) of marine organisms are beginning to be understood (e.g., Anacleto et al., 2018), the impacts of short-term exposure to high temperatures on fish' physiology have yet to be investigated under a MHW context. Therefore, the aim of the present study was to assess the effects of a simulated MHW (category IV; ΔT=+2 °C, 11 days) on the energy budget (i.e. growth, excretion, metabolism and food consumption) of juvenile surgeonfish (Zebrasoma scopas), a tropical species particularly popular in the marine ornamental fish trade, whose stocks largely rely on wild populations and are, thus, particularly susceptible to such events. In fact, the specimens' collection site (Maldives) has been exposed to repeated and severe MHWs during the last decades (1998 and 2016), with massive ecological and socioeconomic costs.

Materials and methods

Juvenile surgeonfish specimens (n=48; 4.7±1.4 g total weight, 5.8±0.6 cm total length) were collected in Maldives in February 2020 and brought to Guia Marine Laboratory (MARE-FCUL, Cascais, Portugal) from Tropical Marine Centre (TMC, Lisboa). Fish were distributed and maintained in 8 tanks (2 treatments x 4 replicate tanks) with independent recirculation aquaculture systems. After an acclimation period at control temperature conditions (29 °C), fish were exposed to two treatments: i) control scenario (29 ºC) for 11 days (n=16, i.e. n=4 per tank); and ii) simulated scenario of a category IV MHW (31 °C) for 11 days, followed by a 10-days recovery period at 29 ºC (n=32, i.e. n=8 per tank). In the MHW treatment, the water temperature was increased around 0.5 °C per day. A 30 years dataset for seawater surface temperature in the region of Maldives was acquired from NOAA (Daily Optimum Interpolation SST version 2; Banzon et al., 2016). The heatwaveR package (Schlegel and Smit, 2018) applies the MHWs definition by Hobday et al. (2018) and was used to determine the average duration (11 days) and the maximum temperature registered (31.3 °C; corresponding to a category IV MHW). At the beginning and after the exposure period, two specimens per replicate/tank were randomly weighted and used to determine EB parameters [growth-G, excretion (faecal-F and nitrogenous losses-U) and metabolism-R] in order to calculate the food consumption-C (C=G+F+U+R). To calculate G, fish were weighted frequently (2-3 times per week) and F, faeces were collected daily, oven-dried at 65 ºC to constant weight and stored at -20 °C. Then, the energy content was measured in fish and faeces by combustion in an adiabatic calorimeter pump. The nitrogenous compounds (ammonia - U) were determined according to Anacleto et al. (2018). Metabolism (R) was calculated as: 100 – G - F - U. Biochemical analyses (dry matter, ash, total lipids, crude protein and gross energy) were determined in the diet and fish body according to the AOAC (2005).

(Continued on next page)

Results and Conclusions

The energy proportion channeled for growth (49.2%) dominated the mode of energy allocation of juvenile *Z. scopas*, followed by excretion via faeces (39.5%). However, this trend was reversed under MHW exposure. It was also found that such exposure led to significant higher protein content in whole fish body and that higher percentage was spent for U in comparison to the control treatment. Moreover, under the recovery MHW period, higher feed intake (FI), feed efficiency (FE) and relative growth rate (RGR) were observed compared to both MHW and control treatments. At the beginning of the experiment (day 0), significantly higher viscerosomatic index (VSI) was found in comparison with MHW and control treatments determined at day 11; higher VSI was also detected under MHW recovery period than after MHW exposure. This study clearly demonstrated that the increased intensity and frequency of such extreme events will affect these tropical fish species, which may be further exacerbated by cascading effects throughout their ecosystem. Additionally, since surgeonfish species is vulnerable to MHWs and has been suggested as a potential candidate for ornamental fish farming (e.g., Holcombe et al., 2022), the data obtained are essential to understand how this species uses the resources ingested, and thus, to optimize its diet in aquaculture to avoid the capture of wild animals. Moreover, since MHW will occur in combination with other environmental drives of change (e.g. acidification, hypoxia), testing multistressor-related climate change scenarios are greatly needed to better understand future ecological impacts, and also for the development and implementation of management and conservation strategies in coral reef ecosystems.

Introduction

One of the cultivation strategies in marine aquaculture is integrated multi-trophic aquaculture (IMTA), where several species from different trophic levels are co-cultivated in the same, or connecting, water systems. Nutrients from the fed species are consumed by extractive organisms. This leads to an increased proportion of the initially added nutrition being utilized for biomass production, which improves the ecological sustainability of the aquaculture system [1]. Previous co-farming experiments have also found positive effects in addition to those emanating from the available nutrients, including improved growth and quality of the extractive species as well as improved fish survival, growth, and immune responses [2]. The aim of this study was to evaluate the effects of co-farming rainbow trout (*Oncorhynchus mykiss*) and sea lettuce (*Ulva fernestrata*) in a recirculating aquaculture system (RAS) on water quality. Health and welfare of the rainbow trout was evaluated through non-invasive welfare indicators, plasma cortisol levels and primary barrier function of skin and intestine. The performance of the Ulva was evaluated as change in biomass growth, nitrogen content and protein content.

Methods

In this experiment, 363 rainbow trout of 115 g ± 2.46 (mean ± SEM) amounting to a total of 41 kilos were housed in 6 tanks (400 L) in a RAS system (total volume 15 m^3). The co-cultivation trial lasted for 16 weeks and was divided in four periods of four weeks each. During the first and third period, only rainbow trout was held in the system. During the second and fourth period 1200 and 1000 grams of Ulva respectively, were cultivated in plastic bags (200 L) in a separate section of the same RAS system (Figure 1).

Water samples were taken from the inflow and outflow of the Ulva bags three times per week throughout the experiment and analysed for pH, NO_2^{2-}-N, NO_3^--N and NH_4^+-N. Ulva was sampled for total biomass once per week and 10 randomly selected Ulva individuals were frozen and later analysed for nitrogen and protein content. Fish welfare was evaluated through scoring of five non-invasive welfare indicators by visual observation every second day, as well as through final sampling of 12 individuals at the end of each four-week period. At sampling, fish were randomly netted, euthanized in 12 mg/L of metomidate and killed by a blow to the head. Blood was sampled, centrifuged and plasma stored at -20 C for later analyses of cortisol using RIA. Live skin and two intestinal regions were sampled for direct analyses of barrier functions using the Ussing chamber technology.

Results and Discussion

The results suggests that it is beneficial to co-cultivate Ulva with rainbow trout. The Ulva biomass increased during the co-cultivation periods, and nitrogen content as well as protein content increased from the start and end of the initial co-cultivation period. Regarding fish health and welfare no effects were found on the visually scored fish welfare indicators or plasma cortisol levels. Intestinal health parameters were slightly affected by the co-cultivation with Ulva with increased active transporting- but decreased barrier functions as a result.

Water quality parameters of dissolved inorganic nitrogens indicated no differences in net system concentrations in response to addition of Ulva. There was an increase in water pH after passage through the Ulva holding bags, indicating that Ulva positively affected the pH locally. This however, did not results in any overall net effect on the entire system. These results taken together show that the Ulva biomass used in the current experiment had the ability to affect the water quality locally, but not overall in the entire system, suggesting that the Ulva biomass was too low in relation to fish biomass and system water volume. Future studies will include adjustment of the relative biomasses in order to more thoroughly investigate possible effects on fish health and welfare.

CREATING NEW LIFE FOR DISCARDED FISHING AND AQUACULTURE GEARS: PREVENTION OF MARINE LITTER GENERATION BY CONTRIBUTION TO MORE CIRCULAR AQUACULTURE ROPES

M. Andrés*[1], O.C. Basurko[1] and L. Arantzamendi[1]

[1]AZTI, Marine Research, Basque Research and Technology Alliance (BRTA), Txatxarramendi ugartea z/g, 48395 Sukarrieta, Bizkaia, Spain
*Email: mandres@azti.es

Introduction

The new Circular Economy Action Plan adopted by the European Commission is driving a change, pushing up the circularity of the existing materials in aquaculture and fishing gears. When aquaculture or fishing gears become worn out, the end of life (EoL) treatment must be considered, but unfortunately, current EoL possibilities are not consistent with the waste hierarchy. Rather, fishing gear waste is often dispensed in the ocean. Abandoned, Lost, or Otherwise Discarded aquaculture and fishing gears (ALDAG and ALDFG) causes not only economic losses and hazards to safety at-sea to aquaculture farmers and fishers, but also impact on marine fauna and can pose substantial ecological and socioeconomic problems. Aquaculture and fishing sectors are associated with 14% to 38% of the items recorded in the surveyed beaches in the north-west of Spain, while they may represent the 54% in weight of floating marine litter in the south-east of coastal waters of the Bay of Biscay. Precisely, in the south-east coast of the Bay of Biscay, the cost caused by a kilogram of marine litter ranges between 0.3 to 6.7 EUR/kg.

In line with the new Circular Economy action Plan, this study aimed at demonstrating the feasibility of using an alternative material for gear making. To do so, discarded fishing nets were recovered, conditioned and recycled into ropes for mussel aquaculture in longline systems; hence, closing the loop, “from the sea for the sea”. The bottlenecks of the process undertaken to converting discarded nets into aquaculture ropes were identified. Furthermore, the performance of the ropes as on-growing ropes were tested at sea in a commercial aquaculture site, where mussels growth (size, weight and condition index), and ropes’ performance (breaking point) were monitored in a production cycle of one year. Technical, economic and environmental assessments were carried out to compare prototypes manufactured with recycled nets with conventional ropes. This study demonstrated that polyamide and polyolefin fishing nets can be recycled and converted in longline ropes for mussel aquaculture.

Material and Methods

Discarded EoL fishing nets and aquaculture ropes were samples from Basque fishing ports. Once the EoL material was recovered and classified, four materials were preselected for upcycling by mechanical recycling (polyolefin fishing nets, polyamide fishing nets, on-growing mussel ropes and holding ropes used to attach on-growing ropes to long lines). Finally based on performance and stock, two waste streams were selected to undertake the whole recycling process: Polyamide-based purse seine nets (PA) and polyolefin-based trawler nets (PO). The recovered nets were conditioned and mechanically recycled into recycled pellets (rPA and rPO pellets) and then monofilament were produced. With the monofilament aquaculture ropes were manufactured. Recycled and conventional ropes (as control) were tested at sea in an industrial longline system for one mussel production cycle. The sea test served to estimate the potential productivity of the ropes and their lifespan, by assessing; growth and survival of the mussels on the ropes, the condition index, the meat yield, the proximal composition and fatty acid profile of the mussels, the concentration of microplastics within the mussels, and physical properties of the ropes (tensile tests and durability traits). From the whole process, 22 technical indicators were calculated for each prototype as for the commercial rope (the reference system). The economic assessment was carried out through the material flow and the cost benefit analysis along the whole value chain of the aquaculture ropes, scaling from the laboratory level to industrial level. The economic flow between different productive sectors was analysed through the Input-Output methodology. Four economic indicators were calculated for each prototype rope. Life Cycle Assessment (LCA) methodology, according to ISO standards 14040:2006, was carried out to identify, quantify and compare environmental impacts linked to the ropes. Sixteen environmental indicators were assessed for each prototype of rope. Environmental social and economic assessment were carried under the umbrella of the circular economy

(Continued on next page)

Results

As a general outcome of the test at sea, it can be concluded that both recycled prototypes, rPA and rPO, presented similar results as the commercial one in terms of production yield, product quality, durability and functionality at sea and the occurrence of microplastics in mussel. Therefore, it can be stated that from the technical point of view, recycled ropes, especially the polyamide-based ropes, can be a suitable alternative as on-growing ropes for mussel aquaculture, thus, helping aquaculture industry to achieve the recycled targets proposed by the Circular Economy strategies.

From the environmental perspective, the life cycle indicators stated that the rPO ropes are better options than rPA or conventional ropes. From the economic perspective and at industrial level, recycled prototypes were more costly than commercial rope (75% and 59% more the rPA or rPO, respectively). Thus, to implement the recycled ropes in the market is required a price premium of, at least, 2-4% over the final aquaculture product (mussel) to compensate the higher costs of the recycled ropes. Despite the success of the technical characteristics of the recycled ropes, rope manufacturers still show little interest to exploit them in the short-term, unless the price premium would be covered by incentives, market demands, or a mandatory measure that would exist to promote recycling EoL gears as secondary raw material for new gear manufacturing.

MARINEHOLMEN RASLAB, PROVIDING DIVERSE AN INNOVATIVE OPTIONS FOR CONDUCTING SEALICE *Lepeophtheirus salmonis* RESEARCH

M. Andrews*, M. Powell

Marineholmen RASlab AS, Thormøhlensgate 41A, 5006 Bergen, Norway
E-mail: melanie.andrews@ilab.no

Introduction

Marineholmen RASLab is a research and innovation company with a focus on in Recirculating Aquaculture System technology. Located in Bergen, at the heart of the aquaculture industry in Norway, RASLab offers state-of-the-art facilities for research into sustainable land-based fish farming. By re-using water in a closed loop RAS system, fish can be grown intensively, using less water resources, and producing a virtually zero environmental impact with a smaller footprint. The technology for providing the life support systems, cleaning the water, and supplying the fish with clean oxygenated water allows us to use technology to advance and transform the future of fish farming. Marineholmen RASLab has 12 self-contained RAS systems, that can run with fresh-, brackish-, or saltwater and are fitted with the latest technology allowing us full control of each system. Providing the capability to control feeding, light regimen, salinity, pH, temperature, and flow in all systems. This provides the opportunity to have replicate systems when conducting feed and treatment trials.

What we offer

Our RAS setup allows us to conduct research in:

- Water quality management
- Feed research
- Bioreactors
- Microbiology
- Sludge and waste treatment
- Sensor development.

We offer general project development and planning, which is vital when working with product development. Working to GLP standards, we ensure high quality results and data handling. This has allowed us to conduct a range of pharmaceutical efficacy and residue contracts in the sealice, *Lepeophtheirus salmonis*, which is a problem parasite affecting Atlantic salmon in the northern hemisphere.

Sealice, *Lepeophtheirus salmonis*, research at Marineholmen RASLab

Sealice are a threat to farmed Atlantic salmon, resulting in huge losses to the industry due to increased handling costs, reduced fish health, and decreased product quality. Methods of treatment and control have been developed to reduce the number of parasites in the salmon farms, however, resistance development has resulted in reduced treatment efficacy. This means that the industry needs to continue identifying and developing new treatment strategies.

Recently we have expanded services offered and can conduct *in vitro* and *in vivo* sealice (*Lepeophtheirus salmonis*) trials. Marineholmen RASLab has the capability to conduct both small scale *in vitro* pilot trials to determine the efficacy of newly identified treatments to larger scale *in vivo* dosage trials. The ability to control different water parameters allows us to conduct a series of trials over time while still being able to compare the results.

By controlling the water temperature, we can control the sealice growth rate, for example fish infected by copepodids at 12°C will reach the preadult II stage in 12-14 days. Decreasing water temperature will slow the growth rate, while increasing the temperature will increase the growth rate. We can therefore simulate real world conditions to determine whether treatment efficacy is affected by seasons. Or we can conduct treatments targeting specific life stages, which can be difficult when working at ambient temperature.

Conclusion

Marineholmen RASLab can provide facilities and knowledgeable staff to conduct product development research in the aquaculture field. Working to GLP standards we provide project planning and management which is vital for laying the groundwork for testing new products. We believe that strong and reliable research will aid in the improvement and development of the aquaculture industry.

ASSESSING THE POTENTIAL OF AN I-RAS SYSTEM USING *Ulva* sp. AND *Sparus aurata*

Introduction

Recirculating Aquaculture Systems (RAS) is a technology well known for reducing water waste and leading aquaculture towards a more sustainable path. Integrated Multitrophic Aquaculture (IMTA) is another key system for a sustainable aquaculture by integration of low trophic organisms, such as seaweeds for high efficiency removal of nutrients in fed aquaculture. The combination of RAS and IMTA, I-RAS, aims to achieve maximum nutrients' reutilization and the creation of a new valuable product, increasing economic return and improving animal welfare (Qui *et al*., 2022). Gilthead seabream (*Sparus aurata*), is a species with a major aquaculture interest, largely cultivated in RAS systems and off-shore cages on the Mediterranean and with special economic interest in Europe (FAO, 2022). Ulva, a green seaweed, is a promising candidate for an integrated system, since it can assimilate dissolved inorganic nutrients (DIN) at a fast rate, use it to build up its biomass.

The aim of this study is to test and optimize the operation of a I-RAS system with Gilthead seabream and Ulva.

Material and Methods

Each of two identical I-RAS (Figure 1) systems were designed so that water from fish and seaweed cultivation tanks is collected in the main filter before re-distribution. Oxygen is added to the main filter. Gilthead seabream originated from EPPO-IPMA broodstock, reared and maintained in the facilities until the experiment started. Ulva was collected at EPPO, cleaned and kept for 3 weeks in a tank with seawater (SW) and aeration, until the start of the experiments. Non-mature bioballs were mixed with matured bioballs for 1 month, and then transferred to the I-RAS system for 9 weeks before this experiment. The experiment was 6 week-long, starting in 15/06/2022. Initial fish density was 11 kg m^3 with a mean 265,28 ± 51,60 g fish weight, one I-RAS was tested without seaweed and one with ulva, at 1, 2 and 3 kg m^{-2}, in triplicate.

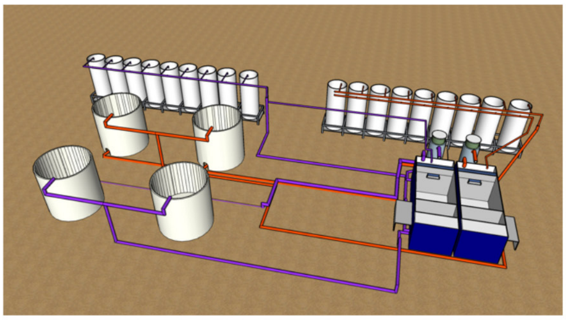

Figure 1. Overview design of the I-RAS systems. Each color represents the piping of one I-RAS system, comprising two fish tanks of 3000 L, nine seaweed tanks of 200 L, one protein skimmer, one 1650 L main filter (with mechanical and bacterial filtration), and one refrigeration unit.

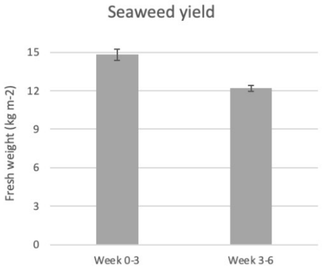

Figure 3. Ulva 3 week cumulative yield on the I-RAS system.

(Continued on next page)

Temperature and oxygen were measured twice a day, pH every day in the morning and salinity was kept at 36. Water samples were taken regularly, filtered, and frozen for posterior nutrient analysis. Feed was given for 1.4% of body weight according to the manufacturer's recommendation and adjusted weekly. Evaluation of fish growth took place at week 0, 3 and 6 were the weight, standard and total length were measured. To assess macroalgae growth, total fresh weight (FW) was measured, by removing the excess of water and weighing once a week. Ulva excess biomass was removed weekly and cultivation restarted at original stocking densities.

Results

During the experiment, mean water temperature was 23,59 ± 2,4°C, oxygen was 4,94 ± 1,01 mg L^{-1} and pH was 7,03 ± 0,19, for all fish tanks. Fish growth is presented on Figure 2, condition factor (K) for the system with seaweed and without seaweed were 1,72 ± 0,003 and 1,67 ± 0,10 initial and 1,79 ± 0,020 and 1,72 ± 0,064 final, respectively. Survival rate was 99,6 ± 0,46 in all fish tanks.

On all seaweed tanks, water temperature was 24,21 ± 2,49°C, oxygen was 7,6 ± 1,05 mg L^{-1} and pH was 7,65 ± 0,29. Ulva yield (FW) is presented on Figure 3.

BIOCHEMICAL COMPOSITION OF *Hediste diversicolor* REARED ON AQUACULTURE SLUDGE AND ITS POTENTIAL AS AN AQUAFEED RESOURCE

Introduction

Sustainable growth of the salmon aquaculture industry is highly dependent on the availability of new feed resources as well as improved management and utilization of waste streams from production (Waite et al., 2014, Tacon et al., 2011). Polychaetes are capable of recapturing and recycling valuable biomolecules contained in aquaculture sludge and at the same time constitute a possible resource for aquafeeds (Wang et al., 2019b). In this study, the potential of *Hediste diversicolor* (OF Müller, 1776) to recover nutrients and energy contained in two types of salmon sludge was evaluated.

Material and methods

A 30-day feeding experiment was conducted assess the effect of two different diets, smolt (S) and post-smolt (PS) sludge, and different feed levels (A-D) on polychaete growth and biochemical composition. Feed levels were calculated based on estimated nitrogen content of diets and polychaetes; the different treatment groups (SA-SD, PSA-PSD) received feed equivalent to 5-40% of the nitrogen contained in polychaetes per day. Growth was calculated following Jørgensen (1990). Sample composition of polychaetes and sludge was analyzed with regards to ash content, total lipid (Bligh and Dyer, 1959), fatty acid profile (Metcalfe et al., 1966), protein, total amino acids and composition (Šližytė et al., 2017).

Results and discussion

Survival ranged from 80-90%, independent of treatment. Specific growth rates in the highest feed levels were significantly higher than in the lowest feed levels and growth was not affected by the type of diet. Similar to other studies, total lipid and total fatty acid contents of polychaetes were positively correlated with feed level while the type of diet had a limited effect (Wang et al., 2019a, Wang et al., 2019b). Fatty acid composition in polychaetes reflected feed levels: in both diet groups, lower feed levels showed a higher percentage of saturated fatty acids, monounsaturated fatty acids increased with increased feed supply in the smolt group and polychaetes fed with post-smolt sludge showed increased polyunsaturated fatty acids concentrations, specifically of DHA, with increasing feed levels. Neither diet nor feed levels affected protein content and amino acid composition in the polychaetes.

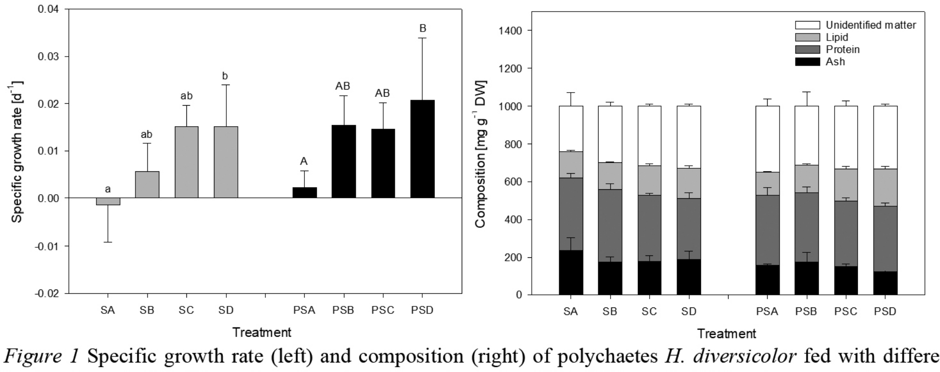

Figure 1 Specific growth rate (left) and composition (right) of polychaetes *H. diversicolor* fed with different levels of smolt (SA-SD, n=4) and post-smolt waste sludge (PSA-PSD, n=4). Different superscripts indicate significant differences ($P < 0.05$).

(Continued on next page)

Conclusion

Overall, *H. diversicolor* cultivated on both smolt and post-smolt salmon sludge was rich in proteins and lipids as well as essential amino and fatty acids, and contained suitable levels of trace elements that match the salmon industry's requirements. Therefore, the species can be considered to not only be valuable for recycling nutrients from salmon aquaculture side streams, but also serve as a potential resource to replace high-value marine ingredients in aquafeeds.

Introduction

In Norwegian salmon farming, about 15% of all salmon are lost during the production phase at the sea. Large sea cages which can hold up to 200,000 individuals are commonly used in Norway, but we have no established technology to properly monitor the fish. Some individual fish may present low growth, emaciated body conditions, and aberrant behaviour (Folkedal et al., 2016), which are referred to as "growth-stunted" (GS) individuals ('loser fish'). Their presence may be an indication of an inappropriate farming strategy (Noble et al., 2018) and can lead to a biased estimation of fish biomass and size distribution (Nilsson & Folkedal, 2019). Our knowledge about GS fish is poor due to the limited visibility of fish in sea cages. A promising method to monitor GS fish in sea cages is to deploy cameras and to develop automatic image processing pipelines. Recently, deep-learning-based tools, such as Convolutional Neural Networks (CNNs), have been successfully employed in marine sciences to automatically analyse video and image data (e.g. Crescitelli et al., 2020). The aim of this study is to classify the GS phenotype in a computer-vision framework by identifying differences between them and healthy fish. We report the results of the best performing classification model, which can be used in the creation of an automated counting system that will provide the abundance and distribution of GS and healthy fish in sea cages. Such knowledge can be used to understand connections between fish and environmental/production factors, which will help us to counteract factors leading to the development of GS fish.

Materials and methods

Video data was collected at a commercial Atlantic salmon farm in Norway by using underwater cameras (GoPro8) placed in a sea cage by cage walls at 4m, 8m, and 12m depths. Frames which included both GS fish and healthy fish were extracted from the videos, and 249 healthy fish, and 103 GS fish were annotated and saved as new images. The images were divided into two collections: one composed of 246 images was used for training models, while another with 106 images was used for testing. For extracting identification features, we used Resnet-101, ResNet-152, FBResNet-152, InceptionV4 and InceptionResNetV2 models which were pre-trained in the ImageNet collection[1]. Each CNN extracted feature vectors with size 2048 for each image. We also used a t-distributed Stochastic Neighbor Embedding (tSNE) method, a visualization technique for high-dimensional data that gives each point a location in a two-dimensional map. A Support Vector Machine (SVM) and a Random Forest (RF) binary classifier were then trained to classify input images as a healthy or GS fish. We also performed a grid search to determine the best parameters for SVM and RF models.

Results

The use of pre-trained CNNs led to effective representations of the visual properties of GS and healthy fish. When comparing the values of the analysed classifiers (Table 1), SVM outperformed RF in almost all of the studied cases. The only case that RF presented a better accuracy was for InceptionV4. The best results were observed when ResNet-101 model was used as feature extractor (Table 1). The classification system was based on SVM classifier, since it was the best classifier (Table 1). After performing a grid search with 5-fold cross-validation on the training set, the configuration of SVM with the best configuration was: *C = 0.1*, *gamma = 1000*, and *kernel = linear.* With this configuration, the classification system reached **97.17%** correct identification in the test set. When analysing the confusion matrix, the best model did not commit any mistakes when classifying GS fish (i.e., 100% accuracy (31/31) on this configuration for the dataset). The accuracy in classifying healthy fish was 96% (72/75). The use of *linear* kernel also corroborates with tSNE analysis, since the dispersion of the data demonstrates that they are well clustered into two well-defined groups (Fig. 1).

(Continued on next page)

Fig. 1. *Two-dimensional representation of the features of healthy (blue) and GS fish (red). Points represent the 2D projection of image ResNet-101 features. Most of the samples belonging to the two classes are well separated in the 2D space.*

Discussion

Preliminary results show that the creation of a video-based automatic system for recognition and counting GS fish is feasible. Cameras deployed inside sea cages are extremely important since we can generate a great amount of images and videos that can have their features extracted. These cameras can also monitor behaviour of fish, and GS fish can be automatically identified by using the obtained insight on GS fish features. The results show the great potential for the use of SVM in the automatic detection of GS fish, leading to a significant reduction of the human workload required for manual analysis. In our future work, we intend to use videos instead of images, and integrate environmental variables, farm operation information such as feeding strategy, and camera locations into the analyses. Such advanced analyses will improve our understanding of factors leading to GS fish occurrence and their spatial and temporal distribution patterns, which will increase fish welfare and farm production.

Introduction

Low trophic aquaculture, such as bivalve species, can be candidate species for the minimization of environmental impact of worldwide growing aquaculture, while providing consumers with high quality and nutritive seafood. Nowadays, mussels are cultured suspended mainly in raft and longline systems, using ropes made of non-biodegradable petrol-based plastic, currently estimated in 1,600,000 to 3,300,000 metres/year. The current growth estimations of mussel offshore productions would correspondingly increase the use of petrol-based plastic ropes. Inadequate waste collection facilities at harbours and end of life (EoL) management possibilities of these ropes, may result in augmenting marine litter and microplastics entering the oceans. EU BIOGEARS project, addresses the challenge of minimizing the use of petrol-based plastics in the sea by developing biobased and compostable ropes, **biogears.** At the end of life, biogears are being validated to entering in-land organic recycling circuits, hence greatly reducing carbon footprint along the whole value chain. Thus, generating new local value chains by promoting biobased circular economy. The aim of this study is to assess and compare the aquaculture performance and quality of mussel cultured suspended in two biogears prototypes vs. commercial rope counterparts in an offshore longline and in a raft.

Material and methods

Biogears prototypes of two different compounds based on commercially available biobased polymers, B1 and B2, were manufactured with currently used industrial processes for aquaculture rope manufacturing. The biogears prototypes were designed to be fit-for-purpose with adequate durability and functionality for mussel productions. Twenty-four ropes of 5m length of prototypes B1 and B2, and a commercial counterpart (GR) were seeded with juvenile mussels (9.44 ± 4.27g body weight, 53.35 ± 15.63mm shell length), at a density of 666.2 ± 89.34 individuals per meter rope (5,632.5 ± 89.34g/m rope). Seeded ropes were deployed in an experimental raft in the port of Mutriku, for a conditioning period of two months (July-Sep 2021). In September 2021, twelve ropes of each type were transported and deployed in a longline system located 2 miles offshore of the coastline, while others remained in the raft. For one production cycle (July 2021-July 2022), the rope effect on mussel grow-out in longline vs. in raft will be assessed and compared. Bimonthly, growth and survival of the mussels, condition index and meat yield, proximal composition and fatty acid profiles are being assessed in both locations (SE Bay of Biscay).

Results and discussion

Preliminary results of the mussel growth performance in the experimental period from September 2021 to March 2022 are shown in Figure 1. After the conditioning period B1 mussel showed a higher shell length and body weight than mussel from the rest of groups (B2 and GR mussel showing similar size, in body weight and shell length). Correspondingly, mussel abundance (in weight of individuals) was also higher in B1 group. Over the six months in culture the overall mussel growth was higher in longline than in raft cultured mussel, both in shell length (~ 5 mm), body weight (~ 4g) as well as in mussel abundance (~ 750 g), irrespective of the rope type. Mussel shell length was not affected by rope type either grown-out in longline or in raft after six months. However, B1 and GR mussels grown-out in longline and B1 grown in raft systems showed higher individual body weights. An overall loss of mussel occurred in all types of ropes over the experimental period. In longline, biobased ropes B1 and B2 showed higher mussel final weight per linear meter of rope than the commercial counterpart (GR). In the raft, the final abundance of mussel was higher in B1 than in the rest of groups, observing similar values among B2 and GR ropes.

Overall, these preliminary results may suggest rope type effect on mussel growth. Biobased rope B1 promoted a higher mussel growth and abundance than commercial fossil-source plastic ropes (GR) in raft. In longline, B1 and B2, promoted higher mussel abundances, which could be due to a better attachment of mussel to biobased ropes. Attachment to ropes is a critical aspect that influences mussel crop loss especially in offshore productions in high energy environments. Thus, biobased ropes could lead to more promising production yields than GR ropes in raft and especially in longline systems. Composition and quality parameters are being analyzed.

(Continued on next page)

Introduction

The settlement and metamorphosis of sea urchin larvae is undoubtedly one of the most critical stages of their life cycle. The transition from the pelagic to the benthic life form implies a radical change in the form of feeding, moving from the filtering ingestion of phytoplankton to an active scraping feeding. In the post-larvae phase, sea urchins start to feed on biofilm composed of various marine microorganisms, such as benthic microalgae, bacteria and fungi. The induction mechanism for settlement is still poorly understood. The sea urchin settlement is promoted by the presence of certain natural chemical compounds (polyunsaturated fatty acids, dibromomethane, glycoglycerolipins, among others) associated with food, and also inorganic chemical compounds such as like ionic salts. To obtain a great number of viable juveniles in sea urchin aquaculture, it is required to provide cultivating conditions that optimize metamorphosis and sedimentation success rates. This success involves the creation of substrates for settlement, previously colonized with biofilm composed of microalgae and other marine microorganisms. The settlement of *Paracentrotus lividus* on solid agar media previously inoculated with three different microalgae was analyzed in this study. The settlement rate was observed between days 20 and 27 DAH.

Materials and methods

For the evaluation of *P. lividus* larvae settlement substrates, petri dishes with solid medium composed of agar (1.5%), Guillard's F2 culture medium and silica were used. Using the agar as solid medium, 5 types of microalgae biofilms substrates were subsequently developed: *Nitzschia closterium* (*Nc*), *Phaeodactylum tricornutum* (*Pt*), *Tetraselmis sp.* IMP3 (IPM3), a mixture of the 3 microalgae (*mix*) and a control (*Ctrl*) without microalgae. For inoculation on the agar substrates, microalgae cultures were spread using the following densities: 2.4 x10^6, 7.5 x10^6, 4.4 x10^6 cell/ml, for *Nc*, *Pt* and *Timp3*, respectively.

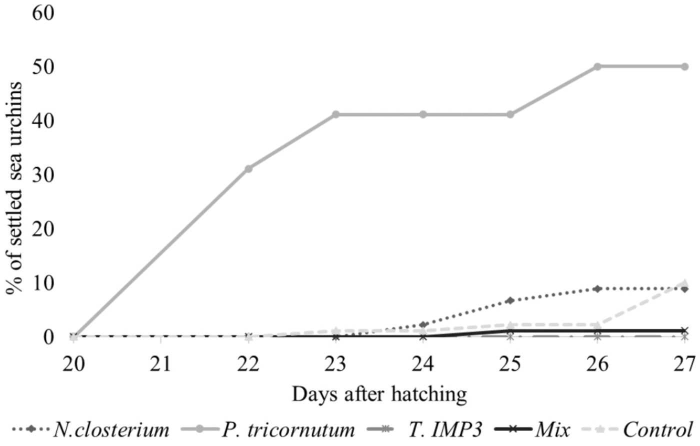

Figure 1- Cumulative percentage of sea urchins (*Paracentrotus lividus*) fixed on the different substrates analyzed *Nitzschia closterium*, *Phaeodactylum tricornutum*, *Tetraselmis sp.* IMP3, mix and control.

(Continued on next page)

In order to obtain *P. lividus* gametes, 1 ml of 0.5 M KCl was injected into the coelom via the peristomal membrane. Fertilized eggs were hatched in a 220 L cylindrical fiberglass tanks with soft aeration and covered with shader to reduce environmental light exposure for approximately 48h. The larval cultivation experiment was carried out in 6L flat bottom flasks without water inlet and with a reduced aeration, with a density of 2500 larvae per liter. During this period the larvae were fed a mixture of 2 microalgae: *Isochrysis galbana* and *Skeletonema costatum*. Periodically, observations were made in a stereomicroscope to follow the larval development. A selection of larvae suitable for the settlement procedure was undertaken on day 20 DAH (rudiment diameter equal to or greater than the diameter of the stomach). For each treatment, 3 petri dishes were used in which 30 competent larvae were introduced, in 40 ml of sterilized sea water. The petri dishes were kept in a phytoclimate chamber at a temperature of 19ºC and a photoperiod of 12 h of day light. An observation and counting of settled larvae were performed every day. Daily, 20% of the culture volume was replaced with sea water containing the planktonic microalgae *S. costatum* (settlement larvae feeding) at a density of $2.5x10^5$ cells/ml.

Results and discussion

When comparing the development of the 3 microalgae in the solid agar medium, there was a lower growth in diatoms (*N. closterium* and *P.tricornutum*) comparing to *Tetraselmis sp*. IMP3. This result was already expected, and Timp3 was chosen due to its great capacity to grow on solid media. Despite being minor, the growth of other microalgae was significant. Analyzing the results of successful settlement, it was found that on day 22 DHA the settlement process began, despite occurring only on substrates with the microalgae *P. tricornutum* (figure 1). In the following days, there was also a gradual settlement in some other treatments, being, however, much more significant in the microalgae. At the end of the test (27 DAH) there was an average settlement rate of 50.0 (± 36.6) % on substrates with *P. tricornutum*. The mean test diameter at this day was 0.33 (± 0.06) mm. For the substrate with *N. closterium* this rate was 8.8 (± 1.9) %. There was no settlement of sea urchins in the substrate with *Tetraselmis sp*. IMP3. On solid substrates without inoculated microalgae, there was a settlement rate of 10 (± 11.5) %. This result shows that benthic diatoms have an advantage over *Tetraselmis sp*. IMP3. The presence of larvae settled in the uninoculated substrate (*control*) suggests two hypotheses still under evaluation: 1) Properties and/or ecological strategies of the *Tetraselmis sp*. IMP3 may suppress the settlement of sea urchins; 2) Verified presence of other marine microorganisms developed in the *P. tricornutum* substrate contributes to a richer and suitable biofilm for the settlement and first feeding of sea urchins. At the present time, microbiological analyzes are being carried out to better characterize the developed biofilm and understand the degree of importance of microorganisms associated with the microalgae substrate. The great variance between the results of the same treatment suggests the influence of other factors besides the type of algae included in the substrate, from handling to the quality of the larvae. However, the effect of microalgae type is clearly significant on the success of settlement.

This work has been financed through the OURIÇAQUA (Fundo Azul) project.

GROWTH PERFOMANCE OF *Phallusia mammillata* (CHORDATA, ASCIDIACEA) AS BIOREMEDIATOR UNDER AN INNOVATIVE IMTA IN THE MAR GRANDE OF TARANTO (IONIAN SEA, ITALY)

Introduction

Since the last twenty years aquaculture sector has been recognized for its essential role in providing nutrition and employment to millions of people worldwide (FAO, 2022). Yet, such industry is not without criticism as its negative environmental impacts deriving from production wastes (Wang et al., 2020), and more sustainable farming methods should be developed. Integrated Multi-Trophic Aquaculture (IMTA) is a polyculture method combining fed organisms (e.g., fish) with extractive organisms or "biofilters" (e.g., suspension-feeders, seaweed), with the aim to create a balanced system for both environmental and economic sustainability (Barrington et al., 2009). In such system fish wastes (i.e., uneaten feed, faeces) are recycled via biofiltration (bioremediation) becoming food for extractive species whose biomass could be exploited as valuable by-product, promoting circular economy (Barrington et al., 2009). So far, edible bivalves and seaweed are almost the only organisms cultured as bioremediators, and experimentation involving other efficient extractive species with valuable biomass is thus desirable.

Ascidians are benthic suspension-feeders, colonial or solitary; widely distributed worldwide and often representing the dominant component of fouling communities in eutrophic environment (Ordóñez et al., 2013). Their tolerance to eutrophic conditions and high filtration rate (Randløv and Riisgård, 1979), combined with their fast-growing rate, nutritional value and potential as source of several bioactive compounds make ascidians ideal extractive organisms to be exploited in IMTA systems (Marques et al., 2022).

In the present work, we report preliminary results over a four-month period of the growth performance of *Phallusia mammillata* (Cuvier, 1815) as bioremediator under an innovative IMTA system developed in the Mar Grande of Taranto

Materials and methods

The study area is located in the Mar Grande of Taranto (40°25′56″ N; 17°14′19″ E) (Ionian Sea), which is a semi-enclosed basin connected to the Gulf of Taranto. The investigation was performed in the aquaculture plant "Maricoltura del Mar Grande (MMG)", partner of the Remedia-Life project hosting the innovative IMTA system. Here, 42 natural fiber ropes (10 m in length) were placed around fish cages in November 2021 and used as fouling collectors to monitor the growth of *P. mammillata* for 1 year. Between March and July 2022, 3 collectors were randomly sampled monthly, and all the individuals of *P. mammillata* were counted and measured in length. Mean values of length and linear density were computed to evaluate the growth of *P. mammillata* over time.

Results

P. mammillata had a linear growth trend showing the maximum value of length in July 2022 (Fig. 1a). Linear density showed a great increment between March and April 2022 settling at about 1 individual·m^{-1} in July 2022 (Fig. 1b).

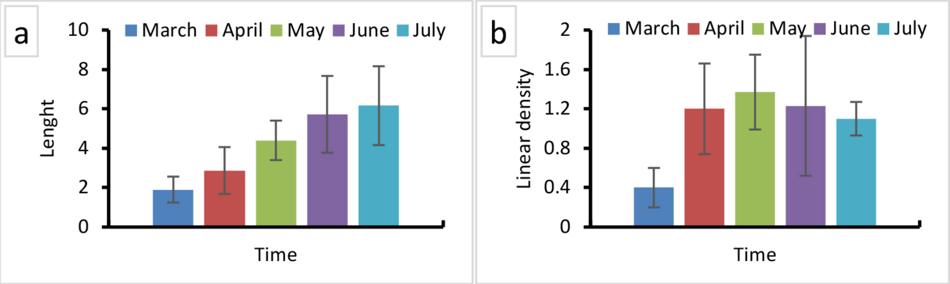

Figure 1. a) Length (cm) and b) linear density (n. individuals·m^{-1}) over time of *P. mammillata*.

(Continued on next page)

Discussion

P. mammillata has performed well under our innovative IMTA system showing in only 4 months an average length increment (224.21 ± 133.08 %) greater than *Sabella spallanzanii* Gmelin, 1791 and *Sarcotragus spinosulus* Schmidt, 1862 cultured at the same conditions (Giangrande et al., 2020), and only few specimens were not survived. Beside March 2022, linear density was quite constant throughout the sampling period since new recruits replacing any lost specimens were observed each month. Such observation is likely related to the higher temperature enhancing ascidian gametogenesis in Spring-Summer in the northern hemisphere (Millar, 1971). Thus, considering all the collectors placed around fish cages, in July 2022 we obtained by natural recruitment potentially about 450 individuals of *P. mammillata* long on average 6.16 ± 2.01 cm. This biomass obtained as byproduct represents an added value for IMTA farmers since ascidians are sources of natural compounds as, for example, the tunicin, a cellulose-like polysaccharide, or numerous molecules with antimicrobial activity to be exploited in several fields (Marques et al., 2022). In addition, the tissues of solitary ascidians have a great nutritional value with high-protein content and a fatty-acid profile similar to fish oil (Hassanzadeh, 2014), making them a good alternative to replace fish oil in the formulation of innovative fish fodder.

IN VITRO AND IN VIVO EVALUATION OF INDUCED *Vibrio splendidus* TOWARD IMMUNE RESPONSE AND CROSS PROTECTION IN *Oyster grassostera gigas*

*Noushin Arratahery
Professor Jens Rolff

Freie Berlin University, Berlin, Germany - Berlin (Germany)
arfa.n@fu-berlin.de

Vibrio splendidus is an oyster pathogen associated with the summer mortalities affecting the production of *Crassostrea gigas oysters* worldwide. The increasing experimental evidence suggests that there are some forms of specific acquired immunity in invertebrates, but the underlying mechanism is not fully understood. In the present study, Pacific oyster (*Crassostrea gigas*) stimulated primarily by exposure to 10^5 *Vibrio splendidus* displayed stronger immune responses levels when they encountered the secondary challenge of 10^8 *V.splendidus*.we tested *Vibrio* primed by exposure to colonized in oysters to investigate their resistance against hemolymph in vivo and in vitro experiments. we investigated the immunological responses in oysters and whether this colonization results in elevated mortality.The selected strains showed higher survival in seconde challenge in oyster model and cross- protection against *Vibrio splendidus* in vitro. A population of oyster selected for resistance to the *Vibrio splendidus* showed increased in vivo survival, in addition, *V.Splendidus* reduction of pathogen shedding. In conclusion, our results suggest that the primary stimulation of *V. splendidus* led to immune priming in oysters when encountering the secondary challenge with *V. splendidus*, in addition, the increased survival of oysters almost certainly by stimulating the immune system in hosts led to prevent vibriosis in the oyster.

IDENTIFICATION OF *Vibrio kanaloa* IN THE *Oyster crassotrea gigas* BY FLUORESCENT IN SITU HYBRIDIZATION

*Noushin Arratahery
Professor Jens Rolff

Freie Berlin University, Berlin, Germany - Berlin (Germany)
arfa.n@fu-berlin.de

Background
An ideal model for studying *Vibrio* and host and their interaction in disease dynamics is *Crassostrea Gigas* in the North Sea, exposing invasive sources to pathogens, especially (*vibrio kanaloae*).

Methods
This study used molecular fluorescent in situ hybridization (FISH) techniques to rapidly identify the diversity of bacteria in the oyster *Crassostrea Gigas* from Sylt Island and 16SrRNA gene sequence validated all strains' identification. Oysters were collected and exposed with *vibrio kanaloae* strains on different tissues were examined utilizing culture-independent methodologies.

Results
the digestive glands, gill and Muscle in *vibrio Kanaloa* were identified as metabolically active by the FISH technique, one of the advantages of the FISH technique is that it is accurate and very easy to use.

Conclusions
This technique allows rapid assessment of *Vibrio* in oysters and seafood.**=**

CHARACTERIZATION OF TOXIN GENES ANTIMICROBIAL SUSCEPTIBILITY OF *Staphylococcus aureus* ISOLATES IN FISHERY PRODUCTS IN IRAN

*Noushin Arratahery
Professor Jens Rolff

Freie Berlin University, Berlin, Germany - Berlin (Germany)
arfa.n@fu-berlin.de

Introduction:
Staphylococcus aureus is one of the most common causes of seafood-borne diseases worldwide, which are attributable to the contamination of food by preformed enterotoxins.

Purpose:
The final aim of this study was to investigate the contamination of fishery products before their purchase and consumption.

Methods:
In this study, a total of 206 (34.3%) Staphylococcus aureus strains were obtained from 600 fish and shrimp samples and were tested by PCR for their antimicrobial susceptibility. We assessed the prevalence of the genes responsible for the staphylococcal enterotoxins (SEA, SEB) and toxic shock syndrome toxin 1 (TSST-1) genes.

Results:
The results indicated that 34% of aqua food samples were contaminated with S. aureus, and 23.8% of these isolates were mec-A-positive. Sixty-four percent of the strains isolated from contaminated seafood was enterotoxigenic S. aureus, and 28.2% of SEs were MRSA-positive. The most prevalent genotype was characterized by the presence of the sea gene (45.2%), followed by the seb gene (18.5%), and the tst gene encoding TSST-1 was found in eight strains (3.9%). Of the 206 S. aureus isolates, 189 strains (84.9%) were resistant to at least one antibiotic.

Significance:
Given the frequent outbreaks of enterotoxigenic MRSA, it is necessary to make revisions to mandatory programmes to facilitate improved hygiene practices during fishing, aquaculture, processing, and sales to prevent the contamination of fishery products in Iran.

ANTIBACTERIAL ACTIVITY OF THE SEA CUCUMBER *Holothuria leucospilota* WHOLE BODY EXTRACT AGAINST METHICILIN RESISTANT AND ENTERTTOXIN PRODUCING *Staphylococcus aureus* STRAINS

*Noushin Arratahery
Professor Jens Rolff

Freie Berlin University, Berlin, Germany - Berlin (Germany)
arfa.n@fu-berlin.de

Introduction:
Preformed enterotoxins of *Staphylococcus aureus* are one of the most common causes of seafood-borne food poisoning worldwide. Aquatic organisms, including those used as seafood, are also a source of organic compounds of potential medical importance.

Purpose:
Within the framework of an antimicrobial activity study of marine macro-organisms from the Persian Gulf, bioactive compounds of the sea cucumber *Holothuria leucospilota* were extracted from whole sea cucumber bodies using chloroform or methanol. The extracts were evaluated for their antibacterial effects against methicillin-resistant *Staphylococcus aureus* (MRSA) and enterotoxin producing *Staphylococcus aureus strains* (SEASA, SEBSA).

Methods:
Antimicrobial activities were determined using three methods: disk diffusion tests, minimum bactericidal concentration (MBC), and minimum inhibitory concentration (MIC).

Results:
The results demonstrate that methanol and chloroform extracts have an inhibitory effect on the growth of all strains tested at MIC concentrations up to 100 mg/ml. Also, the chloroform extract demonstrated bactericidal activity against SEBSA in concentrations of about 100 mg/ml. The extract below 100 mg/ml concentrations also shows bactericidal effects against MRSA and SEBSA. The highest antibacterial activity was found in the methanol extract.

Significance:
Therefore, sea cucumber extract is an interesting candidate for the identification of new antimicrobials, however, comprehensive investigations are needed to separate and identify the active compounds from *Holothuria leucospilota* from the Persian Gulf.

GENETIC VARIATION, GWAS, AND PREDICTABILITY FOR SURVIVAL AGAINST IPNV STRAINS IN RAINBOW TROUT

Introduction

Contagious diseases are a major threat in aquaculture due to losses caused by high mortalities and the reduced growth of surviving fish. Infectious pancreatic necrosis (IPN) is one of the highly contagious diseases of farmed salmonid fish caused by *Aquabirnavirus*. The disease often causes high levels of morbidity and mortality (30–80%, [1]), and ultimately huge economic loses. Juvenile fish and post-smolts during the months following seawater transfer appear to be the most susceptible phases of production cycle. The clinical symptoms of disease outbreak include swollen abdomen and eyes, darkening of the skin, necrosis of the pancreas and spiral swimming [2]. The survivors can become healthy carriers that may infect susceptible animals either by vertical and/or horizontal means. Although a large proportion of rainbow trout are vaccinated against IPN-virus, the protective effect is uncertain. Host genetic make-up plays significant role for survival against infectious pancreatic necrosis virus (IPNV) with some families survive better than the others. Genetically improved resistance against IPNV is a highly valuable tool to improve survival and to reduce losses due to IPN. The aim of current study was to compute genetic variation for survival against IPNV, further look into the genomic architecture of the trait and explore potential for marker assisted and/or genomic selection.

Material and Methods

The population used in current study originated from the breeding nucleus (year class 2021) of Osland Stamfisk AS, comprising 98 full-sib families. Population was created as crosses among 61 sires and 75 dams, with an average family size of 23 sibs per family (N=3 to 47). Challenge test for survival to IPNV was performed at fry stage with immersion method using two different strains of infectious pancreatic necrosis virus: rainbow trout specific strain of IPNV (IPNV-RT) and Atlantic salmon specific strain of IPNV (IPNV-AS). The IPNV strain was obtained from a rainbow trout farm during field outbreak, and IPNV-AS strain was a previously available isolate. The fry were challenged in two tanks, where one tank (E-4, IPNV-RT) had fry from all 98 families, while the other (E-5, IPNV-AS) had fry from 25 full-sib families. The challenge test model had been previously established and optimized by VESO Vikan, where the concentration of IPNV-RT virus in tank E-4 was set to 6.8 x 10^7 $TCID_{50}$ per ml while IPNV-AS virus in tank E-5 had a concentration of 1 x 10^8 $TCID_{50}$ per ml. Survival phenotype was recorded during the challenge test and all the surviving and dead fish were tissue sampled for genotyping to construct pedigree and for the later genomic analyses.

Analyses: Estimation of genetic parameters, genome-wide association analysis (GWAS), and predictions of estimated breeding values (EBVs) were performed using a linear mixed model(s). Estimates of genetic parameters were computed using ASREML v4.2 applying genomic or pedigree information, and the GWAS analysis was performed with GCTA using "--mlma-loco" function [3]. Moreover, the power of predictability was evaluated using cross validation scheme with different models (PBLUP, GBLUP and Bayesian) to assess and compare the potential of genomic and/or marker assisted selection over classical pedigree information.

The applied model and components are explained below,

$$\boldsymbol{y} = \mu + \boldsymbol{Zu} + \boldsymbol{e}$$

Where y is the vector of phenotypes (0 dead or 1 alive); μ is the overall mean; $\boldsymbol{Z}$ is a design matrix to relate the records to genetic values and u is a vector of random additive genetic effects, it is assumed that $u \sim (0, \sigma_g^2[\mathrm{A/G})$, where $\sigma_g^2$is the genetic variance, $\boldsymbol{A}$ is the relationship matrix obtained using pedigree information, $\boldsymbol{G}$ is a genomic relationship matrix computed using VanRaden's method 1. The $\boldsymbol{e}$ is the vector of random residual effects with $e \sim N(0, I\sigma_e^2)$.

(Continued on next page)

Results and Discussion

The obtained heritability estimates for survival to IPNV-RT were 0.33±0.12 and 0.27±0.03 using pedigree vs. genomic information, respectively. These estimates for survival to IPNV-AS were 0.16±0.04 and 0.20±0.06 with pedigree and genomic information, respectively. However, the estimates derived for survival to IPNV-AS are indicative estimates because these are obtained from small set of families (n=25). The bivariate animal model revealed strong genetic correlation for survival to IPNV-RT and IPNV-AS with estimates of 0.85±12. As, genetic correlation was high and therefore general survival as a single trait was also used to obtain estimates. The general survival showed heritability of 0.25±0.03.

The accuracy of predictions and GWAS analyses were performed for each trait separately. However, GWAS and predictability results obtained through general survival are described as follows. The GWAS analysis revealed a strong signal of QTL at chromosome 1 comprising 23 SNPs presenting significant association to the survival trait with P-value crossing genome-wide Bonferroni corrected threshold (Figure 1) The proportion of the genetic variance explained by the highest significant SNP was up to ~27% of the total genetic variance. The genomic Bayesian models performed the best in terms of predictability with ~21% improvement in predictability compared to PBLUP model.

In conclusion, survival to IPNV-RT and IPNV-AS in current population revealed significant genetic variation with one major QTL contributing significant proportion of genetic variation while remaining contribution possibly coming from many other loci. The prediction using genomics-based Bayesian models outperforms the predictions using PBLUP model.

Introduction

Aquaponics is a farming method where the nutrient-rich wastewater from a recirculating aquaculture system (RAS) is utilized to grow plants. In an aquaponic system, the ammonia produced by fish metabolism is oxidized by biofilter nitrification microbes to nitrate which is an essential nutrient for the plants but is also well tolerated by fish. Fish feed contains also other nutrients that are important for plants. It is important to manage the water quality in an aquaponics system and to maintain the optimal growing conditions for fish and plants. Fishes thrive in clean water while the plants require nutrient-rich medium for their growth. In RAS cyanobacteria, *Actinomycetes* and myxobacteria are known to produce off-flavor compounds geosmin (GSM) and 2-methylisoborneol (MIB) which can easily accumulate in fish flesh resulting in earthy and musty flavor and making them unmarketable. Thus, the removal of these compounds by depurating them in flow-through water is necessary before marketing. The aims of this study were to investigate the growth of baby spinach (*Spinacia oleracea*) and rainbow trout (*Oncorhynchus mykiss*) and to compare water quality in RAS, hydroponics (i.e. soilless culture of plants) and in a coupled aquaponic system. Special emphases were given to off-flavor compounds in fish flesh and plants as well as the onset of nitrification process in RAS and aquaponics.

Materials and methods

A six-week experiment was performed with three replicated RAS, aquaponic and hydroponic systems. Twenty rainbow trout (initial weight 108 g) were stocked in each of the six fish tanks: three for RAS and three for aquaponic systems. Twenty-five baby spinach **(*Spinacia oleracea*)** plants were transplanted in each of the six deep water culture rafts (3 for aquaponics and 3 for hydroponics). Biomass for the fish and plants were recorded in the beginning and at the end of the experiment. Chloride, phosphate, sulfate, nitrate, nitrite, GSM and MIB were compared between RAS, aquaponics and hydroponics at the start and end of the experiment. The water quality data (total ammonia nitrogen, nitrite, nitrate, and pH) were collected during the experiment and the nitrification process was compared between RAS and aquaponics treatments.

Results

The fish grown in aquaponics exhibited statistically higher weight (137.1 ± 11.29) compared to fish grown in RAS (109.3 ± 3.05). Specific growth rates were also higher for fish grown in aquaponics (1.95 ± 0.12) than in RAS (1.67 ± 0.08). The feed conversion ratios (feed fed/weight gain) were lower for the fish grown in aquaponics (0.86 ±0.08) than in RAS (1.06 ±0.03). The concentrations of GSM were lower in fish flesh grown in aquaponics (376.0 ± 24.99) than in RAS (466.3 ± 39.40). The concentrations of MIB were at similar levels in fish flesh grown in aquaponics and RAS. The concentrations of GSM and MIB did not differ statistically significantly between the water of the two systems. The onset of nitrification was faster in the aquaponic system than in RAS (Figure 1).

In the aquaponics system, the plant dry weight of spinach was 43 % higher (40 % for shoot and 70 % for root) than in hydroponics. The concentration of GSM was significantly higher in the roots of spinach grown in aquaponics (3579 ± 1682.8 ng/L) compared to spinach grown in hydroponics (191.80 ± 48.78 ng/L), but in the shoots the level of GSM was very low in both treatments (~8 ng/L). The concentration of MIB was higher in the shoots of spinach grown in aquaponics (704.4 ± 73.08 ng/L) than in those grown in hydroponics (278 ± 158.2 ng/L).

Conclusions

The aquaponic system was better than RAS in terms of water quality, onset of nitrification, fish growth and feed conversion ratio and also lower concentrations of GSM accumulated in fish flesh. Spinach grew better in aquaponics than in hydroponics but the difference was not statistically significant.

(Continued on next page)

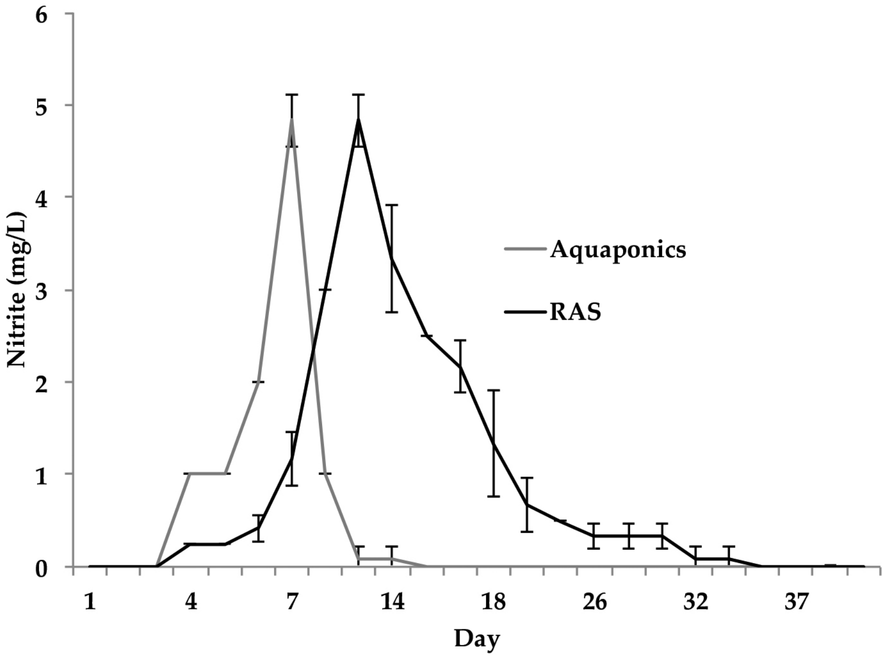

Figure 1. The mean concentration (mg/L) of nitrite in RAS and aquaponics treatments during the 42-day experiment. For the aquaponics treatment spinach was grown in a coupled aquaponics system together with rainbow trout (*Oncorhynchus mykiss*). Repeated measure ANOVA, ± SD (n=3).

ENVIRONMENTAL PERFORMANCES OF SEABREAM-OYSTER-CLAM-SHRIMP IMTA: THE LIFE CYCLE ASSESSMENT POINT OF VIEW

Joël Aubin[1*], Quentin Latourre[1], Francesca Conti[2], Christophe Jaeger[1], Vincent Gayet[3]

[1] UMR SAS, INRAE, Institut Agro, 35000 Rennes, France
joel.aubin@inrae.fr
[2] Università di Pisa, Viale delle Piagge, 2 - Pisa. Italy
[3] Lycée de la mer et du littoral, rue William Bertrand, 17 560 Bourcefranc-le-Chapus, France

Introduction

Integrated Multi-Trophic Aquaculture (IMTA) is a promising way to improve the sustainability of aquaculture systems, by a better use of the nutrients provided, using the trophic complementarity of several aquaculture species (Neori et al., 2004). However, there are still lack of references and knowledge on the real environmental performances of such systems as the addition of supplementary species may induces supplementary impacts (Nederlof et al. 2021). To better understand the multiple environmental consequences of changes of practices, Life Cycle Assessment (LCA) is a key method (Aubin et al, 2015). However in LCA, data collection and methodological points (functional unit, allocation rules…), are still obstacles in complex systems such as IMTA. In our study, we applied LCA to a seabream-oyster-clam-shrimp experimental IMTA conducted in coastal ponds during two rearing periods, and compared with the practices of a private farm producing oysters-clams and shrimp in similar structure but at a higher production level.

Material and methods

This study was conducted in the framework of the EU-Prima SIMTAP project. The experiment was conducted at the Lycée de la Mer et du Littoral (Charentes Maritimes, France), in coastal ponds usually dedicated to production and refinement of oysters. Four ponds (400-700 m^2) were associated in a loop using pumping and spillway. The first pond was dedicated to the rearing of 200g seabreams (*Sparus aurata*), fed with vegetable feed and discarded mussels (*M. edulis*), while the three downstream ponds were dedicated to the growth of mixed oyster (*Crassostrea gigas*), clam (*Ruditapes philippinarum*) and shrimp (*Marsupenaeus japonicus*). The water is sent back to the first pond, after the last pond of oyster-clam and shrimp. Additional ventilation is provided by airlift in each pond.

The experiment was conducted from June to October in 2020 and 2021. After the first year, considering the survival rate and the flesh yield of the shellfish the seeding of clams and oysters was increased. Between the two years, there were also variations in survival in the ponds due to climatic or handling incidents. The resulting production is indicated in table 1. We compared the performances with a commercial farm of 30 ha producing a mix of oyster, clam and shrimp, using formulated feed to sustain the worm productivity of ponds, for the shrimp feeding. The average production performances of the farm are presented in table 1.

LCA was conducted from cradle to farm gate, and calculated with different functional units (results presented by tonne of aquatic products), using SimaPro 9.3 software and Ecoinvent 3.8 and AgriBalyse databases. Four impact categories are presented here: Climate Change (kg CO_2-eq), Acidification (kg SO_2-eq), Cumulative Energy Demand (MJ), Eutrophication (kg PO_4-eq), Land competition (m^2.y).

Results and discussion

In the two SIMTAP trials, the rearing performances were good, with expected growth of seabreams with the innovative feed formula, very high survival rate (~95%) in oyster and very high flesh yields (over 20%), expected survival rates and high flesh yields in clam, and expected survival rates and good growth in shrimp. However, the position order of the pond in the loop induced variation in growth and survival for shrimp, oyster and clam.

The trial SIMTAP 2020 induced the highest levels of all environmental impacts, while SIMTAP 2021 induced the lowest levels in Climate Change, Acidification and Land competition. The Commercial farm induced the highest level in Climate Change, and the lowest level in C. Energy Demand, Eutrophication and Land competition (Fig.1). The analysis of the contribution of the different parts of the system explains these results. First, LCA is very sensitive to production yields. The increase in production of 45% between 2020 and 2021 induced a decrease in the influence of the fixed “environmental costs”, especially the land use and the electricity (for pumping and air supply) which remained at the same level. The electricity consumption was a major impact contributor in the SIMTAP system when compared with the Commercial

(Continued on next page)

Table1: Annual production in kg of the different IMTA systems studied

	Seabream	Shrimp	Oyster	Clam
SIMTAP 2020	418	42	120	92
SIMTAP 2021	443	54	325	151
Commercial Farm		3600	7200	7200

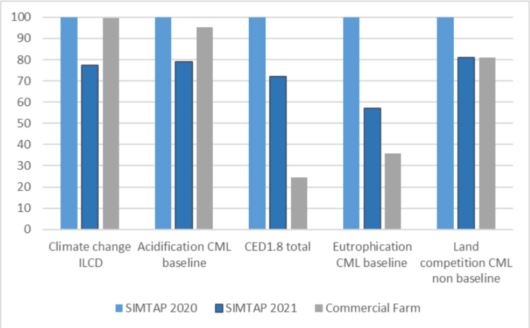

Figure1 : Comparative environmental impacts calculated by LCA, of 1 tonne of aquatic products in IMTA systems : seabream-oyster-clam-shrimp (SIMTAP) in 2020 and 2021, and oyster-clam-shrimp in a commercial farm

farm, which doesn't use pumping for water renewing (water renewal by the tide). Another large difference between the SIMTAP and Commercial farm was the contribution of the large seabreams (200g) entering the system, however it was partially balanced by the lower feed impact in SIMTAP, which leaded to lower Climate change in SIMTAP 2021 than in Commercial farm. Eutrophication due to the emissions of nitrogen and phosphorus in water was also influenced by the pre-grown seabreams.

Conclusion

The SIMTAP has very good potential, as it is productive and permits to reach good environmental performances. However, it is not optimized. The rearing performances show that there are room to increase the production of shellfish. LCA pointed out the question of electricity use, which should be mitigated by the use of renewable energy sources such as solar panels or wind turbines. The size of the seabream entering the system, chosen for their ability to use discarded mussels, has to be questioned in relation to the feeding strategy. Other impact categories are needed in this study to complete the environmental performance analysis, as well as economic and social indicators to compete the sustainability assessment.

As presented here, IMTA seems to be an interesting perspective for aquaculture. However, it is the details of application modalities that will make possible to achieve the expected environmental gain.

Introduction

Freshwater ponds are agroecosystems that provide important ecosystem services (ES) to landscapes, as well as nature's contribution to people (NCP), in particular by hosting recognized biodiversity (Blayac et al., 2014; Rey Valette et al., 2022). These ES/NCP can be influenced strongly by management practices. In France, the low profitability of freshwater ponds for fish production runs the risk that they will be abandoned, and thus that the ES/NCP that they provide will disappear. Moreover, pond management practices in France are poorly documented, as are their influence on pond productivity and provision of ES. Our study aims to recommend new fish stocking practices to meet fish farmers' expectations and better understand relations between management practices, biodiversity and ES/NCP.

Materials and methods

The SEPURE project is funded by the European Maritime and Fisheries Fund. It gathers scientists from various backgrounds (aquaculture, environmental sciences, modeling, ecology) to relate farmer practices, economic and environmental performances and the response of pond ecosystems by monitoring water quality, phytoplankton, zooplankton, benthic macroinvertebrates, aquatic macrophytes and fish populations.

After gathering available stocking and fishing data, a survey was performed and meetings were organized with fishpond farmers in three emblematic pond areas in France: Dombes, Lorraine, and Brenne-Sologne. Based on analysis of the contexts and the farmers' expectations, fish stocking scenarios were developed. At 10 production sites, farmers applied these scenarios, and the practices and ecosystems were monitored. Performances of experiments in 2021 are being analyzed, and a second year of experiments has begun in 2022.

Results and discussion

Eleven scenarios with different mixtures of species were co-designed with the fish farmers. They considered many parameters, such as the complementarity of species based on their trophic and behavioral traits (Lecocq et al., 2019), water availability, water temperature in summer, the existence of local and national markets for the species, the presence of submerged vegetation, pond depth, feeding and liming practices and the use of ponds for other activities (e.g. hunting).

Thus, the scenarios of fish stocking were diverse and covered several objectives, such as maximizing carp production, increasing profitability, allowing aquatic plants to develop to increase habitat availability for wildlife, and applying Chinese food web concepts…As mentioned, 10 of the 11 scenarios were applied in the three regions. As an application, the performance of one pond in Dombes and one in Brenne will be presented, since they differed greatly in term fish stocking and biodiversity. The results for productivity, revenue, biodiversity and environmental impacts will be discussed.

Conclusion

Revitalizing the pond sector in France is challenging. Doing so requires creating and organizing a large dataset to have a comprehensive and multicriteria vision. It is also necessary to validate approaches by applying them in the field in order to assess real-world consequences of management choices. The influence of fish production's sustainability and biodiversity conservation on ES/NCP needs to be assessed to be able to develop agroecological management of fishponds. This information should help support decision making for future development of the pond sector and help maintain local economies in these pond landscapes.

Introduction

We delineated areas that have different levels of suitability for use as tilapia cage culture sites in the Kenyan part of Lake Victoria, Africa. The lake hosts one of the largest freshwater fisheries in the world, providing a significant source of protein in East Africa and exporting fish to the European Union, United States, China and Japan. The study area was 4,100 km^2.

Methodology

The method uses high-resolution bathymetric data, newly collected water quality data from all major fishing grounds and cage culture sites, and existing spatial information from previous studies. The spatio-temporal (space and season) parameters considered are water depth, water temperature, levels of dissolved oxygen, chlorophyll-*a* concentrations, distances to the lake shoreline and proximity to other constraints on cage culture development.

Results

The results indicated that the area most suitable for fish cages comprised about 362 km^2, or approximately 9% of the total area; the remaining 91% (i.e. 3,737 km^2) was found to be unsuitable for tilapia cage culture (Figure 1). We conclude that the successful implementation of this approach would need stakeholder involvement in the validation and approval of potential sites, and in the incorporation of lake zoning into spatial planning policy and the regulations that support sustainable use while minimising resource use conflicts. The results of this study have broader applicability to the whole of Lake Victoria, and other Great Lakes in the world for tilapia cage culture.

Introduction

Successful fish production in RAS depends on microbes: First, microbial conversions of toxic ammonia in the biofilter is fundamental for maintaining a good chemical water quality. Second, the fish is exposed to the complex microbial communities suspended in the water. For optimized fish production, a good *microbial water quality* must be ensured, i.e., detrimental fish – microbe interactions must be prevented by selecting against rapid-growing, opportunistic bacteria in the system. We have previously shown that this can be obtained in RAS[1,2]. The interactions between the microbiota suspended in the rearing water and the gut and skin microbiota of the fish is however poorly understood. We recently showed that membrane filtration in RAS with Atlantic salmon parr reduced the TOC levels and bacterial blooms in a period with high organic loading[3]. In the present study[4], we investigated the gut microbiota of parr of Atlantic salmon from the same experiment, i.e., during periods with varying organic loading in two RAS; one with, and one without membrane filtration. The aim was to elucidate the complex relationship between the bacterial communities in the rearing water and the fish gut, and to evaluate the use of membrane filtration to promote positive fish–microbe interactions.

Materials and methods

Two pilot-scale RAS, one with membrane ultrafiltration of a 10–15% side-stream (mRAS), and one without (cRAS), were operated with Atlantic salmon parr in periods with different organic loading and degree of recirculation (previously described[3]). In the current study we focused on the two last periods of the experiment, Period 2 (P2; day 19–51) and Period 3 (P3; day 52–72). P2 was characterized by high water exchange rate and normal feed load, whereas P3 was characterized by moderate water exchange rate and high feed load. Samples were taken at the end of these to periods for characterization of gut and rearing water microbiomes.

Results and discussion

The rearing water microbiomes differed both between systems (cRAS vs. mRAS) (PERMANOVA $p = 0.002$) and sampling times (Fig. 1A). In cRAS, the water microbiome was more influenced by the high organic loading (during P3), with high abundances of two OTUs representing *Mycobacterium* (OTU_4) and *Spartobacteria* (OTU_6).

The gut microbiomes also differed significantly between cRAS and mRAS (Fig. 1b, PERMANOVA, $p=0.006$ (D50) and $p=0.0001$ (D72)), and gut microbiomes changed considerably more in cRAS than mRAS during P3 (high organic load).

The rearing water and gut microbiomes were generally highly dissimilar, but the similarity increased considerably in cRAS after P3 (Fig. 2a). Analysis of OTU abundances revealed that most OTUs were abundant either in water or gut samples. OTU_4 and 6 stood out as being highly abundant in both water and gut samples (Fig. 2b), and apparently represented bacterial populations that were able to colonize both the rearing water and the fish gut.

Conclusion

Rearing water and gut microbiomes were highly dissimilar, but high organic loading in cRAS resulted in growth of opportunistic bacteria that were able to colonize the fish gut. This led to a higher similarity between water and gut microbiomes. The present study further shows that membrane filtration is an applicable strategy to counteract growth of opportunistic bacteria in RAS and to promote positive fish – microbe interactions.

Introduction

Aquaculture may contribute to a sustainable and expanding food supply. As this industry has to face problems of cost efficiency (Espinal and Matulić 2019), the reduction of fresh water inflow and the health preservation of the cultivated stock are key factors of imrovement (Yavuzcan et al. 2017). Physical plasma offers a cost efficient method for water disinfection in aquacultural systems and thus represents a leverage for such improvements.

Materials and Methods

Water from a recirculating aquacultural system for the cultivation of *Acipenser oxyrinchus* at the Aquaculture Research Station (Born, Germany) was analysed by ion chromatography to determine especially relevant salts, in addition to pH-value, total organic and inorganic carbon and conductivity. Plasma treatment of this water for 30 min was carried out by an inductively-limited discharge at the water surface for a volume of 500 ml (Schmidt et al. 2019).

Results

Experiments were performed with water from a recirculating aquacultural system (RAS) and also a more reproducible model water, which was composed according to the analytical results. The model water was inoculated with common fish pathogens. Plasma treatment of the water from RAS led to an inactivation of up to 2 orders of magnitude of the microbial load in this particular water. In contrast, the total viable count was reduced by 7 orders of magnitude for *Aeromonas hydrophila* and up to 6 for *Vibrio cholerae*, in the model water. The inactivation was dependent on the incubation time after plasma treatment.

Conclusion

The results confirm the already known antimicrobial efficacy of plasma also for fish pathogens. Organic content is assumed responsible for the less effective inactivation of the microbial load in RAS water. Accordingly, respective processes and technology need to be investigated in more detail.

Introduction

Feed cost is one of the highest expenditures in aquaculture production, mainly due to the provision of sufficient protein-content, especially for carnivorous fish. Nowadays, protein supply is covered from fish meal among others, though fish meal production is gradually decreasing while its price is increasing in parallel. Numerous studies have been performed to investigate different alternative protein sources; however, most of them revealed inadequate growth performance in fish with alternative protein feeds. Nevertheless, better economical indexes could be achieved in many fish species with positive selection for feed utilization. African catfish is an important species in aquaculture production in numerous African, Asian, and European countries. Our aim was to investigate the growth performance of African catfish (*Clarias gariepinus*, Burchell, 1822) stocks with low fish meal feed in a half-industrial experiment and to produce a selected line for better utilization of feeds with alternative protein sources.

Materials and methods

African catfish was selected for better performance fed with low fish-meal feed for two generations and a performance test was performed on the F3 generation. Fish were investigated on a half-industrial scale in a flow-through system using 2 m^3 tanks at the Győri Előre Fisheries Co. site (GYE), with a water temperature of 23-24°C, fed with a control and an experimental diet. The control diet contained 8.1% fish-meal, while the experimental diet contained only 6%. Both feeds with similar pellet size (4.5mm) had the same row protein (42%) and row fat (12%) amount. All generations were produced with 4 multifactorial crosses of 5 male and 5 female individuals. Offspring were reared until reaching the market size and body weight (g) and sex by phenotypic traits was detected. In the F1 and F2 generations (n=1683 and n=1783, respectively) three groups were formed for genetic mapping: two experimental groups in duplicate and one control group. For the production of the F2 generation, the biggest and the smallest specimens of these groups were crossed. Additionally, a positively selected line was created in triplicates by crossing the biggest individuals fed with the experimental feed and by selecting the line several times during breeding. In the F3 generation (n=3083) a control group (C) was created from the group previously fed with the control feed and two experimental groups were created from two of the positively selected groups (PS1, PS2), then all groups were divided into two subgroups and fed with the experimental and the control diet to accomplish a performance test. Data analysis was performed with R software (ver 3.5.3) with $p<0.05$ significance level. Association between feed and sex was investigated with Fisher's exact test, and the effect of feed and sex on body mass was tested with ANOVA analysis using a contrast matrix to keep the first order error low. The F3 groups were tested pairwise with the Welch t-test.

Results

Association between feed and sex could not be detected in any generations. In the F1 generation the groups fed with a low fish-meal diet had significantly lower body mass compared to the control group (control: 1461.6±490.34 g, experimental 1.: 1281.67±515.97 g, experimental 2.: 1076.37±464.36 g). Interestingly, sex had a significant interaction with feed: males had higher body mass with the control diet, while females had higher body mass in the experimental groups. In the F2 generation one experimental group had significantly lower (1389.63±507.22 g), while the other had significantly higher (1827.48±506 g) body mass compared to the control group (1597.05±399.49 g). We could not detect interaction with sex in this generation. A performance test was performed on the F3 generation with a control (C) and two positively selected (PS1, PS2) lines all fed with a control (1) and experimental (2) diet. Both positively selected lines had higher body mass fed with all diets. However, the effect of selection for feed could not be detected since the difference in body mass between different diets was insignificant in all experimental groups (PS1: 1.:1599.11±307.92 g, 2.: 1554.47±315.20 g, PS2: 1.:1542.74±266.84 g, 2.: 1624.48±260.18 g).

(Continued on next page)

Discussion and conclusion

We can conclude that the lower body mass of the experimental groups fed with low fish-meal diet experienced in the F1 generation is similar to the results found in other fish species. However, in the F2 generation the experimental groups had similar or higher body mass compared to the control group which might be explained by accommodation to the new diet. The effect of the selection for feed could not be detected in the F3 generation, thus the effect of selection for higher body mass was significant, suggesting that there is a good potential for achieving better performance by selection in African catfish.

Introduction

European eel (*Anguilla anguilla*) is a commercially important species for aquaculture in Europe. Commercial aquaculture of this species still depends on the wild-caught juvenile glass eels entering coastal waters, which are farmed until marketable sizes. However, due to historically low levels of recruitment, a supply of hatchery produced glass eels is required to ensure the sustainability of aquaculture and to assist the conservation of this critically endangered species (Pike et al., 2020). Negative host-microbial interactions (Sørensen et al., 2014) and an immune system under development during the early larval stages (Miest et al., 2019), among other factors, have been reported to challenge the European eel larval performance under captive conditions. Feeds are one of the major sources of organic matter supply during first feeding of fish larvae (Vadstein et al., 2018). Food added to the system favours bacterial growth, in response to which fish larvae might develop an immune response. During this experiment, we studied the molecular ontogeny of the immune system of the feeding European eel larvae and characterized the microbial community structure of larvae and the corresponding rearing water throughout feeding culture.

Materials and methods

European eel larvae were obtained through assisted reproduction that has been previously described (Kottmann et al., 2020). When larvae reached the age of nine days post hatch (dph), they were stocked at a density of ~60 larvae L^{-1} in three 8 L "Kreisel" tanks, which were connected to a recirculating aquaculture system. Larvae were fed five times a day with a slurry type diet until they reached 28 dph. Larval survival was monitored daily throughout the rearing period. Larval samples were collected during the endogenous feeding period (on 0 dph & 9 dph) and exogenous feeding period (on 15, 22, and 28 dph) for analysis of the immune and stress related gene expression. Expression levels of 13 target genes, namely complement component C3 (*c3b1*), catalase (*cat*), complement component 1 q subcomponent c chain1 (*c1qc*), immunoglobulin m (*igm*), interleukin 1β (*il1β*), interleukin 10 (*il10*), interferon regulatory factor 3 (*irf3*), interferon regulatory factor 7 (*irf7*), major histocompatibility complex class ii (*mhc 2*), toll like receptor 18 (*tlr18*), tumor necrosis factor β (*tnfb*), heat shock protein 90 (*hsp90*) and heat shock protein 70 (*hsp70*) and 3 reference genes, namely elongation factor 1 (*ef1*), 18s ribosomal RNA (*rsp18*), and tubulin β (*tubb*) were determined by quantitative real-time PCR. Relative expression of targeted genes was calculated according to the $2^{-\Delta\Delta Ct}$ method (Livak & Schmittgen, 2001). For bacterial community composition analysis, larval samples and samples of rearing water were collected at each sampling point (on 0, 9, 15, 22 and 28 dph). 16S ribosomal RNA gene (rDNA) amplicon analysis is currently being carried out to characterize the bacterial community composition in larval and water samples.

Results and discussion

Expression of all immune and stress related genes studied were significantly ($P<0.05$) influenced by larval age, except the *il10* gene, which showed a constant activity throughout ontogeny, probably indicating basal immuno-protection. Analysis of the first results indicates three further expression patterns. Genes, *c3b1* and *igm* showed highest expression levels at hatch (0 dph) and expression levels decreased progressively with age, probably indicating the maternal origin of these genes, which most likely provided initial protection to the newly hatched larvae (Miest et al., 2019) (Figure 1 A). Moreover, *il1β*, *tnfb*, *irf7* and *hsp90* were expressed at lowest levels on 0 dph and increased with age, providing means of progressive increase of the larvae's immuno-protection. Interestingly, the expression pattern of stress related *hsp90* showed a significant peak on 22 dph, indicating a period of higher activity of the stress/repair mechanism. This, probably signals the effects of the point of no return (around 20-24 dph), resulting in a selection of those larvae that timely and successfully initiated first-feeding (Figure 1 B). Furthermore, *c1cq* and *irf3* showed an upregulated expression on 9 dph, when larvae gained feeding functionality, while expression levels of these genes remained at relatively high levels, indicating the own immune-readiness of larvae throughout the first-feeding and feeding window (Figure 1 C). More genes are being analysed to understand their characteristic expression patterns. Bacterial community composition analysis is also currently being carried out for larval and water samples collected during the experiment.

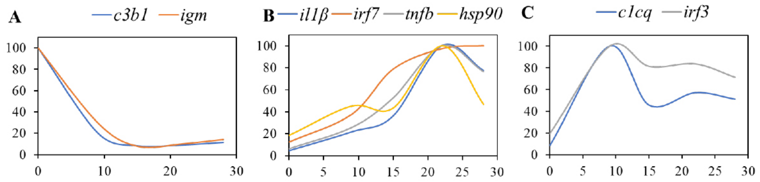

Figure 1: Expression patterns of immune and stress related genes. The x-axis displays age (in days post hatch), and the y-axis displays relative gene expression.

MONITORING THE SPATIAL DISTRIBUTION OF FARMED FISH IN LARGE COMMERCIAL SEA CAGES DEPLOYING A MULTI-BEAM SONAR

Introduction

Spatial distribution of Atlantic salmon (*Salmo salar*) in sea cages is an important welfare indicator. Uneven distribution of salmon inside the sea cages can be associated with an avoidance of unfavorable environmental conditions such as low oxygen, strong light, and suboptimal water temperature (Oppedal et al. 2011). With a good understanding of how salmon are distributed in a sea cage under preferable environmental conditions, we can detect unfavorable environmental conditions just by monitoring changes in their spatial distribution patterns. Echosounders have been used to investigate vertical fish distribution patterns in sea cages (e.g. Bui et al. 2013). These studies brought valuable insight into fish vertical distribution patterns in relation to environmental factors. In Norway, large sea cages can hold up to two hundred thousand individuals. It is likely that salmon distribution patterns inside such large structures are uneven both horizontally and vertically. Single beam echosounders can monitor only a small proportion of the sea cage volume, thus a more reliable assessment of salmon distribution patterns in the entire cage is required. In this study, we use a novel multi-beam sonar WASSP (ENL Group, A Furuno Company, New Zealand) to obtain more representative information of salmon distribution patterns in large commercial sea cages. The sonar can perform 120° fan-shaped scanning, which allows to scan larger proportions of the sea cage volume. Our long-term goal is to understand salmon distribution patterns in large sea cages in relation to environmental and fish-internal factors. Spatial distribution patterns of salmon can be used as behavior-based welfare indicators, which will enable more efficient farm operations (e.g. behavior based feeding, avoidance of stressful operation when fish show unusual behavior). As a first step, we conducted pilot study using WASSP, to establish the method to properly monitor salmon spatial distribution patterns in large commercial sea cages.

Materials and methods

The pilot study was carried out at a commercial Atlantic salmon farm located in Møre and Romsdal county in Norway. We collected data at 2 different sea cages which contained approx. 200,000 (average weight approx. 400g) and 70,000 salmon (average weight approx. 2kg), respectively. The sonar was mounted on a rig with a fixed 30° tilt so that the coverage of the sea cage volume by the sonar was maximized. The rig was placed inside the cage close to the cage net, and it was manually rotated following a horizontal angle of approx. 120° to scan more than 80% of the cage volume. We collected data using combinations of different acquisition ranges (25 m, 40 m, and 70 m) and rotation speeds (6 s/120° and 12 s/120°) of the sonar. 9 GoPro cameras were placed in the sea cage for simultaneous visual monitoring and validation. 8 cameras took images at a frequency of 1 Hz to get a rough estimation of fish density at different locations and depths at a time. A video was recorded next to the sonar rig to assess the potential influence of the rotating rig on salmon behavior (see Fig. 1 for experimental setup). The sonar data is post-processed in Echoview (Echoview Software Pty Ltd., Australia) to filter out all the noises (i.e. echo signals from anything other than salmon in the sea cage) and to create 3D distribution maps of salmon. Relevant environmental data (dissolved oxygen, temperature, salinity, feeding activity) were collected during the data collection with the sonar.

Results

Preliminary results showed that the multi-beam sonar monitors salmon spatial distribution inside sea cages regardless of the fish size. Difference in distribution was evident between small and large fish. Camera data showed that large fish avoided the shallow water layer down to around 8 m, whereas small individuals were present from around 4 m. Sonar data agreed with these findings. The sonar was capable of shooting through the thick layer of fish and detecting individuals distant from the instrument. We are currently post-processing the sonar data to assess the effects of different acquisition ranges, rotation speeds, and the fish size on the sonar data quality, as well as the distribution patterns of salmon. The work we will present is a part of our ongoing research effort.

(Continued on next page)

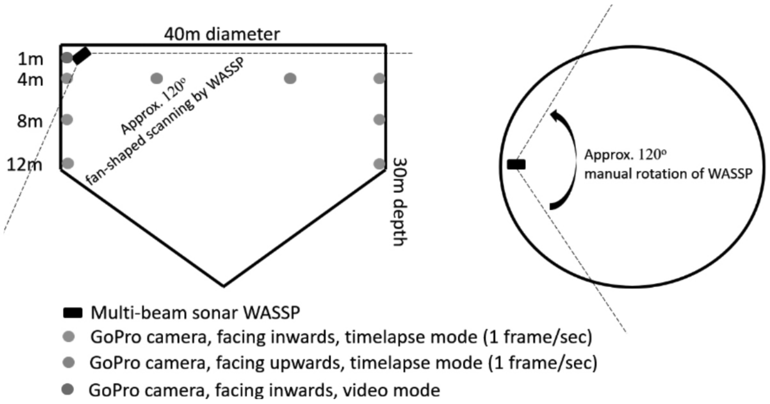

Fig. 1. Illustration of camera deployment and placement and rotation of the multi-beam sonar WASSP. Left: side view of the sea cage. Right: top view of the sea cage.

Discussion

This study shows that the multi-beam sonars have a great potential as a tool to properly monitor salmon distribution patterns in large commercial sea cages. To the best of our knowledge, multi-beam sonars have rarely been used to monitor the salmon distribution in the sea cages, which may be due to the complexity and the enormous size of the data which derives from the instruments. With the use of multi-beam sonar, we can provide more representative information of salmon spatial distribution patterns in large sea cages. We are aware of the potential bias in the sonar data due to shadowing effects by the dense layer of fish. However, it is already shown that WASSP can overcome this challenge. In the future, the rotation of the sonar can be automated so that we can continuously and autonomously monitor salmon distribution patterns and better understand how they react to external and fish-internal factors. From a fish welfare perspective, the use of hydroacoustic monitoring methods such as multi-beam sonar is preferred as it does not require direct handling of fish and applies little stress on fish. Therefore, it is critical to make a continuous effort to apply and refine hydroacoustic tools for the assessment of fish welfare.

Introduction

Animal welfare has become a relevant topic to minimize pain during procedures. Anaesthesia is commonly used in aquaculture and research, but it is necessary to choose the best anaesthetic and the ideal concentration to avoid side effects. Clove oil is a natural anaesthetic alternative to synthetic compounds like MS-222 and 2-phenoxyethanol. Another emerging issue is the use of analgesics, which may improve fish well-being and have synergy effects when anaesthetics are used. This study aims to observe the effect of clove oil (an anaesthetic) and lidocaine (an analgesic) on histological changes in gilthead seabream (*Sparus aurata*) gills.

Materials and Methods

This study was carried out in CETEMARES - Marine and Environmental Sciences Center MARE-Polytechnic of Leiria, Peniche with seabream (61.61 ± 14.57 g). A refinement pre-trial study was performed to determine the best anaesthesia concentration to use. For the trial, an anaesthetic, clove oil (45 mg/L) and an analgesic, lidocaine (2.5 mg/L) were used. With these compounds, two treatments were performed: clove oil (CO) and clove oil + lidocaine (CO + L). The CO + L fish, were first exposed 5 minutes to the analgesic and then set to anaesthesia. Each fish was individually anaesthetised until they reached the deep anaesthesia stage (A5). Then, each fish was transferred to an overdose of the anaesthetic. In each of the treatments (n=10) the gills were sampled for histological analysis. They were fixed in 10% formalin for 24 hours and then transferred to 70% ethanol until processing. Standard histology techniques were used, and sections (5 µm) were stained with Haematoxylin-Eosin. For gill observation, we used, Ortiz-Delgado et al. (2007) protocol, using an optical microscope, Leica DM2000 LED, and the images were captured using a digital camera, Leica MC 170 HD. The percentage obtain corresponds to the number of fish where gill histological changes were observed.

Results and Discussion

The gills are an organ with a large surface of contact with the external environment, through the epithelium, which facilitates monitoring the influence of the aquatic environment on living beings (Marinović et al., 2021).

Through gill histology, it was possible to observe changes in structures (epithelium rupture and lamellar fusion) and morphology (circulatory disorders, lamellar hyperplasia, hypertrophy and hyperplasia from chloride cells) when the anaesthetic was administered, with or without analgesic.

Epithelium rupture was higher when lidocaine was used (80%) comparing with CO (40%). This being the consequence of the addition of one more chemical, causing damage to the gill epithelium, not only because of the concentration but also by a longer exposure time (Reddy & Rawat, 2013).

Chloride cells play a role in ionic transport with the possibility of being involved in detoxification (Mokhtar, 2017). With lidocaine (CO + L) hypertrophy of chloride cells was higher (80%) comparing with single use of CO (50%) probably due to the exposure of another chemical component (Macirella & Brunelli, 2017). Chloride cell hypertrophy can be identified as an adaptive response due to their ionic function to balance with the external environment (Strzyżewska-Worotyńska et al., 2017).

Conclusion

In this study, the use of clove oil as an anaesthetic, and lidocaine as an analgesic showed histological changes in *S. aurata* gills. More tissue changes were presented when using the combination of compounds, due to the increased use of chemical compounds, inducing higher histological changes during exposure.

Introduction

Farmed gilthead seabream (*Sparus aurata*) and common carp (*Cyprinus carpio*) are two of the most valuable commercial fish species produced in Europe, representing, respectively, 16% and 11% of the European aquaculture production and 9% and 7% of the European total apparent consumption (EUMOFA 2020). One third of the world’s population has severe nutritional deficiencies, particularly of iodine (I), selenium (Se), and iron (Fe), which can create adverse effects on human health (Allen et al., 2006). The regular consumption of fish can make an important contribution to make up for the lack of nutrients and in particular to referred micronutrients. Farmed fish is a key resource to meet the increasing seafood demand due to its potential to develop tailor-made biofortified fish products addressing consumers’ nutritional requirements through sustainable, natural, safe, and high-quality feeds (Allen et al., 2006, FAO, 2020). Additionally, consumers’ demand towards easy-to-prepare, ready-to-eat and ready-to-cook food products with extended shelf-life is gaining importance, with frozen products representing 35% of fish and fish products trade (FAO, 2020). The present study aimed to evaluate the effects of frozen storage during 12 months on nutritional values and quality changes of farmed gilthead seabream and common carp biofortified with iodine-rich seaweed (*L. digitata*) and selenium-rich yeast as feed ingredients.

Material and methods

Two diets, (1 control and 1 biofortified with I-rich seaweed and Se-rich yeast) were tested for 3 months in each fish species, simulating a finishing diet period. At the end of the trials, fish were slaughtered following the typical commercial practices. Freezing, glazing and frozen storage were performed according to conventional industrial process, and fillets were collected without skin whenever required. For each treatment, control (CTR) and biofortified (BF), glazed fish fillets (gilthead seabream) or whole fish specimens (common carp) were randomly packed in polyethylene terephthalate (PET) bags and stored in cartoon packages at –20 °C in a frozen food storage chamber over 12 months. Samples ($n = 6$ fish fillets) were taken before (day 0) and after 45, 135, 225 and 360 days of frozen storage. Frozen samples were thawed under refrigeration (4 ± 1 °C) for approximately 12h, and fish fillets were divided in sections for macro, trace and toxic elements content, lipid oxidation (LPO), water holding capacity (WHC), colour and texture analyses.

(Continued on next page)

Results and Conclusions

Results showed that, overall, biofortification strategies through dietary supplementation with I-rich seaweed (*L. digitata*) and Se-rich yeast in gilthead seabream and common carp did not significantly affect the quality parameters during frozen storage. Generally, elements content in seabream fillets were stable, being only found some fluctuations, namely the decreased I content in BF fillets after 135 days of storage, Br content after 45 days and Fe content after 22 days of storage. In general, BF fillets revealed significantly higher contents of I and Se during frozen storage, compared to CTR fillets. Similarly, no specific trend was observed in carp fillets during frozen storage, being only found some fluctuations, namely higher Fe content in BF fillets at days 45 and 360, Ca after 360 days and Cl after 45 days, as well as lower content of As after 135 days of storage. Common carp BF fillets revealed significantly higher contents of I, Se, Zn, Br and As throughout the storage period, compared to CTR fillets. Frozen storage resulted in decreased WHC and increased lipid oxidation (TBARs) values in both BF and CTR gilthead seabream and common carp fillets during 360 days of storage. In terms of colour attributes, no specific trend was observed in both BF and CTR gilthead seabream and common carp fillets. Yet, increased redness and decreased yellowness were observed in BF and CTR gilthead seabream fillets after 45 days of storage, resulting in increased colour intensity. On the other hand, higher lightness and whiteness values were registered in BF common carp fillets, as well as in CTR fillets after 225 days and 45 days of storage, respectively. Overall, the industrial frozen storage did not compromise the nutritional quality of the tested BF gilthead seabream and common carp, particularly in terms of TBARs, WHC, texture and colour, with glazed fillets maintaining good quality during the 360 days of storage at –20 °C.

Introduction

Asian seabass, *Lates calcarifer* is a well-known farmed species with an established market. It is a warm water carnivorous, fast growing euryhaline fish (Schipp et al, 2007). These biological traits together with its consumer acceptance points to the potential for expansion of barramundi farming worldwide (Lawley, 2010). The cultivation of this species in RAS (recirculating aquaculture system) needs further development (Larkin, 2000) and the present study compare the growth performances and morphological – body quality traits of Asian seabass at two different salinity levels, testing also a microalgae extract (*Nannochloropsis gaditana*) for potential benefits to fish growth, health, and fillet traits (Nagappan et al, 2021).

Material and methods

Asian seabass, *Lates calcarifer* (50 fish/tank; initial weight of 64.9 ± 0.1g) reared at two different salinities, 38+/-2ppm (S1) and 14 +/- 2ppm (S2) in RAS. Fish in both systems were fed four times daily to satiation with either a control diet (CTRL) or the CTRL diet supplemented with *N. gaditana* liquid extract top coated at 3% (W/V) (ALG). After the 10 week trial period, a bulk sample weight of all tanks was performed and 8 fish from each tank were sampled to carry out carcass analysis, obtain biometric-morphometric data, as record body quality traits.

Results

At the end of feeding trial, no significant differences were found in the average final weight and SGR among the different treatments. Both treatments reared in S1 had significantly higher FCRs than the FCRs of both treatments reared in S2, compared whilst feed intake of fish in S2 were significantly higher than that of fish fed CTRL (S2)

Although numerical differences were apparent, all biometric, morphometric indexes and fillet yield and quality parameters except VSI were found not to be statistically different between treatments. VSI was significantly higher in fish from S1 compared to S2. Results of body colour intensity (L*, a* and b* coordinate) using a Minolta Chroma-Meters CR-400 cat. 1878-209 showed no significant difference between S1 and S2 in both treatments.

THE EFFECT OF FLOWRATE IN RECIRCULATING AQUACULTURE SYSTEMS ON WATER CHEMISTRY AS IT CONCERNS FEEDING EVENTS OF JUVENILE RAINBOW TROUT (*Oncorhynchus mykiss*)

Jui-Che Chiang, Giovanni Marco Cusimano*, Natalie E. Panasiak, Freya Robinson, Tamás Bardócz, Dannie D. O'Brien

AquaBioTech Group, Research Development and Innovation, Naggar Street, Targa Gap, Mosta, Malta
Email: gmc@aquabt.com

A series of investigations were undertaken related to inlet configuration and flow rate on efficiency of solids removal, maintenance of water quality, and production and welfare indicators in farmed Rainbow trout (*Oncorhynchus mykiss*) in Recirculating Aquaculture Systems (RAS).

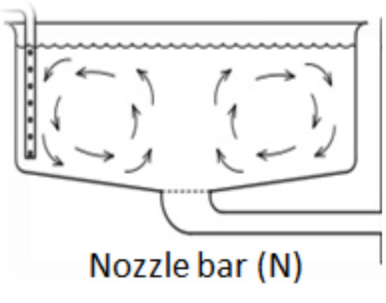
To assess solids removal efficiency of uneaten feed particles during feeding in circular RAS tanks, two inlet design placements (nozzle bar and elbow pipe), and three flowrates were tested including inlet pipe with multiple holes ensuring water input at varying depths (Image 1), and elbow pipe (Image 2) where the angle of inlet was adjusted for water to move parallel to the tank wall (Image 3). Flow rates of 600L/h, 800L/h (normal for trout juveniles), and 1000L/h were investigated, totalling 6 treatments with a combination of variables, inlet type, and flow rate.

In unstocked tanks, feed pellets were distributed at the surface as per normal feeding practice and their movement recorded on overhead video cameras. Primary and secondary flow were assessed, as well as pellet distribution in the tank, settling location at the tank bottom and number of pellets entering the central drain. Primary flow was observed in all treatments and tanks with higher flowrate displayed stronger primary flow in both inlet configurations. Primary flow in the elbow configuration decreased with increasing depth regardless of flow rate. Higher flowrate created stronger secondary flow patterns and the nozzle bar configuration produced higher secondary flow than the elbow pipe, thus, pellets settled earlier than in elbow configured tanks with a nozzle inlet bar. Use of the nozzle bar inlet configuration with higher flowrate showed the most optimal option for waste removal of uneaten feed particles in tested circular RAS tanks.

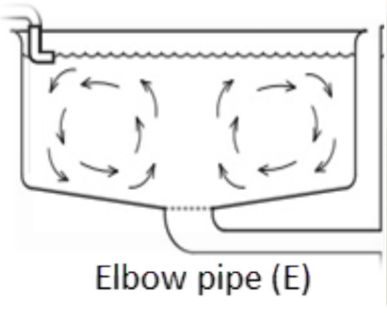
Efficiency of the six treatments for reoxygenation of the system was tested in unstocked tanks by using an oxygen scavenger (Na_2SO_3) to deplete the isolated tanks oxygen level to ~0% and then restoring water flow to assess time needed for each configuration to restore to 100% saturation. At lower flow rates (600L/h) there was a lower reoxygenation rate using the nozzle bar compared with the elbow pipe (N=2), but at higher flow rates the two configurations did not vary significantly and at 1000L/h could achieve tank reoxygenation rates of 1.9 - 3%/min regardless of configuration.

In replicate (3) tanks stocked with 9±0.35g rainbow trout at optimal production conditions (16.5 °C, 1-2ppt salinity, > 6.5 mg/l DO, with automated O_2 injection) considering only the more efficient nozzle bar configuration at the same 3 flow rates (600L/h, 800L/h, 1000L/h), variation in oxygen and CO_2 level were recorded during feeding at 4 samplings over 6 weeks of fish growth. Fish were initially fed at 3% body weight/day, gradually reduced to 2.5%. Feeding was performed by hand 3 times per day at 9.00, 12.00 and 15.00.

1)



2)



3)

(Continued on next page)

Changes to oxygen and CO_2 levels were recorded at 5-minute intervals with a handheld probe from 5 minutes prior to feeding to 1 hour after feeding commenced in the tanks and at the inlet supply. To calculate oxygen consumption during feeding, only the negative data slope was analysed, together with the constant oxygen supply of the system. The oxygen consumption of each treatment during feeding increased significantly as the fish grew and stocking density increased ($P=0.000$), but no difference ($P > 0.05$) was measured within the flow rate treatments in any of the sampling weeks. To calculate CO_2 increase, only the positive data slope was analysed. The carbon dioxide generation changed significantly as fish size, and thus stocking density, increased ($P=0.002$) but no difference was measured among the flow rate treatments in any of the sampling weeks.

Oxygen level was also monitored continually (every 10 mins for 6 weeks) in tanks to detect patterns associated with fish handling events on experimental sampling days. This data showed greater variability in oxygen level, indicating metabolism related oxygen drops and system O_2 injection on days of sampling events compared to non-sampling days, when fish disturbance was only caused by regular husbandry. Additionally, tanks with higher flow rates were shown to mitigate these effects better than tanks with lower flow rates, demonstrating that these higher flow rates assist in homogenising the water environment for fish, and can smooth the effects of handling events on O_2 fluctuations.

Growth performance was assessed for fish in all treatments throughout the experimental period including final weight, FCR, SGR, visual indicators of welfare, as well as condition factor (K) and visceral fat content. Flow rate was not found to have any effect on these factors.

Nozzle-bar inlet placement benefits waste removal performance and best homogenises water quality. Juvenile trout were not negatively affected by higher flowrates regarding either growth performance or welfare, but this is an interesting field of further investigation. Higher flowrates are considered to have better system efficiency in RAS in terms of waste removal and tank reoxygenation rate, further mitigating O_2 stress of fish during growth. Additional studies must establish upper biological limits for fish welfare while considering other interacting factors of RAS.

CONTACT PLATES DESIGNED FOR PRACTICAL USE IN HATCHERIES: POST-LARVAE AND SPAT SAMPLES

J.L. Barja[1]*, B. Suárez[1], A. Villada[2], S. Nóvoa[2], S. Prado[1]

Introduction

Nowadays, hatcheries are essential to sustain bivalve aquaculture. In addition to the larval stage, these facilities must maintain the individuals in culture until they reach the appropriate size to be taken to the outside environment. From the time of attachment and metamorphosis, the specimens are handled as little as possible. The culture usually takes place in bins with forced flow or, in species such as razor clams, buried in sand. During this phase there are episodes of mortalities that should be investigated, since they represent an important economic loss, considering the advanced stage of the culture.

Sampling for microbiological control in hatcheries should include simple procedures that are easy to use by personnel, without the need for complex specific training. In addition, they should be fast processes, given the volume of work in these facilities during peak production periods.

Materials and methods

The USC team developed contact plates, of their own design, based on Marine Agar and Thiosulphate-Citrate-Bile-Sucrose (TCBS) media, commonly used in microbiological controls in the hatchery. The objective was to determine their usefulness for direct sampling of bivalve seed and to evaluate their ability to detect bacterial pathogens.

The Centro de Cultivos Mariños carried out tests with specimens of *Venerupis corrugata* (pulled carpet clam), *Ruditapes decussatu*s (grooved carpet shell) and *Ensis magnus* (razor clam). The samples were taken according to production requirements and routine protocols, comprising sizes between 180*µ* and 6 mm.

Further processing was carried out by the USC-team. Bacterial isolation, preservation and identification of isolates followed the methodologies described in Prado et al. (2014).

Results and discussion

The plates proved to be suitable for processing the individuals, regardless of size, within the tested range.

The presence of known bacterial pathogens in aquaculture could be detected in the processed samples, such as *Vibrio splendidus*-like (VSL), *V. tapetis*, *V. ostreicida*, *V. alginolyticus*, *V. europaeus*, *V. mediterranei*.

The results demonstrate that the designed contact plates are suitable for simple and rapid sampling in the hatchery, with minimal handling of the individuals, to obtain useful results that allow the identification of marine aquaculture bacterial pathogens.

They therefore fulfil one of the objectives of their design, although it should be noted that the post-processing of the samples obtained can be somewhat more complex than that of standard plates and must be carried out by specialised personnel.

Introduction

Bivalve mollusc aquaculture currently needs the supply of hatchery-produced seed to sustain its activity. In addition to larval culture, it is necessary to address pre-fattening, in facilities on land with forced flow or in floating structures ("bateas") with passive flow.

The IGaFA has a mini-hatchery facility with a light greenhouse-type structure for the cultivation of seed of molluscs of commercial interest in Galicia (NW Spain). In this work, we report the results of a pre-fattening trial of pulled carpet clam, *Venerupis corrugata*, in raft at different densities are shown. During development, mortalities were recorded that do not seem to be justified by the densities tested. Given the importance of bacterial pathogens in bivalve mortalities, in larval culture, but also in an external environment, a microbiological study was carried out to evaluate the possible role of bacterial pathogens in the losses suffered.

Materials and methods

At the facilities of the IGaFA, belonging to the Consellería do Mar-Xunta de Galicia, located in Illa de Arousa (Pontevedra, Spain), the hatchery culture of the species *Venerupis corrugata* (Gmelin, 1791) was carried out up to the seed stage.

Two batches of reproductive specimens from the natural bank of "O Bohido" in the Illa de Arousa, which were induced to spawn by thermal shock, were used as the starting point (November 2021). Both batches were developed in the hatchery and the nursery, following the routine procedures, until March 2022, when they were transferred to the outside environment, to a "batea" (raft) in the sea.

On 30/06/22 an experience of seed culture was started with both batches. Cylindrical lanterns with a diameter of 40 cm and 2 mm mesh were used. To determine the possible culture results, using different densities, a trial was designed in which a total of 9 lanterns were used to test 3 different densities (2.000 individuals per floor, 1.000 individuals per floor and 500 individuals per floor). In each lantern, three floors were arranged at the same test density, with floor 1 being the shallowest part of the water column and floor 3 the deepest. The maximum density tested of 2.000 individuals per floor corresponds to 1.591 indiv/cm^2, and the following ones to 0.795 indiv/cm^2, and 0.397 indiv/cm^2, respectively.

On August, the mortality rates in each compartment were recorded. Bacteriological samples were taken and processed in situ, using contact plates designed by USC-team, with Marine Agar (MA) and Tiosulphate-Citrate-Bile-Sucrose. Further processing is carried out by the USC-team. Bacterial isolation, preservation and identification of isolates followed the methodologies described in Prado et al. (2014).

Table 1. Mortality rates in the lanterns at the different densities assayed (high, medium, low) and on the floors within each (upper, middle, lower) recorded after one month.

DENSITY	FLOOR		
	Upper	Middle	Lower
High	0	17.50	46.15
Medium	45.20	58.40	21.60
Low	26.20	32.20	52.20

(Continued on next page)

Results

The sampling carried out on August showed the mortality rates detailed in Table 1.

On the basis of the preliminary mortality data recorded, it does not appear that density can be responsible for the deleterious effects detected.

Preliminary results of microbiological analyses recorded a high presence of vibrios in the samples, including pathogens: *Vibrio ostreicida*, *V. alginolyticus-V. parahaemolyticus*, *V. mediterranei*. Their distribution pattern, as well as the presence of other taxa, is being studied to assess a possible role in the recorded mortalities.

Recent findings from our lab suggest that, contrary to the long-standing paradigm, fish do not have an under-developed immune system compared to mammals. However, because fish lack endogenous metabolic-driven endothermy, they require movement to/from warmer temperatures at different stages of disease to activate protective antimicrobial mechanisms. These dynamic temperature changes are at the core of the crosstalk between fish, pathogens and the environment. Thermal promotion of immune competence is achieved through a combination of earlier, tailored defenses that are quickly followed by efficient inflammation control. This allows for both enhanced antimicrobial protection as well as efficient use of energy resources. Together, this represents an important shift in our understanding of fish immunity and has major applied implications for the aquaculture sector. This presentation will describe salient contributions of thermoregulation during an *Aeromonas* infection, with a focus on restoration of barrier integrity following cutaneous tissue damage.

DIETARY ADDITIVES SUPPLEMENTED IN INERT MICRODIETS CAN MODULATE THE EXPRESSION OF IMMUNITY RELATED GENES OF WHITELEG SHRIMP (*Penaeus vannamei*) POST-LARVAE

Introduction

The whiteleg shrimp (*Penaeus vannamei*) is currently the second most representative animal species in aquaculture, constituting in 2018 a share of 6% in global production. To meet the market demands, whiteleg shrimp larvae and post-larvae (PL) yields in hatcheries increased intensively, globally originating around five million tonnes of adult individuals per year. Nevertheless, initial developmental stages are critical and frequently associated with sub-optimal growth and low survivals, which, in some cases, can be related with nutritional deficiencies or infections by opportunistic pathogens. Hence, problems in larviculture can have an enormous impact on shrimp performance in the long-term, affecting the downstream production of high-quality juveniles and adults. In fact, industrial shrimp farming is characterized by inconsistent yields as it is extremely susceptible to severe pathogenic episodes that result in disastrous consequences to production and significant economic losses (Kibenge, 2019; Shinn et al., 2018; Zou et al., 2020). Besides the fact that shrimp cannot be vaccinated, the use of antibiotics in the aquaculture industry is limited due to inherent food safety concerns, environmental issues, and the increased antimicrobial resistance (Lulijwa et al., 2020). Consequently, the use of functional dietary additives to stimulate the shrimp immune system has been studied as a prophylactic alternative and is regarded as an extremely important strategy to overcome the constrains of intensive shrimp farming. However, information is scarce regarding the effects of using dietary additives for the shrimp early life stages of development and how it could potentially benefit whiteleg shrimp larviculture. Therefore, this study aimed to evaluate the effects of several health promoting nutrients and additives (i.e. vitamins C and E, beta-glucans, taurine and methionine) supplemented in microdiets on the growth performance, oxidative status, immune condition and gene expression of whiteleg shrimp post-larvae.

Methods

Four experimental microdiets were evaluated in triplicates. A commercial like diet was used as positive control (PC), whereas three experimental diets were formulated based on the PC diet. A negative control diet (NC) presented lower supplementation levels of vitamin C and E; the PC diet supplemented with taurine plus methionine (T+M); and the PC diet supplemented with β-glucans (BG). Whiteleg shrimp post-larvae (mean wet weight 9 mg) were kept at around 28 ºC and fed *ad libitum* for 18 days. At the end of the trial, shrimp were weighted for growth performance determination and samples were collected to assess oxidative status, immune condition and gene expression.

Results and discussion

Increasing the Vitamin C and E supplementation levels in the PC treatment did not produce any changes in growth performance, survival, immune and antioxidant parameters when compared to the NC diet. However, the relative expression of the *pen-3* gene in shrimp fed the NC diet was lower than in those fed the PC diet, suggesting that increasing the levels of these vitamins may improve the shrimp resistance to pathogenic agents, as penaeidins have antibacterial and antifungal activities.

PL fed with the T+M diet showed similar growth performances, survival, oxidative status and immune condition to those fed the PC diet but showed significantly higher relative expressions of the gene *crus*, and significantly lower relative expressions of the gene *hmc*, when compared to those fed the NC diet. On one hand, the supplementation of taurine and methionine seems to compensate the decrease of vitamin C and E levels in the diet and increase the shrimp immune response through higher levels of *crus* expression, but on the other hand, the expression of the *hmc* gene decreased.

The inclusion of β-glucans in the diets did not affect the PL growth performance and survival. Nonetheless, lipid peroxidation levels were significantly lower when compared to those fed the PC diet, suggesting that β-glucans conferred antioxidant properties to the diet. When compared to the NC diet, PL fed with BG showed significant increases in tGSH activity levels and in the relative expression of genes *crus* and *pen-3*, suggesting that the β-glucans supplementation can boost the antioxidant capacity and immune condition of whiteleg shrimp PL when the levels of vitamins C and E are reduced.

(Continued on next page)

In conclusion, the results obtained in this study demonstrate that although no improvements in growth performance and survival were observed, all dietary additives tested have the potential to add value to inert microdiets for whiteleg shrimp PL. Amongst the additives tested, the inclusion of β-glucans in the diets seems to be the most promising one as it reduced lipid peroxidation in the shrimp when compared to the commercial-like diet.

Introduction

The annual production of crustaceans has recorded over 9.4 million tons, which is valued at about US$ 69.3 billion (FAO, 2020). However, this growing industry, which is dominated by penaeid shrimps is significantly impacted by disease outbreaks. Acute hepatopancreatic necrosis disease (AHPND) is one of them caused by *Vibrio parahaemolyticus*. To prevent the occurrence of AHPND in shrimps, there has been an increasing effort in developing anti-infective strategies. In this context, nutraceuticals derived from plant sources (e.g. ginger) are being increasingly studied for their disease control biological potential, with the aim to use them as anti-AHPND agents as an alternative to unsustainable chemotherapeutics, such as antibiotics. The plant-based nutraceuticals are non-toxic, biodegradable, and biocompatible (Citarasu, 2010). In the present study, gnotobiotic *Artemia* was used as a biological model to determine the prophylactic potential of ginger extract (GE) against AHPND-causing *V. parahaemolyticus*.

Materials and Methods

At first, a toxicity assay was performed in which *Artemia* were pretreated with increasing concentrations (84, 125, 167, 208, 250, 333 ug/ml) of GE. Non-pretreated *Artemia* were maintained as a control. Secondly, an *Artemia* challenge test was performed using selected non-toxic doses of GE, and as a readout, the survival of *Artemia* challenged with *V. parahemolyticus* was recorded. The dose that showed the most prominent anti-AHPND effect was selected to study the mode of action of GE by focusing on the host *Artemia* immune responses, which include heat shock protein, prophenoloxidase, transglutaminase, peroxinectin, and superoxidase dismutase using qPCR assay. The toxicity and challenge assays were performed in quintuplicate.

Results

The results showed that pretreatment of *Artemia* larvae with GE at a dose of 250 ug/ml led to significant protection of the larvae upon challenge with AHPND-causing *V. parahemolyticus*. Our results also showed that the increase in the survival of the pretreated larvae was associated with a significant increase in the expression of a core set of genes associated with the defense system of *Artemia* i.e. heat shock protein 90, lipopolysaccharide and β-1,3-glucan-binding protein, prophenoloxidase, peroxinectin, superoxide dismutase, transglutaminase1. From the overall results, it can be concluded that ginger extract could strongly enhance the resistance of the host *Artemia* against *V. parahaemolyticus* and thus can be used as a potentially effective prophylactic agent for controlling AHPND in farmed shrimps.

Introduction

Over the last decade, the study of the impact of insect meal-based diets on growth performance and voluntary feed intake of several fish species have emerged, but little is known about their influence on fish appetite. Food intake could be regulated immediately after the first meal with a dietary treatment (short-term regulation), after several days of feeding (mid-term regulation), or after longer feeding periods (weeks, months, or years) reflecting the energy balance of the animal (long-term regulation) (Soengas, 2014). Understanding the underlying mechanisms responsible for central regulation of feeding behavior in fish, namely stimulation (orexigenic) or inhibition (anorexigenic) of appetite is crucial for proper formulation of aquafeeds and consequently ensure the best growth performance of fish. There are evidences that in fish, as in mammals, the key neuropeptides involved in orexigenic action are neuropeptide Y (NPY) and agouti-related protein (AgRP), while those involved in anorexigenic action are cocaine-amphetamine related transcript (CART), and pro-opiomelanocortin (POMC) (Soengas et al., 2018). According to our previous study (Basto et al., 2021), up to 80% fishmeal (FM) replacement by defatted *Tenebrio molitor* larvae meal (*d*TM) (36% *d*TM inclusion) does not affect central homeostatic regulation of food intake of European sea bass (*Dicentrarchus labrax*). However, the study was carried out after 10 weeks of feeding and possible changes in mechanisms involved in the short-and mid-term regulation of food intake remained unknown. In this context, this is the first study evaluating short- and mid-term homeostatic regulation of food intake in European sea bass fed diets not only with partial, but also total FM replacement by *d*TM.

Material and methods

A FM-based diet with 40% FM (47% crude protein) was used as control (CTRL) and two other diets were formulated to include 20% and 40% of *d*TM, replacing 50% (TM50) and 100% (TM100) of FM, respectively. After a 1-month acclimation period, fish were fasted for 24 hours before the experimental trial began to ensure that the basal levels of metabolites involved in the regulation of food intake were achieved. To evaluate the short-term response fish were fed for the first time with the experimental diets and sampled 2 and 24 hours post-feeding. To evaluate the mid-term response fish were fed three times a day and were sampled 2 and 24 hours post-feeding on the seventh day of experiment. In both short- and mid-term trials food intake was registered; hepatic and plasmatic metabolites and the expression of hypothalamic and telencephalic neuropeptides involved in food intake (NPY, AgRP, CART and POMC) were assessed.

Results

The dietary inclusion of *d*TM did not significantly affect fish food intake, neither at short- nor at mid-term. Accordingly, at central level, dietary treatments did not alter the expression of neuropeptide Y (*npy*), agouti-related protein 2 (*agrp2*), pro-opio melanocortin a (*pomca*) or cocaine- and amphetamine-related transcript 2 (*cartpt2*) in hypothalamus and telencephalon, neither in the short- nor in the mid-term. Despite no changes were observed in neuropeptides, the dietary inclusion of *d*TM induced some alterations in hepatic and plasmatic metabolites levels, either in the short- or mid-term. In the short-term, fish fed diets with total FM replacement by *d*TM had the highest glucose levels in the liver, whereas the α-amino acids were the lowest. After 7 days of feeding, specifically 24 hours after feeding the last meal, fish fed TM50 had significantly higher levels of glucose in liver than those fed CTRL and TM100, whereas hepatic triglycerides levels were significantly increased when fish fed TM100, irrespective post-feeding sampling time. Still in the mid-term response, the levels of α-amino acids in liver did not change with dietary treatment nor post-feeding sampling time. But 2 hours after feeding, the α-amino acids levels in plasma of fish fed TM100 were significantly lower than those fed CTRL and TM50.

(Continued on next page)

Discussion and conclusion

The results of the present study showed that the partial and total replacement of FM by *d*TM did not change food intake of European sea bass. The mRNA abundance of neuropeptides involved in the homeostatic regulation of food intake in both the hypothalamus and telencephalon remained unaffected in the short- or mid-term. Though, several changes in hepatic and plasmatic metabolites levels were observed, which may have negative effects on growth performance and/or health status of fish at the long-term. Thus, further studies are necessary to clarify such possible impact on intermediary metabolism of fish to provide further support for the use of *d*TM as a relevant ingredient in the formulation of more sustainable aquafeeds for European sea bass aquaculture.

*E-mail: patricia.diogo@necton.pt

Introduction

Rotifers are essential for the nutrition of marine fish during their early life stages. However, rotifers nutritional requirements are still poorly understood. It is known that *Nannochloropsis* sp. is a microalgae species that promotes high growth efficiency of *Brachionus plicatilis* when adequate environmental conditions are provided. The expansion of the aquaculture sector has led to the intensification of rotifers production, thus increasing microalgae requirements in nurseries. Consequently, the use of industrially produced *Nannochloropsis* sp. products for rotifers nutrition expanded in the past decade (e.g. Phytobloom® Green Formula). The efficacy of the products on rotifers growth depends not only on the microalgae product biochemical profile, but also on its daily dosage adjusted to the rotifers concentration, mode of production and type of aquaculture system. The increase of the daily dosages must be conducted while monitoring systematically the quality of the water in order to establish mitigation strategies and to avoid potential deterioration of the water quality, which is responsible for the reduction of growth efficiency of the population. The objective of this study was to optimize the daily dosage of microalgae liquid concentrate of *Nannochloropsis* sp. (Phytobloom® Green Formula) in rotifers culture in a batch system.

Material and Methods

Different doses of commercial *Nannochloropsis* sp. liquid concentrate (18% dry weight) (Phytobloom® Green formula, Necton, Portugal) were applied in rotifers culture under batch production mode (4 days). Rotifers were cultured in 1.2m^3 cylindroconical tanks with aeration and oxygen with a temperature of 28ºC, 20ppt of salinity and a pH between 7.5-8. Rotifers concentration and percentage of rotifers with eggs were evaluated daily and the dosage adjusted according to the total number of rotifers in the tank. The environmental quality parameters were evaluated daily and the number of purges were increase from 2 to 3 during the experiment and applied throughout the day to remove the debris and maintain high water quality. The different feeding dosages were applied in several batches of rotifers (3-8) to evaluate the efficiency of each dietary protocol (Table 1).

Results and Discussion

The feeding protocols 4, 6 and 7 improved significantly the total number of rotifers obtained in comparison to protocols 1 and 2 (Figure 1A). There were no significant differences in the percentage of rotifers with eggs between treatments (Figure 1B). The 3rd day of batch presents significantly higher number of rotifers when compared the 1st and 2nd day of batch. Rotifers growth was significantly higher in the 4th day of batch when compared to the other days.

Throughout the experiment it was possible to observe that with the increase of the feed dosage there was a slight increase on the ammonia levels. This effect was strategically mitigated by the increase of the number of daily purges (2 to 3). Therefore, the optimization of the rotifers feeding dosages should be performed with a high control of the environmental parameters such as ammonia levels, and with the application of methodological strategies. Moreover, the control of the ammonia levels in rotifers culture is essential to avoid the inhibition of reproduction (3mg/L) (Schlüter & Groeneweg, 1985) and potentially culture crash. The application of the protocols 4, 6 and 7 improve the total number of rotifers obtained in comparison with the previously established protocol (dosage 1). In conclusion, the present study allowed to improve the application of industrially produced microalgae diets for rotifers in high density cultures for aquaculture.

Introduction

Infectious diseases are one of the biggest burdens in the growing aquaculture industry (Assefa and Abunna, 2018). Globally, antibiotics are widely used to treat and prevent bacterial diseases. However, due to increasing prevalence of antibiotic resistance, their use can potentially severely harm the environment, humans, and/or reduce treatment efficiency (Dawood, Koshio and Esteban, 2018)). Therefore, novel alternative strategies to improve fish health and increase disease resistance are urgently needed. The carotenoid astaxanthin is a widely used feed supplement with well-known health benefits for the host and used as a/or colourant for fish flesh/skin. However, due to high productions cost, its use is restricted to high-value species (Lim *et al*., 2018). In the following experimental study, we are testing a novel two-species probiotic - *Bacillus indicus* and *B. subtilis* - as a potential alternative health supplement to astaxanthin in mirror carp (*Cyprinus carpio*). The main goal of the study was to use experimental feed trials and 16 S rRNA microbiome profiling to compare the effects of B. indicus and traditional astaxanthin supplementation on fish performance and health, based on the overall microbial community of the gastrointestinal tract.

Materials and methods

Mirror carp (*Cyprinus carpio)* with an average weight of 40 g were fed for 7 weeks in triplicate groups on one of three experimental diets (negative control: no supplement, probiotic: 0.36 g/kg *B.indicus* + 1 g/kg *B.subtilis,* positive control: 40mg/kg astaxanthin). Fish were raised in a recirculation aquaculture system (RAS, 12 x 200L tanks, Pontus Research) at 21 °C and 12:12 h light: dark regime. Batch weights for fish growth performance were taken throughout the trial (weeks 0, 4, and 7). At the end of the trial blood samples were taken from 5 fish per tank (20 per treatment) for haematological and immunological analysis. For the microbial analysis, a swab sample from the distal intestine of the carp was taken from 3 fish per tank (16 per treatment group). The swab samples were processed at Bangor University following standard procedures of 16S rRNA metabarcoding. Sequencing data were processed in the quime2 pipeline and results were tested for significance using R software packages.

Results

Over the 7-week carp trial, fish fed the probiotic showed a greater specific growth rate (SGR) compared to the control, however not significant. Fish fed astaxanthin demonstrated significantly increased SGR. The haematological and immunological analysis showed significant results in fish fed the probiotic (e.g., increased phagocytic activity). In carp, we found that both treatment groups significantly increased microbial diversity in the distal intestine (Figure 1). The probiotic increased the abundance of potentially beneficial bacteria including *Bacillus spp*.. Overall, the probiotic blend induced a wider community shift compared to astaxanthin. Out of all (37) significant differentially abundant genera, 51.4 % (19) are shared between both supplements, while 45.7 % (17) of the genera are only differentially abundant in the probiotic. One genus was exclusively found more abundant in Astaxanthin. In addition, a greater number of bacteria metabolic pathways were altered in carp fed the probiotic compared to astaxanthin. However, during the microbial analysis, the probiotic bacteria species could not be detected in the distal intestine.

Conclusion

The probiotic supplement *B.Indicus*/*B.subtilis* significantly increased gut microbial diversity in carp, similar to astaxanthin supplementation. However, the probiotic induced greater changes in abundance across the microbial community. Increased microbiome diversity is likely linked to healthier fish (Li *et al*., 2017; de Bruijn *et al*., 2018) for example, our bloodwork analyses demonstrated significantly increased phagocytic activity in fish fed the probiotic, indicating an increased immune response. Despite changes in the microbial community, we could not specifically detect the probiotic bacteria species in the gut region studied. This suggests that the probiotic could not colonise the distal intestine of this host species. However, based on the significant outcomes in fish fed the probiotic, it is possible the probiotic is established in a different part of the gastrointestinal tract, or alters the host gut microbiome during its passage through the gut. Overall, we conclude that the *B.inidicus/subtilis* probiotic has great potential to be used as a replacement for astaxanthin. However, further research is required to understand the mechanisms of *Bacillus spp*. probiotic establishment in fish gastrointestinal microbiomes, and the consequences for fish health.

SOCIO-ECONOMIC CHALLENGES OF THE AQUACULTURE SECTOR IN THE ATLANTIC AREA AND THE POTENTIAL OF INTEGRATED MULTI-TROPHIC AQUACULTURE AS A SUSTAINABLE APPROACH: ASTRAL PROJECT

N. Beaume*, J. Carvajal, R. Le Vaillant, O. Denoual

Pôle Mer Bretagne Atlantique, 525 avenue Alexis de Rochon, 29280 Plouzané (France)
E-mail : nolwenn.beaume@polemer-ba.com

Introduction

Consumption of seafood has grown twice as fast as the population since the 1960s (OECD[1]). When facing with this rising demand, aquaculture stands-out as a response to the need to increase aquatic and seafood production. In fact, according to FAO, world aquaculture production reached an all-time high of 114.5 million tons with a total farm gate sale value of USD 263,6 billion in 2018. This aquaculture growth all over the world and its intensive production causes a significant set of problems (i.e., creation of an anoxic zone, reduction in water quality, destruction of habitat, use of antibiotics, amongst others). In order to meet these demands, the sector must develop innovative, responsible and profitable cultivation methods to optimize efficiency and reach societal requirements. In this context, the Integrated Multi-Trophic Aquaculture (IMTA) farming is a promising system to tackle some of the aquaculture challenges to build up a more sustainable blue economy; in that regard, the EC has funded some projects and the Horizon 2020 project, ASTRAL, is one of them. ASTRAL focuses in IMTA farming as a possible alternative to develop a sustainable, profitable and resilient aquaculture. The project objectives include defining, supporting and promoting IMTA production across the Atlantic area and to identify new value chains. A socio-economic assessment is key to support those objectives and highlight challenges and barriers of aquaculture and the IMTA possible solution approach; here are some of the preliminary results and perspectives of the project.

Methodology

The socio-economic analysis aimed to draw up a state of the art of the aquaculture in the Atlantic area, especially in the ten ASTRAL involved countries: Norway, Spain, France, Portugal, Ireland, United Kingdom (Scotland), Brazil, Argentina, South Africa and Nigeria. This study highlights the main characteristics of the aquaculture sector and the main challenges that it faces. It gives key elements to understand the aquaculture context and provides a framework to enable as a funnel to refine the analysis level.

The methodology used was based on:

- the territory and regional knowledge (macro and meso economic approach) thanks to a strong bibliographic review per country,
- producers' knowledge (meso and micro economic approach) thanks to a survey and preliminary results of producers' one-to-one interviews.

Technology and Innovation

Technology developments and advancements have modernized and upgraded the processes efficiency, product quality and competitiveness in the aquaculture industry. However, access to the latest technology and practices for aquaculture farmers in some countries remains a challenge due to a lack of information, training and capital. The ASTRAL project assesses 6 technologies that are deployed in IMTA systems to identify the systems needs and added value of the species combination throughout the production cycles, developing operation welfare indices (health management), assessing risk of pathogen infection (biosecurity) and profitability. The knowledge transfer will be beneficial to suggest new and suitable IMTA combinations considering the regional challenges.

Economic challenges

In an increasingly competitive environment, farmers must enhance efficiency and profitability when using economic resources. Owning an aquaculture facility can be expensive because of the structure costs to fully develop aquaculture businesses differ depending on aquaculture types and species as well as fixed and variable costs.

(Continued on next page)

Some IMTA research studies have shown economic advantages in comparison with non-IMTA systems, including increased physical production from a given site, greater diversity of production, and more intensive use of facilities, labour and sites (D. Knowler al., 2020). A more concrete study discounted cash flow analysis using 10 years of production data from a salmon-mussel-kelp IMTA farm in the Bay of Fundy, Canada. It found that the IMTA operation was more profitable than standard monoculture expectations and, if a 10% price premium could be obtained for the product, IMTA would produce a substantial increase in net present value (Eumofa, 2020). The advantages must be balanced with the potential economic disadvantages such as greater complexity in terms of marketing (outlets for the different species, operations, juveniles, business planning; and regulatory (potential increase of requirements), more risks, and greater challenges in the site selection. The ASTRAL project contributes to obtain data of this process and bring the experience of the five labs in Scotland, Ireland, Brazil, Southern Africa and Argentina.

Social challenges

Aquaculture plays a key role in urban and rural communities, and in local economies. The development of human resources both in quality and quantity is crucial to sustain the aquaculture industry in the future, especially in the context of increasing complexity ecosystems and changing paradigms. From the perspective of developing IMTA production, it is difficult to gather all the know-how required to cultivate several species within one system. The difficulty of mastering the cultivation of several species at the same time appears to be a major obstacle to the IMTA development. However, IMTA can be a good solution with regards to the social acceptability of aquaculture, once the concept is clearly explained. More social science research on aquaculture is needed, particularly to better understand the influence on consumers' perceptions.

Conclusion

The aquaculture sector is facing a lot of challenges that will need to be tackled in a near future: climate change, rising production costs, sustainable fish feed, working conditions and spatial planning. IMTA can be one of the options to limit these challenges by operating effluent biomitigation, optimizing energy in a production loop, promoting responsible businesses and optimizing the space availability/needs, to appear as a flexible approach according to the types of species, the production sites and the production systems.

However, IMTA is still facing barriers and meeting challenges that might explain its low development in the Atlantic area, such as resistance to change, complexity of setting-up, added costs and efforts and the lack of economic performance demonstration. Within ASTRAL we hope to contribute to this economic and societal assessment.

The ASTRAL project has received funding from the EU Horizon 2020 Research & Innovation Programme under Grant Agreement n°863034

Organisation for Economic Co-operation and development

PRESERVATION OF THE DONETS RUFFE *Gymnocephalus acerinus* POPULATION IN UKRAINE

V. Bekh, M. Zadorozhniy

Aquaculture Department, National University of Life and Environmental Sciences of Ukraine
Generala Rodimtseva 19, Kyiv, 03041 (Ukraine)
Email: vitbekh@gmail.com

At present, 69 species of fish are included in the Red List of Ukraine, the reasons for this position are the disappearance of typical habitats and as a result of changes in hydrological, chemical, biological regimes of water bodies caused by hydraulic engineering construction; water pollution, accidental uncontrolled fishing by amateur fishermen.

In recent years, the problems of conservation of aboriginal species are paid great attention. In particular, this applies to Donets ruffe *Gymnocephalus acerinus* rheophilic species, preserved in some places in rivers where there are no hydraulic structures, for example in the Desna river basin. One of the effective ways to preserve this species is artificial reproduction in aquaculture and further restocking in natural reservoirs. In EU countries, such work is often done by National Parks, universities, research institutions and private enterprises, which work not only with commercial species, but also with small and endangered fish and developing methods for restoring aboriginal species populations in natural bodies of water. In practice, Ukraine has already had successful attempts to reproduce endangered species in artificial conditions, one of which is a set of research projects on the conservation of umbra (*Umbra krameri*) in Moldova and Ukraine, conducted by the Ecological Union “BIOTICA” with the support of the project “Conservation of Endemic European umbra in the lower parts of the Dniester-river”, supported by the British organization Flora & Fauna International. The experiments have been conducted since the early 2000s. According to this technology, fish were caught from natural reservoirs, placed in pre-prepared aquariums, which maintained the necessary hydrological regime for this species and created places for natural spawning, and then the resulting fry were released into the reservoir to create a local natural population.

Within the framework of the scientific program on artificial reproduction of the *Gymnocephalus acerinus* it is planned:
2.1 Low-traumatic catch of broodstock and juveniles from their natural habitats.
2.2 Timely delivery of harvested broodstock and fish of different ages to the center of aquatic bioresources and aquaculture NULES of Ukraine. Creation of artificial habitats close to natural ones.
2.3 Domestication (feeding live and artificial feed, preparation for spawning and artificial reproduction).
2.4 Carrying out artificial reproduction.
2.5 Growing fry and fingerlings to viable stages.
2.6 Stocking and restoration of natural populations in the native area.

At present time scientists of the National University of Life and Environmental Sciences of Ukraine have searched for the locations of *Gymnocephalus acerinus* in the Desna River and planned to catch and further domesticate it.

NON-INVASIVE (PHOTO) INDIVIDUAL FISH IDENTIFICATION OPEN ACCESS LARGE DATA BASE

Dinara Bekkozhayeva, Petr Cisar

Laboratory of Signal and Image Processing, Institute of Complex Systems, Faculty of Fisheries and Protection of Waters, CENAKVA, University of South Bohemia in Ceske Budejovice
Zámek 136, Nové Hrady 373 33, Czech Republic

Introduction

The idea of the precision fish farming concept (Føre et al., 2018) is the automatization of the farming process, which can help control, monitor, and document the biological processes of fish cultivation. One of the optimization ways of the precision fish farming concept is finding an opportunity to get the individualized information about fish. The farmers could have personalized information about each fish in the tank (cage). Identification of individual fish could open a lot of possible solutions for the fish farmers. With the individualized information about fish, the processes of fish production could be more profitable. It helps deceases early detection, which could predict the high mortality. The identification of individuals could be a substitute for the fish tagging method (Andrews, 2004). This method is harmful and stressful for the fish. Fish has to be caught for identification which is time-consuming (Rácz et al., 2021). Non-invasive fish identification (photo-identification) is cheap and faster. The critical part of for individual fish identification method development is the large fish individuals dataset. We collected a large dataset of four fish species and provided it as an open access database for the researchers all over the world to play with and test their own methods on our data sets.. Those data sets were used for developmentof our own approaches for the identification of fish individuals. With the use of those data, three papers were published. One paper (European seabass and common carp) is under submitted status.

Materials and methods

Database is available on our data management platform – bioWES (http://www.biowes.org/). bioWES is a platform for experimental data and metadata management. General protocol (individual fish identification) obtains four different protocols for four fish species. Dataset of four fish species were collected,: Atlantic salmon *Salmo salar*, Sumatra barb *Puntigrus tetrazona*, European seabass, and common carp (Fig.1). Each protocol has two subprotocols. One is a protocol with the original data (data collection) and another one is protocol with the processed data. Some protocols end with the final protocol which have a final paper which was published according to the used data. Below are chapters with the description of four experiments (protocols).

Atlantic salmon - A total of 328 fish were used for short-term identification to test the identification power of the pattern. Thirty of the fish were tagged with PIT tags and used for long-term identification to test pattern stability. A total of 4 data collections were performed over six months at two months intervals. Three types of data were taken in each session: lateral view images of the fish out of the water (in a photographic tent) and underwater (in a small aquarium) and iris of the fisheye. The NIKON D90 digital camera was used to take approximately eight images of each fish in RAW format. Images of the 30-tagged fish were also collected as the long-term dataset during the next six months. The regions of interest (ROIs) were automatically extracted for all images in all datasets using image processing methods.

Sumatra barb - 25 fish individuals of Sumatra barb were used in this experiment. The digital camera with controlled lighting, the background, and the fish position, was used for data collection. Data were collected under different angles and positions; images were taken from one side view of all fish. Data were collected two times during two weeks for fish inside the aquarium. Tree images of each individual were taken in every data collection. The fish detection procedure consists of standard image segmentation based on color subtraction, object detection, filtration, and parametrization.

European seabass - Totally 300 sea bass were used during the experiment. All 300 fish were used for the testing the uniqueness of the visible patterns of the fish for identification of the individuals (short term experiment (ST)). Randomly selected 32 fish individuals out of the 300 fish were tagged by PIT tags for the long-term experiment (LT) to test the stability of chosen patterns during the cultivation period. After two months, the second data collection was performed. Four different ROI (regions of interest) were used for identification. All ROIs were detected automatically in the fish image.

Common carp - Four rounds of data collection were performed over the four-month experiment for carp identification. Thirty-two fish individuals were used in this experiment. Images were taken of the whole fish out of water. Each fish was caught in the cultivation tank, anesthetized in a bucket using clove oil, and moved to the green background for imaging. Automatic data processing consisted of three steps: fish detection, region of interest (ROI) selection, and feature extraction to describe the skin patterns of the ROI.

(Continued on next page)

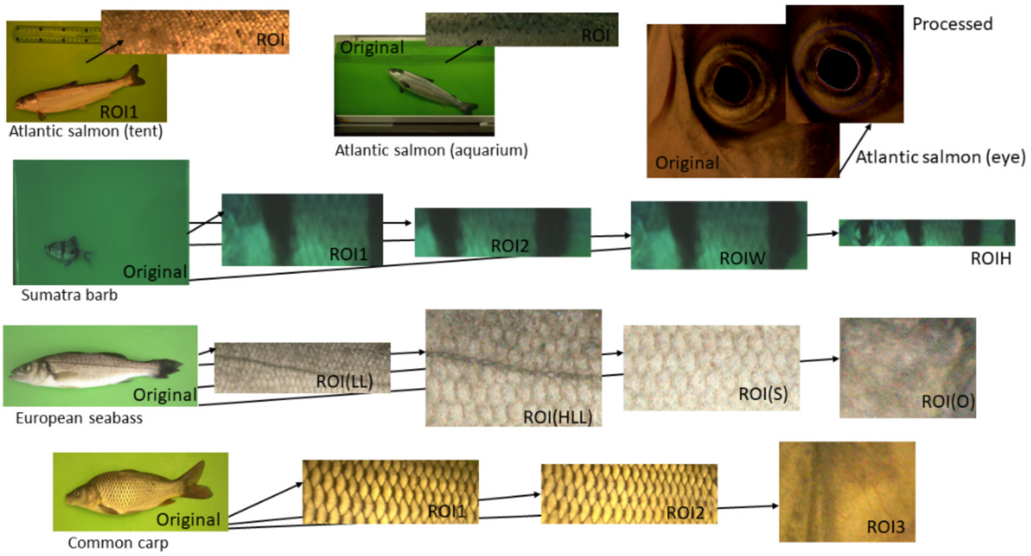

Figure 1. The data base examples. Original data and processed data of four fish species.

Results and discussion

The results of those experiments are fully presented in our papers. The datasets are scaled and focused on the different aspects of fish identification. The first dataset contains images of Sumatra barb. The methods of identification can be first tested on this dataset because of obvious stripe pattern on the fish and data close to the real conditions. We reached the the classification accuracy of 100%. More information is presented in the paper of Bekkozhayeva et al. (Bekkozhayeva, Saberioon, & Cisar, 2021). As a second datasetis the salmon data. Salmon also was strong dot patterns on the body but this dataset contaoins significantly more individuals. This identification resulst results had been described in the paper of Cisar et al. (Cisar, Bekkozhayeva, Movchan, Saberioon, & Schraml, 2021) and Schraml et al. (Schraml et al., 2020). Once the methods are successful dot strongly visinle pattern it can be tested on dataset for carp and sea bass. These fish species has only the scale pattern or lateral line patter which can be used for identification. But the results of European seabass and common carp are not published yet. The paper with the experiments and the results is under submission. In general, those studies demonstrated that the image-based individual fish identification is accurate and could be used for individual fish identification as a substitute for the tagging methods. The pattern stability was proved together with their stability.

Acknowledgments

The study was financially supported by the Ministry of Education, Youth and Sports of the Czech Republic - project „CENAKVA“(LM2018099), the CENAKVA Centre Development [No.CZ.1.05/2.1.00/19.0380] and GAJU 013/2019/Z.

NON-INVASIVE GENETIC TAGGING OF EUROPEAN LOBSTER JUVENILES FOR STOCK ENHANCEMENT PROGRAMS

E. Bello*, L. Latini, G. Grignani, R. Cimmaruta, G. Nascetti and D. Canestrelli

Department of Biological and Ecological Sciences, Tuscia University, Largo dell'Università, snc, Viterbo, Italy
E-mail: ebello@unitus.it

Introduction

Parentage based tagging (PBT) is a valid approach for monitoring the effects of conservation-oriented stock enhancement programs. However, collecting samples for DNA extraction from live decapod juveniles could be challenging, especially during the first developmental stages. In this context, PTB is usually carried out by analysing egg subsets, to reconstruct genetic profiles of siblings. However, this strategy prevents individual-based analyses and monitoring programs (e.g. analyses of survival and dispersal patterns). In this regard, a non-invasive method is required for individually tagging hatchery-reared juveniles designed for stocking programs. Here, we propose a novel, non-letal and non-invasive approach to PBT of *H. gammarus* juveniles, which allows individual genetic tagging from exuviae, overcoming the typical constraints of traditional methods.

Materials and Methods

We analysed individual exuviae obtained from hatchery-reared IV-V stages of *H. gammarus*. 10-20 ng of tissue suitable for DNA extraction were collected from the branchial chamber left inside the exuvia. Sampling was performed randomly, without knowing individual kinship. Three DNA extraction methods were employed: (i) CTAB, (ii) Quick DNA miniprep kit of Zymoresearch, (iii) HotSHot (Montero-Pau *et al*., 2008). Quantity and quality of genomic DNA were assessed by fluorimetric analysis. Extracted DNA was amplified at 12 microsatellite loci (Andrè and Knutsen 2010, Ellis *et al*., 2015). Quality checks of microsatellite data and parentage analyses were carried out using CERVUS (Kalinowski et al., 2007) and COLONY (Jones & Wang, 2010) softwares, respectively.

Results

Genomic DNA suitable for genotyping and parentage analysis was successfully extracted from all three methods. 10-50 ng/μL, 8-22 ng/μL and 14-26 ng/μL of DNA were obtained by using CTAB, commercial kit and HotSHOT method respectively. The 260/280nm ratio was 1.6-1.7, 1.8-1.95 and 1.96-2.09 for CTAB, commercial kit and HotSHOT method respectively. Microsatellite amplification and sequencing was successful for the entire set of 12 SSRs, and parentage analyses allowed to reconstruct mother-offspring relationships with high confidence for all the individual lobsters analysed.

Discussions

This study demonstrates that it is possible to obtain good quality genomic DNA from the exuviae of juvenile lobsters, in a sufficient amount for parentage analysis based on a set of 12 SSR. By allowing the identification of individual lobsters after their release in the wild, this novel approach will open the door to long-term monitoring programs of survival and dispersal patterns. Moreover, considering the good performance of all DNA-extraction methods, we anticipate that this approach could be also useful in post-release monitoring programs of a wide range of decapod crustaceans.

DOWNSCALING COPERNICUS ERA5 WAVE DATA TO IDENTIFY SUITABLE MARINE AREAS FOR MEDITERRANEAN AQUACULTURE

G. Bellotti[1]*, C. Cecioni[1], G. Calise[2], M.P. Campolunghi[2], T. Petochi[2], A. Bruschi[2], F. Cardia[2], G. Marino[2]

[1] University of Roma Tre, Dept. of Engineering, Rome, Italy

Email: giorgio.bellotti@uniroma3.it

Introduction

Lack of marine space and suitable sites for fish and shellfish farming is recognized to be one of the most relevant factor burdening the expansion of mariculture (COM 2021/236 final). The suitability of marine areas for the installation of aquaculture facilities depends on several factors. Among these, the wave climate plays a relevant role, both in terms of average conditions and extreme events. Unfortunately, direct wave measurements are only available at very few points along the coast and it has become widely accepted that a suitable methodology is to employ databases of hindcasted wave conditions, validated and calibrated against available *in situ* measurements. However, these hindcast datasets typically have a low resolution, not adequate to be used in spatial multi-criteria evaluations finalized to identify the most suitable areas for aquaculture (Marino et al., 2020). In order to produce a high-resolution dataset, the results of the global scale hindcast models is used to drive regional and local computations. The procedure, inspired to the modelling chain described in Bellotti et al. (2021), is also known as "downscaling". In this paper, we present an example application of such procedure, starting from the global dataset ERA5, on the south-central Tyrrhenian Sea nearshore areas (Fig. 1) and its use for a Weighted Linear Combination (WLC) analysis.

Materials and methods

The global dataset used to feed the nested model grids is the ERA5 (Hersbach et al., 2020), produced by the ECMWF (European Centre for Medium-Range Weather Forecasts) and freely available in Copernicus (hourly hindcasts since 1950). The selected wave model is the open-source SWAN (Simulating WAves in the Nearshore), developed by Delft Technical University. One single computational grid (Fig. 1) was used to model the wave propagation from the offshore boundary, mostly aligned with the available ERA5 grid points position, up to the coast. Validation and calibration of the model was carried out with reference to the direct wave measurements available in the area (4 wave buoys and satellite products). From the wave time series with information on spectral significant wave height (Hm0) of the computational grid, an "inverse distance weighting" (IDW) interpolation was used to have a regular grid with a resolution of 750m for each cell and within 12 nautical miles from coastline. The percentage of events in which the value of Hm0 fell within optimal suitability ranges for fish (<0.7m) and mussels (<0.2m) was calculated (Marino et al., 2020). A suitability index was assigned considering the observations in the optimal range.

Results

A very good agreement resulted between wave data observations and modelling results as showed for the selected area of Gulf of Naples (Fig. 2), suggesting that the results can be safely used for the present purposes. The wave time series produced by the downscaling procedure and the classification according to defined optimal suitability criteria for fish and mussels, returned two GIS layers (raster format) representing the suitability of marine areas for aquaculture against wave climate (Fig. 3).

Discussion

Robust high-resolution datasets are essential for a correct aquaculture zoning process and to identify marine sites suitable for wave climate and at low risk of extreme events. SWAN model reproduced reliably most of the phenomena of importance in the nearshore of study area. Wave analysis, together with other oceanographic, biogeochemical and marine uses criteria, allows the identification of suitable marine sites for fish and shellfish farming.

OVERVIEW ON ADVANCED TECHNOLOGIES OF NEW MARINE FISH SPECIES AND CHALLENGES LIMITING THEIR COMMERCIAL VIABILITY FROM HATCHERY TO OFFSHORE AQUACULTURE

Daniel Benetti

University of Miami, Rosenstiel School of Marine and Atmospheric Science
4600 Rickenbacker Causeway, Miami, Florida 33149, U.S.A.
Email: dbenetti@miami.edu

Introduction

Aquaculture technology for several commercially important species of tropical and sub-tropical marine fish from hatchery to growout to market has become or is quickly becoming available. Hatcheries are capable of producing juveniles of candidate species for offshore aquaculture such as cobia (*Rachycentron canadum*), hamachi/kampachi (*Seriola rivoliana, S. lalandi*/*S. dorsalis*), pompanos (*Trachinotus carolinus*), snappers (*Lutjanus guttatus, L. peru and L. campechanus*), yellowtail snapper (*Ocyurus chrysurus*), totoaba (*Totoaba macdonaldi*), red drum (*Sciaenops ocellatus*), mahi (*Coryphaena hippurus*), tripletail (*Lobotes surinamensis*) – among others. Steady supply of high-quality juveniles of certain species is still limited, but it is unlikely that this will remain a bottleneck for industry expansion. Likewise, offshore technology is developing fast and advanced systems are already available.

Overview and Challenges

Land-based recirculating aquaculture systems (RAS) and traditional flow-through ponds, raceways and tanks are all viable options. However, large scale production required to feed the world in the next decades will have to be produced in the open ocean - where stronger currents and greater depths increase the carrying capacity of the environment. Raising fish in exposed, high-energy areas offshore require advanced technologies demanding high levels of investment and long-term commitment. Hence, fish produced offshore must be sold at high prices to compensate the high capital and operating costs required, limiting their demand in a highly competitive white fish market.

Offshore aquaculture continues to expand the world over, yet the commercial viability of operations remains mostly elusive. Infrastructure and logistics are in place, and market demand is rising. Technology continues to expand rapidly. Tools for site assessment and selection and environmental monitoring have been established. Hurdles still must be overcome before commercial viability can be secured. Some issues such as optimizing genetics, nutrition, and diseases control are inherent to all forms of aquaculture - whereas managing stocking, feeding, chemical treatments, net cleaning, predator avoidance, escapements, biomass estimates and crop management, mortalities collection and harvesting operations are exacerbated in offshore systems. Full automation is progressing fast but still needs refinement. Machine learning and artificial intelligence tools are becoming available and being incorporated to perfect systems automation. The development of practical, specialized feeds for all developmental stages of selected species remains a challenge. These issues are presented and addressed in this presentation.

Results and Discussion

We present and discuss these challenges and how the industry is collectively working with researchers to address and resolve issues limiting the technological and commercial viability of new species with regards to hatchery and offshore aquaculture.

FIRST-FEEDING DIETS FOR EUROPEAN EEL LARVAL CULTURE: INSIGHTS AT MORPHOLOGICAL, NUTRITIONAL AND MOLECULAR LEVELS

E. Benini [a*], S. N. Politis [a] , K. A. Bandara [a], S. Engrola [b], A. Nielsen [a], L. E.C. Conceição [c], J. Tomkiewicz [a]

Email: elibe@aqua.dtu.dk

Introduction

Closing the life cycle in captivity of European eel is a requirement to develop sustainable aquaculture of this species. Due to the decline of the population together with low levels of juvenile recruitment, this species has become critically endangered and subject to trade restrictions (Pike et al., 2020). Thus, hatchery production of offspring is essential in order to lift limitations on aquaculture production and markets for European eel (Tomkiewicz, 2019). Information regarding the eel early life stages is scarce, which has considerably delayed the development of culture techniques and technologies. The main bottleneck for progressing in rearing hatchery-produced eel larvae is the establishment of an adequate first-feeding regime. First studies showed that European eel larvae successfully ingested a paste made of rotifers, *Brachionus plicatilis* (Butts et al., 2016), but despite successful initiation of first-feeding at 15 dph (cultured at 18°C) and an increased body area, indicating growth compared to starving conspecifics, the larvae did not survive past 24 dph (Politis et al., 2018). However, the latter study showed thatInterestingly though genes encoding the major digestive enzymes were expressed earlier than the actual initiation of first feeding (already at 4 dph), indicating a premature molecular functionality initiation of the gastro intestinal tract. Subsequent studies have focused on the possibility to promote an early maturation of the gut by early introduction of feed, where it was indicated that early availability of dietary nutrients can influence the molecular ontogeny of feeding related mechanisms and processes, but the successful initiation of larval feeding depends on the quality and attractiveness of the diet(s) (Benini et al., 2022). In the present study, three diets were formulated and experimentally tested as potential first feeding prototypes for hatchery produced European eel larvae. Larval mortality was recorded daily from the onset of the first feeding stage at 10 dph until 28 dph, while sampling was conducted at regular intervals to obtain larval biometrics and gene expression patterns to follow the molecular ontogeny of digestive functions and growth of the larvae during the experimental period.

Material and methods

Broodstock management, gametes production and egg incubation was performed according to Kottmann et al. (2021) and culture of the yolk sac larvae were performed according to the protocol described in Benini et al., (2022) until they reach the first feeding stage. When reaching the first-feeding stage, eel larvae were divided into replicated Kreisel tanks (n = 9) of 8 L capacity each, at a density of ~60 larvae/L and randomly connected to three separate, but identical 0.65 m^3 RAS units, where the water was kept at 18 psu and ~20°C, while light (~500 lux) was only turned on during feeding (Benini et al., 2022, Politis et al., 2021, 2017). In each Kreisel tank, larvae received feed at a concentration of 0.5 mL diet per L of water five times per day at two hour intervals. Here, light was turned on and water current was stopped to give larvae the possibility to feed on the diet, which was directly pipetted on the bottom of the tank. Larvae were allowed to feed for 30 min, subsequently the light was turned off and water flow resumed. The remaining feed was flushed away using a gentle jet of water. Larvae were moved into clean tanks daily. The three diets were freshly prepared daily. Diet 1 contained spiny dogfish (*Squalus acanthias*) egg yolk, krill extract and soybean peptide, while Diets 2 and 3 represent modifications of Diet 1. Those two diets had a proximal composition of 60% protein and 30% lipid, but the protein source and molecular size differed. Diet 2 contained fish hydrolysates, which consisted of peptides of approximately 3 kDa in size while Diet 3 contained whey (by-product of cheese making), with a molecular protein weight of 10-12 kDa. Larval cumulative mortality was calculated as a percentage from 10 until 28 dph. Moreover, pools of larvae per replicated tank (n = 3) and diet (n = 3) were sampled at selected developmental stages (0, 9, 15, 22 and 28 dph) for biometrical measurements, dry weight calculations and gene expression analyses.

(Continued on next page)

Results and Discussion

Results showed that eel larvae successfully ingested all three diets with the overall feeding incidence increasing from 37.8% to 54.4%. Gut fullness increased from 20.03% to 24.9% between 15 and 22 dph, with the highest gut fullness registered for Diet 3. Independently from the diet, two periods of high mortality were identified. The first appeared shortly after introduction of feed (10-12 dph), while the second, occurred at 20-24 dph, indicating that the larvae reached the "point of no return". The latter interpretation was supported by continuous upregulation (peaking at 22 dph) of the gene ghrelin (*ghrl*), the so-called "hunger hormone" in all dietary trials indicating that most eel larvae were fasting. However, only in larvae fed Diet 3, the expression of *ghrl* was downregulated beyond 22 dph, indicating that those larvae were not starving. Concurrently, differential upregulation of genes encoding the major digestive enzymes (*try*, *tgl*, and *amyl2a*) at 22 dph for larvae fed Diet 3 supported their prosperity at the molecular level. Furthermore, the expression patterns of those, together with food intake (*pomca*), and growth (*gh*) related genes, continued to increase towards 28 dph for larvae fed Diet 3, while we have no data for larvae from Diet 1 and 2, since very few larvae survived beyond 22 dph. These results together with an improved survival, increased dry weight, and growth in length and body area underline that Diet 3 possesses essential nutritional components, resulting in an improved maturity and functionality of the molecular feeding, digestion, and growth mechanisms. Nevertheless, we observed an early benefit of Diet 1 regarding higher survival, enhanced morphology (length and body area) and gene expression (*amyl2a*, *tgl*, *pomca* and *gh*) but, overall, the inclusion of more complex dietary proteins as in Diet 3, but not hydrolysed peptides as in Diet 2, seems to be beneficial for a successful transition to exogenous feeding. Thus, we conclude that the digestive and assimilation capacity of European eel larvae varies throughout ontogeny and consequently, the dietary regime might need to be stage specifically adapted. Overall, the results of the present study provide an unprecedented step towards establishing a first feeding culture of hatchery produced European eel larvae.

DO FISH ESCAPEES INFLUENCE WILD FISH MARKET PRICES? AN ANALYSIS IN THE SPANISH MEDITERRANEAN

K. Beqiri[1]*, A. Perni[2], K. Toledo Guedes[3]

Introduction

Spain is the main producer and consumer of the seafood in EU, covering over 45% of the total seafood volume consumed and 23% of the total aquaculture production in 2019 (APROMAR, 2021). Indeed, aquaculture is a well-developed sector in the Spanish blue economy, but at the same time, escapees from fish farms are also a source of environmental pressures and economic externalities. The risk of fish escape incidents depends on farmed fish biology, sea storms intensity and farming equipment and operation failures (Jensen, 2006). These events have a significant effect on the local fisheries generating high landings in short periods (Toledo-Guedes et al., 2014). Despite escapees can influence fish abundance, their potential market effects have received little attention in the literature. In fact, there is not quantitative research aimed to estimate to what extent landing anomalies caused by escapees influence wild fish prices. The objective of this study is to analyze the economic effect generated by escaped fish in the local seafood market, in particular, in the first sale prices of seabass (*Dicentrachus labrax*), seabream (*Sparus aurata*) and meagre (*Argyrosomus regius*).

Material and methods

This research uses panel data analysis to quantify the effect of landings anomalies caused by escapees on wild fish prices. Time series of prices and landings for 24 Spanish Mediterranean harbor markets located in Comunidad Valenciana and Murcia for the period 2004-2021 are extracted from Ministry of Agriculture, Fisheries and Food. Anomalies in landings are identified from landing data using R Studio software, (package “anomalize”). Other control variables related to production costs (Castillo-Manzano et al., 2015), presence of fish farms and seasonal factors are included in the model (Toledo-Guedes et al., 2014). The empirical model is defined as follows:

$$\mathrm{Price}_{i,t} = \beta_0 + \beta_1\,\mathrm{LANDINGS}_{i,t} + \beta_2\,\mathrm{ANOMALY}_{i,t} + \beta_3\,\mathrm{OILPRICE}_{t} + \beta_4\,\mathrm{LABOURCOSTS}_{t} + \beta_5\,\mathrm{VESSELS}_{i,t} + \beta_6\,\mathrm{INSTALLATIONS}_{i,t} + \beta_7\,\mathrm{DISTANCE}_{i,t} + \beta_8\,\mathrm{S1} + \beta_9\,\mathrm{S2} + \beta_{10}\,\mathrm{S3} + u_{i,t}$$

Stationarity of time series was tested using the unit-root Dickey-Fuller test. Following Hausman tests, the fixed effect estimator was selected and estimated independently for each specie. Several regression diagnostics were run to obtain variance inflation factors, and to test for serial correlation and heteroskedasticity (Greene, 2018).

Results

Table 1 presents regression results, including only those variables that were statistically significant. All variables present the expected signs, showing that prices are inversely related to landings and anomalies. In average terms, anomalies decrease prices of seabass, seabream and meagre by 4.18 €, 1.9 € and 2.17 €, respectively. The presence of fish farms also seems to have effects on prices, given the direct relationship between distance and prices. It suggests that aquaculture may influence fish abundance and prices in markets close to fish farms.

Average relative effects of anomalies on prices are estimated taking logs for prices (not reported). Anomalies may have the major effect in seabass, decreasing prices by 38.2 %. For meagre, average price reductions due to anomalies are 18.2 %. The lower effect generated by anomaly events seemed to be in seabream by 13.3 % price decrement in average terms along the analyzed time series.

Conclusion

This research detects significant effects of aquaculture on prices of three wild fishes (i.e., seabass, seabream and meagre), as long as the activity induces anomalies in fish landings. However, the quantitative effects here presented must be interpreted with caution, as market specific data for controlling other price determinants was lacking. Indeed, fish escape impact on market prices is a topic which is worth to research further in order to evaluate the total economic impact of these events on the sector as well as the consumers.

DIGIHEART - MACHINE LEARNING FOR PREDICTING AND PREVENTING PRODUCTION LOSS IN AQUACULTURE

L- V Bernhardt*, J Vatn, A Hafver, I B Johansen, A Ødegårdstuen

DNV, P.O Box 3001322 Høvik, Norway
Email: lisa.victoria.bernhardt@dnv.com

Introduction

The annual mortality rate for farmed salmonid fish in Norway has been relatively stable in recent years, reaching up to 20% from sea transfer to slaughter (Sommerset *et al* 2021). Fish mortality poses a serious obstacle to sustainability, ethics, and economy of the Nordic aquaculture industry. Hence, reducing mortality should be considered a top priority. Currently, the causes of stress-related mortality are uncertain, but an increasing body of evidence suggests that the majority of farmed fish die from cardiac failure associated with deviating cardiac morphology or cardiac disease (Poppe *et al* 2003; Frisk *et al* 2020). Throughout production cycles, fish mortality is a key indicator to measure fish health and -welfare, production performance and efficiency.

Since cardiac morphology is a novel and promising indicator of mortality-risk, there is an urgent need to develop tools for on-site evaluation of cardiac morphology and -health, efficiently and standardized. Image analysis of hearts is typically performed by manually segmenting and measuring shapes and angles of the heart, which is a tedious and time-consuming process that require training and alignment of personnel to make consistent measurements. However, this process can be automated using machine learning models for computer vision. By building consensus amongst experts for the annotations the models are trained on, the automated process will allow more objective and accurate morphological scoring and increase capacity and accessibility for less experienced and remote personnel.

Materials and methods

In this study, we developed deep learning models for automation of cardiac morphology measurements in farmed salmonids. A total of 679 hearts (consisting of atrium, ventricle and bulbus arteriosus) from farmed Atlantic salmon (*Salmo salar* L.) were photographed in two projections (i.e., dorsoventral and lateral left). A selection of the images, including 555 and 615 images in the dorsoventral and lateral left projection, respectively, were manually annotated by a team of academic and industrial experts and used to train the computer vision model.

Moreover, to increase the quality of the model an annotation guideline was created that serves several purposes, ensuring that the relevant features are captured and that those features could be reliably produced both by human annotators and machine learning models. The model performance was evaluated qualitatively by a panel of experts to see if the automatically measured result agreed with their expectations.

Results

The trained computer vision model, based on deep learning, successfully segmented salmon hearts and detected points of interest so that the computation of geometric properties could be automated. In the vast majority of cases, the measurements were in agreement with experts' expectation. The intended workflow is that the expert will use the computer vision model as decision support and check all the automated annotations. Hence, even if a minority of pictures need to be annotated manually (in cases where the model output deviates from what the experts judge as reasonable), the model can save significant amounts of annotation time.

Based on the output from this machine learning model, the aquaculture ecosystem will now be able to use standardized data to improve diagnostic accuracy. In combination, this will enable improved forecasting of disease progression and mortality events, hence enabling more informed decisions and implementation of preventive measures. Ultimately, this will contribute to mitigated production losses, reduced environmental footprint and improved fish welfare in the aquaculture industry.

Introduction

Flathead grey mullet (*Mugil cephalus*) is a promising omnivorous fish species for a sustainable Mediterranean aquaculture diversification due to the low dietary requirement of nutrients and the high market price of its roe (bottarga) (Solovyev and Gisbert, 2022)two and ten meals per day (R1, R2 and R3, respectively. Bacterial single cell ingredients produced by fermenting industry by-products represent a sustainable alternative of soybean meal (SBM) and fishmeal (FM) (Glencross et al., 2020). The application of bacterial single cell protein (SCP) ingredient were assessed on the blood biochemistry parameters and the gut microbiota of flathead grey mullet. Gut microbiota structure in farming condition is often associated with nutrients absorption and fish health. To the best of our knowledge this is the first characterisation of grey mullet gut microbiota diversity and structure under captive conditions and fed different diets.

Materials and Methods

Two isonitrogenous and isoenergetic experimental diets containing different SCP and SBM inclusion (SCP0, 0% SCP and 30% SBM; SCP10, 10% SCP and 9% SBM) were tested on triplicated groups of 45 fish (initial weight: 67.9 g) reared in a RAS over a period of 113 days. SCP ingredient consisted of a bulk of dried bacterial (*Corynebacterium glutamicum*) single cell (73.5 % crude protein). Feed was provided to apparent satiation on a 6 hours meal once a day. Somatometric indices, blood metabolic parameters and gut microbiota (GM) (MiSeq Illumina protocol, targeting V3-V4 regions of 16S rRNA gene) were assessed on 12 fish per treatment. Differences among treatments were considered significant at $P < 0.05$.

Results and Discussion

At the end of the trial, no significant diet effect were detected on somatometric indices. The levels of glucose, creatine, Ca^{+2}, Fe, K^+ and the ratio Na / K were found significantly higher in the fish fed SCP0 compared to SCP10 ($P < 0.05$). No significant differences between the treatments were observed for the other blood metabolic parameters considered. With regards to the gut microbiota, the most abundant phyla found in grey mullet gut were Fusobacteria and Proteobacteria (shown in Fig. 1). These two taxa represent about 87% of the whole GM in fish fed SCP0 where Fusobacteria were more abundant, while 83% in fish fed SCP10 where Proteobacteria were more abundant, although no significant differences were detected. The phyla Actinobacteria and Firmicutes seems to be higher in fish fed SCP10 ($P = 0.1210$ and $P = 0.0592$ respectively). Actinobacteria represented by *Corynebacterium* genus agreed with the dietary inclusion of bacterial SCP from *C. glutamicum*, while Firmicutes, especially lactic acid bacteria, have been associated with a beneficial effect and a healthy gut ecosystem. With a focus on the class level, specific compositional differences, although non-significant, where detected in fish fed SCP10 which present high abundance of bacilli ($P = 0.1702$) and clostridia ($P = 0.0621$). These two classes of bacteria include some promising probiotics which have been shown to be beneficial for the immune response and disease resistance in cultured fish (Guo et al., 2020; Kuebutornye et al., 2019). Overall in both groups, the more abundant genus was *Cetobacterium,* which have been found to be dominant in the gut of many freshwater species and have a positive impact on the digestion and metabolism efficiency of the host. Finally (sown in Fig. 2), no difference in the gut ecosystem diversity were detected at phylum and genus level between the two groups, however at species level there is a tendency for higher diversity in fish fed SCP10 (α-diversity; $P = 0.1280$).

Conclusion

Bacterial SCPs are promising circular ingredients which also present a probiotic effect. As such, further research is needed to better understand their application on grey mullet diet. Moreover, data from the gut microbiota contribute to the deep characterisation of the taxonomic diversity of the grey mullet gut bacterial community which is essential for understanding the dynamics of the diet-host-gut microbiota axis.

Introduction

Reducing the number of lethal analyses is fundamental in fish research, therefore alternative non-lethal approaches need exploration. For this purpose, the investigation of blood transcriptomics is of great interest. Blood transports molecules throughout the body and can be sampled even multiple times without sacrificing of the animal. RNA is relatively stable, and small quantities are enough for parallel massive gene expression profiling through high throughput techniques (i.e. RNA-seq). In fish, blood transcriptomics is still underutilized, although the few studies available show how it can be informative in a wide range of assessments. In this work, we focus on the European eel *Anguilla anguilla*, which is a critically endangered species with a key aquaculture interest. In nature, yellow eels may live in different salinity habitats (i.e., fresh-, and seawater), and this information is typically obtained through the analysis of otolith microchemistry, which requires the sacrifice of the fish. We combined blood transcriptomics and machine learning (i.e., random forest) to test the ability of transcriptomic blood-based analysis to predict salinity habitat history guided by their otolith-based classification.

Material and methods

A total of 60 eels were caught between July and August 2020, in different freshwater, brackish water and seawater sites in Norway. From each eel, otoliths and 600μl of whole blood were collected. Otolith thin sections were analysed for ^{24}Mg, ^{43}Ca, ^{55}Mn, ^{88}Sr and ^{137}Ba to classify eels into three different salinity habitat behaviours: freshwater resident (FWR), seawater resident (SWR) and inter-habitat shifter (IHS; i.e. eel that switched one or multiple times between freshwater and seawater habitats).

RNA-seq from RNA of whole blood was performed, generating ~43M of paired-end reads for each sample. Reads were mapped against the European eel reference genome with tophat2 [1]. Read count, the step to determine gene expression on the ~31,000 eel genes, was performed with htseq-count [2]. Differential expression (DE) was performed with Deseq2 [3] comparing SWR and FWR eels to assess the pool of genes to use for machine learning. Genes with adjp-value <0.05 were considered as significantly DE.

Random forest with the DE genes was run over normalized gene expression data, using the R package randomForest (www.stat.berkeley.edu/~breiman/RandomForests/). For this analysis, we considered the whole sample set of eels, which had been previously classified into FWR, SWR and IHS according to their otolith microchemistry. From the first round of analysis with all the DE genes, a further reduction was performed based on Mean Decrease in the Gini Index to consider only genes with the highest classification power. RF was then repeated with the top 150, 100, 50 or 30 genes with the highest Gini values.

Results and Discussion

The DE analysis between FWR and SWR detected 3,451 DE genes. Figure 1 shows the principal component analysis of each eel based on the blood gene expression of these DE genes and labelled according to the otolith microchemistry analysis. FWR and SWR eels are well separated on the plot, with IHS samples between the two groups.

Random forest performed using the complete set of DE genes, classified eels based on their salinity habitat with an average error of 21.07%, with mis-assignments mostly for FWR and IHS (Table 1). The further subset of genes selected, considering the Mean Decrease in the Gini Index value improved the overall results, especially in the correct assignment of FWR individuals, reaching a minimum of 6.9% using 50 or 30 genes, where only four misplaced animals belonging to IHS were misclassified (Table 1).

(Continued on next page)

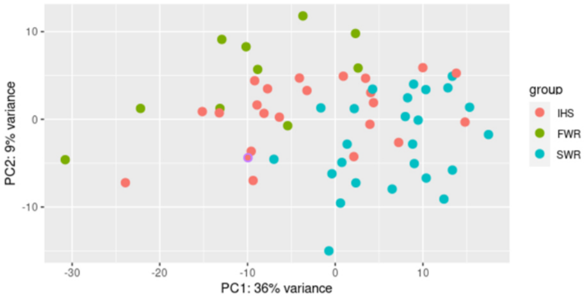

Figure 1. Principal component analysis of the DE gene expression values measured in each eel blood sample. Different colors identify the various habitat histories (i.e., IHS, FWR, SWR) of eels determined by otolith microchemistry analysis.

N. genes	**All DE**	**150**	**100**	**50**	**30**
% overall assigment error	18.97	8.62	8.62	6.9	6.9
% correctly assigned FWR	80	100	100	100	100
% correctly assigned SWR	96	100	100	100	100
% correctly assigned IHS	67	80	80	84	84

Table 1. Random forest overall classification error for each of the gene sets and the details in relation to the three otolith-based classes

Conclusions

The combination of random forest and blood transcriptomic profiling allowed the assessment of the salinity habitat history of European eels with high accuracy, showing potential to replace its lethal assessment. This approach is promising with respect to replacing or reducing other lethal approaches in fish aquaculture and monitoring, and suitable for both controlled and in-field experiments, as well as for longitudinal studies.

*camilla.bertolini@unive.it

Introduction

In the Mediterranean sea Mussels represent 11% of the share of aquaculture production by weight, being the fourth most cultivated species, in terms of value this translates to 3% (Carvalho & Guillen, 2021). Shellfish are increasingly being looked at as sustainable food sources that provide additional ecosystem services, such as water filtration and carbon sequestration. Quantifying some of these ecosystem services (i.e. their as carbon sinks) is a necessary step in order to manage and regulate additional finances to the sector (e.g. via carbon credits). In this study we focused the question on understanding carbon fluxes across Mussel cultivation sites in the whole Mediterranean Sea basin. To avoid arbitrary choices on what fluxes to include, all aspects were considered: the sequestration in soft tissue and shell, the emission of CO2 associated with calcification and the CO2 respired.

Methods

A bioenergetic model based on the Scope for Growth theory (Brigolin et al., 2009) was employed and adapted following Bertolini et al. (2021)their role as CO2 sinks or sources is still debated. To quantify it, shell accretion dynamics should be accounted for. However, the shell component is usually calculated with allometric scaling, in most bivalve models. With this study, shell accretion was added to a bioenergetic model of the Manilla clam (Ruditapes philippinarum to include shell formation. Twelve stations were chosen to span the whole Mediterranean basin in which mussel cultivation is known to take place. Model forcings included sea surface temperature, salinity, chloprophyll-a and particulate organic carbon concentration, ph, and alkalinity. These were acquired for these sites through CMEMS website (https://marine.copernicus.eu) and google earth engine (https://developers.google.com/earth-engine/datasets/catalog/NASA_OCEANDATA_MODIS-Aqua_L3SMI) , and included both earth observation and operational oceanography products. Time series considered spanned over 20 years, starting from 2000 up to 2019. Sea surface temperature data were at a daily frequency, while time series of the other variables had a monthly frequency, and were therefore interpolated by means of a spline algorithm to comply with the daily time step required by the individual model.

Results

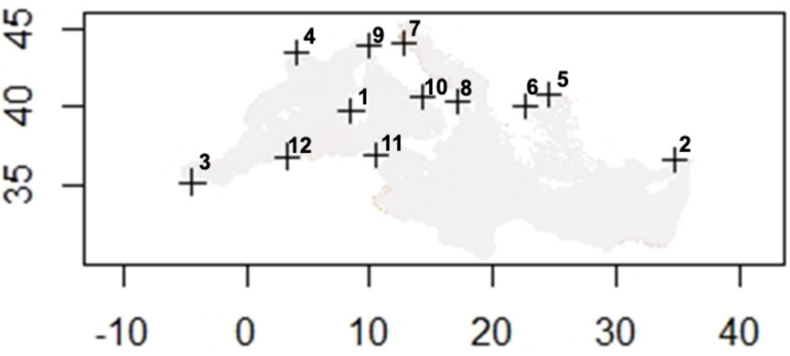

Fig.1 Location of the 12 stations investigated within this work.

When only the two components of shell formation (sequestered minus emitted during the calcification process) are considered, mussels are overall sinks of circa 0.5g CO_{2eq} per mussel. When all components are considered together, mussels can be a sink of c.ca 2g $CO_{2eq.}$

(Continued on next page)

Discussion and conclusion

The extent of sequestration depends upon site-specific mussel productivity, with lower values in areas where mussels are smaller (e.g. stations 2 and 7). Furthermore, the inclusions of different aspects in the carbon budget will depend upon the needs, end goals and management practices within farms (e.g. selling of whole vs processed product, fate of shells…), therefore this approach can be used as an useful tool for budget calculations also as support for financial actions (e.g. carbon credits).

Introduction

Seabream selective breeding is an increasing and key aspect in improving Mediterranean aquaculture, especially in Italy, where this is one of the most farmed species. Despite the recent improvement in genomic tools, breeding programs including genetic or genomic controls are uncommon. Uncontrolled mating could lead to inbreeding increase and to loss of genetic variability in specific genomic regions, so potentially affecting future breeding plans. In this work, we applied a comparative DNA-pooling sequencing approach to compare five pools of juveniles from three different families (broodstock pools) in an Italian hatchery.

Materials and methods

Juveniles were sampled from the same commercial hatchery. These samples were offspring from three different broodstock nuclei (nucleus A, B and C). These samples were used to create 5 different equimolar DNA pools of about 30 animals each: 3 pools for nucleus A (A1, A2, A3), and one for each nucleus B and C. Whole-genome re-sequencing of the five DNA pools was done using Illumina paired-end sequencing. In addition, Pool-seq data from several farmed and wild populations across Europe containing approx. 30 animals each were considered [1]. For each pool, reads were aligned to the gilthead seabream Saurata_v1 reference genome (accession no. GCA_900880675.1) using BWA 0.7.12 with the *mem* function [2] and standard options. Variant calling on the mapped reads was performed with the CRISP software using default parameters [3]. Only bi-allelic single nucleotide polymorphisms (SNPs) with quality >100 and depth ≥40 among the groups were considered. Pairwise FST between juvenile DNA pools was calculated for each SNP located on assembled chromosomes and then averaged on overlapping 500 kbp windows [4].

Results and discussion

The variant calling produced approximately 11M of SNPs. Principal Component Analysis (PCA) detected a similarity of the juvenile pools from the same family (A1, A2 and A) that is close to other farmed pools considered, while the remaining two pools were highly distinct from the rest of the group (Figure 1a) and different from each other (Figure 1b). Therefore, A1, A2 and A3 were considered as one pool for the subsequent FST analyses.

FST analyses detected regions in 11 out of the 29 chromosomes. Some divergences correspond to regions of fixed alleles for pools B and C. The highest number of regions were found on chromosome 6, with distinct patterns for each comparison (Figure 2). This chromosome has been suggested as containing candidate gene(s) for lack of pigmentation in pool A (Bertolini et al. 2021). In these regions, loss of heterozygosity has been detected for pools B and C in correspondence to 22 and 26Mb for pool B and 37 Mb for pools B and C (Figure 2). These regions contain genes with binding and catalytic activities involved in several metabolic processes.

Conclusions

The results of this study provide an overview of possible effects of localized loss of genetic variability in some of the cultivated population and suggest the need to implement genetic control of broodstock in order to control the genomic structure of offspring.

Introduction

Turbot is the most flatfish species produced in the world, China accounting for more than 65 000 tons in 2015. Selective breeding programs emerged in the early 1990s in Spain and France. Still, few heritability and genetic correlation estimates have been reported regarding edible yields, which are lethal phenotypes to measure. Recently, Schlicht et al (2019) filleted turbots and estimated a heritability of 0.15 for fillet yield for sib-selection. At this time, there is no report of relationship between morphometric and non-lethal traits into a variable that may predict the fillet yield of candidates. The aim of our study was thus to estimate the genetic parameters of non-lethal measurements to evaluate the possibility to predict edible yields on live selection candidates in a French commercial line.

Material and Methods

The fish were derived from the France Turbot Ichtus breeding program in August 2018, using 53 sires and 13 dams mated in a partial factorial design by controlled matings, producing 87 full-sib families. Larvae were reared in common environment. Fishes were individually tagged at 666 days post hatching (dph) (~270g). 897 progenies and their parents were tissue-sampled for DNA parentage assignment using a 96 SNPs panel of markers developed in this project (Gentyane, Clermont-Ferrand, France). The turbots were reared until slaughtering at 750 g (1013 dph) without any selection. The individual body weight (BW) was recorded as well as the weights of different parts: dorsal, ventral and head with abdominal cavity. They were modeled with a linear regression with BW to obtain phenotypic and genetic parameters for residual dorsal part weight (rDW), residual ventral part weight (rVW), residual head and cavity weight (rHCW). The sum of dorsal and ventral parts was used as surrogate for the edible yield relative to BW (rDVW). Non-lethal measurements were made: an individual picture was taken as well as 3D coordinates (Microscribe G2X, Revware Inc., North Carolina) at 19 landmarks on each fish. Geometric morphometrics and computation (MorphoJ and R software) enabled to define new traits such as lengths, areas and volumes. This large number of variables (~50) was evaluated using the Regbest function (in R) to define models that predict the yields. These are the best compromises in terms of model accuracy, percentage of prediction and easy to get variables from field data (*e.g.* whole-body area, area of the head, distance from snout to operculum, etc.). Heritabilities (h^2) and genetic correlations for all traits were computed based on multivariate linear mixed animal models fitted by restricted maximum likelihood in VCE (v6, Groeneveld et al., 2008).

	pDW	pVW	pHCW	pDVW
rDW	0.47	0.49	-0.74	0.38
rVW	0.94	0.99	-0.70	1.00
rHCW	-0.91	-0.77	0.90	-0.92
rDVW	0.76	0.82	-0.79	0.82

pDVW	*0.65*	*0.80*	*-0.62*	**0.31 (0.10)**

(Continued on next page)

Results and Discussion

The assignment rate of the progeny to their parents using APIS software (Griot et al., 2019) was 78% (the reason for this lower than expected result is still being explored), the dataset comprising then 707 turbots from 8 dams and 29 sires (56 full-sib families). The edible yields (expressed as residuals) had low to intermediate h^2: 0.12 ± 0.06 for the dorsal part, 0.16 ± 0.07 for the ventral part, 0.23 ± 0.10 for the head and cavity part, and 0.28 ± 0.10 for the sum of edible parts (Schlicht et al 2019 get a heritability of 0.15 ± 0.03 in the range of what we estimated). Their predictors had higher h^2 (~0.30 ± 0.11) (Table 1) but did not differ significantly. Phenotypically, the predictors predicted only a limited proportion of the real yields: 8% for the dorsal part, 9% for the ventral part, 15% for the head and cavity, and 15% for the edible parts. However, the genetic correlations between the real yields and their predictors were strong: 0.47 for the dorsal, 0.82 for the edible parts, 0.90 for the head and cavity part, and up to 0.99 for the ventral part.

Table 1: Heritability (and standard error) of the yield predictors (pDW, pVW, pHCW, pDVW) (in bold); genetic correlations and phenotypic correlations (in italics) between the predictors and the real yields (rDW, rVW, rHCW, rDVW).

The predictors defined in turbot in this study explained a lower proportion of the real yields to predict compared to previous studies in round fish such as rainbow trout (37% for carcass yield, Haffray et al., 2013), common carp (63% for headless carcass yield, Prchal et al., 2018), European sea bass (27% to 38%, Vandeputte et al., 2017). However, the genetic correlations were much higher in our study. And because the predictors are heritable traits, the selection on yield predictors in turbot may be at least as effective as relying on family data acquired by slaughtering the sibs to know the real yields.

Conclusion

Predictors are moderately heritable and positively genetically correlated with the real yield they predict. This means that indirect predictors can be used to index candidates themselves through the use of non-invasive measurements that should enhance accuracy of breeding evaluation, a work in progress.

Acknowledgement

The data presented here were obtained in the TURBOOST (2018-2022) project which received funding from the European Maritime and Fisheries Fund (FEAMP) and by the French Government through the FranceAgriMer national body.

RECENT ADVANCES IN CHEMOSENSING MECHANISMS IN BIVALVE MOLLUSCS: MORPHOLOGICAL AND MOLECULAR INVESTIGATIONS

F. Bianco F, M. Mazzoni, L. Parma, A. De Marco, G. Bignami, G. Lattanzio, P. Clavenzani and A. Bonaldo

Introduction:

Bivalve molluscs are notoriously filter-feeding animals, through the gills (ctenidium) are able to simultaneously hold oxygen and nourishment consisting of microplankton and particles suspended in the water[1]. Currently the mechanism by which microplastics are retained or not inside the bivalves is still unclear. In addition, in literature has been reported how these marine organisms are able to select and discriminate microplankton from microplastics (10 ÷ 15 µm) playing the role of biodepurators[2]. Moreover, some authors indicate that upon exposure of bivalves to microplastics, it is likely that microplastic can enter the pallial cavity and adhere to the mantle or gills and possibly embedded in mucus[3]. It is plausible that the gills of bivalves play a key role in the chemosensing.

In vertebrates, sensing of luminal contents by the gastrointestinal (GI) tract mucosa plays a critical role in the control of digestion, absorption, food intake and metabolism by triggering functional responses appropriate for beneficial or potentially harmful substances. In this complex chemosensing mechanism, taste receptors (TRs) ant their respective G alpha subunit (e.g. α-gustducin) are involved. In addition, the majority of these luminal chemosensors are expressed on enteroendocrine cells (EECs). In this study we showed preliminary data, obtained using immunohistochemistry (IHC), on the presence and distribution of cells expressing markers for TRs, hormones and mucins in mussel's gills.

Aims:

The aims of this study were to investigate on the possible chemosensing mechanism in the gills of molluscs by which these invertebrates discriminate nutrients and non-nutrients (included microplastics) substances present in marine environment.

Material and methods:

IHC was performed in Niedditas mussel's gill using T1R3 (santa cruz sc-50353). We performed also IHC using the pan-neuronal marker HuC/D (invitrogen A21272), mucin 4 (invitrogen 689328A), α-Gusducin (santa cruz, sc395), cholecystokinin-8 (CCK-8, abbexa; abx090677), ghrelin (santa cruz; sc10368) and neuropeptide Y (NPY, Chemicon AB1583). Western blotting was performed on total lysate of mussel's gill using T1R3 antibody.

Results:

By means of IHC, we showed that the T1R3 (sweet and umami receptor) as well as α-gustducin are expressed in the mussel's gill. T1R3 is a heterodimer involved in a sweet, umami and L-amino acids perception. Interestingly, the expression for T1R3 was also confirmed *via* western blotting. Furthermore, mussel's gill expresses orexigenic peptides such as NPY, ghrelin and the CCK considered a potent anorexigenic hormone. In addition, the mussel gills exhibited immunoreactivity for mucin-4 (one of the most expressed glycoproteins in mammal's mucus). Finally, we also observed immunoreactive cells for the pan neuronal marker HuC/D in the gills.

Conclusions:

Collectively, the data demonstrate that the mussel's gill expressed T1R3 and α-gustducin as well as some hormones with an orexigenic / anorexigenic action. The majority of these immunoreactive cells exhibited an elongated shape (generally flask-shaped). These histological features, together with their surface position, suggests that such cellular elements could be of an endocrine nature (similar to mammals "open type" enteroendocrine cells). The presence of the pan neuronal marker HuC/D might suggest that mussels may have a chemosensory system similar to the other invertebrates. As previously suggested by several authors, these cells could be typical bipolar neurons, with cilia projecting towards the free surface (seat of the chemosensing) and with an axon at the proximal end that projects into the central nervous system. This initial finding provides a basis to further investigate the full spectrum of chemosensing mechanisms in this molluscs as mechanism for the food-intake discrimination.

Introduction

In aquaculture the evidence concerning antimicrobial resistance has expanded and evidenced that some antimicrobials are only partially effective against some fish pathogens (Miller & Harbottle, 2018). The growing impact of resistant bacteria on human and animal health, as well as on the environment, indicates the need for supporting agents to antibiotics, such as natural compounds of plant origin. The application of essential oils opens a perspective for an environmentally friendly and sustainable control of diseases caused by pathogens in aquaculture.

Material and methods

Using minimum inhibitory concentration (MIC) assays with microdilution broth technique, we investigated the antimicrobial activity of eleven essential oils (EOs) and two blends (GL mix and BR mix) against pathogenic bacteria that could cause infections and disease outbreaks in fish farms. The pure essential oils were obtained from the species *Origanum vulgare* (Ov), *Melaleuca alternifolia*, *Melaleuca leucadendron* (Ml), *Eucalyptus globulus*, *Mentha x piperita*, *Lavandula angustifolia* (La), *Lavandula hybrida* (Lh), *Cinnamonum zeylanicum* (Cz), *Rosmarinus officinalis*, *Citrus limon* (Cl), *Thymus vulgaris* (Tv)). These oils and blends were all provided by APA-CT (Forlì, Italy) and their chemical composition was analyzed by gas chromatograph coupled with mass spectrometer (GC-MS). Inhibitory effects of EOs were tested against reference and field strains of fish pathogenic bacteria: *Aeromonas salmonicida* ATCC 33658, , *Yersinia ruckeri* ITT 100/16, *Photobacterium damselae* subsp. *piscicida* ITT 210/B/21, *Vibrio harveyi* ITT 11/16, and againstb*Pseudomonas aeruginosa* ATCC 27853 and *Escherichia coli* ATCC 8739 as controls.

Antibacterial susceptibility testing was performed according to EUCAST for broth microdilution assays (2017). The effectiveness of each essential oil and blend was tested at twelve different concentrations, ranging from 3.125% (31.25 mL/L) to 0.0015% (0.015 mL/L) using Alkamus (Solvay Solutions, Milano) 3.75% (v/v) as an emulsifying agent. For most bacteria tested, Mueller Hinton broth (supplemented with 1.5% NaCl for *Vibrio harveyi*) was used as the medium. For *Photobacterium damselae* subsp. *piscicida* Tryptic Soy Broth (TSB) with the addition of 1.5% of NaCl was used. Each assay was carried out in triplicate. A positive control to verify the growth of each bacterium and a negative control containing only the tested concentrations of EOs were run concurrently with the test item(s).

The bacterial suspensions were diluted with sterile saline solution to the concentration of 1.0×10^5 CFU/mL. To avoid loss of moisture and volatile compounds of essential oils during incubation each plate was sealed with sterile, self-adhesive aluminum foil. The microplates were incubated at 37 °C or at 25 °C, depending on the optimal bacterial temperature. After 24h incubation time, the optical density of each well was measured using a 620 nm wavelength Microplate Reader (Life Technologies) and compared to a blank one (broth medium with diluted essential oil) and positive control. Both Minimum Inhibitory Concentration (MIC) and Minimum Bactericidal Concentration (MBC) were determined (EUCAST, 2003, 2017) The MIC is defined as the lowest concentration that completely inhibits the growth of the specific organism, compared with the growth of the positive control; the MBC is defined as the lowest concentration resulting in the death of 99.9% or more of the initial inoculum. To determine MBCs, 10 μL of broth was taken from the well showing no microbial growth, inoculated on growth agar medium and incubated at requested conditions; after the specific incubation time required for each strain, CFU/mL were counted to assess cell viability.

(Continued on next page)

Results and Discussion

Complete suppression of most strains was obtained for most of the tested EOs and blends, except for *Pseudomonas aeruginosa* for which MIC was obtained only for Cz. In particular, the EOs with high antibacterial activity were Ov, Cz, Tv showing an average MIC value of 0.050 % ± 0.06, whereas La, Lh, Ml and Cl showed the lowest antibacterial activity with an average MIC value of 1.9% ± 1.65. The blends showed an intermediate MIC values between the highest and lowest EO MIC values. Obtained preliminary results allow to demonstrate high antibacterial activity of most of the tested EOs on some fish pathogens and their potential applications in the control of fish bacterial infections. Next steps will be aimed to extend MIC assays to other bacterial fish pathogens and to carry out in vivo studies to verify specific EO use in the context of gastrointestinal dysbiosis and pathogenesis.

Introduction

The Italian Society for Applied Shellfish Research (SIRAM) is a non-profit scientific society born in 2011 to promote research studies for the sustainable development of shellfish farming, tackling issues faced by the sector and sharing knowledge and insights to its stakeholders. As such, it fosters dialogue among scientists, industry and regulators to align on a common view of the shellfish sector and its challenges.

SIRAM major areas of interest include quality and food safety, physiology, pathology and genetics, farming techniques, environmental interactions and ecosystem services, the technological innovations and the application of the legislation and recommendations. SIRAM members belong to academic and research organizations, public health institutes for animal health and food safety and competent authorities, independent technicians and consultants, shellfish farmers and producer associations, which participate on research dissemination and exchanges of knowledge and best practices.

This work presents an overview on the main research topics addressed during the annual conferences organized by SIRAM over the past 10 years.

Materials and methods

Scientific papers submitted at the annual SIRAM conferences from 2012 to 2021 were categorized by major topics (i.e. food safety, animal health, environmental issues and farming techniques) and subtopics (i.e. research and innovation, chemical or microbiological contamination of the product, marine biotoxins, diseases, product valorization, analytical techniques, shellfish genetics, legislation aspects, depuration process, information systems, climate changes, zoning, waste, alien species).

Results and Discussion

From 2012 to 2021, 210 papers have been presented to the SIRAM annual conferences, with a mean of 23 per year. Food safety is the most addressed topic (54%), followed by animal health (22%), environmental issues (12%) and farming techniques (12%).

Ranking the papers by subtopic, the most represented are research and innovation (17%), legislation aspects (13%), microbiological contamination of shellfish (12%) and genetics (12%), followed by diseases (9%), marine biotoxins (8%), chemical contamination (8%) and the other research subtopics (21%) as product valorization, depuration process, analytical techniques, information systems, climate changes, zoning, waste and alien species.

Emerging challenges include adaptation to climate change, identification of allocated zones for aquaculture, more eco-friendly production methods, precision farming and valorization of ecosystem services provided by shellfish farming.

In this contest, SIRAM will continue to promote applied research acting as a bridge between industry sector, the technical-scientific community and decision-makers for the sustainability of the national seafood system and ecosystem conservation.

Introduction

The pathogenic bacteria *Vibrio harveyi*, *Vibrio anguillarum*, *Vibrio alginolyticus* and *Photobacterium damselae* (subs p*piscicida* &*damselae*) mainly concern fish farms, causing significant economic losses (Montánchez et al. 2020).

In recent years, molecular PCR tests have been developed for their specific detection (Conejero et al. 2003, Fukui et al. 2007, Pang et al. 2006, Hong et al. 2007, Zhou et al. 2007, Osorio et al. 2000 , Jing-Jing et al. 2011).

This study aimed to develop new rapid molecular methods using Real-Time PCR for the specific detection and quantification of the aforementioned bacteria.

Materials and Methods

Strains of the target bacteria that had been isolated and identified in the past were used as positive controls. Furthermore, bacterial strains isolated from aquaculture fish were used as samples.

Bacterial DNA was extracted using PureLink Genomic DNA kit (Invitrogen, ThermoFisher Scientific). Their identification was carried out with the help of specific primers from the literature or optimized (Table I). The protocols used were optimized for every target gene in order to apply the method of Real-Time PCR.

For the identification of *V. harveyi*, a Real-Time PCR method was developed slightly modifying the primers of Pang et al. 2006 (Table 1).

The identification of *V. alginolyticus*was accomplished using the upstream primer of Jing-jing et al. 2011 and a new downstream primer was designed.

For the identification of *Ph. damselae R*eal-Time PCR was developed using the downstream primer of Osorio et al. 2000 and a new upstream primer was designed.

Results

The sensitivity of the developed Real-Time PCR for the specific detection of *V. harve*yi was tested using a quantified strain of *Vibrio harveyi* and found to be able to reach 4 copies. Moreover, the developed method showed 93.6% efficiency. With this reaction, 70 bacterial strains of the *V. harveyi* species were identified, which were isolated from fish in Greek farms.

The sensitivity of the developed Real-Time PCR for the specific detection of *V. anguillarum* was tested using a quantified *V. anguillarum* strain and found to be able to reach 2 copies. Moreover, the developed method showed 100% efficiency. With this method, DNA extracts from liquid cultures of bacteria were examined and detected as Vibrio anguillarum, 2 bacterial strains.

The sensitivity of the developed Real-Time PCR for the specific detection of *V. alginolyticus* was tested using a quantified *V. alginolyticus* strain and found to be able to reach 2 copies. Moreover, the developed method shows 93.6% efficiency. With this method, DNA extracts from liquid cultures of bacteria were examined and detected as *Vibrio alginolyticus*, 2 bacterial strains.

The sensitivity of the developed Real-Time PCR for the specific detection of *Ph. damselae* was tested using a quantified strain of *Ph. damselae* and was found to be able to reach 2 copies. Moreover, the developed method shows 93.1% efficiency. With this method, DNA extracts from liquid cultures of bacteria were examined and 42 bacterial strains were detected as *Ph.damselae*. Subsequently, these strains were examined by multiplex-PCR (Osorio et al. 2000) to further differentiate them into *piscicida* (N=31) and *damselae* (N=11) subspecies.

Discussion

The outbreak of fish diseases is considered a major threat for the development of the growing industry of fish farming. Therefore, the investigation and early detection of common fish pathogens is considered crucial in order to develop effective preventing measures in any aquaculture setting.

The molecular methods developed and optimized in the present study are fast and reliable in identifying phenotypically similar and phylogenetically related bacterial species.

Therefore, they can support Greek fish farming by helping in the early identification of the main pathogenic bacteria either in fish samples or furthermore, in environmental samples.

Introduction

Mortalities within the Mediterranean populations of Fan mussel, *Pinna nobilis* continues to devastate the populations of the species limiting them in few habitats alongside the Mediterranean coastline (Lattos et al., 2021a). Apart from anthropogenic activities (commercialization, food exploitation, habitat destruction) that led to population declines in the last decades, infections by Haplosporidian parasites alongside with the presence of multiple bacterial pathogens led to mass mortalities in Mediterranean Sea and placed the species in the IUCN Red list of Threatened species (Kersting et al., 2019). Amongst other bacteria, *Mycobacterium sp*. was detected in moribund individuals in Italy and Greece causing heavy lesions in the connective tissue (Carella et al., 2019; Lattos et al., 2020). Consequently, these two potentially pathogenic microorganisms are considered the most important causative agents of mortality events. Regarding the physiological effects of the presence of these two microorganisms little is known. This study aims to elucidate a part of physiology of the fan mussel and correlate the presence and the absence of the *Haplosporidium pinnae* in the collected individuals. Keeping in mind the limited number of individuals, the lack of healthy individuals in Greek coastlines and the presence of *Mycobacterium sp*. in all specimens, an assessment of physiology was implicated with the use of cell indicators of Heat shock (Hsp70 and Hsp90) and immune response (Il-6).

Materials and Methods

Pinna nobilis individuals were collected from three marine habitats in the Aegean Sea, i.e. Thermaikos Gulf, Thessaloniki Kalloni Gulf, Lesvos island and Limnos Island during 2019 period of sampling by scuba diving effort. Respectfully to the crtitical status of the species, a special permission (MEE/GDDDP89926/1117) was obtained from local authorities for the needs of the research. Specifically three samples from Thermaikos gulf, Thessaloniki, two samples from Kalloni gulf, Lesvos island and a single moribund sample from Limnos island, were used for the assessment of physiology (Lattos et al., 2020). Assessment of physiological indicators was conducted with the use of protocols for SDS-PAGE/immunoblot analysis as described in Lattos et al., (2021b). As for the localization of the proteins expression embedded tissue samples were sectioned and stained as described also in Lattos et al., (2021b). One-way analysis of variance (ANOVA) followed by Bonferroni post hoc analysis was employed to test for significance at $p < 0.05$ (5%) level between all experimental groups examined herein (Lattos et al., 2021b).

Results

H. pinnae was histologically detected in four out of the six samples used for the study, while *Mycobacterium sp*. was also histologically detected in all samples used in this study.

Hsp70 was localized, in both cases, mostly in the epithelial cell of the digestive gland and less on the connective tissue [Figure 1(Ba,Bb)]. In contrast, Western blot analysis indicated that individuals additionally infected by *H. pinnae* exhibited higher levels of both Hsp70 and Hsp90 in all three examined tissues, compared to the non-*H. pinnae*-infected individuals, as depicted in grey shaded areas in Figure 1A. In contrast to the Hsp levels observed, analysis of Il-6 levels detected by Western blot did not reveal differences between the *H. pinnae* infected and non-*H. pinnae*-infected individuals (Figure 2A) except for the digestive gland (DG) of individuals from Thermaikos gulf, where Il-6 levels were higher in *H. pinnae* infected individuals and this was also confirmed by IHC detection of Il-6 Figure 2(Ba,Bb), which was observed in both connective and epithelial tissue, regardless of the *H. pinnae* presence.

(Continued on next page)

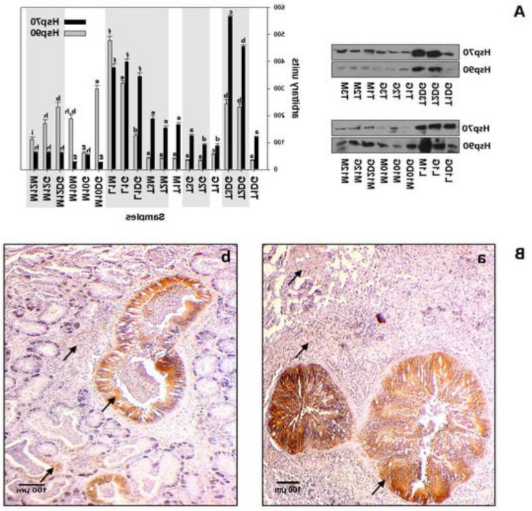

Figure 1. Hsp70 and Hsp90 levels in the digestive gland (DG), gills (G), and mantle (M) of Pinna nobilis specimens from the Kalloni Gulf (Lesvos Island) (M10, M12), from Thermaikos gulf (Thessaloniki) (T01, T02, T03), and from Limnos Island (L1). All specimens were infected with mycobacteria while grey shaded areas represent specimens additionally infected with the haplosporidian parasite.

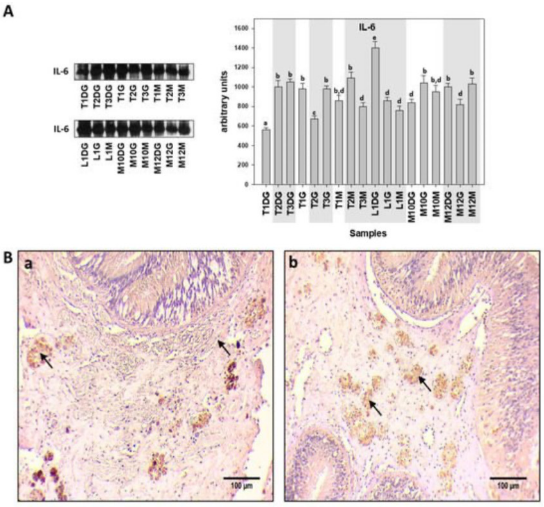

Figure 2. Il-6 levels in the digestive gland (DG), gills (G), and mantle (M) of Pinna nobilis specimens from Kalloni Gulf (Lesvos Island) (M10, M12), Thermaikos Gulf (Thessaloniki) (T01, T02, T03), and Limnos Island (L1). All specimens were infected with mycobacteria while grey shaded areas represent specimens additionally infected with the haplosporidian parasite.

Discussion

Disease etiology of mass mortality events in *P. nobilis* species is considered a complex situation, involving many microorganisms in relation to rapid changes in abiotic factors due to ongoing climate change. The results of the current research are in line with the results of Box et al. (2020), who estimated for the first time *P. nobilis* physiological performance, after the comparison of infected and uninfected animals. Individuals with both pathogens exhibited higher level of protein induction and indicated increased cellular cells, compared to individuals infected only with *Mycobacterium sp*. Hsps enable cells to adapt to various stresses and normal cellular functions are maintained by counteracting misfolded cellular proteins.

Introduction

Red rash syndrome or red spot, is a disease encountered at an increasing level in recent years mainly in cultured gilthead sea bream (*Sparus aurata* L.). It is an important disease in many countries, like Greece, Italy and Spain, affecting different fish species (mainly sea bream, sea bass and sole). It is observed in various sizes with superficial hemorrhagic lesions on the skin and fins (Figure 1). It is usually encountered during the winter and spring months and gradually resolves on its own although symptoms can reoccur in the same cage. Its association with stress factors in different rearing conditions, has been proposed (Zrncic et al, 2020).

The fact that the disease occurs in commercial sizes of sea bream makes it one of the most important diseases in terms of economic impact. Producers in Greece have reported that during fishing, the percentage of symptomatic fish has reached almost 50% of the total population.

Empirically, it has been observed that treatment with oxytetracycline can accelerate skin healing even though no bacterial pathogen has been isolated when tissues were cultured in microbiological media.

The scope of this study was to investigate the presence of bacterial pathogens with the method of 16S rRNA amplicon metabarcoding analysis on skin samples collected from symptomatic fish and healthy ones.

Materials and Methods

During June of 2020 and 2021, skin samples were collected from 10 symptomatic and 10 healthy fish. Symptomatic fish are coded as RS1a,b,c,d, RS2,b, RS3,b, RS4 and RS5, while RSC codes correspond to control samples (normal skin) collected from the corresponding area of skin to the RS samples.

DNA was extracted using ZymoBIOMICS DNA Miniprep Kit (ZYMO RESEARCH, Irvine, CA, USA) according to the manufacturer's instruction. DNA concentration was measured in Qubit 4.0 Fluorometer with Qubit® dsDNA BR assay kit (Invitrogen, Carlsbad, CA, USA).

Bacterial diversity was determined by sequencing the V3 – V4 hypervariable regions of the 16S rRNA gene (≈ 460 bp). The protocol of Illumina "16S Metagenomic Sequencing Library Preparation" (15044223 B) was used to prepare the libraries. The libraries concentration was measured in Qubit 4.0 Fluorometer with Qubit® dsDNA BR assay kit (Invitrogen, Carlsbad, CA, USA).

The size of the DNA molecules of the libraries was estimated by capillary electrophoresis on the 5200 system Fragment Analyzer (Agilent Technologies Inc. Santa Clara, CA, USA) using the dsDNA 915 Reagent kit (35 – 5000 bp). Finally, quantitative PCR was performed to quantify the libraries (qPCR) in Rotor-Gene Q (Qiagen, Hilden, Germany) using KAPA Library Quantification Kit for Illumina Platforms (KAPA BIOSYSTEMS). Sequencing was performed on a MiSeq platform, using the MiSeq v3 reagent kit (2 × 300 cycles) (Illumina Inc. San Diego, CA, USA).

Bionformatics analysis and assessment of the bacterial communities was conducted using Qiime2 (Quantitative Insights into Microbial Ecology 2, https://qiime2.org/) v-2020.2. Raw, paired-end sequences were trimmed, quality filtered and dereplicated into unique sequences and their respective abundances by the DADA2 plug-in. Dereplicated sequences were denoised, chimeras were identified and excluded from the data and the remaining paired-end reads were merged, resulting in the creation of the final ASV table. Bacterial ASVs were taxonomically annotated using the SILVA (138) database. ASV tables containing the frequencies for each ASV in each sample of the data set, as well as their phylogenetic classification, were imported into R programming language v4.1.15, for further processing and visualization of the results. Changes in microbial composition are presented as normalized (%) relative abundance heatmaps.

Figure 2. Heatmap of relative abundance rates of the top 20 dominant bacteria at species level.

Results

A total of 603,504 paired-end sequences were generated. After DADA2 analysis, 313,959 sequences remained for phylogenetic classification ranging between 828 (RSC4) and 49,263 (RS3) per sample (mean = 15,697, n = 20). These sequences were initially mapped to 2,855 unique ASVs.

In Figure 2, heatmaps showing the relative abundance percentages of the total sequences are shown. Eight out of the 10 RS samples (symptomatic fish) and 1 RSC sample are dominated by ASVs classified in the Genus Vibrio, with abundance rates > 90%. At the species level, the most dominant bacterium in the RS samples is *V. natriegens* followed by *V. harveyi*.

Discussion

Red rash syndrome is considered as the second most important disease of gilthead sea bream in the Mediterranean area, with unknown etiology (Muniesa et al., 2020). Due to its empirical treatment with oxytetracycline and yet, the failure to cultivate a pathogen with the classical microbiological methods, the goal of this study was to investigate the presence of bacterial pathogens with the method of 16S rRNA amplicon metabarcoding analysis on skin samples collected from symptomatic fish and compare them to healthy ones. Our results showed that in most of the symptomatic fish the dominant bacterium was *V. natriegens* and *V. harveyi*. *Vibrio natriegens* is widely considered a non-pathogenic bacterium found in the marine environment (Hoff et al., 2020). Furthermore, Lee et al. (2016) studying the bacterial genome, were unable to find known toxin genes or pathogenicity islands suggesting that this organism is a Biosafety Level 1 organism. Yet, there is a citation by Bi et al. (2016), isolating and identifying *V. natriegens* as a pathogen causing mortalities in cultured swimming crabs *Portunus trituberculatusin* in China. To our knowledge, this is the first time that *V. natriegens* and *V. harveyi* are being related to red rash syndrome, yet a lot of research is still needed to reach a safe result considering their correlation with the etiology of this syndrome. It could be stated that these vibrio species colonized the ulcerative lesions yet, their emergence in 9 of the 10 RS samples collected in different time periods, suggests a possible pathogenic role in the red rash syndrome.

Introduction

Significant parts of the ocean are today unavailable to industrial fish farming due to remoteness and exposure to harsh wind, wave, current, and ice. Conventional fish farming along the Norwegian coastline is the second most risk exposed occupation in Norway and have many challenges for the fish and the environment. Thus, conventional fish farming operates at the limits for the fish, personnel, and equipment. Although moving fish farming to more exposed areas can solve some issues, it also introduces new risks. In exposed conditions, the risks are magnified compared with conventional fish farming, making it challenging to avoid injuries, fish escapes, and mortality. Unpredictable weather and sea states lead to short operational windows and delayed or interrupted operations. Regular as well as infrequent operations are challenging. There will be postponed de-licing and longer periods of starvation for the fish.

In the Norwegian research centre EXPOSED, we have studied how exposed aquaculture operations can become robust and safe. Exposed aquaculture operations are defined as operations on aquaculture localities where work or equipment is strongly influenced by current or weather exposure. Exposed aquaculture operations share a line of challenges, that must be addressed to be able to utilize the tricky, exposed areas along the coast and at sea.

Methods

Our studies have been ongoing for seven years and embrace multiple methods. Some of the existing fish farms in Norway currently operate in exposed conditions, and these have been studied with approaches of weather data, accident statistics, technology verification results, digital twins, interviews of personnel, etc. Other methods have been development of technology or experiments with potential materials and constructions for future fish farm concepts.

Five key challenges

Through the studies we have identified five key challenges that needs to be solved to achieve robust, efficient, and safe exposed aquaculture operations.

The first challenge is risk in the human working environment. Exposed operations equal demanding working conditions that result in stress and occupational hazards. There is a need for coordinated action to reduce risks in aquaculture, involving industry and the various authorities.

Challenge two is demanding management and daily operations. Some farms have prolonged periods with ocean swell, and we have seen examples of farms that have been abandoned in periods. One needs to develop agreed competence requirements and design methods for robust technology and decision support.

Vessels serving the aquaculture farms also have demanding conditions, and this is the third challenge. The navigation alongside the farm needs to be gentle to fish that is crowded towards the surface and vulnerable to stream. There is a need for specialized vessel design and operational limits.

Challenge number four is fish welfare. Treating fish under rough environmental conditions inflict additional stress, with a potential for higher mortality. Crowding with large movements, waves, and cold air/water, represents a risk for the fish. Extreme conditions have caused mass mortality. There is a need for robust fish and adapted stocking strategies, and to understand the limitations of the fish and how to monitor its state.

The last key challenge of exposed aquaculture operations is increased risk of escaped fish. 1 of 3 escaped salmon escapes when the weather is bad. Extreme conditions also can cause structural failures. One preventive measure can be automated inspections.

Results

To solve these challenges, we have approached them from different sides. We have analysed exposure limits of fish, personnel and equipment, and found techniques to model and measure environmental loads on farms, as well as exposure degree. This has led us closer to understand how exposure and operational limits can be classified, and how exposed aquaculture operations can be robust, efficient, and safe. A selection of the solutions will be presented in the oral presentation.

PERFORMANCE EVALUATION OF THE SYSMEX XN-1000V AUTOMATED HAEMATOLOGY ANALYSER AND REFERENCE RANGES INTERVAL FOR RAINBOW TROUT BLOOD

Introduction

Haematological parameters are valuable indicators of fish health status. Blood reflects the overall physiological status of the animal and has been widely used as a diagnostic tool to assess health status in fish in response to changes related to nutrition, water quality and pathological conditions. Haematology combined with other routine diagnostic methods can be used to identify and assess conditions that cause stress and/or diseases that affect fish production and performance. Moreover, blood samples can be collected without euthanizing the animals, providing an additional advantage for both ethical and economic reasons. Fish blood haematology analysis is currently performed mainly by manual methods as automated analysers have been scarcely validated and used in fish. Automated methods present significant advantages compared to manual techniques, offering time- and cost-effective options, eliminating operator-tied errors and, consequently, increasing repeatability and reliability of the obtained results. The present study has two main objectives: to validate the automated blood cell analyser (Sysmex XN-1000V) for its potential use with blood samples of the teleost fish *Oncorhynchus mykiss* (rainbow trout) and to establish reference values for the species since those currently available are scarce.

Material and methods

Fish used in the study were netted and anesthetized with tricaine methanesulfonate (MS-222). Blood was sampled from the caudal vein using heparinized needles (25 G) and 2 mL syringes and immediately transferred to Eppendorf tubes with heparin. Samples were analysed within 12 h after the extraction using the Sysmex XN-1000V, Ver. 3 (3.05-00), employing the settings for bird blood samples. Precision, linearity and carry-over were calculated for the results obtained from the analyser in red blood cell count (RBC), haemoglobin (HGB), haematocrit value (HCT), mean corpuscular volume (MCV), white blood cell count (WBC), and platelet count (PLT). Precision was calculated for RBC and WBC counts performed by manual method. A comparison was made between the results obtained by the analyser and the manual method for erythrocytes, leukocytes, haematocrit value and percentages of heterophils and mononuclear cells. Blood from 71 healthy fish was analysed using the Sysmex XN-1000V for the determination of the haematological reference values for rainbow trout.

Results

Precision obtained with the blood cell analyser for low-normal and high cell counts were 2.71% and 0.83% for RBC, 1.43% and 3.94% for HGB, 1.07% and 1.78% for HCT, 4.82% and 4.66% for WBC, and 0.35 and 0.12 for PLT, respectively. For MCV, heterophils (%) and mononuclear (%) the precision was only calculated with blood with normal cell counts and it was 1.39 %, 15.08 % and 2.24 % respectively. Pearson's correlation coefficient (r) for the linearity of RBC, HGB, HCT, WBC, heterophils cells (%), mononuclear cells (%) and PLTs were over 0.99 for all parameters. Carry-over for RBC and PLT were 0, but WBC was 0.57 %. Precision of the manual method was 21.7% for RBC and 17.57 % for WBC. Comparison between Sysmex XN1000V and manual method was good for most parameters with a Pearson's correlation coefficient of 0.78 for RBC, 0.87 for HCT, 0.51 for WBC, 0.68 for mononuclear cells (%) and 0.76 for heterophils (%). Reference interval range for the haematological parameters obtained from healthy rainbow trout was established (Table 1).

(Continued on next page)

Table 1. Reference values of haematological parameters of rainbow trout blood using the Sysmex XN-1000V analyser.

	n	Mean	Median	SD	Lower value	Highest value	Percentile 5%	Percentile 95%
WBC (10^3/µL)	71	22.39	21.44	10.91	2.88	51.64	3.59	43.37

RDW-SD (fL)	71	39.66	38.40	12.60	18.40	73.20	18.66	60.20
RDW-CV (%)	71	13.28	13.05	3.37	7.10	20.90	7.20	18.98
PLT (10^3/uL)	71	3.34	3.00	2.78	0.00	13.00	0.00	8.55
PCV (%)	71	36.71	36.50	7.35	21.00	50.50	21.63	48.35

Discussion

Present results show that the Sysmex XN-1000V produce more accurate and reproducible haematological data than the manual methods. Moreover, the use of the automated analyser overcome one of the main limitations of blood haematology in fish that it is the time consuming and great variability of the manual method. Reference values interval obtained using the Sysmex XN-1000V are similar to those described by the manual methods by other authors with trout blood (Zinkl et al., 1991, Jan et al., 2021) allowing its use in future haematological studies. In conclusion, with this study we validate a new tool that will contribute to the non-lethal and fast evaluation of the health status of wild and farmed fish.

Introduction

Lumpfish and wrasse are currently used as cleaner fish as part of the overall strategy for the prevention and control of lice in Atlantic salmon farming in Norway (Skiftesvik et al., 2013; Imsland et al., 2018). There is a growing concern and criticism about the welfare and survival of cleaner fish in net pens (Treasurer and Feledi, 2014; Imsland et al., 2020; Garcia de Leaniz et al., 2021). However, there is still a lack of studies that have monitored welfare status at several localities over a long period of time. Although operational welfare indicators (OWI) that are used to evaluate welfare in net pens are widely used, there is not yet a standardized overall welfare score that would allow for comparison of welfare data of all cleaner fish species and by different studies.

It is still unclear what factors affect lumpfish and wrasse welfare most negatively. Diseases are often pointed out as the main challenge, but other factors such as suboptimal environmental conditions can also negatively affect welfare. In addition, it is still poorly documented whether production conditions also have an effect on the welfare of cleaner fish. The lice grazing efficiency of cleaner fish is known to be affected by a combination of environmental conditions and biological factors. However, it is not known whether welfare affects lice grazing efficiency.

Material and methods

Lumpfish and wrasse welfare was monitored in 2019-2022, every month, when it was possible. Individuals were weighed with a precision of 1 g. Stomach contents were visually examined and all sea lice were counted. Each OWI was scored from 0 to 3 according to Noble et al. (2019), and thereafter squared to highlight the differences between individuals with several minor injuries and individuals with much more severe wounds. The overall welfare score was then calculated as a standardized weighed sum and categorized in four degrees of severity from good to severely reduced welfare. Timing of mechanical delousing, net change and net cleaning were registered. Seawater temperature and oxygen concentration were continuously registered by each of the sea farms.

Results

Based on our welfare model, results indicate that the welfare of lumpfish progressed negatively after transfer to net pens. While newly transferred lumpfish had good welfare, a large proportion of lumpfish had clearly reduced welfare after 6-7 months at sea. The negative development related to a combination of various factors, with mechanical delousing being the most important. Our results further indicated that reduced welfare negatively impacted cleaning efficacy. Preliminary results suggest that welfare of wrasse was already compromised by the time of transfer to sea, most likely due to challenges in nurseries. Even though welfare generally appeared to improve after transfer to sea, nutritional status seemed to worsen, indicating that feeding regimes of the sea farms were not sufficiently adapted. In addition, handling (delousing and disease treatments) seemed to have a negative impact on welfare of wrasse in net pens.

Discussion

We propose a model for calculating overall welfare from OWI that ensures a systematic and comparable collection of data on large scale monitoring studies. Assessments should not be based on average values for the entire population because it can hide variations between individuals who have very different welfare statuses (Sommerset et al., 2021). Therefore, we propose to estimate an overall welfare score calculated as a weighted sum of OWI scores. This allows to highlight the differences between individuals who have a few scratches that do not greatly reduce welfare and individuals who have much more severe wounds

(Continued on next page)

In accordance with other studies, we suggest that lumpfish should not be use in nets pens in summer, when the seawater temperatures are highest and delousing likely (Sommerset et al., 2021; Hvas et al., 2018). There is a clear need of improving nurseries production strategies to ensure a good welfare of wrasse by the time of transfer to sea. Improving feeding regimes for wrasse in nets pens also are a priority for welfare (Skiftesvik et al., 2017). Control over cleaner fish welfare and lice grazing efficiency in net pens can be achieved by introducing routine monitoring. This will make it possible to identify reduced welfare early, and thus implement preventive measures. Proper and sufficient allocation of resources is necessary to ensure good monitoring and therefore good welfare of cleaner fish in net pens.

INTRODUCTION

Several land-based abalone farms in South Africa operate integrated aquaculture (IMTA) systems, growing the local abalone, *Haliotis midae*, linked to *Ulva lacinulata* grown in paddle-raceways supplied with abalone effluent. Two of these farms currently use the *Ulva* for bioremediation, enabling partial recirculation. Recirculating IMTA systems such as these have been operating commercially in South Africa for more than 15 years.

The farm studied operates routinely at 50% water recirculation, and the *Ulva* removes ammonia enabling continuous recirculation, and is also used as feed (in addition to formulated feed and harvested kelp). The farm is arranged as a series of platforms, each containing four independent modular clusters each consisting of a single *Ulva* paddle raceway (volume 300,000l, with ca. 1,000 kg of *Ulva*) linked with 42 abalone tanks (volume of each tank 8,000l, with each whole cluster containing ca. 10-15,000 kg of abalone).

A series of experiments examined water quality at the standard 50% recirculation, the potential to increase the recirculation to 75% over an extended period, and the effects of short-term 100% recirculation. The latter was designed to test the potential of the system to use full recirculation to combat occasional temporary Harmful Algal Blooms (HABs) in the intake water.

METHODS

An initial pilot experiment measured pH, ammonia (Total Ammonia Nitrogen, TAN and Free Ammonia Nitrogen, FAN), temperature and oxygen at two-hourly intervals, in triplicate clusters at the standard 50% recirculation rate over the course of a day. A second experiment compared three individual clusters operating at 50%, 75% and 100% recirculation, sampling every 6 hours for a 3-day period. The third experiment involved three clusters operating at 100% recirculation, with measurements every 2 hours, again for 3 days, with a single control cluster at 50% recirculation. Finally, a series of more detailed longer-term (ca. 1 month) hourly measurements of pH and temperature were made in both abalone tanks and *Ulva* raceways and water samples for nutrient analysis (ammonia, phosphate, nitrite and nitrate) were collected weekly at different recirculation rates.

RESULTS & DISCUSSION

At standard 50% recirculation, total ammonia nitrogen removal across the seaweed biofilters ranged from 65%-85% (mean 73%). In these conditions, water temperature increased by ca. 2°C in the system, with little difference between abalone and seaweed components. pH at 50% recirculation ranged from 8.1 in the daytime to 7.5 at night, and after mixing in the sump with 50% ambient seawater the pH similarly ranged from 8.0 to 7.5 in the abalone tank inflow. A regression analysis demonstrated a strong positive linear relationship between TAN removal and TAN load to the seaweed biofilter. There was a strong negative correlation between FAN removal and pH: as pH increased across the seaweed biofilters the level of FAN removal decreased. %TAN removal was somewhat higher in the day, while %FAN removal was greatest at night, with lower pH. Thus, whilst the *Ulva* bioremediation is beneficial from the point of view of pH and ocean acidification, the raised pH in the daytime results in some increase in FAN.

There were no significant differences between the 50% and 75% recirculation clusters for temperature, pH, TAN or FAN. At 100% recirculation, temperature was consistently 1°C higher in the daytime, and pH was around 1 unit lower throughout, although pH did not drop below 7.5 until day 3. Also at 100%, TAN and FAN increased rapidly, with TAN values ranging from 0.3-0.8 mg l^{-1} compared with always less than 0.1mg l^{-1} at 50%. The commensurate rapid and considerable decrease in pH meant that the FAN increase was not as high as it would be at ambient seawater pH of around 8.2. Oxygen levels were not considered problematic at any stage in the experiments.

CONCLUSION

It is clear from the data that this system could feasibly run for extended periods at 75% recirculation, with relatively little effect on water quality compared with 50% recirculation. The system was run at 100% recirculation for two separate 3-day periods and, although there were no health effects observed on the abalone, ammonia reached critical levels, from literature values, on the third day. Nevertheless, the lack of obvious effects on the abalone suggests that the potential to use this seaweed bioremediation to mitigate effects of HABs could be beneficial over at least 2-3 days of a bloom event.

ESTIMATING AMMONIA-N AND CARBION DIOXIDE EMISSIONS FROM A LAND-BASED TROUT FARM: A PRECISION FISH FARMING APPROACH

Matteo Bolzonella[1,*], Adriano C. Lima[1] and Roberto Pastres[1]

[1]Department of Environmental Sciences, Informatics and Statistics (DAIS), Università Ca' Foscari Venezia
Via Torino 155, 30172 Venezia Mestre, Italy
E-mail: matteo.bolzonella@unive.it

Introduction

Innovations and decrease of the cost of sensors allow the implementation of the "Precision Fish Farming" approach that can promote the ecological transition of the aquaculture sector. This approach could lead to a new generation of management software and decision support systems for fish farmers based on dynamic models.

In this work, an Individual–Based Model for Population Dynamics (IBM–PD) of rainbow trout, *Oncorhynchus mykiss*, is presented, which enables one to predict the total biomass and the fish weight distribution. The model is forced by water temperature, feed ration and feed quality. The model output includes the daily optimal feed ration, ammonia-N load and carbon dioxide emissions.

Material and Methods

The PFF approach was tested on a rainbow trout farm located in the Northern Italy. Four surveys were conducted during the H2020 project GAIN, lasting at least one month. In these campaigns, two identical probes YSI EXO2 were deployed at the inlet and at the outlet of a selected raceway for water quality monitoring, in particular: hourly measurements of Dissolved Oxygen (DO) concentration, water temperature and pH were recorded. The temporal evolution of fish weight distribution was monitored using Biomass Daily, a non–invasive device based on infrared technology that detects a signal anytime a specimen crosses a square frame. The IBM–PD was tested on mean weight and standard deviation estimated on daily observations collected by Biomass Daily. The population dynamics was simulated excluding any interaction among individuals and, hence, population weight distribution is the result of a set of individual growth trajectories. Each individual growth trajectory is simulated using a bioenergetic model (Bolzonella M. et al., 2022 – submitted). The estimation of daily loads of ammonia-N takes into account the amount of Nitrogen introduced via fish feed and the amount retained by fish to build new biomass based on body composition as suggested in literature (Dumas et al., 2010). Carbon dioxide dynamics will be simulated according to a mass balance considering contribution from water fluxes, fish respiration, exchange with the atmosphere and the chemical reactions of this chemical occurring in water.

Table 1. Comparison of NH_4^+–N emissions estimated by the IBM – PD and literature

Biomass [tons]	N content of feed	$\Delta NH_4^+ - N$	Units	Reference
10 – 16	7%	0.5 – 2.5	$kgNd^{-1}$	This work
20	6.5%	1.5	$kgNd^{-1}$	Bartoli et al., 2007
10 – 16	7%	0.02 – 0.1	$mgNL^{-1}$	This work
24	7.2%	0.045 – 0.211	$mgNL^{-1}$	Varol & Balcı, 2020

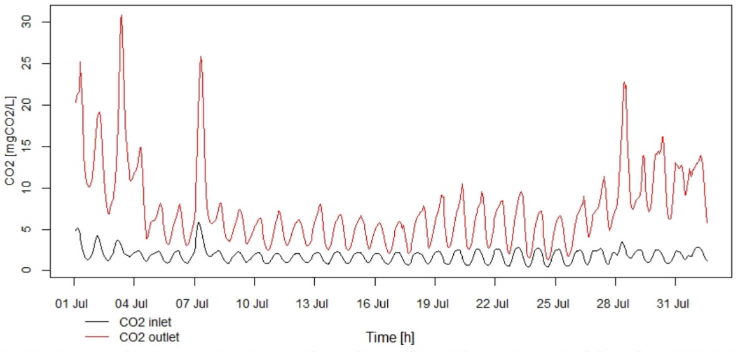

Figure 1. Estimated concentration of carbon dioxide estimated by the IBM-PD model

(Continued on next page)

Results and discussion

The ammonia-N emissions were estimated for a population with mean fish size ranging between 300g and 600g, experiencing both prolongated fasting condition and regular feeding regime. Table 1 presents the comparison of the model output with literature data. As can be seen from this table, the emissions of ammonia-N estimated by the IBM-PD are in good agreement with previous findings.

A preliminary approach based on carbonate chemical equilibria, measured pH and alkalinity was implemented in the model. Figure 1 shows the estimation of the concentration of carbon dioxide estimated by the model at the inlet (black line) and at the outlet (red line). As can be seen from this figure, the model estimated that concentration of carbon dioxide at the outlet could go outside of the optimal range for this species. The model could support trout farmers in controlling the concentration of ammonia-N and carbon dioxide in water to avoid concentrations of these chemicals above optimal level based on reared biomass and husbandry practice. The developed IBM-PD model could then be used for the estimation of the environmental burden released by a trout farm.

Introduction

Marine invertebrates are known to accumulate high levels of heavy metals in their tissues (Rainbow, 2002). They can acquire metals from both water and diet, although diet has been shown to be the dominant pathway (Casado-Martinez *et al.,* 2009). The REMEDIA Life Project (REmediation of Marine Environment and Development of Innovative Aquaculture: exploitation of edible / not edible biomass, LIFE16 ENV / IT / 000343) funded by the European Community, provides, for the first time in Europe, the creation of an integrated system of multi-trophic aquaculture (IMTA) where a new set of bioremediating organisms (polychaetes, porifers, mussels and macroalgae) are placed on collectors around the fish breeding cages. In addition to the restoration activity the project foresees the biotechnological use of the bioremediator biomass, which constitute a by-product of high commercial value potentially exploitable as source of fodder, fertilizers, and bioactive compounds. Being the plant located close to the Taranto city and therefore exposed to a variety of pollutants from anthropogenic activities, the evaluation of biomass quality of some of these by-products was needed. Several important parameters, such as Pcbs, heavy metals, microplastics and bacteria concentration, have been investigated in their biomass. The present paper deals with the presence of heavy metals in the filter feeder bioremediating organisms after one year of growing in the IMTA system. The examined species were the mussel *Mytilus galloprovincialis;* the polychaete *Sabella spallanzanii* and *Branchiomma luctuosum*; and the sponge *Sarcotragus spinosulus*.

Material and methods

The study area is located on the south-west side of the Mar Grande of Taranto (40°25′56″ N; 17°14′19″ E) (Ionian Sea) (Fig. 1), which is a semi-enclosed basin connected to the Gulf of Taranto. The investigation was performed in the aquaculture plant “Maricoltura del Mar Grande (MMG)”, which is a partner of the Remedia-Life project hosting the innovative IMTA system. The investigated specimens were immediately removed from the collectors and carried in the laboratory and employed for the chemical analyses. In particular, analyses were performed on the soft tissues of mussels, the body and the branchial crown of worms and the sponge total body. Ten specimens of each species were examined. They were dehydrated for 48 h at 60 °C and their dry weights measured. Each sample was then mixed with 4 ml H_2O_2 and 6 ml HNO_3, then treated at 180 °C for 10 min using a microwave digestion system (Milestone START D). Samples were subsequently cooled, diluted with ultrapure water to a final volume of 25 ml, filtered through syringe filters (pore size 0.45 μm), and finally measured for element content by using an inductively coupled plasma atomic emission spectrometer (ICP-AES; Thermo Scientific iCap 6000 Series) Results were ultimately expressed as $\mu g\ g^{-1}$ of tissue dry weight.

Results

The obtained results are reported in Table. 1.

Discussion

All the reared organisms after one year of permanence in the plant showed lower values than those reported as not dangerous in literature except for Pb in the sponge *S. spinosulus*, and As and Cd in the crown of polychaetes. As regard sponges the high recorded concentration of cadmium does not represent a problem since their tissues were proposed only for the extraction of bioactive molecules. The high concentration of arsenic and cadmium found in the crown of both polychaete species was already reported by other authors, that suggested a biological role of toxic compounds as an adaptive mechanism against predation (Fattorini *et al.,* 2005; Notti *et al.,* 2007). In the case of polychaetes we proposed to use the entire worm when employed as ornamental animal for aquaria, by contrast we advise to remove the crown when the biomass is exploited as animal feed and as fishing baits.

Introduction

In aquaculture, fish undergo a series of events and practices that can compromise their welfare and health. One of the most frequently used stress indicators in fish is the quantification of cortisol in conventional matrices, such as plasma. Nevertheless, blood sampling can be extremely invasive, becoming itself a stressor and cortisol quick increase after stress may lead to unreliable results. This is why non-conventional matrices such as muscle, fin and skin mucus have already been tested as valuable alternatives to plasma (Bertotto et al., 2010; Sadoul & Geffroy, 2019). Among them, scales have also been recently taken into consideration as less invasive matrices and as novel and reliable marker for chronic stress in European sea bass and other species (Samaras et al., 2021). Cortisol in scales is accumulated slowly, due to their bony nature, making them unsuitable for acute stress studies but essential to evaluate fish stress response over the mid-long term. This study aims to evaluate the stress status of European seabass subjected to hypoxia by quantifying cortisol levels in a suite of matrices using specific radioimmunoassays (RIAs). For a deeper insight into the stress response, measurements of hematocrit and oxidative stress were also taken.

Materials and methods

European sea bass (*n*=60; 158±10 g) were acclimatized for 4 weeks at 22.5±0.5°C and 8.5±0.5 mg/L of oxygen. Fish were then randomly distributed in 6X1000L tanks with a daily renewal rate of approximately 5%. The experiment was performed at the Department of Veterinary Medical Sciences (University of Bologna, Italy) and during the whole period temperature was kept at 26±1°C and the photoperiod was set at 12L:12D. Three tanks were used as control and had normal oxygen levels (8.7±0.4 mg/L), whereas the other three had low oxygen levels (4±0.2 mg/L) to establish hypoxic stress. Fish were sampled at the beginning of the trial, before exposure to hypoxia, and at the end of the trial, which lasted 7 days. During the samplings, fish were sacrificed by excess of anesthetic (MS222 Sigma-Aldrich) and subsequent cut of the spinal cord. Blood was collected from the caudal vein using heparinized tubes and samples of skin mucus and scales were collected by scraping the side of the fish. Immediately after collection, two aliquots from each blood sample were taken for hematocrit measurements, while the remaining part was centrifuged to obtain plasma samples. Small portions of lateral muscle ($1cm^3$) and caudal fin ($1cm^2$) were also collected. All the matrices were subsequently stored at -20°C until the analysis.

Cortisol was measured in all the matrices by a previously validated specific RIA protocol for use in European seas bass (Bertotto et al., 2010). For the scales, different extraction methods were tested and a specific RIA protocol was developed and validated. Plasma was also used for the assessment of lipid peroxidation, i.e. malondialdehyde (MDA), by measuring thiobarbituric acid-reactive substances (TBARS). All the data are expressed as mean ± standard error and were previously evaluated for normality distribution. Differences between treatments were analyzed using a general linear model (GLM) using *time* and *hypoxia stress* as main factors. Correlations in cortisol concentrations between plasma and the various matrices were performed using Pearson's correlation coefficient. The level of statistical significance was set at $p < 0.05$.

Results and discussion

The RIA protocol developed to assess cortisol in the scales showed good parallelism and reproducibility (linear regression curve coefficient R^2: 0.99; CV% intra-assay = 5.14; CV% inter-assay = 4.39) and the recovery test with value higher than 90% confirmed the efficiency of the method for steroid extraction.

Results showed that cortisol concentration in plasma, fin and skin mucus increased over time, although not significantly (p=0.21, p=0.27 and p=0.07, respectively). Neither the exposure to hypoxia affected the hormone levels in the same matrices (p=0.92, p=0.90 and p=0.18, respectively). On the other hand, a significant increase in cortisol concentration in muscle and scales was observed in fish over time (p<0.01 and p=0.001, respectively), but no differences were found in fish exposed to hypoxia stress compared to controls (p=0.83 and p=0.88). As scales are composed of bone tissue and slowly accumulate cortisol, they are little influenced by the acute effect of the sampling and allow to quantify the level of stress in the mid-long term. However, the low oxygen conditions used in this trial were too mild to trigger a strong stress response

(Continued on next page)

and a high increase of blood cortisol, whereas the scales probably seized the low increase of cortisol during the prolonged mild stress response or the increase of cortisol during the first sampling. For the same reason, hematocrit values did not differ (p=0.1) in relation to oxygen conditions, whereas the hematocrit decrease (p<0.05) over time could be a sign of anemia. The correlation of cortisol levels in plasma and in the alternative matrices, i.e. muscle, fin and mucus, was evident and significant (p<0.001, r=0.68; p<0.001, r=0.72 and p<0.001, r=0.60, respectively). Correlation between plasma and scales cortisol levels was also positive, even if less marked due to the different meaning of the hormone in these matrices in term of acute and long stress (p<0.05, r=0.36). Finally, plasma MDA concentrations were not significantly affected neither by the time nor by hypoxia and were similar to those already reported for European sea bass (Vinagre et al., 2012), highlighting the absence of oxidative stress.

Conclusions

The present study confirmed that scales could represent one of the most effective matrices to quantify cortisol levels and to evaluate the effects of sub-chronic and chronic stress, even in mild conditions. The hypoxia conditions applied in this study did not strongly impact European sea bass stress response, indicating that this species might have a high tolerance to poor water oxygenation. Nevertheless, these results need to be confirmed in future trials evaluating a further decrease of oxygen concentration and longer-term effects (beyond 7 days) both in terms of stress response and overall performance of fish.

Introduction

The interest for the use of diagnostic molecular markers to genetically identify species and interspecific hybrids is increasing with both commercial and conservation purposes. Lowering costs and processing time is of primary relevance especially for routine applications in which pureness of individuals must be rapidly assessed such as in the enforcement of commercial controls and in the selection of captive breeders (Toews & Brelsford, 2012; Camacho-Sanchez et al., 2020).

We present a new class of nuclear molecular markers carrying interesting features potentially useful to investigate different levels of fish genetic diversity: introns' polymorphisms.

Material and Methods

Based on an *in silico* analysis of available fish genomes, we isolated several intronic regions potentially conserved across teleosts to be characterized by an opportunely optimized targeted-amplicon high-throughput sequencing method.

A total of 122 intronic loci were selected for primer construction. All primer pairs were validated on 66 species also including important species for aquaculture and conservation purposes. Sequencing data allowed for evaluating suitability and reliability of such introns in detecting species and differentiating populations. We will also present a case study on the discrimination between the *Solea solea* and the very similar *S. aegyptiaca*.

Results

Introns has proven to be highly transferable across species with about 70 loci successfully amplified in over half of the species tested and their sequence variability has proven to have a very high-resolution power in differentiating at the species level. Focusing on the case study of the genus *Solea*, we identified 38 perfectly diagnostic loci with alternative private alleles between the two species. that These loci allowed for setting up fast and cheap identification tool base on introns' polymorphisms.

Discussion

We presented the first panel of highly conserved intron markers, characterized by high transferability between species, and variability in terms of allelic richness, as well as remarkable diagnostic potential for analysis of species and hybrid identification. Obtained results are very encouraging also for many other applications such as detection of population origin and relatedness analysis. What showed in the case study can be optimized for many other fish species.

CAN FOULING SEAWEEDS ON SEA-BASED STRUCTURES ADD VALUE TO AQUACULTURE? A BIODIVERSITY SURVEY AND SEA-URCHIN FEEDING STUDY

S. Bouchemousse*, J. Grassien, L. Costes, L. Gissat, B. Jacquemin and R. Michel

With the increase of aquaculture production, sea-based farming and culture practices must innovate to meet economic and environmental challenges for tomorrow. With more than 10 000 ha of maritime concessions along the French coasts of North Atlantic and Western English Channel, developing aquaculture sectors from a sustainable perspective, by promoting polyculture and IMTA, has become a priority for local authorities. This on-going project aims to guide aquaculture practices to further integrate sea-based structures into marine ecosystems, by using them as support for wild species.

Sea-based aquaculture structures are usually colonized by an important diversity of fouling species including seaweeds. Considered as undesirable, fouling seaweeds are the results of local recruitment and can include species displaying an economical interest for different production sectors (*e.g*. food industry, material, aquaculture). In this study, we explore the potential of ecosystemic services of fouling seaweeds to highlight the contribution of sea-based structures i) for the conservation and dispersal of local biodiversity and ii) for providing add-value seaweed species for farmers. We particularly explore the integration of fouling seaweeds in technical itineraries of sea-based breeding and cultivation, by:

- Evaluating the succession of fouling seaweeds on blank longlines
- Assessing the development of fouling seaweeds on sea-based seaweed culture by comparing blank longlines with seeded longlines of *Saccharina latissima* and *Palmaria palmata*
- Comparing the effect of feeding sources, *i.e*. fouling *versus* cultivated seaweeds, on a sea-based sea-urchins rearing

For this purpose, 200 m of seeded (100 m per species) and 200 m of blank longlines were installed on a sea-based seaweed cultivation structure in January 2022. Eight cages of 0.3 m^3, each containing 25 sea-urchins, were added to the structure in April 2022. Sea-urchins are fed every 15 days, four cages with cultivated seaweeds and four cages with fouling seaweeds. Specific Richness and Relative Biomass of seaweeds on both longline types, as well as Mortality Rate, Relative and Specific Growth Rates, Food Consumption and Conversion Ratios in each sea-urchin cages, are evaluated every month.

After 2 months, a total of 12 taxa were identified on longlines: 8.0 ± 1.0 on fouling longlines, 2.3 ± 0.6 and 5.0 ± 1.7 on *S. latissima* and *P. palmaria* cultivated longlines, respectively. As expected, seeded longlines are dominated by the cultivated species reaching biomass values (wet weight) of 460.2 ± 32.2 $g.m^{-1}$ and 296.6 ± 162.3 $g.m^{-1}$ for *S. latissima* and *P. palmaria*, respectively (Figure 1), while fouling longlines are dominated by brown algae*, i.e*. diatom colonies and filamentous species (*Hincksia sp*., *Pylaiella sp*.).

Next results of seaweed biodiversity and first data on the sea-urchin rearing will be obtained during May 2022, and will provide first insight of the role of fouling seaweeds in a sustainable approach of off-shore aquaculture.

BILE IMPRINT ON THE PARIETAL PERITONEUM IN RED SEABREAM AND GILTHEAD SEABREAM: EFFECTS OF DAYS OF FASTING, STRESS AND ICE-STORAGE

Introduction

Recently, a common complaint of Mediterranean farmed fish retailers is the occurrence of the bile imprint on the parietal peritoneum observed when fish are eviscerated or filleted. This bile mark is unattractive to the consumer who may also complain about a bitter taste of the fish flesh. The bile imprint has occurred in a more frequent and intense way in farmed red seabream, although present in the other Mediterranean farmed fish also. To our knowledge there are not related published works and the cause has not yet been identified. The aim of the present study was to investigate the possible involvement of common procedures applied before fish harvesting (i.e., days of fasting, stress due to confinement and netting), as well as ice-storage of fish, on the occurrence of the bile imprint in red seabream *Pagrus major* and gilthead seabream *Sparus aurata*. Besides, plasma and bile osmolality and cholesterol levels were evaluated in search of a reason of bile diffusion to the peritoneum.

Materials and methods

Two factorial experiments were designed, one for red seabream and one for gilthead seabream. For each trial 144 fish of mean initial body weight 185±1.3 g (red seabream Trial) and 200±2.8 g (gilthead seabream Trial) were randomly distributed, in groups of 6 fish, in 24 tanks. Fish were fed at a fixed ratio for approximately 3 weeks. At the end of the rearing, 8 tanks were randomly assigned to 1 day of fasting (DoF), another 8 tanks were assigned to 2 DoF and the last 8 tanks were assigned to 3 DoF. For each DoF, 4 tanks were sampled undisturbed and 4 tanks were stressed by confinement for 20 minutes. All fish were euthanized by an overdose of anaesthetic and were individually weighed and measured. Blood (centrifuged to separate plasma) and bile sampling took place from the first three fish of each fish group (0 h of ice-storage). The other 3 fish of each fish group, whole and ungutted, were stored in refrigeration at 2±1 ^{o}C for 48 h (48 h of ice-storage). They were placed in polystyrene boxes provided with outlets for water drainage, covered with protect-ice plastic film and filled with ice. Fish packaging was done according to the protocol followed in commercial production, i.e. 20 fish were packed in one 50 x 30 x 16 cm box. After 48 h of ice-storage, bile sampling took place. For both 0 h and 48 h fish, parietal peritoneum was photographed in LED Photo Box to ensure similar lighting conditions. Plasma and bile were analyzed for osmolality and cholesterol. Colour evaluation of the bile imprint, if present, was performed by measuring optical density of the imprint by means of digital image analysis software.

Results

Red Seabream Trial. None of the 0 h fish had a bile imprint. Instead, after 48 h of ice-storage a bile imprint was present in all the fish. Colour of the bile imprint was greatly affected by number of days of fasting, i.e. the more the DoF the more greenish the bile imprint colour. Moreover, the imprint was more intense in stressed fish no matter days of fasting. Bile osmolality was not affected by DoF. In 0 h fish it was significantly lower than plasma osmolality and was not affected by stress, while plasma osmolality was higher in stressed fish. After 48 h of ice-storage bile osmolality was highly increased, especially in stressed fish. Regarding cholesterol (0 h), confinement stress resulted in higher levels in plasma and did not affect bile levels. Days of fasting affected bile cholesterol and 3 DoF resulted in lower levels compared to 1 DoF. Generally, bile cholesterol (0 h) was lower than plasma cholesterol. In 48 h fish, bile cholesterol was significantly reduced, especially in unstressed fish.

Trial GS. Currently, the Trial has just been completed and samples and photos are being processed.

Discussion

The present “incomplete” abstract will be replaced in due course.

BLUE FOOD PLANNING AND CLIMATE CHANGE: FOOD WEB MODELS AS TOOLS FOR THE ANALYSIS

D. Brigolin[1], E. Donati[1]

[1]Dipartimento di Culture del Progetto, Università IUAV di Venezia, 30135 Venezia, Italy
* dbrigolin@iuav.it
Tel. +39 041 2571318
e-mail: dbrigolin@iuav.it]

Introduction

Forecasted long-term trends in environmental parameters, induced by climate changes, need to be considered in the ongoing and future management of blue food productions (*sensu* Blue food assessment, 2022), in order to attempt a sound adaptation to changes that are likely to affect these activities (Cochrane et al., 2009; FAO, 2015). Here we apply a dynamic food web model in a marine coastal area located in the Gulf of Venice (Northern Adriatic Sea), were longline mussel farms (Mediterranean mussel, *Mytilius galloprovincialis*) coexist with different types of fisheries, including, recreational, artisanal, clam dredging and trawling, and with important conservation assets, including a marine rocky bottom Natura 2000 site. Our final aim is to produce forecasts considering both scenarios of climate change and interaction of aquaculture with other uses of the sea, in order to support the analysis of future blue food production potential in the area in the framework of maritime spatial planning.

Methods

An existing food web model (based on Ecopath with Ecosim) of the northern Adriatic Sea was adapted to this coastal area (Donati et al., 2021), characterised by the presence of mussel farms, a sandy bottom hosting clam beds of high commercial importance, and biogenic rocky outcrops relevant for biodiversity conservation. 28 trophic groups were defined in the model, see Figure 1, considering different habitats and tolerance to environmental drivers. Mussel farming was characterised based on previous studies in the area (Brigolin et al., 2009). Fishing activities was described considering 6 different fleets (including different trawling gears, hydraulic dredge, artisanal and recreational fishery). Dynamic food web simulations were performed by introducing time series of water temperature and primary production (climate change) and fishing effort/aquaculture production (bluefood management). Simulations considered a time frame of 40 years, from 2014 to 2054, comparing 2 scenarios RCP, 4.5 and 8.5. Downscaling for forcing variables were taken both from the EURO-CORDEX CMIP5 and from biogeochemical model outputs (ERSEM), produced in the framework of the CERES H2020 project. The FWM provided as an output time series of group biomasses, catches, and ecosystem functioning indicators. The temporal variation of ecosystem functioning indicators and of trophic groups biomasses was assessed with respect to a baseline scenario.

Results and discussion

Tolerance curves identified (Figure 2left) and used in the dynamic FWM allowed to derive a comprehensive set of ecosystem functioning indicators under the two CC scenarios considered (as shown in Figure 2 right, considering only temperature induced changes). Higher percentage of variation was presented by those indicators associated to groups biomasses, as the commercial B and Kempton (K), showing decrease ranging between 10 and 15%. Indeed, different groups including species of high commercial interest presented a substantial biomass decrease. Results provided differing assessments when considering only variations in mussel aquaculture and fishery productivity, or the overall ecosystem functioning of the area. This is discussed with regard to the ecological carrying capacity concept.

Introduction

Future scarcity in phosphorus resources is a challenge directly linked to food security, and solutions are needed to shift the current phosphorus use into more sustainable forms (Cordell et al., 2009, 2011). The release of biogenic waste from finfish aquaculture along coast lines can have negative impacts on marine ecosystems (Jansen et al., 2018), as well as being a wasteful practice with limited resources like phosphorus. Recirculation of biogenic waste from aquaculture can be done by co-cultivating species like *Saccharina latissima,* in integrated multi-trophic aquaculture (IMTA) systems (Chopin et al., 2001). This study characterizes storage of phosphorus in *S. latissima* cultivated close to salmon sea cages and evaluates the recycling potential of this species.

Materials and methods

A 4-month cultivation study was conducted by deploying vertical ropes (5 m) with *S. latissima* seedlings along a gradient within and downstream from a salmon farm. Ropes were grouped as integrated among pens (I-SL, -150 to 0 m), and downstream from farm edge (D-SL, 100 to 280 m), assuming different nutrient availability between groups from farm proximity. Biomass registration, water- and tissue samples were collected and analyzed after 2 (April) and 4 (June) months in the sea. Tissue samples were analyzed for carbon (C) and nitrogen (N), and phosphorus (P) content from three areas of the seaweed to characterize internal distribution: basal- (B), mid- (M), and apex area (A).

Results and discussion

Tissue content of P (Figure 1) varied significantly between I-SL and D-SL group. The content was highest in the B area in April for both groups ($p<0.05$), indicating prioritized accumulation of nutrients in the meristematic tissue to facilitate growth in young individuals. This support phosphorus as an important element for physiological functions involved in growth (Hurd et al., 2014). The A and M area was significantly different ($p<0.05$) in the D-SL group but not for the I-SL group, indicating an effect of nutrient availability affecting internal content of P. Overall, the magnitude of P content suggest that algae cultivation solely for recycling P is not recommended.

Biomass yields were significantly higher in the I-SL with a peak yield of $7.01\pm0.88\ \mathrm{kg_{FW}m^{-1}}$ in June, supporting studies with increased biomass yield by cultivation near salmon farms (Marinho et al., 2015). However, within the I-SL group biomass yield was highest at the farm edge, decreasing further in-between salmon pens (Figure 2). Suggesting that other factors could be limiting light and water movement patterns, affecting seaweed growth (Klebert et al., 2013). This supports cultivation of seaweed closely downstream from salmon farms, ensuring high biomass yield. Biomass yield was promoted the main factor for estimating bioremediation potential.

Conclusion

Understanding of biochemical composition, and how it relates to growth is important when establishing the seaweed cultivation industry. Nutrient availability can be an important factor, but this study also shows how physiological mechanisms regulate internal nutrient availability to ensure rapid growth at the right time.

The cultivation of *S. latissima* in IMTA systems can be an opportunity for recapturing phosphorus in a production of biomass for a new value chain. However, phosphorus content by itself is not an ideal measure for assessment of bioremediation potential.

USING SEA URCHIN FAECES AS A DIETARY SUPPLEMENT FOR JUVENILE ABALONE: EFFECTS ON GROWTH, SURVIVAL AND THE MICROBIOME

Marissa Brink-Hull*[1], Mark D. Cyrus[1,2], Aimee Cloete[1], John J. Bolton[1], Brett M. Macey[1,2]

[1]Department of Biological Sciences, University of Cape Town, Rondebosch 7701, South Africa
[2]Department of Forestry, Fisheries and the Environment, Cape Town 8001, South Africa
*marissa.brink-hull@uct.ac.za

Introduction

During the early post-settlement juvenile stages, the abalone *Haliotis midae* has a known ecological relationship with the Cape sea urchin *Parechinus angulosus* in nature. The urchins provide the juvenile abalone with shelter and protection, as well as with improved food supply and possibly provide beneficial microbial communities, all of which could act as drivers of the relationship between these species. These species are therefore strong candidate species for integrated multi-trophic aquaculture (IMTA), as they also have a similar preferred temperature range (12 - 20°C). Furthermore, hatchery-produced abalone could benefit from sea urchin faecal matter supplementation during early juvenile stages as the transfer of microbial communities could aid in digestion, growth and overall health. Therefore, the aim of this study was to evaluate the potential benefits for abalone growth, survival and subsequent changes in the microbiome associated with using sea urchin faecal matter as a supplementary feed or probiotic for juvenile abalone.

Materials and Methods

An 8 week experiment was conducted in a commercial hatchery in South Africa (Buffeljags Abalone) where two sets of three tanks, each tank (L x W x D: 0.68 m x 0.50 m x 0.12 m) with 25 000 juvenile abalone with starting shell lengths of ca. 3 mm that were fed a mixed diet of diatoms, formulated feed, *Ulva lacinulata* and *Gracilaria*. One set of tanks was only fed the mixed diet (control) and the other set was provided with a daily supplement of sea urchin faecal matter collected from 310 sea urchins per tank. Sea urchins were only fed *U. lacinulata* and were held in baskets in separate tanks (L x W x D: 0.68 m x 0.50 m x 0.12 m) as preliminary trials indicated that this simplifies animal husbandry practices for these species.

Juvenile abalone growth and survival was monitored for the duration of the trial. Abalone growth was assessed by measuring shell length and width (in cm) of 300 randomly chosen animals per tank at each timepoint (0 weeks, 1 week, 4 weeks and 8 weeks). Survival was assessed weekly by collecting and counting mortalities per tank. Using the Illumina MiSeq next-generation sequencing platform, a 16S rDNA and ITS2 metagenomics approach was used to characterise bacteria, fungi and oomycete communities. Metagenomic samples (n = 75) included incoming seawater (500 mL) that was collected on 0.22µm filters, sea urchin intestines and faecal matter, abalone intestines and faecal matter, as well as each of the feeds. Once raw sequence data is received, data will be processed using QIIME2 (Boylen et al., 2019). Bacterial 16S reads will be mapped against the SILVA 16S rRNA reference database (Quast et al., 2013) for taxonomic identification. Fungal and oomycete ITS2 reads will be mapped against a custom fungal and oomycete database that included the UNITE database (Abrenkov et al., 2021) and oomycete sequences downloaded from the National Center of Biotechnology Information (NCBI). MicrobiomeAnalyst will be used to assess within- and between sample diversity, as well as to quantify and visualise taxonomic abundance and differential abundance analyses (DESeq2). Lastly, the functional capabilities of the identified taxa will be assessed.

Results & Discussion

Results from the large-scale trial showed that the shell length of juvenile abalone were statistically significantly larger ($P < 0.05$; one-way ANOVA) at 1 week, 4 weeks and 8 weeks (Figure 1), with shell width being statistically significantly larger at 1 week and 4 weeks.

Although there were limited statistically significant differences in survival, the growth results suggest that the faecal matter and possibly the microbes transferred from the urchins to the abalone provides an advantage in the early post-weaning stages. This trophic transfer of microbial communities will be further assessed in this study. Enteric bacteria are thought to play roles in the synthesis of essential amino acids, provisioning of digestive enzymes, improvement of digestive efficiency, nitrogen metabolism, as well as access to essential micronutrients.

(Continued on next page)

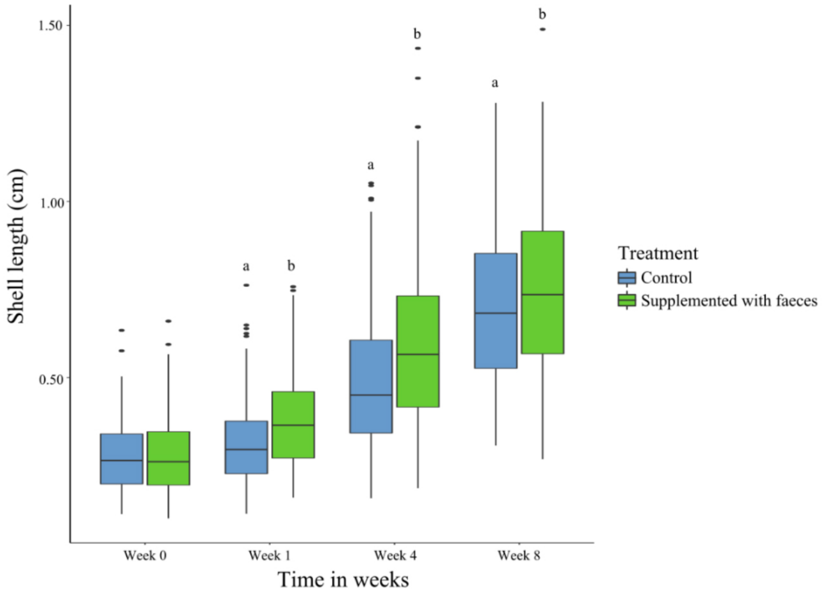

Figure 1. Average juvenile abalone shell length (cm) over a duration of 8 weeks across abalone fed only diatoms, a formulated feed, *Ulva* and *Gracilaria* (control, n = 300 per time point) and abalone fed diatoms, a formulated feed, *Ulva* and *Gracilaria* while being supplemented with sea urchin faeces (n = 300 per time point).

Conclusion

Supplementing juvenile abalone diets with sea urchin faecal matter is advantageous for abalone growth and health in their early juvenile stages, possibly as a result of microbial community transfer from the sea urchins. The intestinal microbiome is often established during the juvenile stages for aquatic animals and could have long-lasting effects on digestion, overall performance and health, possibly through the microbial provisioning of digestive enzymes. This study will provide insight on the potential benefits and effects of supplementing juvenile abalone diets with sea urchin faeces.

AN ENVIRONMENTAL ASSESSMENT OF AN AQUACULTURE SYSTEM IN PORTUGAL FROM LIFE CYCLE PERSPECTIVE

Andrei Briones-Hidrovo*, Paula Quinteiro, Ana Cláudia Dias

Centre for Environmental and Marine Studies (CESAM), Department of Environment and Planning
University of Aveiro, Campus Universitário de Santiago, 3810-193 Aveiro, Portugal
Email: *ahidrovo@ua.pt

Introduction

Within the food sector, aquaculture has its share in supplying animal-source food and protein worldwide. Fish harvested from aquaculture amounted to 73.8 million tonnes, accounting for 44% of total aquaculture production, contributing this way to meet current needs (FAO, 2016). The overall aquaculture production in Portugal was 16,999 tonnes in 2020 with the vast majority taking place in marine and transitional waters (coastal ecosystems) (INE, 2021).

To date, aquaculture systems have been poorly assessed in Portugal from an environmental perspective, and in particular, using Life Cycle Assessment (LCA). LCA is a widely applied methodology that determines the potential environmental burden of products and services throughout their entire life cycle. Additionally, the linkage of resources, food and nutrition are likewise poorly addressed in the literature. This study aims to analyse the environmental impacts of a small-scale aquaculture system in Portugal by applying LCA.

Materials and Methods

The aquaculture system (AQS) is located in the Ria de Aveiro which is classified as a coastal lagoon ecosystem. The AQS is a semi-closed-extensive system and comprises 3 natural ponds, with a net area of 28 hectares (ha). It produces seabass (70%) and seabream (30%), being the production cycle of 18 months.

The LCA methodology follows the standards ISO 14040 and ISO 14044 (ISO, 2006)"title":"Environmental management. Life cycle assessment. Requirements and guidelines.","type":"report"},"uris":["http://www.mendeley.com/documents/?uuid=b1102395-0dee-41cb-8faf-6ec7c94fc4e4"]}],"mendeley":{"formattedCitation":"(ISO, 2006. Based on the product output, 1 kg of medium size fish (MSF) was chosen as functional unit (FU). The system boundaries encompassed the pre-production that includes the transportation of juveniles and the production that consists on fish fattening and growth. Primary data were directly collected at the aquaculture farm by means of questionnaire and by interview. As environmental impact assessment method, it was adopted the Environmental Footprint method that is proposed by the European Commission (Fazio et al., 2018). The impact categories included were climate change (kg $CO_{2\text{-eq}}$), acidification (mol $H+_{eq}$), freshwater eutrophication (kg P_{eq}), marine eutrophication (kg N_{eq}), water use (m^3 deprivation) and fossil resource use (MJ).

Results

The overall results indicated that the majority of the impacts are concentrated in the production process (Table 1). Moreover, within this process, the production of fish feed represented the largest share (99%) of the total impact in all impact categories. The life cycle impacts are presented in the table below. In terms of resources, the results showed a very high dependency on abiotic n on-renewable resources (fossil fuels), accounting for 59% of the total resource impact. Fish soy-based feed production has the largest share in the consumption of fossil fuels.

Table 1 – Impact assessment results expressed per FU

Impact category	Unit/FU	*Pre-production*	*Production*	Total
Climate change	kg CO_{2eq}	9.28E-03	2.87E+00	2.88E+00
Acidification	mol $H+_{eq}$	2.30E-05	2.71E-02	2.72E-02
Eutrophication, freshwater	kg P_{eq}	6.65E-07	5.56E-04	5.56E-04
Eutrophication, marine	kg N_{eq}	4.47E-06	8.93E-03	8.94E-03
Water use	m3 depriv.	1.18E-03	3.99E+00	3.99E+00
Resource use, fossils	MJ	1.65E-01	2.38E+01	2.40E+01

(Continued on next page)

Conclusions

Although the results are in the same order of magnitude concerning LCA studies available in the literature, the assessment of the culture of seabass and seabream revealed lower impacts than the majority of existing case studies. Notwithstanding, the impacts cannot be overlooked, mainly from the fish feed. Therefore, it is suggested to look for strategies that ensure the long-term environmental sustainability of this type of aquaculture system. These strategies could point towards incentivizing small-scale and local organic aquaculture, using more sustainable fish feed, and seeking to benefit from the natural conditions by harnessing provisioning and regulating ecosystem services, thus increasing the renewability of the systems.

GIS APPLICATION FOR OFFSHORE AQUACULTURE SITE SELECTION ALONG THE RED SEA, SAUDI ARABIA

G. Brizzi[1], J.J. Jose[1], A. C. J. Schmidt-Roach[1], A.M. Widaa[1], and A. Al Shaikhi[2]

Introduction

Early aquaculture practices have failed thus far to incorporate environmental impacts and sustainability into their establishment and production plans, resulting in numerous negative environmental (Fernandes, Eleftheriou et al. 2001) and long-term production impacts, inefficient production cost effectiveness and negative public views about aquaculture practices (Froehlich, Gentry et al. 2017). However, industry, regulatory agencies, and public mindsets have recently shifted towards more sustainable aquaculture practices and technologies that primarily include the identification of suitable sites to be matched with the assessment of their carrying capacity. A geographic information system (GIS) creates, manages, analyses, and maps all types of spatial data. This provides a foundation for mapping and analysis that is used in science and almost every industry. This study uses GIS to identify sustainable sites for aquaculture development: using numerous criteria and parameters. Several sites suitable for offshore aquaculture development were identified along the Saudi territorial waters.

Material and methods

On the basis of pre-existing usage, a relevant part of the Saudi territorial waters was excluded from the number of available areas for offshore aquaculture.

The site selection process started by establishing a panel of scientist and aquaculturist experts in the domain in Saudi Arabia, with the aim of defining the most relevant criteria to be used in aquaculture site selection. Due to the Red Sea specificity, the agreed criteria were:

1. Bathymetry
2. Port distance
3. Reef distance
4. Current average
5. Naval traffic
6. Coast distance

For each of these criteria, a range of values were established, classifying aquaculture sites as:

- Optimum, score 1
- Average, score 2
- Poor, score 3

Those scores were subsequently weighted, assigning them an average weight on the basis of the expert's judgement of their importance in running an aquaculture activity in Red Sea. The assigned weight ranged between 1 (maximum weight) to 0 (minimum weight).

The areas identified as suitable for aquaculture activities were then partitioned by a 500x500 m grid. Each of the squares were finally ranked, assigning each one a final score for each criterion, represented by the initial score multiplied by the weight assigned by the expert panel.

The sum of the final scores, over the whole available criteria, determined the final tier to be assigned to each 500x500 m square over the map. This sum ranges from 4.3 to 12.6.
The final tiers were assigned as follow:

- Up to 4.3, optimum overall conditions, tier 1, color green;
- Up to 8.6, average overall conditions, tier 2, color yellow;
- Up to 12.9, poor overall conditions, tier 3, color brown.

(Continued on next page)

Results

The GIS exercise covered most of the Red Sea and allowed for the identification of several areas suitable for offshore aquaculture. These areas were further classified on an optimum- average-poor scale on a 500x500 m grid and displayed on the map in three different colors (Figure 1).

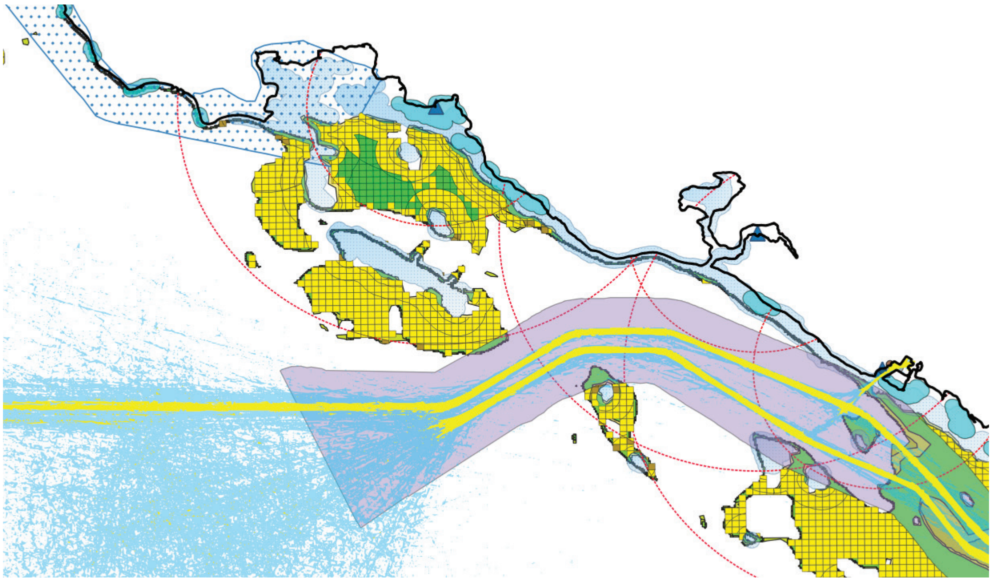

Fig. 1 *GIS output for a section of the Saudi Arabian Red Sea Coastline*.

Most of the areas suitable for offshore aquaculture are located in the southern region of Saudi Arabia, characterized by extensive shallow bottom, gentle sloping topography and surrounded by coral formations.

Conclusion

The uses of the Red Sea in Saudi Arabia are mainly driven by decision taken at the of central or local authority level. This shortens the process of assessing the aquaculture compatibility of areas and makes the selection process rather different from those carried out elsewhere (Marino et al., 2020). This exercise in fact mainly dealt with the areas left open by other existing activities, and most of the work focused on identifying the marine activities and the sensitive areas to be buffered, also assessing the reasonable buffer extent. The coral reefs were identified as the most sensitive communities to be protected due to their endangered status at the global level and to their specific sensitivity to nutrients. The value of corals reefs for Saudi economy is particularly huge, and for these reasons a double buffer level, the first derived from literature, the second, more conservative, from field observation, was set.

Introduction

Upon request from Saudi MEWA, King Abdullah University of Science and Technology is initiating comprehensive and detailed work to design and engineer a sustainable offshore fish farming in the Red Sea. The dedicated team will evaluate the environmental carrying capacity and optimal farming operations at six selected sites along the Saudi western coast. Farmed species at these sites will be selected from 5 species candidates. Field surveys will be conducted and fish farm models will be run to simulate operations and environmental impact for each of the sites. The simulations will be run using AquaModel, an advanced 3-dimensional, ecological and operational model that has been developed over the last 20 years by System Science Applications (see AquaModel.net). Stakeholders around the world have used this software, which runs on Windows PCs, for environmental monitoring, siting, licensing, and addressing regulations.

AquaModel provides a 3-dimensional simulation of growth and metabolic activity of multiple farmed finfish species along with associated flow and transformation of nutrients, oxygen and particulate wastes in waters surrounding the farm. The software is the first and only computer model for net-pen aquaculture and kelp growth in the world that can simultaneously calculate and display real-time feed ingestion, growth, respiration and egestion by cultured organisms. AquaModel has simulated fish farm operations for 11 species of finfish as well as sugar kelp. Fig. 1 shows processes that are described in the 3-dimensional simulation.

Materials and Methods

Data from the field surveys, output from KAUST's Red Sea circulation model, and laboratory measurements of species growth and metabolism will be ingested into site specific project files. Inputs to the simulations will include a high-resolution 3-D ocean current data, bathymetry and coastline, presence-absence of coral reefs and nearby beaches, and ambient sediment conditions such as sea bottom grain size, bottom water oxygen and nitrogen, hydrogen sulfide, as well as TOC and POC. Oceanographic inputs to the simulation will also include as best as possible time series of water temperature, chlorophyll, mixed layer depth, oxygen, nitrogen, salinity, irradiance, and winds. The simulations will also include operational variables of the farms within the 6 sites. These include location, number of pens, spatial coordinates of each pen, height/length/depth dimensions of each pen, cultured species, duration of operation. Stocking, feeding and harvesting schedules for each farm will also be entered into the calculations. Physiological models for four finfish species will been created using available literature as well as farm and laboratory data. A plankton sub-model that runs in AquaModel will be expanded and parametrized to include model parameters for both large and small ensembles of phytoplankton and zooplankton characteristic of the Red Sea.

Results

Figure 2 shows screenshots of model output concerning one site 5 km offshore along the southern coast. The left panel of figure 2 is a screenshot of the flow field at a single step of the simulation. The small cross seen offshore is the location of the cages of the farm. The plot on the left of the screen or a control panel for viewing the simulations and the panel below is used to set-up operations of the farm. The scale of current velocity in the flow field are shown on the right. The right panel is a zoomed in view of farm and shows cages, a dissolve nitrogen plume from the cages, current vectors. On the left are plots of the depth distribution of the nitrogen plume, a time series of current velocity and the increase in fish biomass of the farm. On the left are legends for current velocity, nitrogen concentrations at the sea surface, and detailed information on conditions within selected cages.

(Continued on next page)

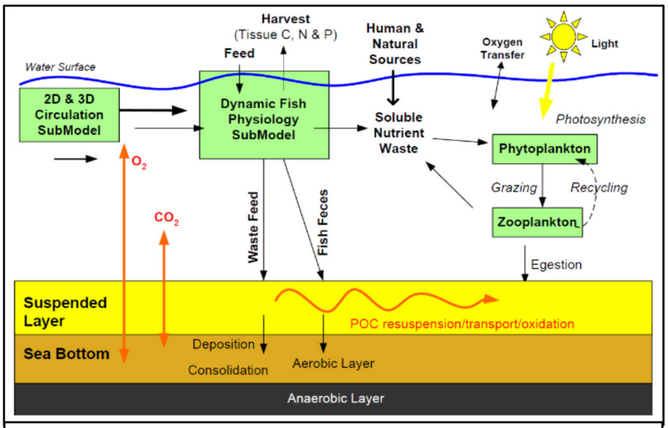

Fig. 1. AquaModel components for finfish aquaculture.

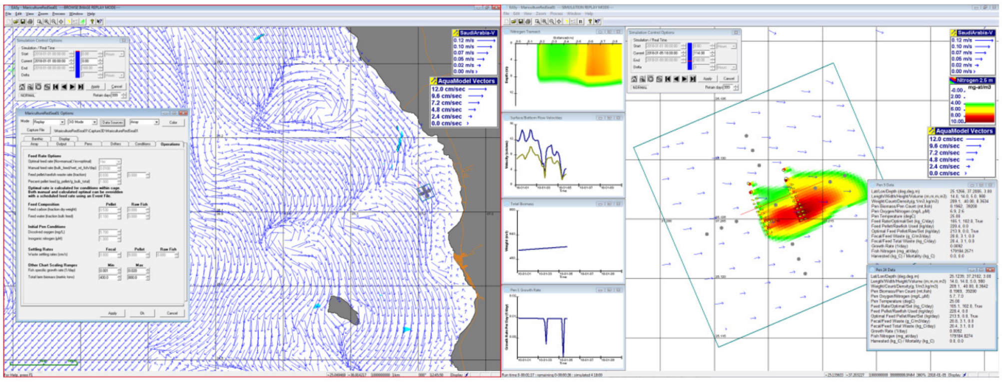

Discussion

AquaModel output enables to determine the environmental pressure for each farm site. This output can be analyzed to suggest sustainable carrying capacity at each of the six sites, and can lead to recommendations for farm operation modification, monitoring and further research.

Conclusions

This exercise allows for the assessment of the carrying capacity of the selected sites, by simply increasing the production level assigned to each farm until the maximum sustainable production is attained, even separating the points of emissions as adding new farms in the selected area. The maximum carrying capacity is highlighted by the interference of the nitrogen plumes with surrounding coral reefs over space and time dimensions.

35 YEARS OF CONSERVATION OF THE ADRIATIC STURGEON: PAST AND FUTURE

P. Bronzi,[1]. E. Boscari,[2], L. Congiu,[2]

[1] WSCS, - Via Lombardia 32, 20853 Biassono (MB), Italy
++39 3463504723
aerespe@mac.com
[2] Dept. of Biology, University of Padova, via U. Bassi, 58/B, 351231 Padova, Italy

The Adriatic sturgeon (*Acipenser naccarii*), endemic of the northern Adriatic Sea and its main tributaries, is the only one still surviving of the three sturgeon species once living sympatrically in Italy. The other two formerly present species were the common sturgeon (*A. sturio*), distributed also along all the Italian coasts and the Beluga, (*Huso huso*).

The survival of the Adriatic sturgeon has been possible thanks to a variety of conservation actions conducted in the last almost 35 years by different public and private entities, but, most importantly, were possible only thanks to the efforts of a private trout farmer who, anticipating the extinction of this species, collected and maintained in his fish farm about 90 animals of wild origin caught in the Po and other northern rivers of the Padana Valley. From this stock, since 1988 hundreds of thousands of animals have been produced through controlled ex situ reproduction and were mostly released in the wild and in part retained as future breeders.

The different conservation activities carried out in Italy have been crucial for the preservation of the species, in spite of the lack of global coordination that led to a suboptimal management of the residual population at different levels: i) choice of individuals to reproduce to maximize genetic diversity, ii) establishment of training and releasing protocols to maximize the fitness for survival of the reintroduced animals, iii) organization of an effective and coordinated monitoring activity.

The present report will trace the whole history of the conservation of the Adriatic sturgeon in Italy, combining the main actions carried out into a single picture, from the beginning until the recent findings of some mature female and fingerlings and juveniles in some rivers, most probably the results of some natural reproductions. Furthermore, a huge and ambitious project for the establishment of a center for the conservation of freshwater biodiversity of the Padana Valley, presently in progress, will be presented.

FIRST COMPARATIVE EVALUATION OF *Ostrea edulis* (LINNAEUS, 1758) AND *Crassostrea gigas* (THUNBERG, 1793) BIODEPOSITION IN TWO MEDITERRANEAN LAGOONS

G. Brundu*[1], C. Frongia[1], S. Pagani[12], A. Chindris[1], P. Graham[1], and S. Carboni[1]

Introduction

Oyster farming represents 33% of global bivalve production. The Pacific cupped oyster *Crassostrea gigas* (Thunberg, 1793) is the most reared species (~653,000 tons in 2019), while the production of the European flat oyster *Ostrea edulis* (Linnaeus, 1758) is less substantial (~2,200 tons in 2019) (FAO, 2019). Oyster farming is associated to some important ecosystem services (Clements and Corneau, 2019), but simultaneously it could negatively impact on the sea bottom health, through the release of faeces and pseudofaeces, rich in inorganic and organic matter (Newell, 2004), hereafter collectively referred as bio-deposits. High amounts of bio-deposit production can cause structural changes in benthonic communities, leading to hypoxic events, loss of biodiversity and predominance of detritivorous species (Newell, 2004). Eutrophic environments such as coastal lagoons are characterised by large amount of phytoplankton and suspended particulate matter available for filter-feeders, thus representing suitable sites for oyster farming but also resulting in a large production of bio-deposits (Newell, 2004). The aim of this study was to compare the daily bio-deposition rate of two oyster species, *C. gigas* and *O. edulis*, in two coastal lagoons potentially suitable for farming and characterised by different environmental and trophic conditions.

Materials and methods

This study was conducted in two shallow eutrophic lagoons (Magni et al., 2008) located in the central-western coast of Sardinia Island (Western Mediterranean, Italy), S'Ena Arrubia and Corru S'Ittiri. In September 2021 and over a period of 24 hrs, we evaluated the bio-deposit production of the two oyster species and the natural deposition rate of the lagoons: Total Particulate Matter (TPM), Particulate Inorganic Matter (PIM) and Particulate Organic Matter (POM). Seven replicates per treatment were performed. Individuals had a mean wet weight of 43.4 ± 0.8 g (*C. gigas*) and 46.3 ± 0.6 g (*O. edulis*), they were of hatchery origin (Marinove, France) and they were reared in the same lagoons. Prior to the trials, individuals were brushed cleaned to remove epibionts and acclimated for a week to the natural conditions of the lagoons. The bio-deposit production and the natural deposition were evaluated by using 21 (7 per treatment) cylindrical PVC tubes with a close-end fund (200 mm, height; 100 mm, diameter), suspended on a floating rope at 15 cm depth. Environmental parameters (temperature, salinity and dissolved oxygen) were measured with data loggers placed at 15 cm depth. Trophic conditions were assessed on surficial water samples collected in triplicates for measurement of chlorophyll a (Chl-a), TPM, PIM and POM, following the methods described in Parson, Maita & Lalli (1984). Data were analyzed by Statistica 6.1 StatSoft, Inc. (2004).

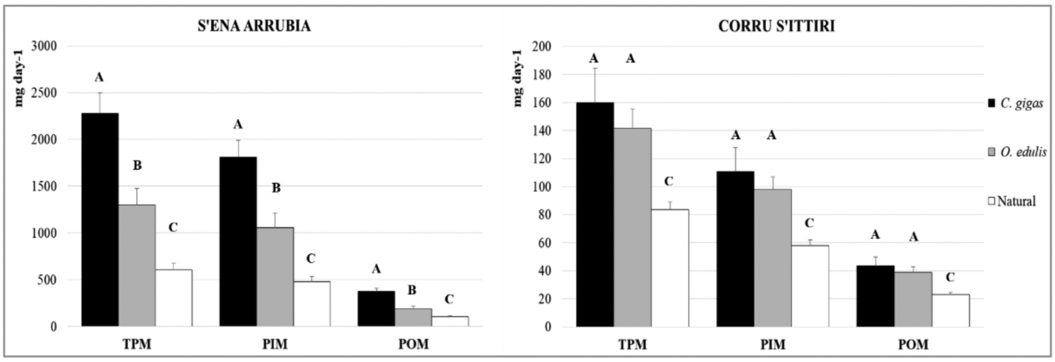

Fig. 1: TPM, PIM and POM production of *C. gigas*, *O. edulis* and Natural sedimentation in Corru S'Ittiri e S'Ena Arrubia. Superscripts indicate significant differences among treatments (n=7).

(Continued on next page)

Results

In S'Ena Arrubia, the bio-deposit production was significantly different between species, *C. gigas* showed higher production of TPM ($p < 0.01$), PIM ($p < 0.01$) and POM ($p < 0.001$) than *O. edulis*. In Corru S'Ittiri, although we registered high values of TPM, PIM and POM produced by *C. gigas*, no significant differences were highlighted in comparison with *O. edulis*. Natural sedimentation resulted significantly different between lagoons, with a higher production of TPM, PIM and POM in S'Ena Arrubia than Corru S'Ittiri ($p < 0.01$) (Fig. 1). Environmental and trophic parameters were significantly different between S'Ena Arrubia and Corru S'Ittiri. In particular, Corru S'Ittiri registered a higher salinity ($p < 0.05$) and Chl-a ($p < 0.001$), and a lower amount of TPM ($p < 0.001$) and PIM ($p < 0.001$) than S'Ena Arrubia.

Discussion and conclusions

According to our results, the bio-deposit production of oysters was different between species and varied on the basis of the farming site characteristics. In the two lagoons the amount of bio-deposit produced by *C. gigas* was higher than those produced by *O. edulis*, this probably due to a higher filtration activity and metabolic rate of *C. gigas*, as previously observed by Nielsen et al. (2017) under laboratory conditions. Regardless of the oyster species we recorded a higher bio-deposit production in S'Ena Arrubia, probably due to the higher amount of TPM and PIM in the water column in comparison with Corru S'Ittiri, rather than the amount of Chl-a, which was higher in Corru S'Ittiri. In conclusion, the two oyster species produce different amount of bio-deposit, the production is site-specific and vary on the basis of the farming site characteristics, in particular the amount of available particulate matter. This indicates that the effects of oyster aquaculture on the sediments of the farming site must be evaluated specifically in each location.

Introduction

Soil-independent, closed environment agriculture (CEA) has potential to meet challenges in food production, such as climate change and soil deterioration by assuring yield, improving water and fertiliser efficiency, decreasing the incidence of pathogens and pests, among others. The use of recovered or recycled fertilisers instead of chemically pure mineral fertilizers would further contribute towards increasing the sustainability of vegetable production. By combining hydroponics (HP) with aquaculture, nutrient-rich aquaculture effluent is recirculated, thereby diminishing or removing the need for inorganic fertilisers. As additional benefit, cultivation in aquaponics seems to provide competitive presence of beneficial microorganisms that contribute towards mitigation of root rot infections1–3. However, detailed studies of this are rare. Pythium spp. are root pathogens that often cause root rot in soil-less grown vegetables. To test the hypothesis that aquaculture effluent contributes toward fighting against Pythium spp. infection, lettuce (Lactuca sativa, variety Salanova) was cultivated in either conventional HP or in the effluent of a commercial aquaculture farm before being inoculated with the pathogen.

Materials and Methods

Twenty-four lettuces were grown in rafts in a climate chamber (23-15 °C day/night, 65% relative humidity, 16-8h day/night, 0.12% CO_2) and underwent two treatments in duplicate boxes of 6 plants each: *(i)* HP solution of demineralised water with added nutrients and NaCl to mimic the composition of the aquaculture effluent; *(ii)* aquaculture effluent from a commercial RAS rearing pike perch at 37 kg/m^3 (AP). AP contained 782 mg/L Na^+ and 830 mg/L Cl^- (4.2 mS/cm) as the farm used NaCl to prevent disease in fish. K and Fe were added in AP as KOH and Fe EDTA, respectively, to meet lettuce requirements. pH at the end of the trial was 7.95 and 7.88 in HP and AP, respectively. On day 29 after seeding, 0.25 g *Pythium* sp.-infected millet was inoculated onto each rockwool cube of one replicate. After 60 days from seeding, chlorophyll, flavonoid, and nitrogen levels were estimated with Dualex® (ForceA, France)[4]. On day 61, the lettuces were harvested, shoots and roots were weighed separately and thereafter dried at 60 °C before determining dry matter. The elemental composition was analysed by XRF spectrometry (SPECTRO analytical instruments GmbH, Germany). R software[5] was used to perform a two-way ANOVA with factors system (S; levels: HP, AP) and infection (I; levels: no, yes), followed by a Tukey's test.

Results and Discussion

All parameters, except shoot dry weight, root dry weight, and nitrogen balance index, differed between HP and AP systems ($p<0.05$ or smaller; Table 1). Plant growth in the AP system was lower than in the HP system, as found elsewhere[6]making it difficult to accurately determine deficient nutrients limiting crop yield and quality across the systems. To avoid interference with background nutrients, we used reverse osmosis water in this study. The objectives were to identify critical nutrients that affect the yield and quality of cherry tomato-, basil-, and lettuce by characterizing nutrient composition and concentration in aquaponic systems in comparison to hydroponic systems. Daily release rate (mg L−1. There were no visible signs of infection on lettuces from either system. AP plants undergoing *Pythium* infection did not show differences from the non-infected ones, while the percentage of shoot dry weight on fresh weight in infected HP-grown lettuce was significantly higher. Infecting the plants also led to a not significant increase in the levels of flavonoids (stress response) and chlorophyll (possibly related to nitrogen status[7]), irrespective of the system. However, the nitrogen balance index was not significantly different, indicating that the nitrogen status of leaves was not sharply affected.

Na, Ca, Mg, P, Cl, Mn, Cu and Zn contents were significantly higher in shoots of HP-grown plants, while there were no differences in K, Al, and Si; Fe and Ni were higher in the shoots of AP-grown plants (Table 2). The levels of Fe in shoot biomass seemed to be lower in the infected plants. The lack of replicates did not allow to detect statistical differences between the different treatments in the element concentrations in root samples.

Conclusions

The study showed that HP and AP nutrient solutions containing similar values of pH, nutrients and salinity could both sustain Salanova lettuce growth. Infection with *Pythium* sp. did not compromise the lettuce growth; however, the beneficial effect could not be confirmed. As there were no visible signs of infection on lettuces from either system, *inocula* containing more active spores should be tested to delve into the capacity of AP system to provide beneficial bacteria against pathogens.

FIRST SUCCESFUL ATLANTIC BLUEFIN TUNA (*Thunnus thynnus*) FEEDING DEMONSTRATION WITH FORMULATED DIETS: THE ONLY SUSTAINABLE FUTURE FOR TUNA FARMING

Alejandro Buentello[1], [2]* Vladimir Muñoz, Paula Gamas[2], Daniella Acevedo[2] and Mario Reguera[2]

Introduction

The tuna ranching industry is a global, high-value aquaculture activity. Current feeding practices are impractical, unsustainable and pose serious ecological risks. The daily feeding of large quantities of fresh/frozen fish results in extremely high feed conversion rates (>20 : 1) and significant nutrient leeching (1, 3, 4, 7, 8). Seasonal availability and quality variation plus the absolute dependence on exotic baitfish brought to the Mediterranean Sea highlight the urgent need for a balanced feed. Objectives for the present experiment were to compare performance and quality indicators of Atlantic bluefin tuna (ABFT, *Thunnus thynnus*) fed herring/mackerel or a compound tuna feed based on sustainable American soy.

Materials and methods

A fourteen-week feeding demonstration was conducted in two oceanic net pens moored east of San Pedro del Pinatar, Murcia, Spain (37°49.835' N 000°39.822' W). Each cage held ~45 fish, weighing approximately 99.5 kg (average initial individual weight, evaluated both by expert visual ranking and corroborated by the AQ1's AM 100 fish sizing system). Feed consumption and condition factor were recorded. At harvest, dorsal loins were collected and color, mercury, proximate composition, scombrotoxin levels, oxidative stability index and peroxide values were evaluated in the resulting tuna steaks. In addition, a blind sensory evaluation and a commercial taste assessment were performed on the main sashimi cuts obtained from fish fed either diet.

Results

Steak samples from formula-fed fish had similar lipid contents as those fed baitfish but exhibited improved flesh color, texture and had increased oxidative stability and reduced histamine. Results from sensory and organoleptic evaluations (professional sashimi chefs) indicated that sashimi slices from formula fed fish were similar in flavor but more stable on the counter and superior in color. Importantly, there was a significant reduction in tissue mercury in formula-fed fish as compared to baitfish fed ABFT (6).

In addition, the formulated diet offered feed management options that are quite compatible with the present operation and equipment available at commercial tuna farms in the Mediterranean Sea (2, 5). A preliminary economic evaluation (2021 prices) indicated that tuna feed is significantly more cost-effective than imported frozen baitfish.

Discussion and conclusions

Given increased fishing quotas for ABFT and the severe difficulties in sourcing baitfish experienced by Mediterranean tuna farmers, the formulated diet offer a viable alternative to baitfish feeding. In conclusion, these results indicate that the balanced feed provided suitable nutrition for adult ABFT, enhanced the quality and shelf life of tuna flesh, and may enable management strategies to optimize performance, thus increasing farm efficiency and reducing the environmental impact of commercial tuna ranching. This research was supported in part by the United States Soybean Export Council.

Introduction

After accumulating mutations, cancers diverge from the host becoming a new organism inside it, unable to survive autonomously. However, the parasitic status of cancers could be disputed on this basis —they are non-contagious. But some cancers evolved the ability to transmit from host to host (Dujon et al., 2020). They spread by transmission of living malignant cells becoming atypical parasitic life forms: parasites with a host-related genome. The transmissibility of these cancerous cell lines has been demonstrated through i) the presence of genetic chimerism in the diseased animals, with genetic differences between tumor and host cells, (ii) the genetic similarity between tumors of different individuals, iii) successful experimental transmission. Several transmissible cancers have been described, most in bivalves, including farmed marine mussels. MtrBTN2 lineage has been detected worldwide in various *Mytilus* species (Burioli et al., 2019; Hammel et al., 2021; Skazina et al., 2021; Yonemistu et al., 2019), crossing the species barrier. We accumulated data on epidemiology, genetics and phenotypic traits of MtrBTN2, focusing on those reminiscent of a parasitic lifestyle.

Material and methods

Between 2017-2022, we collected over 5000 mussels of the two species farmed in France (*M. edulis* and *M. galloprovincialis*), in 10 sites along the French coasts. Samplings were carried out on farmed and wild batches. We used cytology, FACS and genetics to diagnose MtrBTN2. We investigated the potential effect of size/age, sex, environment type, season, and presence of other co-factors (such as other parasites) on prevalence. Characterization of survival capacities in the outside-host environment is lacking for MtrBTN2 cells unambiguously demonstrated to be transmissible. We assessed the survival capacity of cancerous cells in seawater (SYTOX). Host colonization success depends also on the ability of parasites to proliferate in their hosts. Thus, we evaluated in-host proliferation rates by performing EdU incorporation assays. As a consequence of their lifestyle, parasites often have profound effect on the fitness of their hosts. When parasites harbor significant multiplication rates, the intra-host load that can be reached depends strongly on the host resources available for parasite population growth (i.e. host carrying capacity). An increased host carrying capacity can be achieved by manipulating host energetic resources to the parasite profit, for instance through host castration. Thus, we investigated the cost of MtrBTN2 infection on the host fecundity. We determined the reproductive condition by histology.

Results and discussion

We observed a quite low prevalence in all sites (0% to 25%), with significant differences among them, and rather constant along seasons. No correlation was noticed with host size/age, sex, and presence of parasites. However, we observed a strong species-related sensitivity, higher in *M. edulis*. We evidenced the coexistence of two MtrBTN2 sub-lineages that we characterized genetically and phenotypically. They differ highly on their DNA content (about 10N and 17N).

MtrBTN2 cells survival rate in seawater (Fig. 1) was significantly higher than that of hemocytes over 7 days with a median survival time of MtrBTN2 cells equal to 6 days, as opposed to 4 days only for hemocytes. With almost 100% cell survival over three days, chances to infect neighboring hosts are high. MtrBTN2 cells were also characterized by a high proliferation capacity, more than 17 times higher than that of normal hemocytes in healthy mussels. They favor a rapid increase of intra-host population size (mean doubling time of~3 days). Finally, MtrBTN2 appears to induce host castration (Fig. 2), favoring resources re-allocation and increasing the host carrying capacity.

Altogether, our results indicate that MtrBTN2 cells behave like unicellular castrator parasites.

TEMPORAL AND SPATIAL VARIABILITY IN TEMPERATURE AND OXYGEN ALONG SOUTHWEST NOVA SCOTIA USING GLIDER OBSERVATIONS

Introduction

Climate change has threatened coastal ecosystems through elevated sea temperatures combined with increased nutrients through expanding development. Both warmer waters and higher nutrient loads have resulted in intensification of coastal oxygen deficits (Breitburg et al. 2018). This loss in oxygen can impact ecosystem functioning, degrading coastal habitats, and threatening the aquaculture industry that are often established in these areas. Previous studies have documented temperature and salinity variability across the Scotian Shelf (Nova Scotia, Canada), however oxygen distribution has not been as well characterized (e.g. Dever et al. 2016). This study explores the along-shore and cross-shore variability in temperature, salinity, and most importantly dissolved oxygen, while also exploring the interaction between offshore observations and those within a bay suitable for aquaculture farms. The inner Scotian Shelf and bays are intrinsically linked thus it is important to understand the oxygen dynamics between them, ultimately allowing for better farm management.

Materials and methods

A Slocum underwater profiling glider was deployed between September 25 and October 12 2020 along the inner Scotian Shelf between Shelburne Bay and St. Margarets Bay. A novel zigzagging method was used to collect high-resolution temperature, salinity and dissolved oxygen data and capture both along-shore and cross-shore variability. Additionally, a real-time optical sensor was deployed within St. Margarets Bay to record temperature and dissolved oxygen for comparisons with the offshore glider data.

Results

The along-shore transect was characterized by strong vertical stratification in temperature and oxygen between September 26 and October 9. This was followed by a strong vertical mixing event, resulting in a collapse of the thermocline and cooling of the water column from 15.5 ± 0.73 °C (mean ± SD) to 5.35 ± 1.14 °C. This mixing event lasted for about 11 h before the thermocline was re-established. The cross-shore transects depicted more variability below the mixed layer with distinguished inner and outer profiles with respect to the coast. The inner profiles were warmer (8.32°C inner and 6.42°C outer), fresher (31.3 inner and 31.6 outer profiles) and less oxygenated (8.93 mg L^{-1} inner and 9.32 mg L^{-1} outer profiles). Lastly, the inshore sensor located within St. Margarets Bay captured the vertical mixing event 30 h after the glider observations, indicating the upwelled waters from further offshore likely advected inshore resulting in decreased temperatures, and increased oxygen, observed in the Bay.

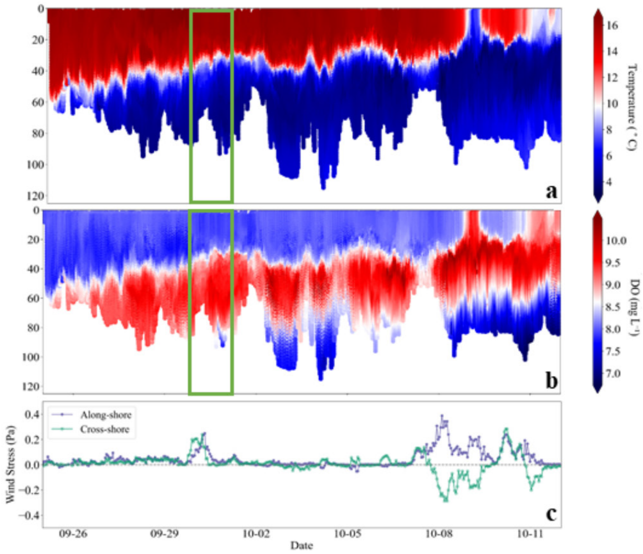

Figure 1. (a) The vertical distribution of temperature (°C; b), and dissolved oxygen (mg L^{-1}; b), along the Slocum glider transect. The glider was programmed to turn 2 m above the seafloor. (c) The along-shore (U, m s^{-1}; purple) and cross-shore (V, m s^{-1}; teal) wind stress components.

(Continued on next page)

Discussion

Strong along-shore winds to the northeast result in surface waters moving offshore and subsequent replacement with cool, deep waters, ultimately leading to the cooling of the upper water column observed on October 9. This mechanism follows the expected response due to Ekman transport for Nova Scotia waters (Shan and Sheng 2022). Cross-shelf vertical structure has been observed along the Halifax line (Dever et al. 2016), however the method employed in the present study is novel and allowed for multiple cross-shore observations along the inner shelf-coast of southwest Nova Scotia. This demonstrates the efficiency of glider observations for temporal, alongshore and cross-shore variability of hydrography and DO concentration over the inner Scotian shelf. Higher DO was associated with lower temperatures observed in the outer region of the transect due to increased solubility, though the glider may have also intercepted a water mass with differing properties to those more inshore. Lastly, this study showed how an increase in oxygen due to upwelling along the shelf can be horizontally advected towards the shore, ultimately allowing for increased oxygen concentrations around potential aquaculture farms. Having access to high spatial and temporal resolution around bays will help to quantify the role that the coastal shelf may play in oxygen dynamics within the bay, ultimately leading to improved aquaculture farm management.

Introduction

Observations on sturgeon by-catch during sprat trawl fishing operations in the Black Sea were conducted in framework of Discard monitoring program as part of the GFCM project "Select Activities Implemented of the Mid-term Strategy towards the Sustainability of Mediterranean and Black Sea Fisheries" (BlackSea4Fish). Studies were carried out by observers aboard of Ukrainian SChS and PTR-type vessels (about 25 m length). The study period lasted from August to November in 2018, from April to November in 2019 and in August-September 2021.

Materials and methods

Observations were performed according to the methods described in the FAO manual (FAO, 2019). The sprat fishery was conducted in the north-western Black Sea in the area bounded by longitude 31.3200 E from the east, latitude 46.0000 N from the south, and the coastline from the north and west. The trawling operations were carried out using midwater trawl in the near-bottom layer at the depths of 9 to 33 m at a distance of 1.5 to 50 km from the coast. The vessel speed during tows was 3.5–4.0 knots. All fishing operations were conducted during daylight hours. The duration of one trawling operation varied from 0.5 to 3–4 hours. The sprat trawl fishery in the NWBS is characterized by high selectivity. The proportion of all other fish species in catches (whiting, anchovy, sturgeons, turbot, sand smelt, shad, horse mackerel, etc.) did not usually exceed 1.0–1.5%.

The catch composition was studied during 342 fishing operations (see Table 1). The average sprat catch per hour of trawling (catch per unit effort, CPUE) was 0.57 ton in 2018; 0.44 ton in 2019 and 0.85 ton in 2021.

Results and discussion

The most undesirable phenomenon registered during the period of observations was the by-catch of young sturgeons - the most "vulnerable" group of fish in the Black Sea. The Starry sturgeon *Acipenser stellatus* (Pallas, 1771) and the Russian sturgeon *Acipenser gueldenstaedtii* (Brandt & Ratzeburg, 1833) were quite regularly presented in mid-water trawls in 2018-2019. Beluga *Huso huso* (L., 1758) was also caught in 2021 and even in greater numbers than Russian sturgeon. In 2018-2019, sturgeons were recorded in 50 trawls out of 283 (approximately in one haul out of six). And in 2021, they were registered in 52 hauls out of 59, that is, in almost every trawl.

Individuals of Starry sturgeon absolutely dominated among all sturgeons in trawl by-catches. Their share was 89.7% in 2018, 98% in 2019 and 93.8% in 2021. The share of Russian sturgeon in this by-catches was 5.1% in 2018-2019 and 2.8% in 2021. The share of beluga was 3.4% in 2021.

All sturgeon species in the by-catch were represented mainly by young individuals, which were characterized by relatively small size and weight (Table 2).

Only one Russian sturgeon and two Starry sturgeons had a body length of more than 1 m and could potentially reach sexual maturity among all the sturgeons caught in 2018-2019. The number of large individuals in the by-catch slightly increased in 2021: Russian sturgeon – 2 ind., starry sturgeon - 13 ind. Among 10 belugas caught in 2021 two had a body length exceeding 2 m, which allows them to be classified as sexually mature. Thus, we can state a slight upward trend in the size and weight characteristics of sturgeons over the past two years. The extremely low proportion of adult fish in this by-catch can be explained by their elimination by illegal fishing in the Danube and Dnieper rivers and at sea.

(Continued on next page)

Table1. Fishing efforts and by-catch of sturgeons in the NWBS in 2018-2019 and 2021

Year	Month	N of hauls	Sprat catch, t	*A. stellatus*		*A. gueldenst.*		*H. huso*	
				n	m, kg	n	m, kg	n	m, kg
2018-2019	VIII-XI, IV-XI	283	278	74	120	4	16	-	-
2021	VIII-IX	59	91	272	502	8	53	10	394

Table2. Size-weight characteristics of sturgeons in trawl by-catch.

Year	*A. stellatus*		*A. gueldenstaedtii*		*H. huso*	
	l, cm	m, kg	*l*, cm	m, kg	*l*, cm	m, kg
2018-2019	32 -102	0.2 – 4.7	42 - 102	0.5 – 9.6	-	-
2021	40 -109	0.3 – 6.3	60 - 112	2.2– 13.0	98 - 256	9 -150

Proportion of sturgeons among all by-catch fish weight amounted to 61.2% in 2021. The number of sturgeons caught per trawl operation has increased significantly over the past two years. It amounted to 0.24 ind. in 2018, 0.28 ind. in 2019, and already 4.91 ind. in 2021. If in 2018 the by-catch of one individual of sturgeons accounted for 5.8 tons of sprat, in 2019 - for 2.3 tons, then in 2021 - only for 1.54 tons of sprat. So the fact of a noticeable increase in the number of at least one species - starry sturgeon in recent years is difficult to deny.

Obviously, the observed recovery of the Starry sturgeon population in the NW Black Sea was made possible by relatively successful natural spawning in the Danube River. Beside it can be assumed that the growth of sturgeon populations has been facilitated by restrictions on fishing in this marine area provided by the Russian Navy.

Some special study was conducted to search for CWT tags using T-wand detector to assess the role of artificial sturgeon stocking carried out massively in Romania with tagging of all individuals released in 2008-2015. 69 Starry sturgeons, 4 Russian sturgeons and 3 belugas were examined in trawl by-catches. The presence of tags was detected for two individuals of the Russian sturgeon only. Nothing tags were found in individuals of the other two species. This fact may indicate that the rate of the natural spawning of Russian sturgeon in the Black Sea basin is extremely low, and artificial stocking of this species can significantly help to preserve its population.

EFFECTS OF SCP FROM *Candida utilis* ON GROWTH PERFORMANCE, PLASMA BIOCHEMISTRY, GUT MICROBIOTA, AND IMMUNE RESPONSE OF GILTHEAD SEABREAM (*Sparus aurata*)

Introduction

The increasing global need to find alternative and sustainable protein sources has promoted research in the field for non-conventional feed ingredients, such as single-cell proteins (SCPs). SCPs production is based on the fermentation of microorganisms like yeast, bacteria, microalgae, and filamentous fungi. Many of these species have high protein content, and some have amino acid profiles like that of fishmeal (FM)[1]. The studies conducted on yeast SCPs indicated that dietary inclusion of up to 30% improves feed efficiency[2,3], and can reduce inflammatory processes in fish[4]. To date, a variety of substrates have been utilized to cultivate microorganisms for the purpose of SCP production, such as agricultural wastes, fruit processing wastes, methane, and animal wastes[5]. This study was undertaken to assess the effects of different inclusion levels of SCPs on growth, feed utilization, fish plasma biochemistry, immune response, and gut microbiota of gilthead seabream reared under normal and after suboptimal conditions. The product utilized in this trial is a dried, inactive *Candida utilis* produced from sustainable feedstocks to partly or fully replace traditional protein sources in fish feed.

Materials and methods

One trial with gilthead sea bream was conducted in a closed recirculation aquaculture system (RAS). Fish (initial weight: 24.8 ± 0.1g), were fed over 76 days with four experimental diets containing different inclusion levels of SCPs meal (0% CTRL, 5% SCP5, 7.5% SCP7.5, and 10% SCP10) in substitution to FM. After the end of the trial, fish were subjected to suboptimal rearing conditions (high water temperature, 30°C, and low oxygen, 70% saturation level) for 8 days. Growth and feed efficiency parameters (specific growth rate, SGR, feed intake, FI, feed conversion rate, FCR), blood biochemistry, immune response marker genes of the kidney and distal intestine (Interleukin 1 β, Interleukin 8, Interleukin 10, Interleukin 6, Transforming growth factor β, Tumor necrosis factor α), and gut microbiota were assessed at the end of the trial and after suboptimal rearing conditions. Data were analyzed by a one-way ANOVA followed by Tukey's multiple comparison test.

Results

At the end of the trial, no significant differences ($p > 0.05$) due to the different treatments were observed in FI, while significant differences ($p > 0.05$) were observed in final body weight, SGR, and FCR (Figure 1).

Discussion and Conclusion

The results show that experimental diets containing different levels of SCPs inclusion from *Candida utilis* led to statistically significant differences in growth performance. In particular, differences were found in the average final weight and in the SGR and FCR indices, from which it emerged that the 7.5% inclusion of SCP is more beneficial to the growth performance of the animals.

CHEMOSTAT OPERATION AND PRODUCTIVITIES IN A 25 L TUBULAR SYSTEM AT DIFFERENT LIGHT INTENSITIES AND DILUTION RATES

Thomas O. Butler[1*], Pieter Oostlander, and Jeroen De Vree[1]

Lgem/Synalgae B.V., Achterweg 65, 1424 PP, De Kwakel, The Netherlands
Email: thomas.butler@lgem.com

The production process of complicated and fragile microalgae species including *Rhodomonas* is essential for industrial implementation of microalgae in aquaculture. Using our proprietary Lgem photobioreactor (PBR) systems we are able to cultivate many fragile microalgae species with high efficiency and reliability. Here we present the data on small-industrial scale production of *Rhodomonas sp.* for aquaculture applications. In this presentation we showcase significant improvements in a production process that can be made with the correct tools and a team of experts.

Due to its fragile nature, data for large-scale production of *Rhodomonas* spp. is limited. We investigated the effect of light intensity (124-189 umol m^{-2} s^{-1}) and dilution rate (0.19-0.74 d^{-1}) on the biomass productivity and biomass yield on light, during continuous operation (chemostat) under low-cost light emitting diodes (LEDs) in the Lgem LAB-25 tubular PBR.

A maximum biomass productivity (1.09 g L^{-1} d^{-1}) and biomass yield on supplied light (0.53 g mol^{-1}) was obtained at a dilution rate of $\mu = 0.74$ d^{-1} under high light (189 µmol m^{-2} s^{-1}) compared with 0.72 g L^{-1} d^{-1} and 0.54 g mol^{-1} respectively at a dilution rate of $\mu = 0.42$ d^{-1} under low light (124 µmol m^{-2} s^{-1}). Biomass productivity increased with higher light intensity (except at $\sim\mu = 0.40$ d^{-1}), but was not significantly affected by dilution rates (see Fig. 1a). To reduce the cost of indoor production utilising artificial light, a high efficiency of light use (biomass yield on light) is required. All tested conditions resulted in a high, but not significantly different, biomass yield on light supplied (Fig. 1b). This high yield on light reveals the efficiency of the Lgem PBRs in cultivating fragile microalgae species at pilot scale. Lower dilution rates ($\mu = 0.29$ d^{-1}) result in a 2.3-fold higher biomass concentration (3.42 g L^{-1} DW) compared to high dilution rates ($\mu = 0.74$ d^{-1} at 1.48 g L^{-1} DW) while maintaining similar biomass productivities, resulting in lower water usage and pumping requirements.

The cost of production in aquaculture hatcheries was calculated at ~€286 kg^{-1} at small production scales (25 m^2 scale). By utilising Lgem PBRs the biomass cost can be reduced to <€53 kg^{-1} through the use of artificial illumination at larger production scales (1500 m^2) (Oostlander et al., 2020). The assumptions for the technoeconomic assessment conducted by Oostlander et al. (2020) are taken into account in the current study. Major cost factors are the lighting (investment and operating cost), the efficiency at which this light is used, and the required amount of labour including labour linked to downtime for cleaning. In the presented chemostat study >200 days of operation were achieved without downtime and no fouling was observed whilst maintaining high biomass yield on light under all tested conditions (see Fig. 1b). With Lgem PBRs at large-scale fully automated operation is possible, lowering the requirement for skilled labour in your microalgae production facility.

With *Rhodomonas* sp. as an example we present our reliable and easy-to-use PBR-systems to develop your microalgal production process at our cutting-edge AlgaeHUB®. We have over 15 years of experience in the microalgal industry and specialise in PBR operation and design. In our completely unique 7000 m² facility (near Amsterdam Schiphol airport, The Netherlands), we offer our latest services: lab scale, pilot scale, and commercial scale production systems which are available for testing purposes. Furthermore, we offer various technologies for upstream and downstream processing suitable for fragile microalgae species.

(Continued on next page)

Results

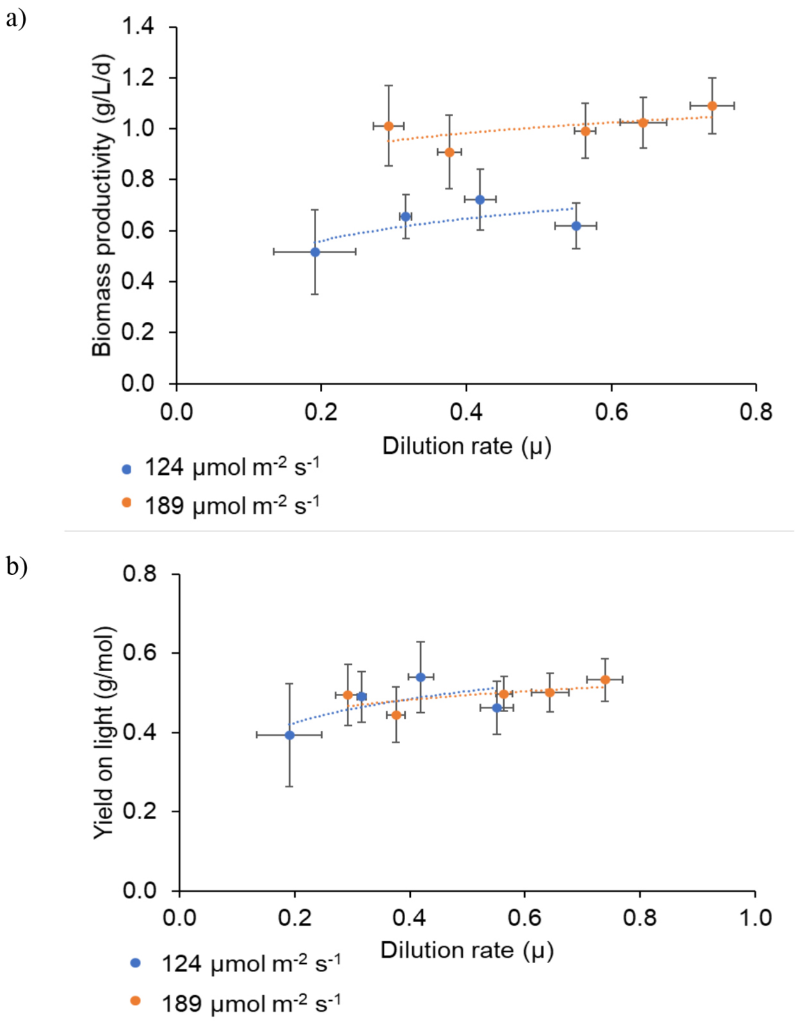

Fig. 1. a) Biomass productivity (g L^{-1} d^{-1}) and b) biomass yield on supplied light (g mol^{-1}) versus dilution rates under chemostat operation in an Lgem LAB-25 tubular PBR (32 mm tube diameter) under red:white light emitting diodes (LEDs) in operation for >200 days. Steady state was defined as at least 3 x culture volumes or a minimum of 9 days for dilution rates <µ = 0.2 d^{-1}. Steady state was obtained when variations in biomass concentration and dilution rate revealed <15 % variation.

Introduction

The use of phytogenics as a method for prevention and control of disease outbreaks in aquaculture has been proposed in recent years [1]. Among the different phytogenics, plant extracts derived from *Allium* spp. such as garlic (*Allium sativum*) and onion (*Allium cepa*), hold a large promise due to their variety of bioactive compounds including polyphenols and organosulfur compounds.

Within the different sulphur compounds present in *Allium* spp., Propyl-Propane-Thiosulfinate (PTS) and Propyl-Propane-Thiosulfonate (PTSO) stand out due to the stability that gives them suitability for their use in feed processes [2] together with multiple functional properties that may contribute to reducing the risk of diseases in fish farming.

In the present study, the *in vitro* antibacterial effect of PTS and PTSO was studied against a number of relevant pathogens for a variety of farmed fish species. Moreover, the effect of both compounds in juvenile gilthead seabream (*Sparus. aurata*) challenged with *Photobacterium damselae* subsp *piscicida* was also evaluated.

Materials and Methods

The *in vitro* antibacterial activity was screened by the disk-diffusion method proposed by Kirby–Bauer [3] and modified by Calvo and Asensio [4]. Sterilized cellulose discs were impregnated with 20 μL of PTS or PTSO at a dose of 2.5, 5, 10, 25, and 50 mg/mL, and placed in the centre of agar plates that were previously inoculated with the target bacterial strains at an adjusted concentration of $1x10^6$ CFU/mL.

The effects of PTS/PTSO on the fish health status were tested in an *in vivo* intraperitoneal (IP) trial against *P. damselae* subsp *piscicida* after 12 weeks of dietary administration of these natural extracts. 90 juveniles gilthead sea bream (*S. aurata*) weighing 4.45 ± 0.39 gr were divided into 2 groups in triplicate after acclimatization at 21 ± 1°C, pH 7.5 ± 0.5, O_2 6.5 ± 1 ppm. Two experimental diets consisting of 0 and 150 mg/Kg feed of PTS/PTSO in proportion 1:1; w/w were formulated for this purpose.

Results

The susceptibility of bacterial pathogens responsible for main diseases in *S. aurata* is shown in figure 1. All pathogenic strains proved to be sensitive to both compounds. PTSO exhibited a highly inhibitory effect ($\geq$ 20 mm) against all target strains from 10 mg/mL, whereas PTS had such effect from 25 mg/mL.

The fish fed with PTS/PTSO presented a higher probability of survival ($p<0.01$) compared with those fed the basal diet (Figure 1). The survival probability values in the CONTROL group were 66.7%, while, in the ALLLIUM group was 91.1%.

Introduction

As marine aquaculture does not depend on fresh water sources and does not compete for space with terrestrial agriculture, it is considered to play a vital role in feeding the growing world population. However, a problem with modern finfish aquaculture is that it largely depends on fish meal coming from already overexploited natural fish populations as its main protein compound. Although considerable progress has been made in substituting animal protein for vegetable protein in fish feeds, further reductions are still required and there is continued research in finding relatively cheap, high quality and easily digestible protein.

The EU Horizon 2020-funded Innovation Action project SIMBA has the aim to create a better EU Agro-Aqua-Food system using microbiomes. One of the tasks of the WP dedicated to marine microbiomes is the optimisation of fish feed for more sustainable fish farming. This included the optimisation of fermentation mixes to produce high protein fermented vegetal products that can (in part) substitute less sustainable protein sources in fish food, such as fish meal. In this work we present the results of an evaluation of new feed mixes containing fermented compounds in the important Mediterranean finfish aquaculture species gilthead sea bream and sea bass.

Material and methods

Effects of dietary administration of rapeseed meal-seaweed fermented with lactic acid bacteria (EP199, 15% addition substituting 50% of fish meal) and soybean meal-seaweed fermented with lactic acid bacteria (EP299, 30% addition substituting 50% of fish meal) were evaluated on fish performance parameters, biometric and somatic indices, variation of gut microbiota profiles (analyses pending), water quality, main innate immune system indicators and final fillet quality in gilthead seabream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*). A total of 720 gilt head bream and European seabass juveniles of 10.73 ± 0.02 and 9.13 ± 0.01 mean body weight respectively, were grouped into 6 treatment diets and fed for 12 weeks. Effects of the diets were compared to those of a standard commercial diet.

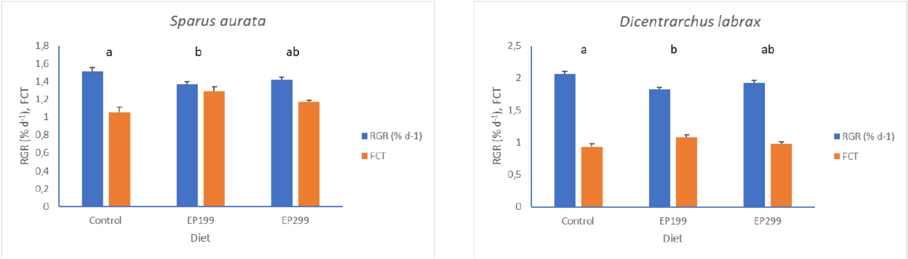

Fig. 1: Fish performance (growth rate and feed conversion rate) in two experimental diets containing fermented compounds (EP199 and EP299) to a standard control diet in *Sparus aurata* (left) and *Dicentrarchus labrax* (right).

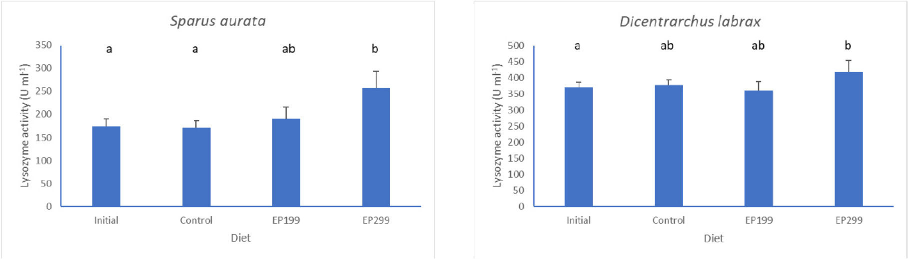

Fig. 2: Lysozyme activity in *Sparus aurata* (left) and *Dicentrarchus labrax* (right) fed two experimental diets containing fermented compounds compared to a standard control diet and initial values.

(Continued on next page)

Results and discussion

Fish performance as measured by growth rate and feed conversion was significantly lower (± 10%) for both fish species in the feed containing the EP199 compound than the control, whereas there was no significant difference for the EP299 feeds. The same pattern was observed for feed conversion, the best conversion was found for the control (Fig. 1).

Considering innate immune system indicators, the most obvious effects were found for lysozyme activity, especially in sea bream. Higher values were found for both EP199 and EP299 feeds, however the difference was only significant for EP299. For sea bass the differences were not significant (Fig. 2). With respect to fillet composition of the fish, preliminary analyses show that there was generally no significant difference in proximate composition nor in fatty acid profiles. However, it appears there is an effect on amino acid composition, especially in sea bass.

Current results indicate that in particular the compound EP299 shows promise as a sustainable alternative for fish meal protein, without causing negative effects on growth. In addition, there might be a positive immunomodulating effect, although this appears to be species specific. Further studies should be directed towards optimising the compound mixture and inclusion percentage of the compounds in the feeds.

Introduction

Captive fish are confronted with human-induced stressors deemed necessary for their rearing, such as husbandry procedures. For this study, we explored husbandry procedures in gilthead sea bream (*Sparus aurata)* brood-stock. Gilthead sea bream are commonly cultured fish in Southern Europe and are highly valued and consumed. Little research has been published regarding husbandry stressors for the brood-stock of this species, albeit their immeasurable value for producers.

In this project, our aim was to measure the welfare effects of daily husbandry procedures, such as feeding, netting attempts, and tank cleaning, as well as prophylactic measures such as an antiparasitic bath, in brood-stock gilthead sea bream. Our objective was to measure the stress caused by these husbandry procedures by monitoring their heart rate before, during, and after the procedures. To achieve this goal, we implanted internal bio-loggers that collected the heart rate and internal temperature of the fish automatically, without having to manipulate the subjects at the time of the physiological recording.

Materials and Methods

Subjects and Housing Conditions

We implanted bio-loggers in 18 adult sea bream distributed in six 3,000 L cylindrical tanks (2 m diameter x 1 m, water level 90 cm). The subjects were housed with seven more fish in the tanks (with and without enrichment), which made a total of 10 fish per tank (mean weight 791.3 g), and were housed in this conditions for five months.

Surgery Procedure

We followed the steps developed by Mignucci et al. (2021). The subjects were anesthetized with 2-phenoxyethanol (0.5‰, Sigma–Aldrich), and maintained anaesthetised during the procedure with a gill bath of 0.25‰ 2-phenoxyethanol. After skin disinfection with 5% povidone-iodine (Betadine), a 2 cm abdominal incision was performed along the ventral midline to insert the bio-logger (DST milli HRT, 13 mm × 39.5 mm, 12 g, Star-Oddi, Iceland, www.star-oddi.com) in the intraperitoneal space of the thoracic cavity, in close proximity to the pericardium. The bio-logger was attached to the ventral thorax by one stitch of non-absorbable monofilament nylon suture and another one of silk suture. The abdominal incision was closed with absorbable monofilament glyconate suture. Right after the surgery the fish was placed in their experimental tank and monitored until full recovery.

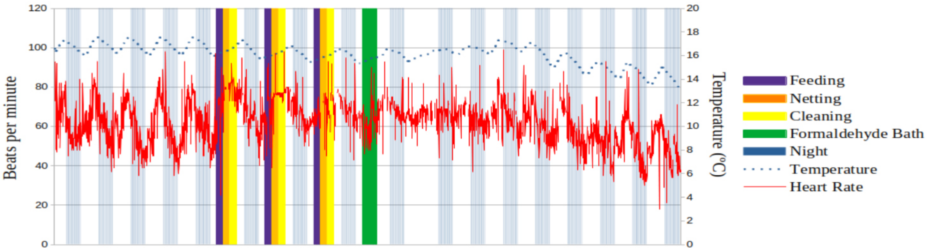

Fig. 1. Heart rate (red line) and temperature (blue dotted line) recordings of one adult gilthead sea bream over 17 days. Purple, orange, yellow and green columns represent the treatment events. Blue columns illustrate the night period.

(Continued on next page)

Treatments and Procedures
Treatment 1 - Feeding. We fed all the fish 0.5% of their body mass at 10:00 to measure the effect of feeding on their heart rate.

Treatment 2 - Routine net chasing simulation. We uncovered the tanks and moved a net (~2000 cm^2) on each tank at 11:00 for 5 minutes. The movement was from side to side and from the front to the back of the tank in a steady pace to simulate a catching event. We did not chase the fish with the nets and never caught any fish inside the net.

Treatment 3 - Routine cleaning simulation. At 12:00 we closed the air influx and cleaned the sides and bottom of the tank for 8 minutes with a broom (22 cm wide) while lowering the water 8 cm. We then waited 2 minutes for any dirt to sink and opened a purge system at the bottom of the tank for 10 seconds, which lowered the total water volume 10 cm more. We covered the tank and left the water reach its regular height.

Treatment 4 - Anti-parasite treatment. We lowered the water level up to 1/3 of the tank. We added 150 ppm formol (37% formaldehyde, <= 10% metanol, Sodacasa, Portugal) into the tank and left the fish undisturbed in the tank for one hour. After this time, the sides of the tank and any structure in them were cleaned with two brooms and we opened the drain and created a circular movement of the water by steering it with the two brooms, while we mixed it with clear water to eliminate most of the formaldehyde. The water level was 20 cm high, when we stopped the drainage and started filling up the tank. Two hours after the water had been filled up, we lowered the water level again to 1/3 of the tank, and filled it up with clean water. This step ensured any formaldehyde remaining in the tank would be diluted. The fish were not fed on the day of this treatment.

Treatments 1, 2 and 3, started five days after the surgeries and were repeated on three consecutive days. Treatment 4 was performed only once on the eighth day after surgeries. After the last treatment was performed, we continued monitoring the heart rate and temperature of the subjects for eight consecutive days.

Preliminary Results and Discussion

Data from one bio-logger (Fig. 1) showed a clear circadian rhythm of the heart rate with a decrease during the night and an increase during the day, a daily fluctuation between 40 and 80 bpm. The heart rate was maintained at high rates during the stressful events and consecutive hour, and it decreased overnight. However, consecutive days of stressors prevented the subject to reach its basal heart rate during the night. The final stressor, i.e., the prophylactic bath, maintained the heart rate of the individual above 60 bpm for the following day and night, and only got to its basal level on the sixth night after the treatment. Our preliminary results show that consecutive daily stressors and strong stressors such as prophylactic baths increase the heart rate of brood-stock gilthead sea bream, and one night of rest is not enough to reach their overnight basal levels. Gilthead sea bream might require several days to recover from strong stressors.

Introduction

Profitably maximizing production is one of aquaculture's priority objectives, focusing on optimizing feeding processes. In this regard, feed restriction has been artificially applied in aquaculture to induce compensatory growth without compromising fish growth. This phenomenon constitutes an effective strategy to control the fat content in the body of cultured animals and improve their feed quality, favoring an increase in feed intake and utilization (Argüello-Guevara *et al*., 2020). In addition, starvation can provide information on physiological processes without the interference of other factors derived from digestion and nutrient absorption processes (Barreto-Curiel *et al*., 2017). The greater amberjack (*Seriola dumerili*) is particularly interesting for the aquaculture sector due to its rapid growth rate, good performance in captivity, and high commercial value (García and Díaz, 1995); however, its cultivation in Spain is still incipient (APROMAR, 2021). Knowing how this species responds to some situations, such as starving, is an important challenge for aquaculture since it would help to prevent possible damage to fish health and, consequently, to optimize production. This work aimed to evaluate the metabolic strategies of *S. dumerili* to face a short period of starvation and subsequent refeeding.

Materials and methods

Greater amberjack juveniles were provided by a commercial source (Futuna Blue S.L., El Puerto de Santa María) and acclimated to the indoor experimental facilities at the *Servicio Central de Investigación en Cultivos Marinos* (SCI-CM, CASEM, University of Cadiz). After an initial acclimation period, 28 animals were used with an initial mean body mass of 54.6 ± 2.1 g and were fed a commercial diet for 4 weeks twice a day (CF). At the end of the continuous feeding period (94.3 ± 6.2 g), a biometric sampling was performed where biological samples were extracted from eight fish. The rest of the animals (n=20) were subjected to a starvation challenge for a week and subsequently, biological samples were extracted from eight of these specimens (St). The remaining animals (n=12) were re-fed for a week and, as with the previous two groups, biometric sampling was performed and biological samples were taken at the end of the experiment (RF). Different biometric, somatic, and feeding indexes were analyzed and some metabolic and endocrine parameters in plasma and liver.

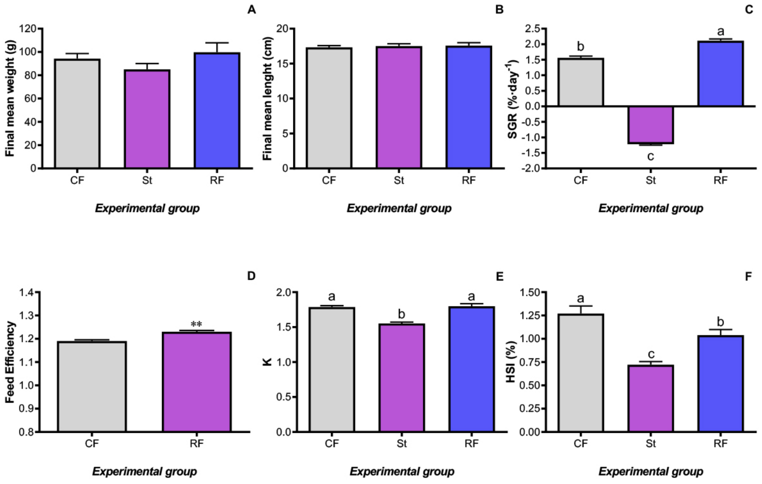

Fig. 1. A. Final mean weight; B. Final mean length; C. Specific growth rate (SGR); D. Feed efficiency; E. Condition factor (K); F. Hepatosomatic index (HSI) in *Seriola dumerili*. Results are expressed as the mean ± SEM for each group.

(Continued on next page)

Results and discussion

Both CF and RF experimental groups had positive and continuous growth throughout the study period. The final mean weight and mean length obtained showed no significant differences between experimental groups, although both results were higher in the RF group (Fig. 1A, B). The specific growth rate (SGR) was higher in the RF group concerning the CF and St groups (Fig. 1C), whereas a decrease in the SGR was observed in the latter. In terms of feed efficiency, significantly higher values were obtained in RF individuals, that consumed a higher amount of feed than CF individuals (Fig. 1D). This fact suggests that fish experienced a state of craving and increased appetite leading to increased feed consumption after refeeding, which results in a higher increase in body weight (Liu *et al*., 2018). The condition factor (K) also showed significant differences between groups, being significantly higher in the CF and RF groups (Fig. 1E). On the other hand, liver weight (HSI) was affected by the fasting period (Fig. 1F).

To survive situations of fasting or starvation, fish mobilize their energy reserves, which imposes metabolic adjustments that depend on the species, age, nutritional status, etc. (Navarro and Gutiérrez, 1995). Regarding plasma metabolites, no significant differences were found in glucose and lactate levels, although an increase was observed in the RF group. Triglyceride, cholesterol, and protein concentrations followed a similar trend, being significantly lower in the St group when compared with the CF and RF groups. At the hepatic level, a significant increase in glucose was observed in starved and refed animals, whereas hepatic glycogen showed no differences. Lactate and TAG levels were similar in the three groups, although with a tendency to increase in St and RF (data not shown). These observations can be also attributed to higher plasma cortisol levels in re-fed fish. Moderate increases in cortisol in the body stimulate the production of neuropeptide Y (NPY), which promotes feed intake and feed anticipatory activity (Bernier *et al*., 2004), which would support the results obtained with the growth performance indices and metabolic parameters. In conclusion, compensatory growth in *S. dumerili* is possible after 14-day starvation followed by refeeding without affecting fish welfare. The fasting period was compensated in part by an increased feed intake and feed efficiency. These results represent a promising alternative to improve the feeding schedule of this specie.

Introduction

The feed used in aquaculture is highly dependent on fishmeal (FM) and fish oil (FO) as the primary source of nutrients. The declining availability of these products, coupled with the rising costs of fishmeal (FAO, 2018), has prompted research into alternative sources of protein, and in particular into the use of plant-based proteins (Naylor *et al*., 2009). The use of healthy diets that include ingredients/additives with functional properties on the organism is a very promising option (Gatesoupe, 2005). In this context, nutraceuticals develop a fundamental role, improving numerous benefits for the health and physiological state of the animals, including the prevention or treatment of diseases (Burr *et al*., 2005). The aim of this work was to evaluate the potential benefits of two functional feeds for the gilthead seabream (*S. aurata*), which contain low inclusion of two microalgae-based products in vegetized diets, named as LB-ImmunoBoost (IB) and LB-LiverProtect (LP).

Materials and methods

Four diets were formulated at the Experimental feeds Service facilities (University of Almería, Spain). The control diet (C+) did not include any functional additives, with a nutritional composition based on fishmeal and fish oil. The second diet consisted of a high percentage of fishmeal and fish oil substitution (75%) by vegetal proteins and oils (C-). In addition, the C- diet was supplemented with 1% of LB-ImmunoBoost and with 1% of LB-LiverProtect, constituting the IB and LP experimental diets, respectively. The feeding trial was carried out at the facilities of the Aquaculture Technological Centre (CTAQUA, El Puerto de Santa María, Cádiz, Spain). After an initial acclimation period of 14 days, juveniles with 27-28 g initial mean body weight were randomly distributed in twelve 400 L tanks (n=30 fish per tank). Experimental diets were offered to satiety (*ad libitum*), two times per day, 5-6 days per week for 90 days. At the end of the experimental period, final sampling was carried out when biometric parameters were measured for all specimens and biological samples were collected. Different biometric, somatic, and feeding indexes were analyzed. Plasma cortisol levels were measured with a commercial Cortisol Enzyme Immunoassay Kit. In addition, a representative panel of genes related to stress and growth pathways was performed by semi-quantitative PCR with a CFX96 Real-Time System and expressed as relative gene expression (ΔΔCq Normalize Expression Gene Study) by using the Bio-Rad CFX Manager™ 3.1 software.

Results and discussion

Diets with high levels of substitution of animal ingredients by plant sources achieve good growth rates as long as the feeds are balanced in terms of protein, lipids, and carbohydrates (Perera *et al*., 2020). Even so, the results showed better growth performance and metabolic rates in fish fed with C+, although the compound IB partially reverts the detrimental effects produced by the plant protein-based diets.

Gene expression of some genes related to the hypothalamus-pituitary-interrenal (HPI) and growth axes was studied in fish. In the hypothalamus, the expression of *crh*, *crhbp* and *nr3c1* genes were significantly higher in the C+ and IB diets than in the C- and LP diets, with clear negative feedback produced by plasma cortisol (Fig. 1). In the pituitary, *gh* expression was low in the C+ diet while *pomca* expression was significantly higher in the group fed the LP diet. On the other hand, *pomcb* expression was higher in the control diet and significantly lower in animals fed a high substitution of plant-based ingredients (C-), concomitantly with a higher expression of *ghr-I*, *ghr-II* and *nr3c1* genes in animals fed the C- diet. No significant differences in *star* expression were detected in the head kidney, whereas results on *11B-hydroxylase* showed a significantly lower expression in the two diets supplemented with the nutraceutical compounds. The *nr3c1* expression was higher in animals on the IB diet and lower in those fed LP.

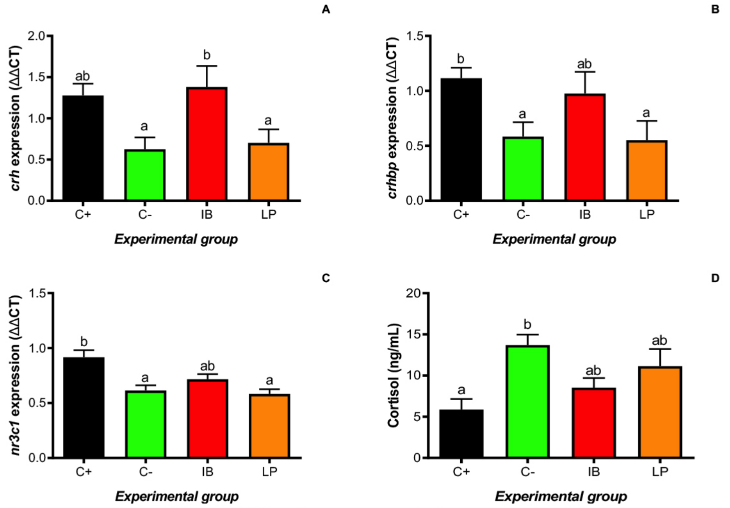

Fig. 1. Relative expression of three HPI axis genes and plasma cortisol levels concerning diet in *S. aurata*. A. *crh* gene; B. *crhbp* gene; C. and *nr3c1* gene; and D. cortisol. Results are expressed as the mean ± SEM of the triplicate tanks.

These results suggest that the expression of all aforementioned genes was significantly influenced by the dietary treatments, where the HPI axis is modulated at different central levels, orchestrating growth performance and welfare. Interestingly, the inclusion of the nutraceutical ImmunoBoost showed a decrease in stress levels and partially alleviated the negative effects of the substitution of raw materials in the diet, suggesting its potential use in aquafeeds.

Introduction

Fish production from aquaculture has expanded greatly during the last decades, and aquaculture is recognized as a major food production industry (FAO, 2020). However, concerns about environmental issues, sustainability and animal welfare in aquaculture are increasing. About sustainability of aquaculture, major concern is related to use of fish meal and oil in fish feeds that are coming from wild caught fish (Naylor et al., 2021). In this study, we evaluate the effects of an innovative diet (with replacement by a new yeast-based protein ingredient) on the health and welfare indicators of European sea bass (*Dicentrarchus labrax*), a key species of the European marine aquaculture. In this work, we monitored level of stress molecular indicator (*HSP70*), physiological blood parameters of interest (e.g. haemoglobin, cortisol, glucose, lactate, lysozyme), as well as the growth performances of sea bass reared in sea cages fed the innovative diet. In addition, a sub-sample of fish has been implanted with accelerometer tag for continuous monitoring of acceleration, a proxy of energy expenditure (Carbonara et al., 2021), for about two months.

Materials and methods

European sea bass were monitored from May 2020 to July 2021. Feeding trial started on August of 2020. Six experimental cages were used (n=~2200 fish per cage) in the farm of AVRAMAR at Palairos (Greece). Fish were fed two feeds; a commercially available control feed which was offered in three cages and the experimental innovative- diet which was offered in the remaining three cages. Innovative diet was based on the control diet but with reduced fishmeal inclusion aiming to reduce FIFO (Fish in:Fish out) ratio. Throughout the experimental period fish were fed *ad libitum*, 2 – 4 times daily depending on their weight and the water temperature. Sea water parameters such as water temperature and dissolved oxygen were recorded daily. Over the trial, three samplings were carried out at three different times (T0: in May 2020 'control' before starting the feeding, T1: in April 2021 and T2 in July 2021). At the three sample times, growth measurements and blood and organs samples were carried out. At T1, n=5 fish per cage were tagged using accelerometer tags with 'tailbeat mode' algorithm, allowing to measure fish acceleration (m/s^2), which is a proxy of energy expenditure (Carbonara et al., 2021). At each sampling point, fish were gently caught from the rearing tanks or cages and bathed into anesthetic (clove oil) for 2-3 min before proceeding to blood sampling. The blood samples were taken from the caudal vein, and used to assess the basal levels of the following physiological indicators: cortisol, glucose, lactate, hematocrit, hemoglobin, red blood cell count (RBCC), noradrenaline, adrenaline and lysozyme. The quantification of these parameters was performed as described in Carbonara et al., (2019). Also, the levels of total proteins, prealbumine, albumin, alfa1, alfa2, beta1, beta2, Gamma and Immunoglobulin M in plasma were assessed according manufacturer instructions. Organs (spleen, liver, kidney, gills and brain) were also sampled to further quantify HSP70 though quantitative rRT-PCR.

Results and discussion

At the end of the trial, fish growth rates differed between treatments only in the final sampling; the average weight of fish fed the commercial diet was significantly higher compared to the average weight of fish fed the innovative diet ($p<0.05$). Similarly, SGR was found greater in fish fed the commercial diet than fish fed innovative one ($p<0.05$). Despite the significant greater feed consumption from the commercial group ($p<0.05$), the FCR, K-factor and the total mortalities showed no significant differences between feed treatments

(Continued on next page)

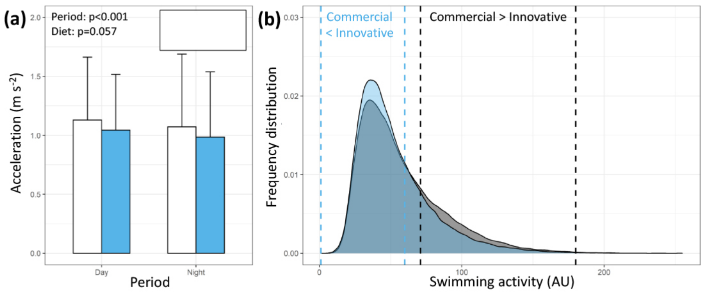

Fig. 1. (a) Acceleration (mean±SD; m/s^2) in fish fed commercial (white) or innovative diet (blue) during day and nightime. **(b)** Frequency distribution of the swimming activity values recorded in fish fed commercial (black) and innovative diet (blue).

Based on the physiological sensors data, sea bass displayed a diurnal pattern regarding acceleration; they were more active during daytime than nighttime. This was consistent with what has been observed in previous experiments where fish were more active during feeding at daytime (Carbonara et al., 2021). Only a tendency for significant difference between the two feeds (p=0.057) has been observed (i.e., fish fed innovative diet tended to display lower acceleration; Figure 1.a). When looking at the distribution of swimming activity values recorded by sensor, fish fed commercial diet displayed greater number of low activity values than fish fed innovative one, and oppositely fish fed commercial diet displayed lower number of low activity values than fish fed innovative one (Figure 1.b). This could be indicative of greater use of anaerobic metabolism for fish fed commercial diet.

Finally, regarding all the physiological parameters measured in plasma during the trial, only few were affected by the innovative diet. In more details, we found lower level of cortisol, glucose and hemoglobin in sea bass feed innovative diet than fish fed commercial one (p<0.05). Also, we measured greater level of total proteins in sea bass feed innovative diet than fish fed commercial one (p<0.05 for all). Some change in stress parameters (i.e. cortisol, glucose) has been measured punctually in one of different sampling times but levels were returned to similar level in other sampling time, suggesting that this change should be linked more to sampling time than diet.

Overall, this study provides a global assessment of sea bass physiology under innovative diet coping with sustainability challenges of European aquaculture. At the end of trial, the average weight difference between the two diet treatments was 30g, a weight that can be gained between 10-20 days depending of year period in the Mediterranean Sea. In addition, the health and welfare of sea bass was not significantly affected by this feeding. In conclusion, such innovative feed could be promising for the future of sustainability in the European aquaculture.

Introduction

The global production of European Seabass, *Dicentrarchus labrax,* has increased constantly from close to 71,000 Metric Tonnes (MT) in 2000 to 236,000 MT in 2019.

The production of good quality live prey is a basic requirement for good fry production. Although hatcheries have achieved high standards of production, this type of activity could present some difficulties due to the variability of the nutritional quality of the product and possible production problems, which affects the survival and quality of the fish produced.

In order to increase flexibility in terms of production, the aquaculture industry is moving towards partial live food using specifically formulated diets in the larval rearing phase.

The present study, conducted on a commercial scale, investigated the effect of different feeding protocols in the regime of live prey replacement by introducing dry feed from the first days of exogenous feeding. The scope is to evaluate the effect of the dry feed in combination with different levels of live food reduction focusing on the period in which Artemia is fundamental for the growth of the seabass larvae.

Materials and methods

Seabass experiment

Hatched Seabass larvae, originating from the same pool of eggs, were stocked at the density of around 60 larvae.l^{-1} in 6,000l larval rearing tanks. Different feeding protocols were used to evaluate the best combination of dry feed and live feed from 0 to 56dph.

In all treatments, *Artemia* has been fed from 9dph onwards and early weaning was completed by 45dph.

A photoperiod of 14L/10D was used and the treatments were done in duplicate.

During the larval rearing period, from 7dph weekly biometrics were carried out to compare growth rates. Salinity stress tests were done to determine the stress resistance. At 56dph, growth, larval survival, produced biomass per tank, and deformity levels were evaluated.

Results

The Seabass larvae reared in a regime of reduced live food and use of dry diets, showed similar performance in terms of growth and stress resistance if compared with a standard feeding protocol.

Conclusions

This study shows that Seabass larvae can be reared obtaining a good survival rate and good fry quality when a balanced diet is used from the first days of exogenous feeding at the same time as a careful replacement of Artemia in the right moment of larval development.

The use of a high-quality diet is fundamental to obtain optimal growth and quality in the larval rearing of Seabass. Even in the absence of rotifers, the partial replacement of Artemia is an achievable goal, optimizing its use during the most critical phase of larval rearing.

DIETARY SUPPLEMENTATION WITH OSTEOGENIC EXTRACTS DURING THE PRE-ONGROWING PHASE IMPROVES SKELETAL QUALITY OF GILTHEAD SEABREAM AT THE ONGROWING PHASE

Introduction

The high incidence of skeletal deformities in farmed gilthead seabream (*Sparus aurata*) is a major concern due to the negative impacts on fish market value and animal welfare[1,2]mainly in the hemal and caudal body regions. Four hundred and twenty-two hatchery-reared sea bream from Italy, France and Spain were checked for skeletal malformations and meristic counts. The same skeletal descriptors were examined in 72 wild-caught sea bream. Correspondence analysis (CA. Dietary supplementation of natural extracts rich in compounds with health-promoting effects on the skeleton offers a cost-effective strategy to reduce the incidence of deformities in farmed fish[3].

Materials and Methods

Experimental diets (Sparos Lda) were supplemented with ethanolic extracts prepared from the microalgae *Skeletonema costatum* (SKLT) and *Tetraselmis* sp. CTP4 (CTP4) and fed to gilthead seabream juveniles (~5 g; reared in triplicates in 250 L tanks at a density of 1.7 individual/L) until triplication of their weight (33 days). A first sampling (T1) for growth, hematological parameters, and skeletal quality was conducted on ~45 fish (~15g of individual weight) per condition. The remaining fish were fed with a commercial diet for an additional period of 6 months to evaluate if short-term dietary supplementation during the pre-ongrowing phase could yield an improved seabream quality in the ongrowing phase. A final sampling (T2) was conducted on 40 fish per diet and skeletal quality and shape differences were determined from radiographic images through morphometric analyses (**Figure 1**).

Results

Results from T1 revealed that fish fed with the CTP4 diet weighed more than fish from the control group ($p<0.05$); however, there were no significant differences in the total length (TL) at this time. Interestingly, results from T2 revealed that both the SKLT and CTP4 dietary groups produced longer fish than the control group (TL, $p<0.05$). Fish fed with the CTP4 diet displayed a lower incidence of severe anomalies at both T1 and T2. A Principal Component Analysis (PCA) applied to morphometric features identified on radiographs from T2 revealed that dietary conditions can explain the shape differences between groups (**Figure 2**). Furthermore, Thin Plate Spline warp analyses suggest that fish from the CTP4 condition are characterized by slender and elongated features.

Discussion

Our results indicate that dietary supplementation with ethanolic extracts of Skeletonema costatum and Tetraselmis sp. CTP4 applied during a brief pre-ongrowing window, is able to improve juvenile seabream growth and skeletal health with long-lasting beneficial effects. Furthermore, fish fed with the CTP4-supplemented diets display more elongated and slenderer morphometrical features compared to control fish. It is well known how fish external appearance influences the product consumer perception and therefore its profitability4. Our finding highlights that choices in feed formulations may represent a useful tool that farmers could use to intervene on fish shape and external appearance.

(Continued on next page)

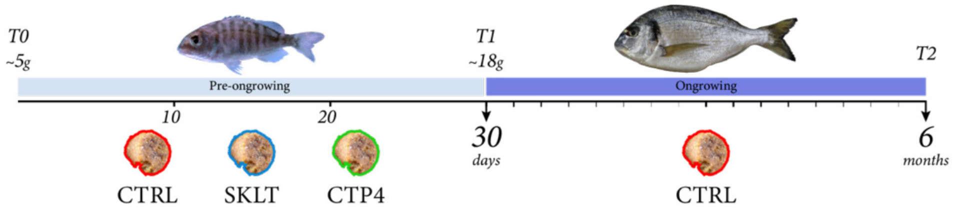

Figure 1. Schematic displaying the experiment timeline.

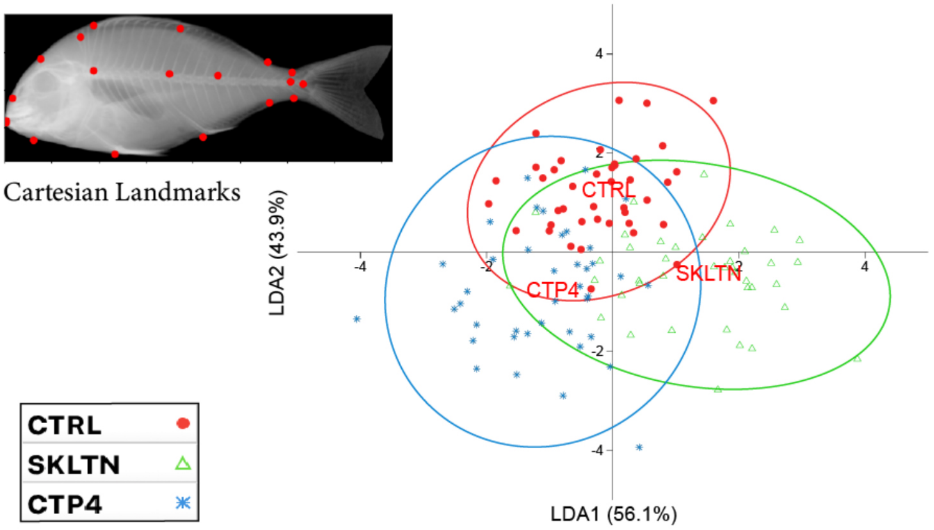

Figure 2. The PCA revealed significant differences in fish shape among all the three dietary treatment groups (Wilks' λ, p<0.00001). Pairwise Mahalanobis squared distances were significantly different between all the conditions (post hoc with Bonferroni corrections, p<0.00001).

SAFER PROJECT - IMPROVING THE INNOVATION PERFORMANCE OF THE SEAFOOD SECTOR BY INCREASING TECHNOLOGY ADOPTION AND TRANSNATIONAL COOPERATION IN THE ATLANTIC AREA

J. Carvajal*, J.M. San Emeterio, E. Wattrelot

Pôle Mer Bretagne Atlantique, 525 avenue Alexis de Rochon, 29280 Plouzané (France)
E-mail : juliana.carvajal@polemer-ba.com

Introduction

The seafood sector is becoming more and more important in the present context of growing world population and consequent increase in food demand. Seafood not only represents the main source of proteins for millions of people in the world but also generates a lower carbon footprint than animal production in land. Atlantic countries have a strong stake in the growth of the seafood sector, both in terms of production and consumption. In 2017, United Kingdom, France and Spain were ranked in the top five of the main EU aquaculture producers. EU aquaculture is characterised by its high specialisation at regional and country level and is strongly influenced by geography and the natural habitat of the species, which makes the Atlantic Ocean a major asset for its coastal regions.

In order to continue to meet the growing demand for aquaculture products, while balancing with sustainability goals and the preservation of natural heritage, the seafood industry needs to respond to different challenges and opportunities requiring innovative solutions.

The SAFER Project was started in 2017 to respond to these challenges in the Atlantic area. SAFER aims to boost the adoption of technology and transnational cooperation and to improve the innovation performance of the seafood sector in the Atlantic regions and here are some of the results and perspectives of the project.

Methodology

SAFER (Smart Atlantic Seafood Clusters) is developed in three complementary actions:

1. A unique innovation services platform available online and designed for stakeholders from the seafood sector. It provides a catalogue of more than 80 services for effective organisation, governance, and innovation best practices in the Atlantic.
2. Seven living lab pilots in the Atlantic area developed to apply these tools in different companies involved at different steps of the seafood value chain and foster innovation adoption.

3. The production of recommendations for the Regional Innovation Smart Specialisation Strategies (RIS3), which will help the transfer of services to other businesses and local actors in the Atlantic.

Promoting innovation throughout the seafood value chain

Inspiring technology and collaboration within the seafood sector is at the heart of the SAFER project. The implementation of pilots is the most effective and tangible opportunity to illustrate the benefits of the innovation platform and its potential to be replicated by seafood actors in the future, across the Atlantic and beyond. The SAFER project jointly implemented 7 living lab pilots of innovative Industry 4.0 technologies, all based on a tailor-made approach of the 5 Atlantic regional nodes' needs and expectations.

The pilots implemented are a good example in terms of sustainability. They helped to reduce the environmental impact, i.e., the marine water treatment pilot minimises the marine water demand due to lower water exchange requirements with the surrounding media. They also helped to reduce the impact on the carbon footprint through a more effective management of stocks, logistics and production processes as it is the case of the Manufacturing Production Control Systems implemented in Ireland, France and Portugal.

Regional Smart Specialisations: an ocean of potentialities for research & innovation in the seafood sector

The SAFER pilots, in addition to concretely contribute to the transfer of innovation from one company to another, also offers an interesting source of information in the development of regional policies, in particular the so-called Regional Smart Specialisation Strategies (S3).

Smart Specialisation Strategies are a tool to support investments in key regional sectors with a competitive potential. Given the bottom-up approach of S3s, they implicitly support the creation of partnerships among different territorial actors of specific sector of specialisation, such as academia, business, and research centres for the development of a long-term sustainable growth.

The seafood sector features prominently in the Smart Specialisation Strategies of Atlantic Regions. The analysis of the S3s of Atlantic Regions showed that 15 Atlantic regions selected fisheries and aquaculture as a S3 in the period 2014-2020.

Among these regions, Cantabria Region (Spain) directly used SAFER as a mean to gather regional stakeholders of the seafood value chain and support the seafood chapter of its new regional S3 in 2021-2027.

It can be observed a general maintain of the seafood sector in the Atlantic regions' S3 for the new Multi-Annual Financial Framework (2021-2027), though not all the Regional Smart Specialisation Strategies have not been published yet. The regions share the view that the sector has economic, social, and environmental potential for regional growth given the increasing global demand for seafood products and high-quality healthy food.

In this context, SAFER will remain pertinent to support further guide the implementation of S3 related to the seafood sector.

Conclusion and perspectives

Seafood is a strategic blue economy sector for Atlantic regions and plays a vital role in the present context of increasing food demand and need for sustainable and resilient food systems. However, the sector must face several challenges to compete at the global scale while at the same time protecting the marine environment and avoiding additional pressures on already fragile ecosystems.

Hence, innovation is key to modernise this traditional sector and improve its sustainability, competitivity and resilience. The SAFER project, answering to these challenges and using the resources shared by a transnational network of different stakeholders, unlocked the innovative potential of the sector in Atlantic regions by testing and implementing living lab pilots which successfully helped mature established businesses to adopt technology and increase, in this way, final product quality, ensuring product traceability and reducing industrial costs. All these technologies promote the improvement of processes and products which comes at a crucial moment and paves the way for the sustainable transition of the Atlantic seafood sector.

SAFER 2.0 current and future actions

SAFER is exploring the concept of Industry 5.0 in the seafood sector. Industry 5.0 is a new concept which provides a vision of industry that aims beyond efficiency and productivity as the sole goals and reinforces the role and the contribution of industry to society.

It places the wellbeing of the worker at the centre of the production process and uses new technologies to provide prosperity beyond jobs and growth while respecting the production limits of the planet. This is of special relevance to the seafood sector where a sustainable management of sea resources is crucial.

THE EELS OF NORTH ADRIATIC LAGOONS AT DIFFERENT SILVERING STAGES: TOO YOUNG TO REPRODUCE?

Casalini, P. Emmanuele, L. Gentile*, A. Elmi, R. Brusa, O. Mordenti

Department Veterinary Medical Sciences, University of Bologna, Viale Vespucci 2, 47042 Cesenatico
Email: laura.gentile2@studio.unibo.it

Introduction

The European eel (*Anguilla anguilla*, Linnaeus 1758) is a catadromous fish with significant cultural, scientific, and commercial value. The population has declined alarmingly over the past 30 years (Van den Thillart *et al.*,2009; Dekker *et al.*, 2018); this condition has led to the classifying of this species as "critically endangered" according to the International Union for Conservation of Nature (IUCN). One of the conservation measures taken for this species is artificial reproduction, which has yielded excellent results over the last 10 years (Mordenti *et al.*, 2013; Di Biase *et al.*,2016). This work aims to study North Adriatic populations of European eel and test artificial reproduction on animals considered residents (yellow eel), pre-migrants (i.e., not ready to migrate) and migrants (i.e., ready to migrate and consequently reproduce) by the Durif *et al.* (2005) classification.

Materials and methods

A total of 854 European eels were caught in the North Adriatic lagoons (n.7). All eels caught were subjected to the detection of morphometric parameters. The initial stage of eels relative to the silvering process (Silver Index-SI) was determined according to the classification system described by Durif *et al.* (2005). Gonads were collected from a sample of eels (10%) for human consumption from each lagoon and the gonadosomatic index (GSI) was calculated. Age was determined by examining scales in 50% of the eels caught. To compare reproductive potential, n.48 females (14 SI II residents, 21 SI III pre-migrant, and 21 SI IV/V migrants) underwent induced reproduction following the originally developed protocol by Mordenti *et al.* (2018). For each spawning event, the reproductive performance of the eels was analysed to identify differences in gonadal maturation, number of reproduced-spawned females (%) and number of eggs production (% BW) (Mordenti *et al.*, 2018).

Results

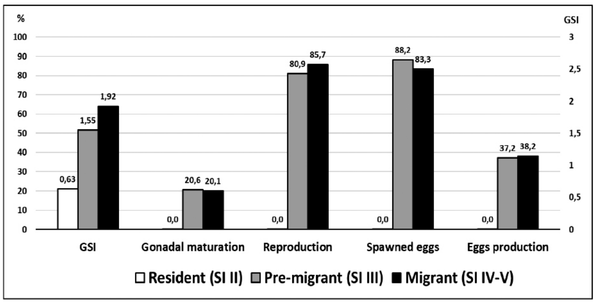

Fig.1 Main reproductive performance of the North Adriatic eels

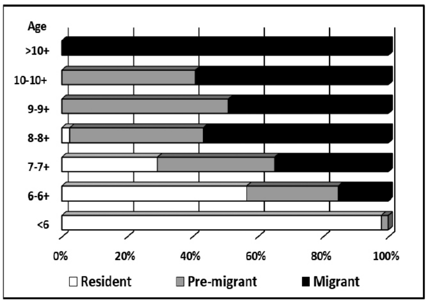

Fig. 2 Age classes of eels

(Continued on next page)

Discussion

This study aims to know about the North Adriatic eel population and to test the reproductive capacity of pre-migratory and migratory eels. The results are reported in Fig.1-2. Regarding artificial reproduction, both the hormone treatment and the number of spawned eggs (%BW) yielded similar values for both migratory and pre-migratory eels, while no positive response was observed in resident eels (Fig.1). The pre-migratory eels seem to have all the prerequisites to become fully-fledged eels ready for migration. Reinforcing the ability of these eels to reproduce is the fact that the pre-migratory eels (SI III) had almost the same gonadal maturation (GSI) as the migrating eels (SI IV-V) (Fig. 1). Furthermore, this could also be justified by the fact that we observed a certain overlap in the age of the pre-migrating eels with the migrating ones. Especially in the 8-10+ age range, pre-migrant and migrant eels are equally distributed (Fig. 2). Perhaps this can be explained by the fact that the transition from sedentary eel (SI II) to migrant eel (SI IV-V) is in our case a very rapid process that develops in a very short time (probably in just one growing season) in which the explosive weight gain is associated with a strong gameto-genetic intensity that is probably faster than complete metamorphosis (Gentile *et al*., 2022). The same study by Durif *et al*. (2005) argued that the silvering process is conditioned by various environmental factors that play a key role in this process. In fact, favorable growth conditions make the second metamorphosis of eels faster; the same favourable conditions encountered in the North Adriatic lagoons. Therefore, the functions developed by Durif *et al*. (2005) on Atlantic populations to distinguish silver eels cannot be fully adopted for Adriatic eels.

Conclusion

In general, this study increased knowledge North Adriatic population of European eels and demonstrated that eels considered pre-migrants have the same reproductive capabilities as migrants, and so pre-migrant eels can successfully contribute to sea release programs and artificial reproduction. With the contribution of the Life Programme of the European Union – Project LIFEEL (LIFE19-NAT/IT/000851).

Introduction

Aquaculture continues to be a key pillar of future food production systems and there is an ambition within the sector for increased sustainability and circularity. Strategies such as the European Green Deal, World Ocean Initiative and Strategic Guidelines for a more Sustainable and Competitive EU Aquaculture, also promote innovation, integration and the adoption of a multi-sectoral approach, to maximize ecosystem services while providing social and economic benefits.

Integrated Multi Trophic Aquaculture (IMTA) is acknowledged as a promising solution for sustainable development of aquaculture. IMTA is shown to remove waste materials from fed species and lower the nutrient load in the water (FAO, 2018). Further development of IMTA and low-trophic aquaculture are two elements outlined in the EU strategy for sustainable aquaculture development which can play an important role in improving the environmental performance of EU aquaculture. Furthermore, changes in consumer attitudes has seen a parallel demand in low trophic products such as invertebrates and seaweeds (Barbier, 2019). Despite these development, the EU remains one of the world's largest importers of fisheries and aquaculture products, importing 70% of the EU consumption (STECF, 2021). There is a need to enable nutrient recapture and transition current production to a more circular model.

Technology, equipment and infrastructure were identified as 3 of 9 major issues facing IMTA by a recent report for the Blue Bio-economy (EUMOFA, 2020). The proposed technology adapted in this project, facilitates the natural ability shellfish and seaweed provide to recycle the nutrients or waste that are present in and around fish farms. This helps improve the environmental performance of aquaculture production sites, maximises the use of space and the greater diversity of species provides extra economic benefits.

Methodology

The Marine Institute operates a fully licensed pilot scale multi species research site on the West Coast of Ireland. Infrastructure on site consists of a traditional 6 x 50m circumference pen grid for fish culture, approximately 0.25 the size of a commercial pen. To increase diversity and quantity of lower trophic species, a significant upgrade to the mooring systems was made to better integrate the extractive species in a way that considered cost, visual impact, environmental impact, benthic impact and capital expenditure.

Situated downstream of the modelled nutrient dispersion from fish waste at the pens; the new Low Trophic Grid (LTG) is designed to create a pathway for current monoculture facilities to 'add' productivity to their sites. The grid model aims to maximize available space and minimize environmental impacts. The grid is comprised of two 60 x 35m submerged rectangular grid rings, secured to the existing mooring ring of the fish pens, at a depth of 3m. This expands the site footprint with capacity for an additional 780m of longlines. The design allows the operator to adjust orientation, depths, and spacing of culture lines using multiple attachment points to facilitate a range of low trophic species. This new LTG was moored as an annex to the existing grid structure for fish culture in September 2021 and was fully stocked in October 2021.

Results

The novel development of the LTG, adds to the sustainable research infrastructure at the site enhancing research and production methods/technologies. By creating this new structure there is increased habitat and biodiversity at the site for low trophic species, and a reduction in the environmental nutrient load, delivering a healthier production system.

As the grid structure is submerged there is less visual impact, suspended culture limits interaction with the benthic environment and by utilising the main grid for fish culture, the co-location maximises uptake of nutrients released from fish rearing activities and reduces the number of anchor points by 50% when compared to traditional longlines. Expansion of cultured species to 10, primarily extractive species across lower trophic levels such as primary consumers and macro algae production. First point harvest 2022, included 4 tonnes macroalgae and 2000 shellfish and other invertebrates. The increase in production from the site is discussed using data on biomass accumulation and crop yields to provide expected nutrient uptake rates, compositional make up and value of additional products to the site.

Introduction

Turbot (*Scophthalmus maximus*) is an economically valuable flatfish species of great relevance for marine aquaculture mainly in Southern Europe. However, aquaculture production of this species is still hampered by high and variable survival rates during the early development stages at hatcheries, due in part to unknown larval nutritional requirements and detrimental microbiological conditions in the rearing system (e.g. the presence of pathogens). A number of studies has demonstrated that nutrition plays a key role in the modulation of fish microbial communities and consequently on their susceptibility to pathogenic infection (see the review of Ringo et al., 2016). Therefore, optimization of hatchery's protocols, through the development of premium microdiets that fulfil larvae and post-larvae nutritional requirements and maximize their resistance to pathogens, is essential to improve larvae and juvenile quantity and quality. In this context, the present study aimed to evaluate the microbiota responses in the gastrointestinal tracts (GIT) of turbot post-larvae fed microdiets with different combinations of marine and vegetable protein sources.

Material and Methods

Turbot post-larvae with 31 days after hatching (DAH) (initial body weight, IBW = 0.10g ±0.01) originated from FLATLANTIC hatchery (Praia de Mira, Portugal) were randomly assigned to 12 flat-bottom tanks in a closed water recirculating system (initial density of 1900 larvae/tank). Three isoproteic diets (62% dry matter)- a basal commercial-like diet, used as control diet (CTRL), and 2 experimental diets (D1 e D2) including different combinations of marine and vegetable protein sources (squid meal, krill meal, hydrolised fish proteins, wheat gluten, pea protein, fish meal) - were randomly assigned to those tanks. Dietary treatments were tested in 4 replicates. From 31-33 DAH turbot post-larvae were co-fed with enriched Artemia and one of the 3 microdiets. After 33 DAH until 66 DAH post-larvae were fed in intervals of 45min from 9h00 to 22h00 (automatic feeders) with dry microdiets exclusively. System water parameters were measured daily with commercial probes and adjusted to maintain temperature at 19 °C, oxygen saturation level above 90% and salinity at 20 g. L^{-1}. Fish were sampled at 31 (n=36 individuals/treatment) and 66 DAH (n=120 individuals/treatment) to determine length, weight, relative growth rate (RGR) and feed conversion rate (FCR). Survival rate in each treatment was determined at 66DAH. Moreover, post-larvae entire GIT (n = 4) were sampled at 43 and 54 DAH and pooled (one sample per replicate tank) for the assessment bacterial community analysis (high-throughput sequencing of the 16S rRNA gene).

Results

Although there were no differences in RGR, feed utilization (FCR) and survival amongst dietary treatments, post-larvae fed D1 diet presented lower weight when compared to CTRL group (Table 1). The PCO analysis of ASV composition showed that diet did not have a significant effect on the bacterial communities in the GIT of turbot post-larvae (PERMANOVA: F=1.024; P=0.368; Figure 1), yet age (i.e., DAH) was a significant predictor of the bacterial composition of fish (F=0.086; P=0.001). Bacterial composition had no clear dominance by any bacterial order and was mostly composed by proteobacterial ASVs (>49% of reads). Moreover, a taxon-specific statistical analysis revealed differential abundances among key bacterial groups, but no clear ordination base on diet was found when analyzing the fifty most abundant ASVs.

(Continued on next page)

Table 1. Growth performance indicators of turbot post-larvae throughout the experimental period fed the different diets (CTRL, D1, and D2).

		Diets			1-way Anova
		CTRL	D1	D2	*p-value*
	Age				
Weight (g)	66DAH	5.32±1.09^{b}	4.90±1.36^{a}	5.25±1.22^{ab}	0.024
Lenght (cm)	66DAH	6.59±0.51	6.64±0.68	6.73±0.58	0.258
RGR (% day^{-1})	31-66 DAH	12.1±0.44	11.7±0.78	12.1±0.48	0.560
FCR	31-66 DAH	0.52±0.08	0.60±0.10	0.56±0.07	0.435
Survival (%)	31-66 DAH	95.6±1.6	95.6±1.9	95.9±1.1	0.952

Values are expressed as mean ± SD. Different subscription letters (a, b) indicate differences between larvae from different dietary treatments at the same age ($p < 0.05$). Absence of letters indicates no statistical differences ($p > 0.05$).

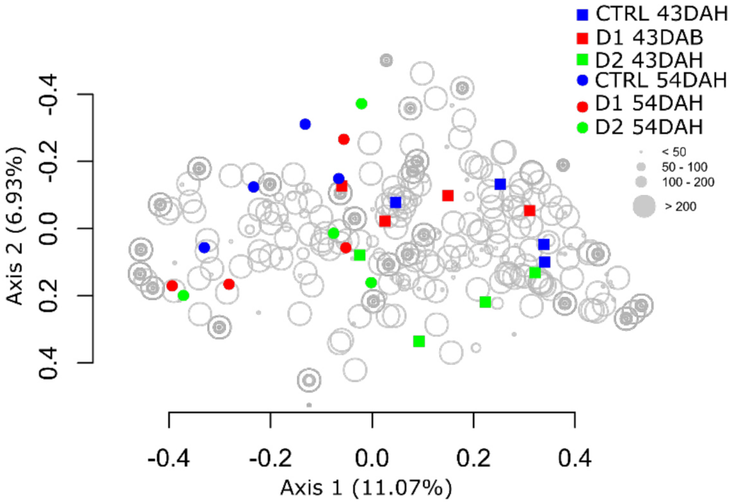

Figure 1 - First two axes of principal coordinates analysis (PCO) of ASV composition. Colored symbols are samples. Grey outlined symbols are weighted averages scores for ASV (size is proportional to abundance). Samples are control (CTRL) and experimental (D1 and D2) diets at 43 and 54 DAH.

Conclusion

Overall, the results showed that different microdiets tested had no major effects on the bacterial community in the GIT of turbot post-larvae. However, the zootechnical performance of turbot post-larvae fed with different diets showed that experimental diet D2 offers a viable alternative to commercially available microfeeds (CTRL diet) for turbot post-larvae.

Introduction

Nowadays plastic pollution is a worldwide problem and concerns all type of aquatic environment. Particularly, the presence of microplastics (size < 5 mm; MPs) has been found in the oceans constituting a source of pollution for aquatic organisms. Several studies have found the presence of MPs in marine animals, from the lowest trophic level to the top of the food chain. The presence of microplastics was also detected in sea-farmed aquatic species that showed similar rates of accumulation of MPs as those evidenced by wild specimens. More recently, the problem of MPs contamination in farmed fish has been extended also for land aquaculture. Fish meal products used in aquafeeds are made from fish-processing by-products or from low-value fish from wild fisheries. If recycling of by-products as feed ingredients contribute to support the sustainability livestock production their safety must be guaranteed not only for microbiological and chemical contaminants but even for microplastic. Furthermore, it has been shown that the concentration of MPs in fish meal is higher than that found in the raw materials from which it is derived. The reason lies in the fact that the processing procedures and packaging (polyethylene is one of the most widely used materials to produce "storage bags" for fishmeal) of the ingredients contribute significantly to the contamination of the feed. MPs contamination can have negative effects on both wild and farming fish production during different life-cycle stage. Many of these effects have been found primarily in the larval stages during which fish can exchange zooplankton for MPs resulting in gastrointestinal tract obstruction, a reduction in predatory activity caused by an apparent feeling of satiety, reduced growth and swimming capacity, and induction of inflammatory responses in the intestinal tract and other tissues because of translocation processes. However, despite the large number of publications on the presence of MPs in fish, little is known about their translocation after ingestion from the gastrointestinal tract to other target organs such as liver and muscle. The present study aims to assess the effects of a feed-induced MPs contamination during fish larval development, giving particular emphasis to growth and welfare, by monitoring the gut health status and the stress and immune response, and to the MPs fate to other target organs in relation to their size. In light of this, zebrafish (*Danio rerio*) represents an excellent experimental model being a fish widely used in nutrition and toxicology studies, with a short life cycle that allows to easily study its different phases under controlled conditions. Zebrafish has been widely used to study the effects of MPs exposure and the transparency of its embryos and larvae provides a significant experimental advantage for studying the tissue localization of fluorescent MPs.

Materials and Methods

A control diet containing fish meal as major protein source was prepared according to a commercially available standard diet for zebrafish (Zebrafeed, Sparos ltd, Portugal). Four experimental diets were prepared by adding to the basal diets two different sized fluorescent MPs (Polyethylene, 40-47 µm and an amino formaldehyde polymer, 1-5 µm), both from Cospherics (Santa Barbara, USA) at two different concentrations (0.05 g/kg and 0.5 g/kg). Zebrafish were fed the experimental diets (daily dose corresponding to the 3% of the body weight) from 5 to 21 days post fertilization. At the end of the trial, survival rate and specific growth rate were measured. To detect the presence of the fluorescent MPs ingested by the larvae and their possible translocation from the gastrointestinal tract to other organs, the whole specimens were analysed through Nikon A1R confocal microscope. For the quantification of the MPs accumulated by fish, larvae were chemically digested, and the product of digestion was filtered. Filters were then analysed through fluorescent microscopy to detect and count the number of MPs per larva. Histological analyses were performed to assess a possible damage to intestine absorptive epithelium induced by the MPs while molecular analyses were performed to analyse the relative expression of genes involved in immune (*il1b*, *tnfa*, and *il10*) and stress response (*nr3c1* and *hsp70.1*), appetite regulation (*ghrl*, *npy*, and *lepa*) and oxidative stress response (*SOD* and *CAT*).

(Continued on next page)

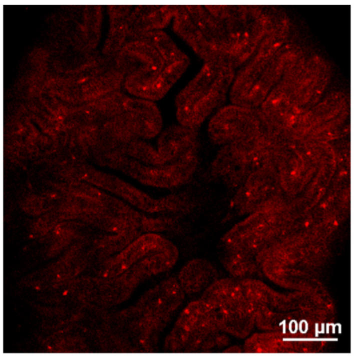

Fig. a: MPs detected by confocal microscopy in the intestinal villi of a zebrafish larvae fed a diet including the smaller MPs polymer at 0.05 g/kg. The size of the MPs beads (bright red) is of 1-5 µm.

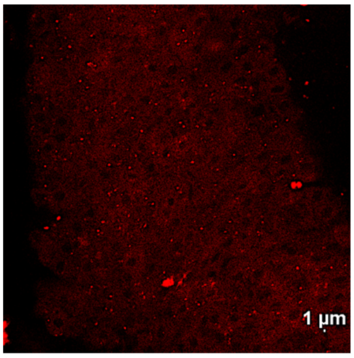

Fig. b: MPs detected by confocal microscopy in the liver of a Zebrafish larvae fed a diet including the smaller MPs polymer at 0.05 g/kg. The size of the MPs beads (bright red) is of 1 µm.

Results and Discussion

After the trial no differences in survival rate and growth were detected among the experimental groups. No MPs were detected in the control group, while their presence was observed in all the other experimental groups in a dose dependent way. Confocal microscopy evidenced that only 1-5 micron sized MPs were able to enter the intestinal epithelium (Fig. a) and only the 1 micron ones were found in the hepatic parenchyma (Fig. b) evidencing the presence of selective biological barriers.

The confocal microscopy results were coupled to the histological analyses on the gastrointestinal tract. Finally, fish fed with experimental diets showed a different expression of genes involved in stress, immune and oxidative stress response, and appetite regulation.

Introduction

Methionine (Met) is an essential amino acid for the fish growth and it is notably under-represented in compound feeds based on plant protein sources, such as soybean meal. In order to meet fish nutritional requirement for Met, the strategy is to supplement their diet with synthetic (crystalline) forms of Met (Rolland et al., 2016; Yuan et al., 2011). However, the high leaching in the water and high intestinal absorption rates represent the main limits of the plant-based diets supplemented with crystalline amino acids. To overcome these limits, several technological processes have been developed, such as coating, encapsulation, microencapsulation, or polymerization (Guo et al.; 2020; Xiao et al., 2017). Currently, the Met sources used to supplement aquafeeds include L-Met and its derivative forms, such as DL-Met (the racemic mixture of D- and L-isomer of Met), and Methionine Hydroxy Analogue (MHA). The main MHAs are 2-hydroxy-4-methylthiobutanoic acid (HMTBa) and its calcium salt, HMTBa-Ca, both precursors of L-Met. DL-methionyl-DL-methionine (Met-Met) is a new dipeptide formed by dehydration and condensation of two DL-Met molecules. Moreover, the coated Met (Co-Met) has been used as exogenous feed supplements.

Accordingly, the aim of the present work was to evaluate the effects of different exogenous Met forms added to the rainbow trout diet on fish growth performance, hepatic SAM/SAH ratio levels, and mRNA copies of three genes: *SAHH* (S-adenosylhomocysteine hydrolase), *CBS* (cystathionine-beta-synthase), and *BHMT* (betaine-homocysteine methyltransferase) involved in the Met metabolism.

Materials and Methods

A two-month feeding trial was conducted with rainbow trout (*Oncorhynchus mykiss*) fingerlings (3.40 ± 0.40 g). Fish were divided into seven experimental groups with three tanks/group. The feeding protocol consisted in using two control diets, the first one being a FM-based diet (CTRL+) and the other one a vegetable meal-based with Met deficiency (CTRL-). To prepare the five experimental diets, 5 g of each Met form (Met-Met; L-Met; HMTBa; DL-Met, and Co DL-Met) was firstly mixed with fish oil and then added to the CTRL- diet. At the end of the feeding trial, the growth performance indices were calculated. Then, 3 fish per tank (9 fish per diet) were sampled for the whole-body composition (WBC), whereas 6 fish per diet were sampled for liver tissue analysis, which consisted in gene expression analyses of three genes: *SAHH, CBS*, *BHMT,* as well as the S-Adenosylmethionine (SAM) and S-Adenosylhomocysteine (SAH) quantification in HPLC (High Performance Liquid Chromatography).

Results and Discussion

Fish readily accepted the experimental diets and at the end of the feeding trial, they tripled their weight. However, no significant differences were found for the growth performance parameters between the different dietary groups. In a similar way, the performance indexes of red drum fed with MHA and DL-Met supplemented diets resulted not significantly different from fish fed with L-Met supplemented diets (Goff et al., 2004).

All the WBC parameters were affected by dietary treatments. In particular, Met-Met and L-Met promoted a significant body lipid reduction, whereas the protein retention was significantly increased in fish fed with HMTBa and Co DL-Met. These latter also affected the Met metabolism increasing the mRNA copies of *CBS* gene in the liver tissue, promoting an enhancement of the Met transulfur pathway. In agreement with our results, Zuo et al. (2019) found that HMTBa increased the transcripts level of *CBS* in hepatic cells from porcine. On the other hand, L-Met increased the expression of the *BHMT* gene, which is known to be involved in the Met re-methylation pathway, thus contributing to maintain the intracellular Met pool. Moreover, the Met free form, L-Met, increased the hepatic SAM and SAH concentrations, thus suggesting a higher Met bioavailability. Similar metabolic response was found in Atlantic salmon liver, too, in which Met intake affected hepatic SAM level (Espe et al., 2008).

With regard to *SAHH* gene expression, no significant differences were found between fish fed different diets, thus suggesting that the tested Met sources did not influence the methylation ratio (SAM/SAH).

(Continued on next page)

Conclusion

The present study showed an optimal dietary intake of the different exogenous Met sources with similar promoting effects on fish growth, and hepatic Met metabolism. Nevertheless, the mechanisms underlying these effects warrants further investigation.

FROM FARM TO WHERE?
THE OBSTACLES OF SEAWEED-BASED SUPPLY CHAINS

M. Cerca [1,2*], A. Sosa[1] and F. Murphy[1, 2]

[1] University College Dublin, School of Biosystems Engineering, UCD Belfield, Dublin 4, Ireland

Introduction

Seaweed farming is a fast-growing aquaculture sector and is considered a more sustainable way of farming since does not require land, freshwater, fertilisers or pesticides (Baghel et al., 2020). It has been largely investigated for its potential in carbon sequestration and wide applications in food and feed industries, fertilizers and biostimulants, along with cosmetics, pharmaceuticals, bioplastics and biofuels (Collins et al., 2022)life cycle costing (LCC. Moreover, the prospect development of new supply chains based on cultivated seaweed could strengthen the path towards a circular blue bioeconomy, with food or bioremediation applications as well as promoting alternative revenue sources or employment opportunities to marine communities (European Commission, 2020). However, macroalgae cultivation is still in the early stages of development in the European context and several uncertainties underline the deployment and management of new supply chains based on macroalgae biomass (Araújo et al., 2021). Hence, the aim of this study was to enhance understanding of marine macroalgae cultivation from a management perspective towards responsible sourcing and new supply chains.

Material and methods

The study was based on a qualitative case study of emerging seawed cultivation sites in Ireland. Empirical case studies enable a profound investigation of a phenomenon of interest given a particular context (Rashid et al., 2019) and therefore particularly relevant to expanding understanding of the exponential interests involving marine macroalgae cultivation with wide different uses in the European context.

Results

The findings indicate several barriers to the expansion and deployment of seaweed businesses and supply chains, particularly in what relates to licensing, seed supply, processing methods and capacity as well as distribution. Moreover, seaweed supply chains from aquaculture are highly connected to institutional levels for planning and support involving policy, financing and regulations. Cooperation between seaweed farmers and research institutions suggests opportunities for development and innovation whereas cooperation between actors in the marine sector indicates a potential increase in bargaining power to overcome barriers and for business entrance or diversification.

Conclusion

Based on the study case in Ireland, multiple opportunities arise from the cultivation of marine macroalgae given the potential socio-environmental benefits seaweed can generate. However, multiple efforts are still needed, which from a grower's perspective involve trading potentials and commercialisation, government support of the aquaculture sector as well as technological development and transfer.

Introduction

One of the major current challenges of aquaculture industry involves the development of new commercial diets with the aim of reducing the unsustainable consumption of fishmeal while improving fish nutrition. In this context, *Nannochloropsis gaditana* is a microalgae rich in beneficial lipids, antioxidant compounds and amino acids, which has demonstrated improvements in growth and product quality in juvenile *Sparus aurata* (Ayala et al. 2020). In that sense, external barriers such as skin and gills can be used to measure how diets can affect and modulate the animal's metabolism. Both tissues are covered by a mucus secretion that includes a high number of microorganisms and molecular components of the immune system. The aim of the work is to observe what changes occur at the microbiota level in the skin and gills of commercial-sized *S. aurata* fed with a diet supplemented with raw and hydrolysed *N. gaditana* microalgae for 90 days.

Material and methods

N. gaditana biomass was produced in closed tubular photobioreactors at the Estación Experimental de las Palmerillas de la Fundación Cajamar following the standard procedure. Fresh *N. gaditana* was hydrolysed using commercial enzymes with cellulase activity (Vizcozyme®). The experimental feed was formulated by the Experimental Feed Service of the University of Almeria. The feeding trial was carried out at the facilities of the Central Service for Marine Culture Research of the University of Cadiz, where juvenile *Sparus aurata* weighing 10-15g were divided into 400L tanks and fed for 90 days with the study diets: a commercial diet (Control), a diet supplemented with hydrolysate and crude extract of *N.gaditana* at 5% (Hydrolysate and Crude, respectively). After 90 days, fish were anaesthetised and dissected for further analysis.

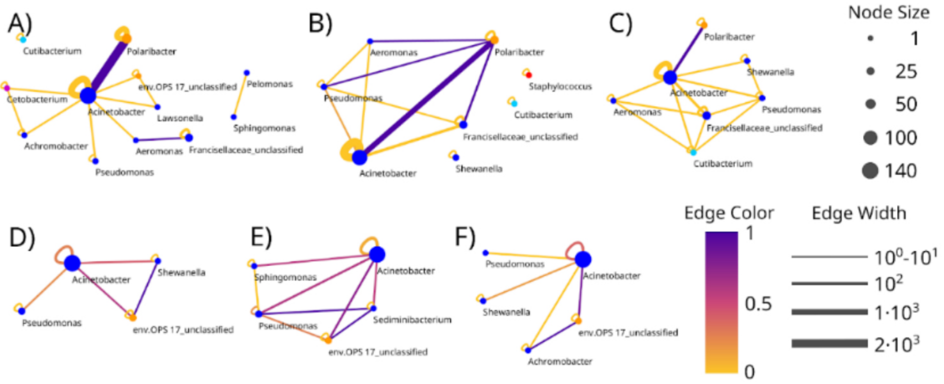

Figure 1. Genera involved in co-occurrence networks. Control diet (A), raw diet (B) and hydrolyzed diet (C) samples of gills. Control diet (D), raw diet (E) and hydrolyzed diet (F) samples of skin. The colour of the interactions is marked by the proportion of negative interactions.

(Continued on next page)

Skin and gill DNA was extracted according to Martinez et al., (1998). The 16S rRNA gene of the samples was sequenced using the Illumina® MiSeq platform (Illumina, San Diego, CA, USA) by pairwise sequencing (2 × 300 bp) at the Ultrasequencing Service of the Bioinnovation Centre of the University of Malaga (Malaga, Spain). Data processing was performed bioinformatically using a workflow based on the DADA2 library of R, using the SILVA 138 database with 99% clustering. Results were considered significant between Shannon index if t-student's $p<0.05$; while taxonomic comparison was performed using the R package DESeq2 ($p<0.05$). Co-occurrence networks were inferred from ASV abundances, based on Spearman correlation with the Hmisc library in R. Only Spearman correlations $p<0.01$ and with $\rho>|0.60|$ were considered statistically significant (Barberán, 2012) and visualised in Cytoscape 3.9.1. Only the ASVs present in more than half of the samples for each diet and tissue were considered in this network analysis.

Results and discussion

1416 and 694 ASVs in gills and skin respectively were preserved in the taxonomic analysis after filtering. The predominant *phylum* in gills was Proteobacteria (~50%) in the control and hydrolyzed groups and reached 70.58% in the raw diet. The Bacteroidota *phylum* was the most represented and Firmicutes and Actinobacteria were close to 3% in all treatments in this tissue. However, in all three different treatments, the phyla abundance was similar in skin samples, ~90% of which corresponded to Proteobacteria. Bateroidota (5.5%–5.9%), Firmicutes (1.8%–2%) and Actinobacteria (<1%) constitute the other phyla. Significant differences between treatments for each tissue were calculated. In gills, 13 significantly higher ASVs were obtained in the control (such as *Achromobacter*, *Acidobacter*) versus 4 whose abundance was higher in the hydrolyzed diet. The number of ASVs that differed significantly between the gill microbiota in the control vs. raw group amounted to 70, most of them being ASVs corresponding to the genus *Shewanella* (43) higher in the raw diet. Nevertheless, in the skin samples, Control group showed a significant increase of abundance related to *Acinetobacter*, *Achromobacter*, *Pseudomonas*, *Shewanella*, *Vibrio* and *Sphingomonas* among others. In the hydrolyzed group, the most significant abundance was associated with the genus *Pseudomonas*, *Vibrio*, *Pseudoalteromonas*, *Ralstonia* o *Cutibacterium*. In the case of the skin raw samples, there were ASVs corresponding to the genus *Acinetobacter*, *Streptococcus* or *Pseudoalteromonas* that were significantly different respect of control.

Taking the ASV abundance matrix for each diet and tissue, 6 co-occurrence networks were constructed. In all treatments in gills, *Acinetobacter* was a central genus in the network, and exhibited a negative correlation with *Polaribacter*. Besides, in the raw group, *Polaribacter* also showed negative correlation with *Aeromonas, Pseudomonas* and *Francisellacea*. In skin, *Acinetobacter* was involved in a major proportion of co-exclusion relations interacting with *Acinetobacter, Sphingomonas, Pseudomonas, Sediminibacterium* and env.OPS17 (Figure 1). This work shows that *Acinetobacter* has a key role in the balance of mucosa microbiota and was in co-exclusion with *Polaribacter*

EVALUATION OF A NEUROSENSORIAL FEED ADDITIVE ON *Litopeneaus vannamei* SHRIMP STRESS REDUCTION

Amine Chaabane*, Jean-François Gabarrou

Laboratoires Phodé, 8, avenue de la Martelle, 81150 Terssac France
E-mail : achaabane@phode.fr

Introduction

The marine shrimp aquaculture industry, in particular the whiteleg *shrimp Litopeneaus vannamei*, has experienced exponential technological development, with different production systems worldwide. Shrimp farming is made up of several stages and transitions that represent stressful events for the animals, which have a direct effect on reducing appetite and feed intake. Appetite is regulated by various factors as shrimp has a highly developed and sensitive sensory system, and appetite messages are known to reduce stress messages. In this context, modulating shrimp appetite can have a positive effect on stress reduction. A trial was conducted to evaluate the effect of a neurosensorial feed additive (NFA) on shrimp stress reduction through feed intake.

Material & Methods

During 8 weeks, 900 Pacific white shrimp (*Litopeneaus vannamei*) with an average initial weight of 0.5g were divided into 18 ponds of 220L in brackish water with 15 ppt salinity. Faecal matter was siphoned daily, and 60% of the water was changed every third day. The balanced feed used had a protein content of 35% and 7% lipids. The feed was distributed to the shrimp 4 times/day. The NFA was applicated at a 3kg/T rate. Each treatment was replicated 4 times. Feed intake rate, live weight, survival rate, and total biomass were measured at the end of the experiment (week 8). To measure stress reduction, an acute stress induction protocol was started at week 4.

Results

The use of the NFA led to a global improvement of survival rate, from 44 to 62% (Fig.1). After the stress induction protocol, it was observed that immobility time was reduced from 25 to 5 seconds with the NFA. These results suggest that a neurosensorial product have a beneficial effect on stress and mortality reduction in shrimp

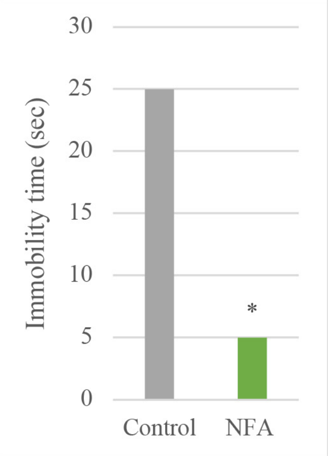

Fig.2 Average immobility time after acute stress in week 4 *p <0,05

EVALUATION OF A NEUROSENSORIAL FEED ADDITIVE ON Litopeneaus vannamei SHRIMP FEED INTAKE WITH LOW-FISHMEAL FEEDS

Jean-François Gabarrou*, Amine Chaabane

Laboratoires Phodé, 8, avenue de la Martelle, 81150 Terssac France
E-mail : achaabane@phode.fr

Introduction

One of the biggest challenges of shrimp aquaculture industry is the reduction of the use of fishmeal and fish oils, with balanced feed called "low-fishmeal (LFM)" feeds. These alternatives often fit well to animals from a nutritional point of view, but tend to under look the taste and attractivity aspect, in which fishmeal plays a huge role. The present study aimed to evaluate the effect of a neurosensorial feed additive (NFA) on feed consumption of shrimp fed with HFM (High-fishmeal) and LFM feeds.

Material & Methods

During 8 weeks, 900 Pacific white shrimp (Litopeneaus vannamei) with an average initial weight of 0.5g were divided into 18 ponds of 220L each in brackish water with 15 ppt salinity. Faecal matter was siphoned daily, and 60% of the water was changed every third day. The balanced feed used had a protein content of 35% and 7% lipids. The feed was distributed to the shrimp 4 times/day. Diet HFM contained 20% of fishmeal whereas diet LFM contained 10% of fishmeal and 10% of soy protein. Each diet was tested with the inclusion of the NFA (1,5 kg/T) and a control, and each treatment was replicated 4 times. Feed intake rate, live weight, survival rate, and total biomass were measured at the end of the experiment (week 8).

Results

Results suggest that the NFA improves low-fishmeal feeds consumption, with similar levels to those of high-fishmeal feeds.

The NFA could be a good solution to implement an efficient strategy to replace fishmeal in shrimp feeds.

E-mail : achaabane@phode.fr

Introduction

Most salmon farming systems involve practices that expose animals to acute handling stressors, which have negative consequences on behavior, growth, performance and survivability. Sedatives or anesthetics are commonly administered to fish to mitigate these consequences (Aydin & Barbas, 2020). Nevertheless, these products can cause mortality and damage to fish. The present experiment aimed to study the effect of an antistress functional feed additive (AFFA) mainly based on proprietary blend of essential oil bioactives, on the stress induced by handling and crowding subsequent stages.

Material & Methods

500 Atlantic salmon (*Salmo salar*) with an average weight of 196.74 ± 2.88 grams were equally divided into 5 tanks at a stocking density of 30.27 kg/m^3. The fish received a standard pelleted diet and after a 14-day acclimatation period, each tank labeled from A to E was exposed to the following in-water concentration of AFFA; A-0 ppm (negative control), B-20 ppm, C-40 ppm, D-60 ppm and E-20 ppm at time 0 min + 20 ppm at 2 hrs. The fish were transferred to external containers 35 min after the addition of the AFFA and crowded to a density of 85Kg/m^3 to reproduce typical conditions of salmon transportation. These containers contained the same concentration of AFFA as the original tanks. Fish stress responses were measured through: behavioral observations, cortisol levels at 5 different times following the AFFA addition (0 min, 35 min, 2 hrs., 4 hrs. and 48 hrs.) and time to reach a 30% oxygen depletion after transfer. Finally, feed resumption was measured from the transfer on each batch. Data were analyzed using ANOVA (General Linear Model) when appropriate.

Results

Regardless of the essential oil bioactives concentration, salmon's body orientation wasn't affected through the study and was similar to control fish. However, at 4 hours, fish in treatments C and D were excited while a decrease of swimming activity was observed in treatments B and E, compared to the control one. The oxygen depletion time was significantly the longest for fish in treatment E and the lowest for control fish (17.4 *vs.* 11 min; p=0,054). One day after the transfer, treated fish from treatment E displayed a quicker resumption of feed intake compared to the control fish (2.05 g *vs.* 0.69 g). The cortisol level observed in each group was increased from 35 min ($P<0,001$), which indicates a stress response to the experimental transfer model. It became significantly lower ($P<0.05$) in treated groups 4 hours post-treatment, and once again Group E stood out displaying the lowest cortisol level at this time compared to the control fish (204 *vs.* 547 nmol/l; $P<0,01$).

These results suggest the potential of using an AFFA for fish sedation at 20-ppm concentration repeated every 2 hours.

THE IN-POND RACEWAY SYSTEM (IPRS) TECHNOLOGY: PROMOTING THE USE OF HIGH VALUE FEEDS AND INGREDIENTS FOR OPTIMZING PRODUCTION AND PROFIT

Jesse A. Chappell*, Philip Kemp, and Sirri Kayhan

United States Soybean Export Council (USSEC)
16305 Swingley Ridge Road, Suite 200, Chesterfield, MO 63017, USA
chappj1@auburn.edu

The United States Soybean Export Council (USSEC) has worked for over 35 years with the aquaculture industry worldwide to promote a profitable, responsible, feed-based aquaculture industry while specifically promoting the use of United States soy products in aquaculture feeds. Though the primary target of the program is to work with feeds, an important aspect of the program is to help farmers with improving their aquaculture production systems, including introduction of better technology approaches.

Use of diets manufactured with high quality ingredients (macro and micro) is fundamental to success and profitability in modern aquaculture. However, nutritional strength and high levels of digestibility by themselves are not enough to assure sustainability or profitability. Animal health and high survivorship to market target weight is the most critical element to any successful aquaculture business.

USSEC has supported the development and adoption of the In-pond Raceway System (IPRS) technology, an alternative to traditional pond culture, which allows more efficient and productive use of water volume. IPRS operational principles combine to allow managers to increase annual yields 200-300% with no water exchange. IPRS provides the system manager with the necessary tools and fish culture environment to achieve high levels of survivorship, nutrient digestibility and retention leading to profitable and therefore sustainable operations. After many years in development and commercial application, IPRS has been increasingly adopted globally as a highly successful, predictable, and sustainable strategy for pond production.

A core of this technology's success is the use of high-quality feeds and good feeding approaches that balance a low feed conversion and fast growth rate to optimize the use of the production unit, which helps to promote a lower cost per unit production. This presentation will discuss the linkage of feed and ingredient quality and how it helps to optimize the use of the IPRS technology.

TRANSPOSING CIRCULAR ECONOMY PRINCIPLES TO AQUACULTURE

Moving from a linear to a circular economy (CE) is perceived a way to reduce the environmental impacts of human activities, including those of (blue)food productions, by closing materials and energy loops, and by implementing transformational changes in production and consumption. CE and its principles are still underexplored in aquaculture, although its fundamentals (i.e., reduce, reuse, recycle, recover) have already been largely applied. A recent study presented a set of 5 principles applicable to food and non-food systems to guide biomass use towards a circular bioeconomy (Muscat *et al.*, 2021): safeguarding and regenerating the health of our agroecosystems; avoiding non-essential products and the waste of essential ones; prioritizing biomass streams for basic human needs; utilizing and recycling by-products of agroecosystems; and using renewable energy while minimizing overall energy use. Most of the examples provided by the authors were based on terrestrial food production systems (i.e., agriculture and livestock), questioning therefore their applicability to the aquaculture sector and their novelty in comparison to well-known sustainability schemes.

The main objective of this study is to transpose the 5 principles developed by Muscat et al. (2021) to the field of aquaculture, identifying the implications of a transition towards more circularity in aquaculture and highlighting current knowledge gaps to initiate this transition. We performed a literature review to address several questions emerging from the CE paradigm including: Which aquaculture forms and what farming practices can safeguard and regenerate the health of our aquaecosystems? What makes aquatic products essential, and where and for whom are they essential? Are all aquaculture products equally essential? Given the use of human-edible ingredients in aquafeed, what is the net contribution of aquaculture products to human food provision? How can the aquaculture sector be used as a sink to recycle by-products from the food system and close nutrient loops at farm, or higher levels (e.g., territory)? What are the main levers to reduce the energy footprint of aquaculture products?

Introduction

Fish play an important role in the Mediterranean diet, providing high-quality protein content, vitamins, minerals, and large amounts of ω-3 polyunsaturated fatty acids. Although, aquaculture products cover a large percentage of fish production, consumers still have a preference to wild catches. *Epinephelus* is a genus of predatory fish, including 89 recognized species, found in seas throughout the world. They are among the highest priced species in fish markets, and only a few species are used in aquaculture (Heemstra and Randall, 1993). Two of the most common representatives in Greece are the dusky grouper *E. marginatus,* a reef-associated species distributed in the Mediterranean Sea, Atlantic and Indian Ocean and the white grouper *E.aeneus,* a demersal species distributed in the Mediterranean Sea and the Eastern Atlantic Ocean (Fishbase). According to the IUCN Red List of Threatened Species, *E. marginatus* has been classified as "Vulnerable" and *E. aeneus* as "Near threatened" species. Both species are distributed in Greek markets and restaurants, with high demand especially during the summer period. The fact that Greek Small-Scale Fisheries (SSF) often work seasonally, fish stocks decline and imported representatives of *E. marginatus* and *E. aeneus* are also traded in the Greek market, raises the question of authenticity, traceability and proper labeling of *Epinephelus* fish from Greek catches. In addition, incidents of Grouper fillets substitution by cheaper fish species, such as the Nile perch (*Lates niloticus*) or the wreck fish (*Polyprion americanus*) have been reported in Spain (Asensio et al., 2008). Molecular techniques based on DNA, e.g., COI barcoding, are currently being used for accurate and robust species identification, by using samples of any form: raw, cooked, processed, frozen. However, sequencing-based methodologies can be time consuming and not applicable for rapid food controls in the market. For the discrimination between closely related species or populations within species, data could be drawn from mtDNA regions. In this study, regions of mtDNA from *E. aeneus and E. marginatus*, captured in the Greek seas, as well as their imported counterparts sold in the Greek markets, were sequenced. Barcodes were used to identify the species and data inferred from other gene sequences were tested by non-sequencing based techniques such as PCR-RFLPs, multiplex PCR, HRM analysis, in order to establish a fast and reliable method for the identification of *E. aeneus and E. marginatus* from Greek catches.

Materials and Methods

The specimens examined were: (a) wild *E. aeneus* (40 samples) and *E. marginatus* (35 samples) caught in the Greek seas, FAO subareas 37.2 (Ionian Sea division 37.2.2) and 37.3 (Aegean and Cretan Seas), (b) imported samples labelled as *E. aeneus* (10 samples) and *E. marginatus* (11 samples), purchased from fish markets and supermarkets, (c) cooked samples collected from restaurants (3 samples of *E. aeneus*) and (d) *L. niloticus* and *P. americanus*. When available, fish were identified according to their morphological characteristics and categorized in groups by their origin. Total DNA was extracted from different tissues (muscle, liver, fins) using either NucleoSpin® Tissue and/or NucleoSpin® Food Macherey-Nagel, according to the manufacturer's instructions. For barcoding, a COI fragment of 648 bp was amplified using universal primers (Ward et al., 2005). For the amplification of mtDNA regions new primers were designed with Geneious Prime® 2022.2.1 Biomatters. Sequences were identified with Blast l, compared and aligned with sequences from GENBANK and BOLD databases and aligned with Clustal Omega, Molecular Systems Biology. For both species (a) PCR-RFLP analysis was performed (*E. aeneus*, 3 fragments and *E. marginatus* 1 fragment), (b) Multiplex PCR, (4 fragments were amplified for *E. aeneus* and 6 for *E. marginatus)* and (c) High-Resolution Melting (HRM) analysis (fragments of 80-120 nt for COI, 16sRNA *cytb* and *D-loop*).

Results

By barcoding, all samples of fish from Greek catches and 8 samples of imported fish from Senegal, Tunisia and Spain were identified as *E. aeneus*. Two imported samples from India were identified as *E. undulosus* and *E. poecilonotus*. Respectively all fish morphologically classified as *E. marginatus* were confirmed by barcoding. The same samples were analysed by PCR-RFLP but only an 875bp fragment of ND1-ND2 region digested with SacI could distinguish between *E. aeneus* compared to *E. undulosus* and *E. poecilonotus*. Multiplex PCR analysis of 4 fragment for *E. aeneus* showed a pattern that could distinguish between *E. aeneus* compared to *E. undulosus* and *E. poecilonotus* but not between domestic and imported specimens. Respectively the analysis of 6 fragments for *E. marginatus* showed no distinction between Greek and imported specimens. HRM analysis using different mtDNA regions showed that: (a) both COI and *cytb* fragment were species indicative, but not applicable for the discrimination between Greek and imported specimens, (b) 16s and CR regions were indicative for both fish species and population identification.

(Continued on next page)

Conclusions

Fishing plays a crucial role in employment and economic activity (trading, catering, tourism) for Greek coastal communities (FAO 2020). As many Mediterranean fish populations *E. aeneus* but mainly *E. marginatus* populations are in deep crisis, therefore sustainable fishing and conservation of the stocks are of high importance. By the assessment of authenticity and traceability of fish products not only consumers are protected, but also fish stocks are surveyed. In this study, the molecular identity of each species has been determined, even if the fish have been processed (exfoliated, fillet or cooked) thus ensuring, originality and authenticity of Greek fishery products. Our data show that HRM is a promising methodology that can be used as a rapid tool against fish mislabeling and phenomena of fish fraud.

Introduction

Feeding behavior can be described through a variety of factors, involving anticipation, stress, health, and activity. Measuring each one can be hard, because they are interdependent or underly circadian clocks.

Accurately describing the behavior preceding feeding is difficult but can lead to improvements on feeding schedules to optimize nutrition usage. We therefore investigate the nature of Food Anticipatory Activity (FAA) displayed in sea caged European seabass, especially with respect to diving behavior and acceleration activity. Our work expands the aquatic knowledge in FAA and is a step towards precision aquaculture with accurate feeding schedules independent from internal rhythm patterns.

Materials and methods

Around 10 thousand individuals of European seabass (*Dicentrarchus labrax*) with an estimated weight of 450 grams each were held in a sea cage of 40m diameter and 9m cage depth at an aquaculture facility off the island Crete, Greece. The feeding schedule consisted of once a day manually feeding between 8am and 10am local time. 24 fish were prepped with a tag with two transmitters, which sent depth and GPS position every 5 minutes, and alternately temperature and activity using a 3-axis accelerometer. Three receivers positioned around the cage collected positional, temperature and activity data from the transmitters between 28.05.2021-06.06.2021 to analyze positional and behavioral changes in the feeding process. We split the entire water column of the sea cage into three segments: The upper water column ranged from 0-3m depth, the middle water column ranged from 3-6m depth, and the lower water column ranged from 6-9m depth.

Results

Figure 1 shows an almost identical relative distribution of recorded fish positions between the three water columns. The day-night distribution was around 75% to 25% across the water columns, if the different twilights (official, nautical astronomical) are counted in as day. The difference in time spent in each water column during and before the feeding window (Fig. 2, red and green chunk in the first vertical bar) hinted at: 50% of the time where the seabasses were in the upper water column (0-3m) was before and during feeding, whereas for the other two water columns, less time was spent there before and during feeding. When residing in the middle water column, around half of the fish position pings were recorded after 2pm. Figure 3 illustrates 24-hour periods where activity was higher during day and fell lower during night with the twilights as transitional periods. On a weekly scale, we noted that activity followed the temperature curve, and slightly increased towards the end of the experiment (see Fig. 3).

Discussion and conclusion

The day-night distribution of 75%-25% described in Figure 1 was not surprising, since the tags transmitted in an even interval combined with long days in Crete. For example, the night stretching from the astronomical sunset on the 26.05.21 to the astronomical sunrise on the 27.05.21 is 6 hours 11 minutes long, which is approximately 25% of a 24-hour day, verifying our data quality. We were not able to detect a significant positional change throughout the day in Fig. 1, neither water column-wise nor timewise, suggesting that the fish were using the entire water column.

Due to the discrepancy between the different water columns just around and before the feeding time, we argue that the E. seabass was anticipating food and swimming up to the upper water column to prepare for food intake, which falls under FAA. We conclude that the cyclic regular feeding method created a habit in the fish to await food and therefore to swim up and be “prepared”. It appears therefore as the FAA was also at least correlated with the time of day, since we could not observe any FAA during nighttime.

(Continued on next page)

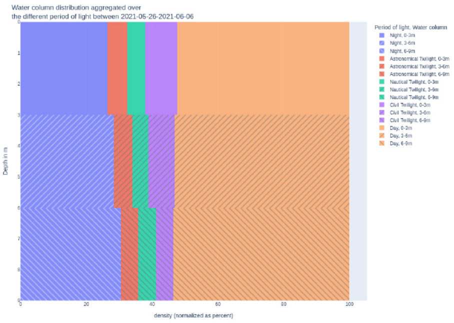

Figure 1: The aggregated density of the E. seabass throughout the water columns colored by the light period.

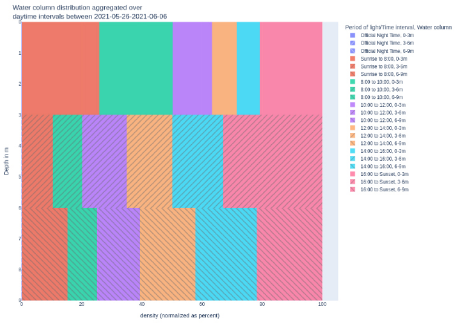

Figure 2: The aggregated density of the E. seabass throughout the water columns colored by different time intervals.

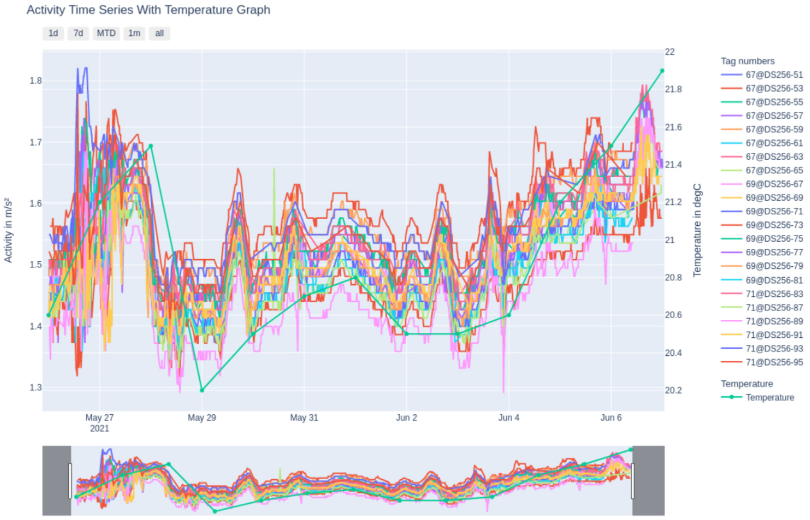

Figure 3: Activity of the tagged fishes during the experiment with a temperature line as overlay (green).

Higher activity throughout the first week of June was expected, since we know that temperature correlates with the activity of fish, as Figure 3 illustrates. It is remarkable that individual fish tend to stay in their hierarchy when sorted after “most active” to “least active”, which we argue is due to the different physiological traits the individuals have. The spike in the beginning of the experiment with the high complex interweaving of the lines may be due to the initial habituation period where the fish had not established activity profiles yet. It remains to be discussed more thoroughly though.

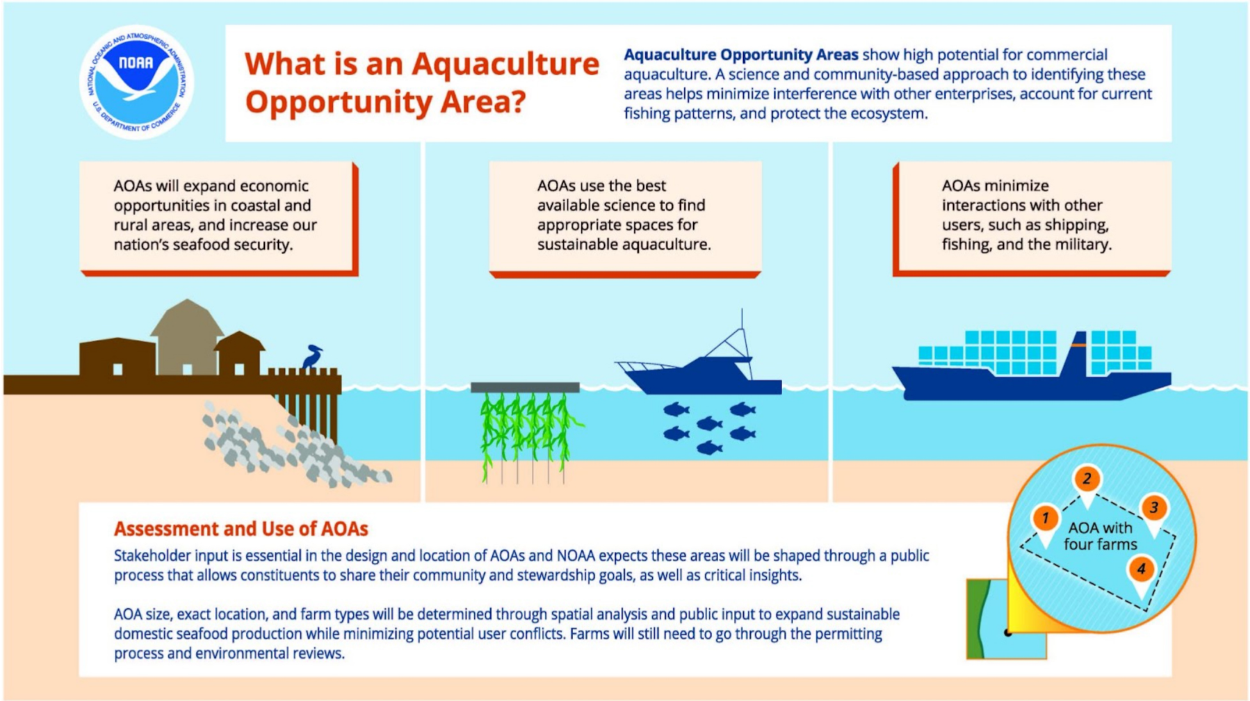
AQUACULTURE OPPORTUNITY AREAS: A NEW APPROACH TO U.S. AQUACULTURE DEVELOPMENT

Kristine Cherry*, Kristy Beard, Phaedra Doukakis

NOAA Fisheries Office of Aquaculture, Silver Spring, MD 20910
E-mail: kristine.cherry@noaa.gov

With a new vision and strategic plan to support aquaculture development, NOAA is leading a shift-change in U.S. aquaculture development through the identification of Aquaculture Opportunity Areas (AOAs). The search for AOAs in U.S. waters is a planning process, not a regulatory process, to identify defined geographic areas that are environmentally, socially, and economically appropriate for commercial aquaculture. By pursuing AOAs, we increase the confidence of both entrepreneurs and regulators via proactive planning measures that inform the permitting and environmental review processes for projects proposed to be sited within an AOA.

The process to identify potential AOA siting options and complete a Programmatic Environmental Impact Statement (PEIS) for each AOA will rely on the best-available scientific information and involve extensive public engagement. AOAs are intended to minimize interactions of aquaculture development with other ocean uses and important environmental resources, maintaining NOAA's commitment to ocean stewardship. NOAA will provide information on our progress towards identifying the first two geographic areas containing locations suitable for commercial aquaculture, drafting the PEIS for each of those two areas, and the opportunities for stakeholder input into the process.



What is an Aquaculture Opportunity Area?

Aquaculture Opportunity Areas show high potential for commercial aquaculture. A science and community-based approach to identifying these areas helps minimize interference with other enterprises, account for current fishing patterns, and protect the ecosystem.

AOAs will expand economic opportunities in coastal and rural areas, and increase our nation's seafood security.

AOAs use the best available science to find appropriate spaces for sustainable aquaculture.

AOAs minimize interactions with other users, such as shipping, fishing, and the military.

Assessment and Use of AOAs

Stakeholder input is essential in the design and location of AOAs and NOAA expects these areas will be shaped through a public process that allows constituents to share their community and stewardship goals, as well as critical insights.

AOA size, exact location, and farm types will be determined through spatial analysis and public input to expand sustainable domestic seafood production while minimizing potential user conflicts. Farms will still need to go through the permitting process and environmental reviews.

Figure 1. What is an Aquaculture Opportunity Area?

ANTIVIRAL FUNCTION OF NKEF AGAINST VHSV IN RAINBOW TROUT

Introduction

Natural killer enhancing factor (NKEF) belongs to the peroxiredoxin family of proteins, a group of antioxidants that has been extensively studied in mammals. Recently, we identified NKEF in the immunoprecipitated proteome of rainbow trout red blood cells (RBCs) exposed to viral hemorrhagic septicemia virus (VHSV). In the present study, we evaluated the role of NKEF in the antiviral response of rainbow trout against VHSV by examining the expression profile of NKEF in VHSV-exposed RBCs and rainbow trout gonad-2 (RTG-2) cell line.

Material and methods

Through silencing and overexpressing NKEF, using siRNA or a plasmid vector, respectively, we determined the effect of NKEF in the infectivity of VHSV, in rainbow trout RBCs *ex vivo* culture, RTG-2 and EPC cell lines. We also evaluated, by means of qPCR, the implication of NKEF in the modulation of the antiviral immune response.

Results

We found a correlation between decreased VHSV replication and increased NKEF expression in RBCs exposed to VHSV, however, this was not found in RTG-2 cells where *nkef* transcripts remained almost unchanged while the infection increased with the time. In addition, siRNA silencing of the *nkef* gene in rainbow trout RBCs and RTG-2 cells resulted in increased VHSV replication. We also found a correlation between *nkef* gene silencing and a decrease in the expression of genes related to type 1 interferon (IFN1) pathway. These findings indicated that NKEF is involved in the antiviral mechanisms of rainbow trout RBCs against VHSV and thus support its antiviral role and implication in the modulation of the immune response. Finally, overexpression of NKEF in an EPC cell line significantly reduced VHSV infectivity and was coupled to an increment in IFN1-related genes. Therefore, we could conclude that NKEF may be a potential target for new therapeutic strategies against viral infections.

ALIEN SPECIES ASSOCIATED TO COMMERCIAL BIVALVE TRANSLOCATIONS

S. Chiesa*, L. Di Blasio, G. Marino

ISPRA, Italy
Email: stefania.chiesa@isprambiente.it

Introduction

Council Regulation (EC) N. 708/2007 concerning use of alien and locally absent species in aquaculture, aims to assess and minimize the possible impact of these species and associated non-target ones on aquatic habitats. It provides indication to Member States to develop procedures for risks analysis and contingency plans for mitigation. However, the traceability data for bivalve introductions and translocations are currently lacking and must be improved not only in Italy, as well as in whole Europe.

Aquaculture practices include importation of seeds and live animals from different countries and their translocations within European marine waters; these practices represent one of the main vectors of the biological invasions from alien species, with increasing risks for farming activities, food and consumers' safety, as for environmental and biodiversity.

In Italian aquaculture, shellfish cultivation plays a relevant role, and it is mainly based on 4 species: the native Mediterranean mussel *Mytilus galloprovincialis* (Lamarck, 1819), the alien Manila clam *Ruditapes philippinarum* (Adams and Reeve, 1850), the native grooved carpet shell *Ruditapes decussatus* (Linnaeus, 1758) and the alien Pacific oyster *Magallana gigas* (Thunberg, 1793) (see Salvi & Mariottini, 2016), previously known as *Crassostrea gigas* (Thunberg, 1793). Native flat oyster *Ostrea edulis* (Linnaeus 1758) production declined in all Europe and in Italy too; alien blue mussel *Mytilus edulis* (Linnaeus, 1758) is also locally farmed with small productions in Sardinia Region.

Considering the current scenario, the aim of the present review was to draft an updated synthesis of literature data on alien species associated to translocations of commercial bivalves. Collected data will be useful to improve the traceability system for farmed bivalves in Italian marine waters, with particular reference to non-target species spread and diffusion.

Materials and method

Google Scholar, Scopus and WoS (Web of Science) were used for this bibliographic research with the following parameters: years from 2000 to May, 2022; selected topics and/or keywords "shellfish introduction", "shellfish translocation", "shellfish aquaculture", "oyster", "mussel", "clam", "Pacific oyster", "*Magallana gigas*", "*Crassostrea gigas*", "Manila clam", "*Ruditapes philippinarum*", "blue mussel", "*Mytilus edulis*", combined with "alien species", "hitchhikers", "associated NIS", "pathogens" and "virus". *C. gigas* was also used for bibliographic research since it was the valid species name until 2016.

For the present review, only papers concerning shellfish species cultivated in Europe were considered; the bibliography of collected papers was also used to integrate our data.

All the species names were carefully checked, confirmed, and updated on WoRMS - World Register of Marine Species (https://www.marinespecies.org/), as to describe the original range of species distribution.

Results and discussion

After removal of duplicates, 48 scientific papers were collected and analyzed. From literature synthesis, overall, 147 taxa (genus or species) have been identified for Bacteria, Chromista, Plantae and Animalia, plus three viruses or variants, already introduced though shellfish farming, or potentially suitable for introduction or translocation by commercial species of oysters, clams and mussels.

These alien species may affect (i) directly the cultivated bivalves (pathogens and parasites), (ii) the environmental quality (potentially toxic phytoplankton) and/or (ii) other marine species, with impacts on biodiversity.

Literature data herein collected also showed that many alien species introductions may have been facilitated by oyster, clam and mussel farming activities, although their further diffusion have then improved by other vectors.

(Continued on next page)

Among the cultivated bivalve species herein considered, oysters have been identified as the major vector of introduction for many alien species, with particular reference to Pacific oyster *M. gigas*. Despite its faming is now limited to the 1% of the Italian production, it has been growing since 2018 (FAO, 2022), representing a promising sector of national shellfish aquaculture (Marino et al., 2020). Therefore, it should be carefully monitored and managed to avoid the risks of new introductions and spread of associated alien species.

From this literature collection clearly emerges the necessity to improve the traceability system in bivalve aquaculture, especially for shellfish translocations: main efforts should be made at national and European level on the definition of biosecurity plans for non-target species, such as those already applied in Ireland, Australia, New Zealand.

Improving the knowledge on non-target species associated to shellfish aquaculture is therefore necessary to further implement the Council Regulation (EC) N. 708/2007, but also to support the monitoring activities referred to Descriptor 2 of the Marine Strategy Framework Directive.

"SOY PRODUCTS AS SUSTAINABLE INGREDIENT IN AQUA DIETS; WITH SPECIAL REFERENCE TO U.S. SOY"

Iani Chihaia

USSEC – United States Soybean Export Council
16305 Swingley Ridge Road, Suite 200, Chesterfield, MO 63017, U.S.A.
ichihaia@ct.ussec.org

From a global perspective, sustainability is a topic of much importance. The UN Sustainable Development Goals (SDGs) were set by the 193 member states of the United Nations in 2015 with a timeline to achieve the goals by 2030. Sustainability in the aquaculture value chain begins with the raw materials used in the feed. Raw materials represent the cornerstone for fish health and growth, and therefore ultimately for the fish farming success.

Historically, the base raw materials for aquaculture feeds have been fishmeal and fish oil, which is sourced from small forage fish, such as anchovies, sardines and capelin. Every year about 19 million tons of wild fish – some 20% of the total quantity caught around the world – are rendered in to fish meal and fish oil. Increasing use of forage fish is unsustainable and, because an additional 37.4 million tons of aquafeeds will be required by 2025, alternative protein sources are needed (Hua K et al. ,2019).

The total production of aquafeeds for all aquaculture species is projected to increase by 75% from 49.7 million tons in 2015 to 87.1 million tons in 2025 (Hua K et al., 2019). Analysts predict that the increased demand of aquaculture for fish meal and fish oil will outstrip the supply of small forage fish, by 2037.

Consistent with available evidences from a range of research trials, plant proteins can replace fish meal either in part or completely when certain dietary recommended conditions are respected. This is relatively well accepted for omnivorous species but less so for carnivorous fish despite solid research results for specific species (Kaushik et al., 2004, Dani, 2018; Kotzamanis et al., 2020, Zapata, 2021). As soy ingredients become an increasingly significant ingredient, it is only natural to focus on sustainability and reducing environmental impact. Soy crops are often connected to environmental issues such as deforestation and other unwanted Land Use Change (LUC) issues. Retailers, NGO's and consumers in Europe are increasingly concerned that this conversion leads to CO_2 emissions, land degradation and biodiversity loss.

The LCA (Life Cycle Assessment) method was used to evaluate the environmental impact of a soybeans throughout their entire life cycle. The method assesses every stage of the production, processing and use of soy, from raw material, packaging and transport to retail, consumption and waste-processing. This work was carried out by Blonk consultancy (The Netherlands) for USSEC.

Results showed that the carbon foot print (in kg CO_2-eq/kg product) - without taking the estimated LUC (Land Use Change) into consideration - averaged 0.37, 0.34 and 0.46 kg CO_2-eq/kg soybeans for the USA, Argentina and Brazil respectively. For all three countries cultivation accounted for more than 50 % of the CO_2-eq. production but there were major differences among the three countries in the effect of transport and processing with Brazil having a much larger impact of transport. Including LUC in the calculations resulted in pronounced differences in carbon foot prints with averages of 0.39, 5.56 and 5.75 kg CO_2-eq/kg soybeans for the USA, Argentina and Brazil, respectively. This clearly emphasized the importance of the cultivation methods and the differences among the three major regions in managing natural resources in the production and marketing of soybeans. The U.S. system being characterized by a rotational production in which land conservation plays a major role, and where the use of cropland has decreased by an average of more than 600,000 ha/year over the past 35 years. Over the same period, in the USA, forest land has increased by 2.1 million ha while this has decreased in South American countries.

These data support clearly the potential of soy protein as a sustainable alternative to other protein sources used in aqua production. Replacement of classical protein sources such as fish meal or animal proteins, but also a wide range of plant protein, can be accomplished through the use of responsible and sustainable soy protein. Of course, this requires the establishment of official organization supervising and certifying the sustainability of soy production. Such mechanisms are in place for US soy production, but need to be developed for soybeans of other origin.

Introduction

The fish processing industry has experienced significant growth over the last decades due to a rapid increase in urbanization, industrialization and consumer request. This process has contributed to generate more and more waste and by-products that are ususually discarded or minimally recovered. In order to promote a circular economy, these sidestreams like fish heads, skin, bones, spines and viscera, are still a source of low value compounds that can be turned into added value compounds through biotechnological process. Therefore, the selection of microroganisms capable of growing and fermenting these substrates is of croucial importance (Marti-Quijal et al., 2020; Ideia et al, 2020).Microbial fermentation or release of enzymes, such as proteases and lipases, can generate functional peptides, lipids, flavouring compounds, and chitosan. The aim of this study, performed in the framework of the European project "NewTechAqua", was to select and exploit safe microroganisms capable of fermenting fish waste and by-products and producing added value molecules or enzymes.

Materials and Methods

Different strains of yeast (*Yarrowia lipolytica*, *Debaryomyces hansenii*) and bacteria (*Lactiplantibacillus plantarum, Lacticaseibacillus paracasei, Bacillus subtilis, Pseudomonas* spp.) were screened for their enzymatic activities (proteolysis and lipolysis) using skim milk, gelatin plate, and spirit blue agar, respectively (Abbas et al., 2020; Cotârleț, Stănciuc & Bahrim, 2020; González et al., 2020). Selected microorganisms were then incubated for 72h in a solution containing 10 g of waste (fish bones, shrimp shells, viscera and blood) and 10 ml of glucose 30%. After fermentation, the supernatants containing protein hydrolysates were collected by centrifugation (4000 rmp for 10 min), quantified using Bradford and OPA assaies, and assessed for their antioxidant (DPPH, ABTS, TBARS), anti-hypertensive (anti-ACE assay) activities, and the ability of inhibiting pathogenic bacteria (*Escherichia. coli* EC15992, *E.coli* 555, *Salmonella* SE155, *Listeria monocytogenes* SCOTT A and *L. monocytogenes* 56LY) (Hong et al., 2014; Gottardi et al., 2014). Moreover, the production of flavouring compounds was evaluated by SPME/GC-MS technique. Protease production was evaluated according to Si et al., (2018).

Results

Among the microorganisms tested *in vitro*, all the strains of *Y. lipolytica* showed good proteolytic and lipolytic activities, followed by *Bacillus* spp. strains. The most promising strains were then incubated in a solution containing fish waste and by-products. *Y. lipolytica* generetaed more functional peptides. In fact, fresh hydrolysate obtained from *Y. lipolytica* 2 and 4 were those with the highest peptide content and the strongest radical scavenging activity (up to 86 % for DPPH, and 1.6 mg/ml equivalent to Trolox for ABTS). Moreover, the same samples hinhibited the growth of some strains of *E. coli*, *Listeria monocytogenes* and *Salmonella* spp.. Growth of *Y. lipolytica* also generated several volatile molecules, especially aldheydes, that could be exploited as food aroma. Fermentation obtained with Lactic acid bacteria and bacilli produced proteases that could be extracted and applied in the food industry.

Conclusion

This work has shown the relevance of fermentation as a useful tool to valorize fish waste and by-products, reducing their environmental impact and giving them an added economic value.

Introduction

The importance to study the intestinal microbiota of the prawns contributes to the knowledge of the resident bacteria with probiotic capacities. In recent years, the search for new sustainable aquaculture technologies has allowed the development of biofloc culture systems, in which microbial oxide reduction processes are carried out through the addition of a carbon source (Ferreira et al., 2015). Therefore, during the present study, the diversity and abundance of the microbial community in the culture water and the gut of the prawns cultured in biofloc and with the addition of the probiotic *Lactococcus lactis* were evaluated.

Materials and methods

For the study, 240 post-larvae of prawns were placed and distributed in 12 containers of 250 L capacity (Emerenciano et al., 2012). During 127 days of culture, an experiment was carried out with four treatments with three replicates (Emerenciano et al., 2012). Treatments: T1 consisted of prawns cultured in biofloc; T2 prawns cultured with biofloc and the addition of two doses of *L. lactis* at a concentration of 1×10^7 CFU ml^{-1} incorporated through *Artemia*; T3 corresponded to the addition of two doses of the probiotic at the same concentration; T4 cultured in clear water. Survival and weight were measured to determine individual growth. To determine the bacterial diversity in water and gut samples were taken and performed using MOTHUR (Schloss et al., 2009) to calculate five metrics to assess bacterial communities, including the number of observed OTU's, Shannon diversity index, and Inv-S estimators.

Results

The survival and the final weight of the prawns in the treatments BFT (100 ± 0), BFTPROB (100 ± 0) and PROB (93 ± 1.3) was significantly higher than that observed in the prawns in the CONT (80 ± 4.1) treatment. The highest weight gained (g) and SGR were obtained in the prawns subjected to the BFTPROB (3.3 ± 0.7) treatment, which was significantly higher than that observed in BFT (3.1 ± 0.8) and PROB (3.2 ± 0.5), while the lowest results were obtained with the CONT (2.8 ± 0.8) treatment, indicating a higher efficiency when incorporating biofloc and probiotics in the culture systems. Water quality parameters during the study were generally within tolerance ranges to maintain efficient growth rates in the prawns (Avnimelech, 2012). Respect the metagenomic analysis, the lowest number of OTU's and richness index (Chao) was PROB in the intermediate phase of the water samples (240 and 280.94 respectively) and the treatments with the highest number of OTU's and richness were BFT in the intestine (300 and 357.36 respectively) and PROB in water in the final phase (300 and 358.89 respectively). The diversity of the bacterial communities' indices per experimental stages were similar in values, except for the CONT 17.70 (17.86– 17.53), it was the lowest. The results of the metagenomic analysis indicate that the microbial community of the water in the biofloc/probiotic treatments samples were represented by 17 populations of taxonomic classes (Figure 1 and 2).

Discussion

According to the results, the survival and growth of the prawns of the BFTPROB treatment were significantly higher compared to the CONT prawns; this can be attributed to the action of the microorganisms (heterotrophic bacteria, phytoplankton, zooplankton, ciliates, rotifers, nematodes, and copepods) present in the biofloc as a source of natural protein in situ and available 24 h a day (Emerenciano et al., 2013). It is possible to consider that an ecologically efficient way to maintain water quality in general and, particularly, the concentration of nitrogenous metabolites during a commercial culture is the use of bacterial bioflocs, which contribute to maintain the concentration at values lower than those toxic to the prawns. The results about the 17 classes indicate that there is a direct relationship between the bacteria present in the water and those found in the gut samples, it is known that Proteobacteria are a microbial group that is responsible for the nutrient recycling process and mineralization of organic components in aquatic systems (Cardona et al. 2016). On the other hand, the absence of the probiotic *L. lactis* as part of the dominant microbiota in the PROB and BFTPROB treatments is probably due to it was displaced by the biofloc bacterial community (Cardona et al., 2016; Cienfuegos et al., 2018; Deng et al., 2019).

(Continued on next page)

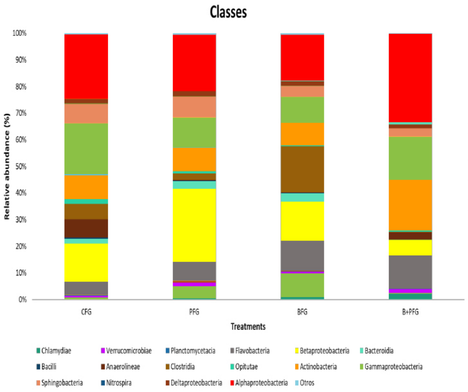

Fig 1. Average relative abundance (%) of the classes of bacteria in the gut samples of the experimental prawns.

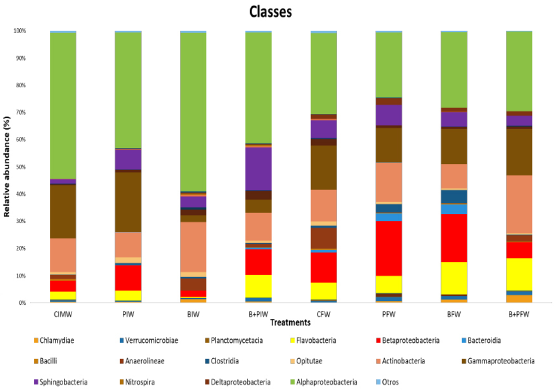

Fig 2. Average relative abundance (%) of the classes of bacteria present in the water samples from the experimental treatments.

Conclusions

This study expanded the knowledge about the diverse bacteria that develop in the biofloc and when probiotics are added, because in most of the investigations only phyla Firmicutes, Proteobacteria and Actinobacteria have been reported as dominant; with the results of this research 17 classes were identified within which Alphaproteobacteria, Gammaproteobacteria, Betaproteobacteria, Flavobacteria, and Clostridia were considered the most abundant. The probiotic *L. lactis* was not observed as part of the dominant microbiota in the treatments where it was added, this is probably because it was displaced by the microbial community of the biofloc. Despite this, significant differences were observed in the growth and weight of the prawns; survival was higher in the treatments with respect to the control.

Introduction

Depletion of natural stock of edible sea urchins turns them into target species for aquaculture practices that could secure high-quality seeds, juveniles and adults 1. Positive results were obtained using vegetable discards as diet for the gonad enhancement of Paracentrotus lividus (Vizzini et al., 2019), the most exploited Mediterranean sea urchin. Here, we analysed the embryo-larval development in offspring from adults reared under five diets (four based on Lactuca sativa discards and one on macroalgae), while the Integrated Toxicity Index (ITI, Morroni et al., 2016) was applied to assess diet quality in terms of normoformed/abnormal larvae. Finally, Stable isotope analysis were conducted to evaluate each diet assimilation.

Materials and Methods

Four diets were made with *L. sativa* discards of (86%) and to lesser extent (10%) of one of four seafood meals (fish, Diet-F; krill, Diet-K; mussels, Diet-M; and fish discards, Diet-D). A fifth diet was composed of 48% of both *Ulva* sp. and *Laminaria* sp. (Diet-A). 110 adults of *P. lividus* were collected at Santa Marinella (Italy) and transported to the LESA Lab. of University of Rome "Tor Vergata". 75 females were allocated into 15 tanks (3 for each diet) of a recirculating aquaculture system and fed *ad libitum* for five months. Then, spawning was inducted and the eggs collected and fertilized. After 48h in a thermostatic chamber, larvae were fixed with Lugol's iodine and observed under inverted microscope to assess the embryo-larval development and to calculate the Integrate Toxicity Index (ITI). Stable isotope analysis was conducted both on the experimental diets and on eggs produced at the beginning of the experiment (Egg-W), and at the end of the feeding trial (Egg-A, Egg-F, Egg-K, Egg-M, Egg-D).

Results

According to SIA, eggs produced by sea urchins fed with the experimental formulations diverged from $\delta^{13}C$ and $\delta^{15}N$ initial value towards the respective diets (Figure 1). ITI showed a different performance in larval development for the five experimental diets (Figure 2), with Diet-A presenting the best results thanks to the highest percentage of normorformated plutei, followed by Diet-M and Diet-D characterized by high amount of early normoformed plutei. Differently, Diet-F and Diet-K presented high relative abundance of abnormal pluteus, resulting in higher ITI values.

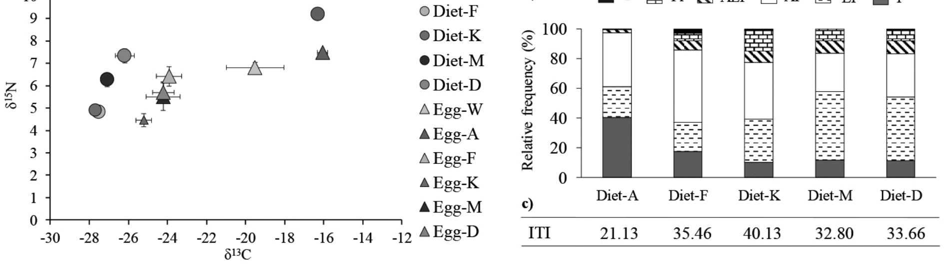

Figure 1. (a) Isotopic composition ($\delta^{13}C$ and $\delta^{15}N$) of the five diets and of the eggs produced before the start of the feeding experiment (Egg-W) and by sea urchins fed the respective diets. (b) Relative frequency malformation observed in larvae produced by sea urchin fed with the five experimental diets and the respective integrate toxicity index (ITI) value. Normal pluteus (P), early pluteus (EP), abnormal pluteus (AP), early abnormal pluteus (EAP), prism (Pr), gastrula (G).

(Continued on next page)

Discussion and Conclusion

Diet effect on produced eggs was clearly highlighted by changes in isotopic values, with Egg-A that showed an increase in both $\delta^{13}C$ and $\delta^{15}N$, according to Diet-A isotopic signature, while egg produced by sea urchin fed the four lettuce-based diets were characterized by a more negative $\delta^{13}C$ and a lower $\delta^{15}N$, resembling isotopic values of the respective diets and confirming diet assimilation [5]leading to improved productivity, sustainability and further diversification. In the case of aquaculture nutrition, a vast amount of knowledge has accumulated in relation to different physiological responses elicited by experimental diets and feeding regimes. By measuring assimilation, inferences can be made about the specific dietary components that were digested, incorporated into tissue and used for metabolic functions. One of the most common methods applied to estimate assimilation consists of measuring stable isotope values at natural abundance levels in feeding items and consuming animals. Isotopic measurements have been of great assistance to identify nutrient sources contributing to the growth of larval and juvenile organisms. The techniques have also been useful to determine nutrient flows in several types of aquaculture systems. The present manuscript reviews the most recent applications and findings derived from studies that have used stable isotope analyses to (1. Analysis on larval development confirmed that broodstock diet could deeply influence reproductive success affecting larval development [6]embryos and early larvae of the tropical echinoid Tripneustes gratilla (Linnaeus 1758. The higher relative amount of normal plutei observed for Diet-A suggest a faster development and thus better performance in larval production. Present findings are in contrast with De Jong-Westman et al. (1995) that found the worst performance in larval development with sea urchin fed kelp rather than in sea urchin fed formulated feed, due to the low quality of broodstock diet. Nevertheless, the high production of malformed or delayed larvae produced by sea urchins fed with the vegetable base diets enriched with animal meal, usually considered high nutritional source for sea urchins, confirm that also nutrient quality could affect larval development, as observed by other authors [8]"ISSN":"00448486","abstract":"This study investigated the growth and fatty acid composition of the sea urchin larvae Paracentrotus lividus fed on four types of diets: the microalgae Dunaliella tertiolecta, two types of microencapsulated formulated feeds and a concentrated algal paste. The larvae were successfully raised to metamorphosis on three diets, including the microalgae and the two formulated feeds. No significant difference was found in survival rate and metamorphosis rate for larvae fed with microalgae, formulated feeds, or microalgae plus formulated feeds. The fastest growth rate was obtained for larvae fed with microalgae, while normal growth and survival were only achieved for larvae fed with formulated feeds at a high frequency feeding rate. Normal larval development was not supported by either of the formulated feeds at a low feeding rate. A concentrated algal paste was also used for the low ration experiment, but failed to support any larval growth. Post-larval development was better for larvae fed on the formulated feeds, presumably reflecting the nutritional value of these feeds. P. lividus larvae grew well on D. tertiolecta which had a relatively low content of protein (37% dry weight. The best performance of diet A suggests that macroalgae contain macro- or micronutrients in an adequate proportion to promote larval development. Therefore, the introduction of an aliquot of macroalgae in the broodstock diet should be considered in echioculture.

MACHINE LEARNING FOR OBJECTIVE ESTIMATION OF FISH LOSSES CAUSED BY CORMORANT AND OTTER

Petr Císař, Ján Regenda, Zdeněk Adámek, Jakub Polenský

Faculty of Fisheries and Protection of Waters, CENAKVA, University of South Bohemia in Ceske Budejovice
Zámek 136, Nové Hrady 373 33, Czech Republic
E-mail: cisar@frov.jcu.cz

Introduction

The Eurasian otter (*Lutra lutra* L.) and Great cormorants (*Phalacrocorax carbo sinensis*) belong to the piscivorous top predators causing high losses of fish in aquaculture and natural water bodies. The otter is a protected species both in many countries and by the EU law or international conventions. Its targeted hunting is prohibited in the Czech Republic and also many other countries, and therefore, the fish farmers are getting financial compensation based on the estimation of otter activity in their farming facilities. The appropriate agency of nature protection regularly estimates the number of otters based on spraints counting or footprints occurrence in five-year periods. These methods of monitoring are, however, time-consuming and must be done by a trained person. This kind of monitoring is an indirect method without any information about otter behavior around the ponds, and it is not supported by any records of the otter itself. The monitoring (direct counting) cormorant on Central-European carp (*Cyprinus carpio*) ponds is currently the only possible source of information for the evaluation of the extent of losses they cause to fish farmers. This way of monitoring is based on the regular (optimally daily) counting performed by the farmers as the applicants for compensation; however, it can be easily biased by irregular observations and mistakes in the counting of individual birds, particularly when cormorant flocks consist of tens or even hundreds of individuals. Such monitoring is not supported by any kind of records except for the observer's notes on counting and can therefore be considered subjective to some extent. We introduce a new objective methodology of otter and cormorant documentation which eliminates the biases and mistakes of human monitoring, automatizes the detection, provides a record for further evaluation, and documents the otter and cormorant behavior in a particular pond area. The methodology is based on the neural network detection of the otter in the video records from the photo traps, which monitor the selected sites. The cormorants are detected and counted in the images of a thermal camera mounted on the UAV. The solution and web services system were implemented for automatic detection of the otter and cormorant. It provides statistical information about predators' appearance at the pond and records their movements. The methodology can be adapted to any animal species which can be monitored by the photo traps or AUV.

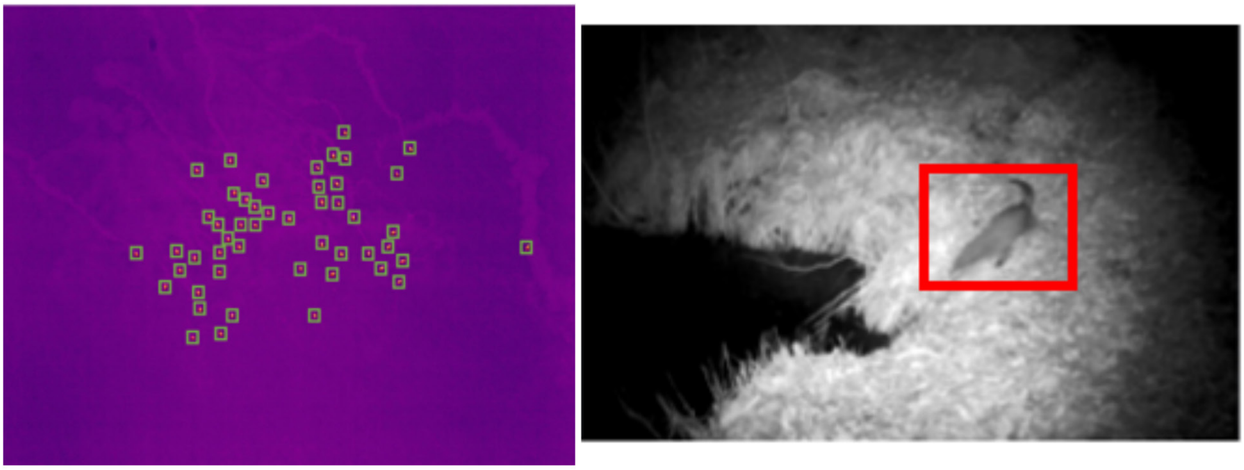

Figure 1. Left – thermal image of cormorants sitting on the water surface. Green rectangles depicts automatically detected cormorants. Right – image from the photo trap video sequence containing the otter. Red rectangle depicts automatically detected otter.

(Continued on next page)

Materials and methods

The data collection was performed for three years (2019 – 2021) at two carp pond farming sites in South Bohemia (Czech Republic) - pond system area nearby České Budějovice (hereafter CB, 49.0194933N, 14.3553972E) and the pond system nearby Nové Hrady (hereafter NH, 48.7986167N, 14.8102142E). The CB pond system area consists of 16 ponds (40 ha – 520 ha) used as ongrowing and overwintering carp (*Cyprinus carpio*) pond facilities. The NH pond system consists of 10 ponds (0.2 – 3.5 ha) mainly used as a nursing and/or ongrowing carp ponds. The ponds are arranged in a system mutually interconnected by canals. The presence of otters and cormorants was confirmed in both sites by direct monitoring of spraints, typical pathways, and observations. The monitoring of otter spainting was performed on three occasions (March 2020, February, and March 2021) at DM and five times at NH pond system (November 2019, March and May 2020, January and May 2021). The monitoring confirmed the presence of at least three otter individuals at NH pond system and at least five individuals at the DM pond.

The dataset for cormorant monitoring consisted of images from the thermal camera from 15 ponds for two years (2020 – 2021). The spring and autumn period of cormorant migrations has been documented by the datasets. More than 500 images from UAV were recorded. The data comprise 3 to 450 cormorants in one image under different weather conditions (sun reflectance, snow, rain). In addition to cormorants, three other bird taxa (gull, duck, goose) were recorded on the images.

The dataset for otter monitoring consisted of the video records from 10 ponds (20 cameras) for three years (2019 – 2021) from two locations. The video records covered the year's seasons with different weather conditions (sunny, snow, fog). More than 800 video records documented the otter (1-6 individuals) presence, and more than 14000 video records captured other animals or detections caused by the weather conditions (sun reflectance, snow, rain).

DJI M300 drone with H20T thermal camera was used for cormorant imaging. The thermal camera H20T has a resolution of 640*512 pixels and a spectral band 8-14 µm. It is also equipped with a color zoom camera with 5184 × 3888 pixels resolution. The images were taken from the top (the image plane is parallel to the water surface) at an altitude of 80 meters to eliminate overlapping of individual birds as may happen to the human observer from the viewpoint on the pond bank.

Four types of photo traps (Bunaty full HD, Bunatty wide full HD, UOVision LTE GLORY, Evolveo StrongVision 4GA) were used for data collection of otters to compare the differences in the accuracy of otter video recording. All photo traps are equipped with a passive infrared sensor (PIR) for object detection. A near-infrared illuminator at the wavelength of 940nm was used for night video recording in all photo traps. The optimal position of the photo traps was tested during the three years of monitoring.

The automatic detection of otters in the video records was implemented as a combination of motion detection followed by convolutional neural network classification into two classes: otter / no-otter. The automatic detection of cormorants in the thermal image was implemented as detection of bright spots in the image. The temperature of cormorants is significantly higher than the temperature of the background.

Results and discussion

The accuracy of otter detection was 86%, and the accuracy of detected otter classification was 98%. The accuracy of detection of cormorants was 96% in the thermal images. Both methods were implemented in the form of web service to be easily available for fish farmers and the bodies involved in fish loss estimation. The web interface is available here: http://wat.frov.jcu.cz/ login: uks.demo@email.cz, password: Slun94koSv9t9. The tools enable the fish farmers to simplify and objectify the process of fish loss estimation. The system also provides evidence of the otter and cormorant activity in the monitored region.

Introduction

Viral nervous necrosis (VNN) otherwise known as viral encephalopathy and retinopathy (VER), is the most threatening infectious disease in Mediterranean aquaculture. VNN is caused by the nervous necrosis virus (NNV) a bisegmented ssRNA+ virus included in the genus *Betanodavirus*, family *Nodaviridae*. NNV genome consists of two molecules named RNA1 and RNA2, which encodes for the RNA-dependent RNA polymerase and the coat protein, respectively. Four genotypes of NNV have been so far described: RGNNV, SJNNV, BFNNV, TPNNV (Sahul Hameed et al., 2019). Furthermore, reassortant strains have emerged from the reassortment between the RGNNV and the SJNNV genotypes and named RGNNV/SJNNV and SJNNV/RGNNV according to the RNA1 and RNA2 origin. Currently, several NNV strains are co-circulating in the Mediterranean Basin with a high prevalence of the RGNNV genotype and the RGNNV/SJNNV reassortant strain and a more limited diffusion of the SJNNV genotype and the SJNNV/RGNNV reassortant (Bandin and Souto, 2020; Volpe et al., 2020). So far, identification of NNV genotype and reassortant strains is based on amplification, sequencing and phylogenetic analysis of both viral genome RNA molecules requiring time and expertise. As viral identification is an essential information for the management of the disease in the field (Toffan et al., 2021), the development of an easy and affordable method to genotype betanodaviruses was developed in the framework of the H2020 Peformfish Project, an industry-driven project targeting industry defined priorities.

Materials and methods

RGNNV-RNA1, RGNNV-RNA2 and SJNNV-RNA2 specific primers were designed based on conserved regions within each genotype's sequences. The primer sets were selected according to their position within each genotype's RNA sequence, the melting temperature and the predicted amplicon size to amplify fragments of different sizes specific for RGNNV-RNA1, RGNNV-RNA2 and SJNNV-RNA2. After optimisation the novel multiplex RT-PCR assay was tested for analytical specificity and sensitivity and for repeatability thought intra- and inter-assay variability tests. Furthermore, the diagnostic sensitivity and specificity was calculated using seventy-six samples including 50 European seabass and 23 gilthead sea bream brains and 3 Artemia salina (nauplii) samples and comparing the mRT-PCR to the OIE validated real-time RT-PCR taken as the "Gold Standard". The robustness of the method was assessed testing samples included in the third VER interlaboratory proficiency test (VER-IPT) organised by the OIE reference laboratory. Finally, the accuracy of the genotyping performed via the new developed mRT-PCR was assessed subjecting to the conventional genotyping a selection of positive samples which reported different range of results at the mRT-PCR assay.

Results

A one-step multiplex RT-PCR was developed to detect and simultaneously identify the presence of RGNNV, SJNNV or one of their reassortant strains through the amplification of a specific band pattern for each genotype/reassortant strain. No cross-reactivity with viruses and bacteria frequently associated with gilthead seabream, European seabass and marine environment was observed. The mRT-PCR showed a sensitivity ranging from $10^{2.3}$ to $10^{3.4}$ $TCID_{50}$ ml^{-1} depending on the viral strain and a high repeatability with negative, weakly, and distinct positive samples. The mRT-PCR accurately detected no NNV-RNA in NNV-negative samples and produced at least one specific amplification band in all NNV-positive samples assuming a diagnostic specificity and sensitivity of 100%. The application of the mRT-PCR to the samples from the third VER-IPT enabled to correctly detect their positivity/negativity and to genotype them. Multiplex RT-PCR was able to assign to a genotype the RNA1 of all the positive samples and the RNA2 of 88% of positive samples.

(Continued on next page)

Discussion and Conclusion

Several NNV strains are currently co-circulating in the Mediterranean Basin. Genotyping and reassortant identification are an essential information for the management of the disease in the field. However, proficiency tests performed by the OIE reference laboratory pointed out a limited capability to properly identify the NNV variants (Toffan et al., 2021). Identifying the genotypes and reassortant strains is so far based on traditional genotyping that consists in amplifying and sequencing of both viral genome RNA molecules. Only the analysis of both viral genome segments (RNA1 and RNA2) led to reassortant identification. This method is time-consuming and requires highly specialised staff and equipment, resulting in a limited number of laboratories able to perform a complete and correct viral species identification. The developed multiplex RT-PCR represents an easy, rapid, and affordable method to identify NNV variants circulating in the Mediterranean: RGNNV, SJNNV and the reassortant RGNNV/SJNNV and SJNNV/RGNNV strains. The method can find wide application in several sectors of the study of the VNN contributing to improve its knowledge and therefore leading to a better disease control. It can also be used for confirmatory diagnosis in NNV outbreaks in the Mediterranean increasing laboratories' capacity to correctly identify the betanodavirus genotype.

Email: stefclaessens92@gmail.com

Introduction

Litopenaeus vannamei, commonly known as Pacific white shrimp or whiteleg shrimp, is the most cultivated shrimp species worldwide with a total volume of more than 6.5 million tons in 2018 and had a growth in production of 8.78% in 2020 (FAO, 2020). *L. vannamei* is a tropical species, originally farmed in tropical areas and known to be sensitive to low temperatures. Due to its high economic value, the farming areas have been expanded to the sub-tropical areas. Therefore, low temperature has become one of the major constraining factors in the *L. vannamei* production. To overcome temperature related environmental stress factors, the robustness of the *L. vannamei* must be improved.

Material and methods

Five diets based on the formulation of a commercial shrimp diet were tested with different inclusion levels of mussel meal (*P. perna*): 0% (control), 1%, 2%, 3% and 4%. The experiment was carried out at the Marine Shrimp Laboratory (Laboratório de Camarões Marinhos – LCM/UFSC) at Barra da Lagoa, Brazil, where in total twenty polyethylene tanks of 400 liter were used (n = 4). Each tank was stocked with 40 shrimps (3.5 ± 0.5 g) and were kept for 8 weeks at a temperature of 28 ± 1 °C under constant aeration with a 100% daily exchange of water.. During these 8 weeks growth was measured for the different treatments and after the 8 weeks a potential lethal cold shock treatment was performed to verify the robustness of the shrimps.

Results

The final weight (g) and weekly weight gain (g/week) were significantly higher in the 1% and 2% mussel meal diets after 8 weeks (figure 1 & figure 2). The survival was >94% after 8 weeks in all treatments.

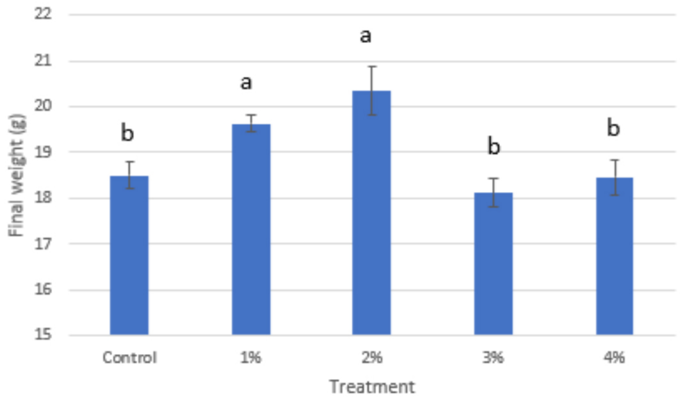

Fig 1. Final weight in grams from the five treatments after 8 weeks. The final weight from the 1% and 2% mussel meal diets were significantly higher than the Control, 3% and 4% of mussel meal diets.

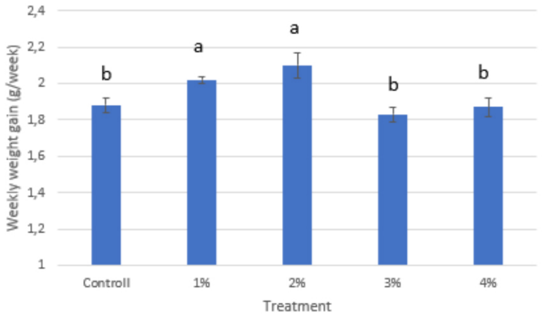

Fig 2. Average weekly weight gain in grams from the five treatments in 8 weeks. The weekly weight gain from the 1% and 2% mussel meal diets were significantly higher than the Control, 3% and 4% of mussel meal diets.

Conclusion

Mussel meal can be used as a potential ingredient in diets for the whiteleg shrimp *(Litopenaeus vannamei)*. It even improved growth when putting 1% of 2% of mussel meal in the diets.

BACTERIAL COMMUNITY IN AFRICAN CATFISH (*Clarias gariepinus*) RECIRCULATION AQUACULTURE SYSTEM UNDER DIFFERENT STOCKING DENSITIES

Júlia Clols-Fuentes*[1], Julien A. Nguinkal[2], Patrick Unger[1], Bernd Kreikemeyer[3] and Harry W. Palm[1]

Introduction

African catfish (*Clarias gariepinus*, Burchell 1822) is a good candidate for Recirculating Aquaculture Systems (RAS), since it tolerates adverse environmental changes (FAO, 2020). To maintain optimal water quality relies on certain physicochemical parameters (Keramat Amirkolaie, 2008) and on the microbial community (Lucas and Southgate, 2012). However, the identity and activity of nutrient cycling bacteria population remains poorly understood while producing *C. gariepinus*. The aim of the present study is to describe the microorganisms community composition (at phylum, family and genera taxonomical levels) during *C. gariepinus* rearing trial, testing three different stocking densities: intensive (S1), semi-intensive (S2) and extensive (S3).

Material and methodology

Samples of water were collected in triplicate from three RAS at the research facility "FishGlassHouse", University of Rostock (Germany). Three sampling groups were considered: i) filtered water that enters the fish tanks (water inflow); ii) water leaving the fish tanks (water outflow), and iii) water from the sedimentation tank (sedimenter water). Each system had specimens of *C. gariepinus* stocked at three different densities: extensive (25 individuals/m^3), semi-intensive (70 ind./m^3) and intensive (120-130 ind./m^3). Water temperature, dissolved oxygen (%), pH, salinity (‰), conductivity (μS cm^{-1}) and redox potential (mV) were measured. Molecular approaches (RT-PCR and Miseq Ilumina sequencing) targeting the V3-V4 16s rRNA hypervariable region were used to construct a library of amplicon sequence variants (ASV) and assess microbes' identification, abundance and diversity. Statistical analyses were performed at phylum, family and genus levels using different packages in R version 4.1, and custom R scripts.

Results

Overall, Proteobacteria and Bacteroidetes were the predominant phyla in all types of samples. The S1 and S3 groups showed different patterns, as taxonomic abundances of certain dominant phyla tended to change between in- and outflow water. The S2 group had the highest accumulative abundance of ASVs and tended to be similar between sample groups. All samples from the S2 were grouped with less disparate separation between them, contrarily to S1 and S3, where few families appear to be dominant. The following genus of pathogenic bacteria were identified at all systems: *Mycobacterium*, *Pseudomonas*, *Edwardsiella*, *Flavobacterium*, *Yersinia*, *Rickettsia* and *Aeromonas*.

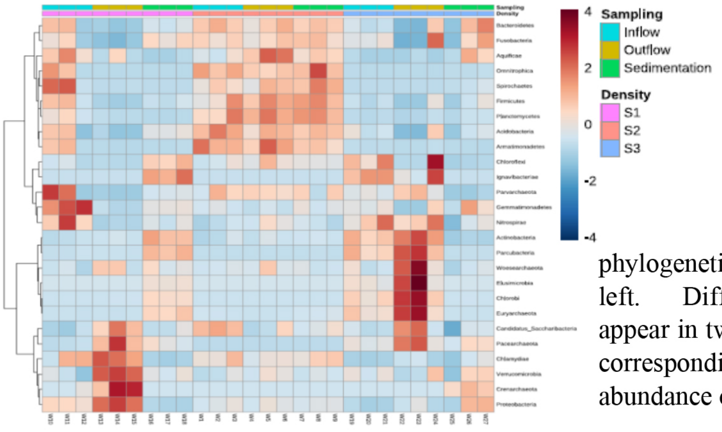

Fig. 1. Heatmap showing the relative abundances of the 26 most abundant families from water inflow, outflow and sedimenter at S1, S2 and S3. The phylogenetic tree appears on the left. Differential abundances appear in two colors, red and blue, corresponding to low and high abundance of ASVs respectively.

(Continued on next page)

Discussion

Our study comparing systems with different stocking densities is a clear example of community structural variability influenced by fish biomass. In this study we detected 42 phyla at three sample points of the RAS. The most abundant groups identified at all compartments of S2 included sulfur redactor families. Other abundant groups were mainly heterotrophic. When high amounts of organic carbon are available, heterotrophic bacteria may outcompete nitrifies for available oxygen and space, and the nitrification rate decreases (Michaud et al., 2006). In general, at S1 and S3 we detected high diversity of metabolic functions, and the dominant families detected at water inflow and outflow participate at the nitrogen cycle and organic matter degradation. Heterogeneity of communities is usually attributed to environmental changes (Krotman Y, 2020) or water treatment processes (Ma X, 2017). Potential pathogens were more abundant S2, which had low water exchange and high fish biomass, although it may not directly affect fish health and/or growing performance. Each RAS holds dynamic microbial communities, which change in response to the accumulation of nutrients, and participate to the maintenance of proper water quality (Califano et al, 2017). This knowledge can be used to further develop *C. gariepinus* RAS, detecting potential shifts of the microorganism's populations with increasing fish biomass and possible implications on the fish health.

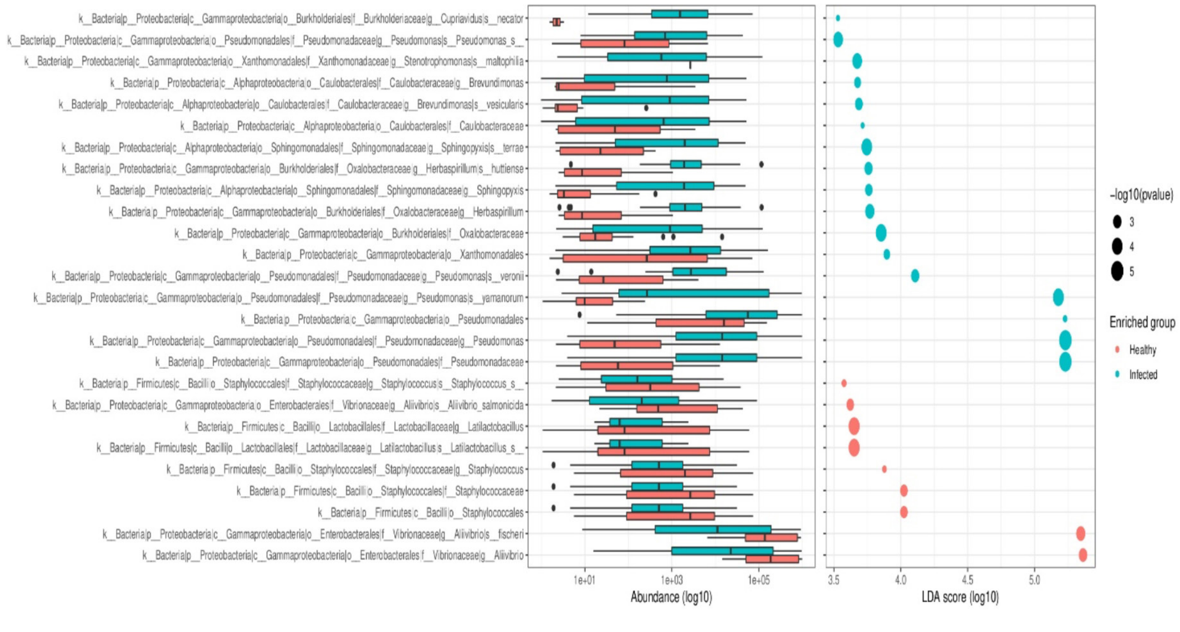
Introduction

In Chile, SERNAPESCA (the National Fisheries Service) has identified *Piscirickettsia salmonis* (SRS; Salmonid Rickettsial Septicemia infection) as the most severe health problem facing the Chilean salmon industry owing to its highly aggressive nature, recurrent outbreaks, and widespread transmission, among other cultivated salmonid species. The total mortality of salmon due to specific diseases in Chile is associated with SRS and is in the order of 50% to 97%, which translates into direct and indirect annual losses of close to 700 million dollars. The changes caused by the pathogen *Piscirickettsia salmonis* in the gastrointestinal microbiota in *Salmo salar* during infectious outbreaks due to this pathogen in Chile are unknown and not widely researched. Therefore, knowing which microbial species in the gut are affected or favored by the pathogen *Piscirickettsia salmonis* is the main objective of this research.

Material and Methods

The salmonids analyzed in this study correspond to the Atlantic salmon (*Salmo salar*) (weight: 2869.34 g +/- 3160.42 g) from six Chilean farms located in the Los Lagos and the Aysén Region. Salmonid samples were taken during infectious outbreaks with *Piscirickettsia salmonis* in four salmon farming: C1, C2, C3, and C4. During January and February, summer in the southern hemisphere. Samples were taken from six *Salmo salar* per farm, with clinical skin signs of infection by *Piscirickettsia salmonis* in each salmon farm, as mentioned earlier. Additionally, 12 healthy fish from two salmon farms (C5 and C6) that did not present reports of infectious outbreaks of *Piscirickettsia salmonis* were analyzed to confirm that the *Salmo salar* taken as control did not present the pathogen infections, clinical, histological analyses of the organs (kidney, liver, and spleen) were performed.



(Continued on next page)

The 16S rRNA primer pair, 515F GTGYCAGCMGCCGCGGTAA / 806R GGACTACNVGGGTWTCTAAT, evaluated the microbial ecology of each sample on NovaSeq with methods through the bTEFAP® DNA Analysis Service. Each sample was subjected to a one-step 35-cycle PCR using the HotStarTaq Plus Master Mix Kit (Qiagen, Valencia, CA). After PCR, all amplicon products from different samples were mixed in equal concentrations and purified using SPRI beads.

Raw reads were quality trimmed using Fastp v0.20.1 (REF), removing the first 10 nucleotides, discarding all reads with one or more Ns, then using the right to left sliding windows method with size 4 and minimum q-score 30 and finally, all reads with mean q-score lower than 30 were discarded. High-quality reads were de-noised, filtered against chimeric PCR artifacts, and merged using the R package DADA2 version 2.1.18 (REF), producing clean 16S amplicon sequence variants (ASVs). The taxonomic assignment was performed with the same R package using as reference SILVA 138.1

Results

This study showed that the main bacterial phyla of all salmon sampled are Actinobacteria, Firmicutes, and Proteobacteria. The research also found that the control groups in the study (*Salmo salar* without clinical signs of SRS infection) have concentrations of this pathogen in their gastrointestinal system. The study also found a high concentration of Proteobacteria in the gut of all *Salmo salar* sampled, suggesting that the salmonids are dysbiosis. Interestingly, this study found co-occurrence networks between the pathogen *P. salmonis* and other aquaculture pathogens that did not manifest clinical signs of infection in the sampled salmon. Finding other pathogens in cohabitation with pathogen *P. salmonis* is undoubtedly one of the most exciting findings of this research.

SUSTAINABLE BUSINESS MODEL INNOVATION IN A LOW CARBON OFFSHORE AQUACULTURE VALUE CHAIN: ORGANIZATIONAL FACTORS AND INSIGHTS FOR MANAGERS

Introduction

This paper examines how firms engage in sustainable business model innovation (SBMI) in a multi-stakeholder public-private offshore aquaculture innovation project in Norway. To address Grand Societal Challenges (GSCs), firms engaging in SBMI must also collaborate with other stakeholders, including research institutions, policymakers, NGOs, and the general public. Further, organizational design can impact firms' ability to engage in SBMI. In this paper, we explore these challenges and their implications in the case of a new green offshore aquaculture value chain in Norway. Leveraging an action research case study approach, we analyze how organizational factors impact SBMI in this context and build theoretical and managerial insights for how firms engaged in multi-stakeholder innovation projects can succeed with SBMI, particularly in the aquaculture industry.

Background

Until now, salmon aquaculture in Norway has only been in sheltered inshore waters. But as production has increased substantially along the coastline negative environmental externalities have increased. Offshore aquaculture has recently received attention as an avenue for sustainable production growth. Offshore ocean areas, representing 90% of the Norwegian economic zone area, provide opportunities for reducing environmental externalities substantially. However, offshore aquaculture faces extreme wind and wave conditions, long distances from shore to farms, and significant up-scaling of production with potential new biological and technological challenges. In order to become economically and environmentally sustainable offshore aquaculture requires an entirely new value chain with technological innovations at all stages, and multi-billion USD investments to achieve economies of scale. In 2020 the Norwegian government established the 'Green Platform' innovation program, primarily as a policy tool to meet Norway's climate gas reduction obligations under the Paris agreement. The programs aims to address Grand Societal Challenges in the green transition towards a low carbon society by stimulating the establishment of new consortiums of companies and research institutions with sufficient complementary resources for large-scale innovation projects. The case presented here examines one of the consortiums that successfully applied for Green Platform co-funding from government: a coalition of 7 aquaculture value chain companies and 10 research institutions, working to develop a low emission offshore aquaculture value chain. The first and second authors were involved in preparing the application for this project. The project involves research and innovations on electrification of transportation and farming processes, new salmon feeds, and digitalization and automation of farming operations, with a. total budget of 185 million NOK (approx. 18 million EUR), including government co-funding of 93 million NOK.

Methods

We leverage a qualitative action research case study approach (Bocken et al., 2017; McManners, 2016). This approach "combines the focus on inquiry and action offered by action research with the case study methodology described by Yin (2013). It allows researchers to go beyond the role of neutral observer to a participatory role whilst retaining academic rigour (McManners, 2016), and is seen as instrumental in the transition to a sustainable world (Gustavsen, 2008; McManners, 2015)" (Bocken et al., 2017, p.10). We followed Yin (2013) in selecting this case for a single case study, as it is particularly unique and offers unusual revelatory potential. Inductive methods are increasingly recognized in the management literature as being appropriate for addressing Grand Societal Challenges (Eisenhardt et al., 2016). Interview questions were developed and data was analyzed following a grounded theory approach (Gioia et al., 2013; Locke, 2001). Data included semi-structured interviews (11), participant observation (30+ meetings), and document analysis. Interview data was categorized into 1st- and 2nd-order concepts and themes, and triangulated with observation and textual data.

(Continued on next page)

Results

Preliminary results reveal themes which provide insight for SBMI in collaborative contexts. Level of vertical integration, organizational culture, existing infrastructure for open innovation, public innovation requirements, and project context impact SBMI. Action research can influence project outcomes and lead to sustainability improvements. Firms engaging in collaborative SBMI in collaborative contexts can lead to broader sustainable ecosystem innovation (Snihur & Bocken, 2022).

POSITIVE WELFARE EFFECTS OF PHYSICAL ENRICHMENTS FROM THE NATURE-, FUNCTIONS- AND FEELING- BASED APPROACHES IN FARMED RAINBOW TROUT *Oncorhynchus mykiss*

V. Colson[a*], V. Brunet[a], A. Kleiber[a,b], A. Patinote[a], P.L. Sudan[a], C. Duret[a], G. Gourmelen[a], E. Moreau[c], C. Fournel[c], L. Pineau[c], S. Calvez[c], S. Milla[d]

Introduction

In captive animals, the concept of positive welfare is defined as the physical and mental states that exceed what is strictly necessary for short-term survival (Fife-Cook and Franks, 2019). Therefore, it becomes essential no only to prevent poor welfare, but also to give animals greater opportunities to experience positive affects by generating various forms of comfort, pleasure, stimulation, interest, and sense of safety in order to induce long-lasting positive affective states, close to the positive welfare concept. Environmental enrichment is a deliberate increase in environmental complexity and is one of the strategies investigated to improve the living conditions of animals reared in stimuli-deprived environments, including farmed fish. Physical enrichment, a category of environmental enrichment, consists in adding structures (stones, plants, kelps, sand, gravels) into the rearing tanks, but is rarely used in aquaculture. Fish welfare can be approached from three different angles: nature-, functions- and feelings-based (Huntingford et al., 2006). Physical enrichment is closer to the nature-based approach meaning that fish should live in an environment close to the natural habitat of the species, in order to promote more natural behavior (Martins et al., 2012). According to the functions-based welfare approach, fish must be able to maintain their biological functions and zootechnical performances. Growth (Kientz et al., 2018) and health (Karvonen et al., 2016) were shown to be improved when adding physical structures into the tanks of salmonids species. The third approach to consider fish welfare is “feeling-based” and set in terms of subjective mental states. From this point of view, negative emotional experiences must be decreased and positive experiences should be promoted. Providing fish with physical enrichment may be an effective way to meet the positive welfare concept from the feeling-based approach also by stimulating fish, encouraging exploration and facilitating their curiosity and interest.

In the literature investigating the influence of enrichment on fish welfare, the three different perspectives are often disconnected and rarely evaluated within a whole experiment. The present study aimed to investigate whether physical enrichment had positive effects on the welfare of rainbow trout, the first continental fish species produced in Europe, through these nature-, functions- and feeling-based approaches.

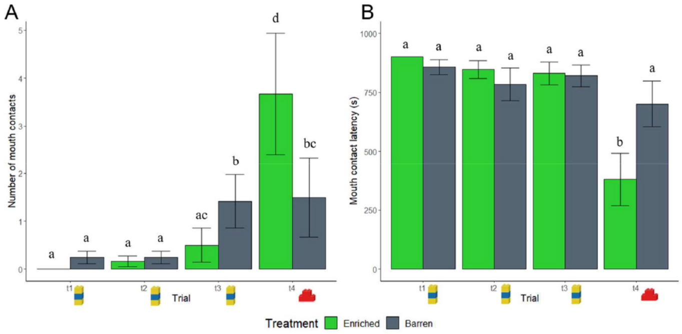

Fig. 1. Number of mouth contacts with objects (A) and mouth contact latency (B) after the introduction of the objects at each trial (t1, t2, t3, t4: novel object) of trout raised in enriched environment (E: green) or barren environment (B: grey) during the novel object test. Values are means and the mean standard error is represented. Statistical differences are represented by different letters (P<0.05, n=12).

(Continued on next page)

Material and Methods

Female triploids rainbow trout (*Oncorhynchus mykiss*) were split in two experimental treatments: an enriched environment (E) and a barren environment (B) from 99 days post-fertilization (dpf) to 333 dpf. The enriched environment was composed by PVC pipes, plastic plants and white stones. For the nature-based approach, groups of rainbow trout (3 tanks/treatment; 30 individuals each) were observed in their home tanks (enriched vs. barren) provided with video cameras for 4 weeks (from 162 to 187 dpf) to analyze fish group behavior (dispersion, aggression and stereotypies). Fin erosion was also recorded at the end of this period as a marker of aggression. To assess welfare from the functions-based approach, fish growth was monitored (from 102 to 333 dpf) and immune analyses (lysozyme, complement component ACH50) were carried out at 208 dpf. Two behavioral tests were performed to assess fish welfare from the feeling-based perspective: (i) a novel-tank test to evaluate the fear-related responses (behavior and plasma cortisol release) at 208 dpf, and (ii) a standard novel object paradigm to characterize fish boldness and curiosity (at 250-260 dpf). The analysis of the behaviors expressed during these tests was performed with the EthoVision XT software.

Results and discussion

Our findings demonstrate that providing physical structures in the environment of farmed rainbow trout decreases aggressive behaviors in the group, as confirmed by lower fin erosions. Physical enrichments might restrict territorial range and visual contact, thereby decreasing the probability of encountering and consequently reducing aggression towards conspecifics (Zhang et al., 2021). Moreover, the possibility for subordinate fish to hide into shelters is likely to promote positive welfare for those fish. Decreased aggressive behaviors, accompanied by fewer stereotypic behaviors, induced more opportunities for resting and exploring in shoal cohesion close to the structures. Heightened shoal cohesion is considered as a marker of positive emotions in zebrafish (Franks et al., 2018). The lower level of aggression probably contributed to improve growth, without any effect on health parameters. When subjected to the emotional reactivity test, enriched fish displayed fewer fear-related behavior (decreased angular velocity and higher exploration) but plasma cortisol levels remained similar between groups. When exposed to a novel object, enriched fish were bolder and less neophobic, spending more time close to the object (Fig. 1), without exhibiting anxiety-like behaviors. Enriched environment seems to give captive fish opportunities to experience positive affects by generating various forms of stimulation, interest, and sense of safety, inducing long-lasting positive affective states, as observed by lower anxiety-related behaviors, higher exploration, and decreased neophobia towards novelty, meeting the positive welfare concept.

Conclusion

Complexifying the environment through the addition of physical structures which stimulate and encourage fish to explore promotes rainbow trout's welfare in farming conditions, according to the nature-, functions- and feeling-based welfare approaches.

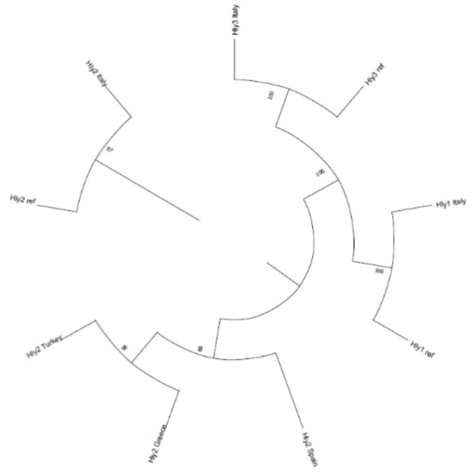
Introduction

Aquaculture production has expanded significantly in recent years. Nonetheless, infectious diseases remain a key concern, preventing future escalation. *L. garvieae,* a warm-water pathogen, is one of the main issues for aquaculture in the Mediterranean area. It is the aetiological agent of lactococcosis in freshwater and marine farmed fish, a disease marked by hyperacute hemorrhagic septicemic infections. The Mediterranean's moderate climate and higher water temperatures, due to the global warming, contributed to the emergence of lactococcosis outbreaks in this region. Virulence factors seem to act as main actors of *L. garvieae* pathogenicity. One of these factors is the capsule: the link between the pathogenicity of the strains and the capsule is not fully understood. However, differences in the capsule's polysaccharide composition might explain the virulence or non-virulence of some strains. Other factors are hemolysins because of their lytic actions. Hemolysins and their role in virulence and disease have been examined at the molecular level in various pathogenic bacteria, including *L. garvieae*. By generating pores and altering phospholipid structures in the membrane, their enzymatic actions promote the lysis of red blood cells and phagocytes. On blood agar, *L. garvieae* displayed hemolytic activity, and three hly genes were found in the genome: hly1, hly2, and hly3. In the context of the European project SUPERTROUT (Improving SUstainability and PERformance of aquaculture farming systems: breeding for lactococcosis resistance in rainbow TROUT), aimed at sustaining small-scale farming systems of trout production in the Mediterranean area by using an innovative approach to control lactococcosis, archivial strains collected in the Countries participating to the project (Italy, Spain, Greece and Turkey) were characterized for hemolisin genes and for the capsule cluster genes.



(Continued on next page)

Materials and Methods

80 archival strains from local rainbow trout farms (one for each Nation participating to the project) collected in the five years before this study were analyzed.

The pathogenicity of the three hemolysin genes was determined by sequencing the amplicons obtained by positive strains. DNA was extracted using the freeze-boiling thawing method and amplified as described by Teker et al. (2018). For DNA sequencing, BigDye 3.1 chemistry was used. Sequences were aligned with the reference sequences genes present in Genbank, hemolysin 1 (GenBank accession number: MG999526), hemolysin 2 (MH316613) and hemolysin 3 (MH316614) using Lasergene (DNASTAR) software.

The presence of the capsule gene cluster in *L. garvieae* strains was screened using the protocol reported by Ture and Altinok (2016). Amplicons were confirmed by agarose gel electrophoresis, comparing amplicon size with the positive control and a 100 bp DNA ladder.

Results

A total of 80 strains from Italy, Spain, Greece, and Turkey were tested for the presence of hly1, hly2, and hly3 genes. Only the Italian strains were positive for the amplification of hemolysin 1 and 3 genes. Amplification of hly1 was negative in four strains. Hemolysin 2 was amplified for *L. garvieae* strains in all countries and presence of the hly2 gene in Italian, Spanish, Greece and Turkish strains were 100, 100, 95 and 60%, respectively. Sequences for each hemolysin were submitted to GenBank with the following accession numbers: Italian hemolysin 1 OM663244; Italian hemolysin 2 OM810256; Turkish hemolysin 2 OM810257; Greek hemolysin 2 OM810258; Spanish hemolysin 2 OM810259; and Italian hemolysin 3 OM663245. The Maximum Parsimony method was used to estimate the evolutionary history of hemolysin gene sequences. A bootstrap (1000 replicates) consensus tree was inferred using MEGA X.

Discussion and Conclusions

Data from hemolysin phylogenesis revealed a higher similarity among strains, particularly those from Greece, Turkey, and Spain, and a lower similarity with Italian strains, suggesting the strains' geographical origins. Furthermore, when compared to hemolysin 3, Teker et al. (2018) found hly1 and 2 as key virulence factors. Turkish strains seem to be less virulent than other strains based on the percentages of amplification achieved for hemolysin 2, as well as the lack of hemolysin 1 and 3, yet substantial mortality was found in the farms where the strains were collected. Because of the reciprocal interaction between host and pathogen, other variables such as host susceptibility linked to genetic determinants and environmental characteristics such as water parameters or rearing density should be addressed in the progression of the infection.

Introduction

Lactococcus garvieae is a well-known fish pathogen that affects a wide range of farmed and wild marine and freshwater species. Lactococcosis, caused by *L. garvieae*, is a septicemic disease of significant clinical and economic relevance in the farmed trout industry. Affected fish exhibit erratic swimming, darkening of the skin, lethargy, exophthalmia, anorexia, coelomic distention, and hemorrhages at the fin bases, mouth cavity, and operculum. Internally, affected fish have congested and enlarged kidneys, livers, and spleens, as well as hemorrhages in the brain, swim bladder, and intestine. *Lactococcus garvieae* has long been thought to be the unique *cause* of lactococcosis, but *Lactococcus petauri*, another species of the genus Lactococcus first isolated from a facial abscess in a sugar glider (*Petaurus breviceps*) (Goodman et al. 2017), has recently been linked to lactococcosis outbreaks in Europe and North America, with mortality rates of 40% (Savvidis et al., 2007; Shahin et al., 2021). The genome sequences of *L. petauri* and *L. garvieae* are quite similar, as are their morphological characteristics and biochemical profiles (Goodman et al., 2017). Differentiating *L. garvieae* and *L. petauri* isolates in diagnostic laboratories is a tough task because the molecular diagnostic methods currently available do not differentiate between both species. In the context of the SUPERTROUT European Project (https://mel.cgiar.org/projects/supertrout), we used the genomes of a collection of *L. garvieae* isolates from different sources to calculate their average nucleotide identity (ANI) and digital DNA-DNA hybridization (dDDH) values, which are widely used for differentiating species (Chun et al., 2018), to accurately establish their correct species assignment.

Material and Methods

dDDH and ANI values calculation

The assembled genomes of 21 field Spanish isolates previously identified as *L. garvieae* and 28 genomes of *L. gavieae* available in Genbank (https://www.ncbi.nlm.nih.gov/genome/browse/#!/prokaryotes/699/) were used for ANI calculation (https://www.ezbiocloud.net/tools/ani). ANI values were computed for pairs between these genomes and the genomes of the type strains of *L. garvieae* CCUG 32208^T (VXKD01000001) and *L. petauri* 159469^T (MUIZ01000010). The pairwise ANI values use the Orthologous ANI algorithm using the USEARCH program (Yoon et al. 2017). Moreover, dDDH analysis was performed using the GGDC 3.0 method, which was recommended for draft genomes (https://ggdc.dsmz.de/ggdc.php).

Phenotypic studies

Three representative strains [*L. garvieae* CCUG 32208^T, *L. petauri* 159469T and the Spanish clinical fish isolate *L. petauri* 8831 (initially identified as *L. garvieae*)] were biochemically characterized using the Rapid ID 32 Strep, API 50 CH and API ZYM systems. In addition, the morphological characteristics of the colonies of these three strains as well as other field Spanish isolates were compared after their growth on trypticase soy agar (TSA) supplemented with 5% sheep blood and M17 agar.

Results and Discussion

Twenty-one of the 49 isolates analyzed had dDDH values ranging from 80.9 to 99.9% and ANI values ranging from 98.1 to 100% with the type strain of *L. garvieae*, indicating their accurate identification. In contrast, 19 previously identified *L. garvieae* isolates had dDDH values ranging from 80.3 to 90.8% and ANI values ranging from 97.9–99.0% with the type strain of *L. petauri*, indicating that they should be reclassified. The dDDH and ANI values of nine isolates were lower than the recommended species demarcation limits (70% for dDDH and 95–95% for ANI), indicating that they do not belong to either species. Strains isolated from various sources (fish, water, mammals, and humans) and countries were properly

(Continued on next page)

recognized as *L. garvieae*, those that should be reclassified as *L. petauri*, and those that are neither species. These findings suggest that many of the *L. garvieae* isolated from cases of trout lactococcosis and other sources should be reclassified as *L. petauri*. As a result, both species should be regarded as the causative agents of fish lactococcosis. Many *L. garvieae* isolates are identified using 16S rRNA gene sequencing or PCRs targeting this gene, and the high similarity in the 16S rRNA gene sequences of both species (99.93%) may explain why many strains of *L. petauri* have been misidentified as *L. garvieae*. It should be noted that colonies of those field isolates that should be reclassified as *L. garvieae* based on dDDH and ANI values did not have the orange-colored morphology of *L. petauri* when grown anaerobically for 24 hours at 30°C on M17 agar, nor did they have the beta-hemolytic activity of *L. petauri* on blood agar. Biochemically, the strains *L. garvieae* CCUG 32208T, *L. petauri* 159469T, and *L. petauri* 8831 were quite similar. However, both strains of *L. petauri* hydrolyzed hippurate and produced acid from methyl-D-glucopyranoside, sucrose, and tagatose, but the type strain of *L. garvieae* did not. These findings should be validated by testing a large number of isolates. To obtain a better understanding of the roles of both pathogens in the epidemiology of lactococcosis, an in-depth review of previous *L. garvieae* isolate identifications will be required, as well as the development of new molecular diagnostic tools that allow efficient and reliable differentiation between the two pathogens.

Introduction

Up to now, usage of antibiotics in aquaculture played a pivotal role in achieving major advances against bacterial infections. Still, Bacteria may gain antibiotic resistance and spread as a consequence of inappropriate and extensive use of antibiotics. The rapid emergence of antibiotic resistant bacteria endangers the efficacy of antibiotic and leads to the spread of resistance genes. In the present study, phenotypic antibiotic resistance against 12 antibiotics and the presence of 14 antibiotic resistance genes were evaluated in archival *Lactococcus garvieae* strains isolated from small-scale rainbow trout farms in Turkey, Italy, Greece, and Spain.

Material and methods

Twenty archival *L. garvieae* strains of each country were previously isolated from diseased rainbow trout (*Oncorhynchus mykiss*). Antibiotic susceptibility tests were performed by the disk diffusion method using kanamycin (K; 30 μg), ampicillin (AMP; 10 μg or 25 μg), gentamycin (CN; 10 μg or 30 μg), florphenicol (FFC; 30 μg), streptomycin (S; 10 μg), erythromycin (E; 15 μg), oxolinic acid (OA; 2 μg or 10 μg), flumequine (FLM; 30 μg), penicillin (P; 10 μg), amoxicillin (AMX; 20 μg or 25 μg), neomycin (N;30 μg), and oxytetracycline (OT; 30 μg) discs. Presence of florfenicol (*floR*), tetracycline (*tetA*, *tetB*, *tetC*, *tetG*), erythromycin (*ermA*, *ermB*, *ermC*), streptomycin (*strB*), β-lactamase ampicillin (*blaSHV*, *blaOXA*, *blaTEM*), quinolones oxalinic acid (*gnrA*), and quinolones flumequine (*gyrA*) resistance genes was tested by PCR.

Results

Overall, antimicrobial susceptibility tests indicated that 93.8% of the isolates were resistant to oxolinic acid, followed by flumequine (91.3%), streptomycin (88.8%), kanamycin (72.5%), and neomycin (66.3%). Whereas, the highest susceptibilities were seen toward gentamycin (100%), oxytetracycline (97.5%), florfenicol (75%), ampicillin (73.8%), and amoxicillin (72.5%). Among all strains (n=80), 96.3% (n=77) had at least one resistance gene and 57.5% (n=46) had 2 or more antibiotic resistance genes. Among the screened tetracycline genes, *tetC* (57.5%) was the most prevalent gene followed by *tetG* (33.8%), *ermC* (23.8%) and *tetB* (21.3%), whereas *floR* (2.5%), *ermA* (2.5%), *tetA* (3.8%), and *blaSHV* (6.3%) were among the least detected genes. Antibiotic susceptibility differences and variation in antibiotic resistance genes were recorded among Turkish, Italian, Greek, and Spanish archival strains which indicates possible genetic and phenotypic differences among strains. Prevalence of resistance to commonly used antibiotics in aquaculture and detection of resistance genes in strains may lead to prolonged treatments and to the increase *L. garvieae* related mortalities. This study provides a starting point for comprehensive monitoring of antimicrobial resistance of *L. garvieae* strains in rainbow trout aquaculture in the Mediterranean Region.

ROADMAP FOR DEVELOPING A MICRODIET FOR WHITELEG SHRIMP (*Penaeus vannamei*) POST-LARVAE

Luís E.C. Conceição[1,2*], André Barreto[1], Wilson Pinto[2], Rui J.M. Rocha[1]

[1] RIASEARCH Lda, Murtosa (Portugal)
[2] SPAROS Lda, Olhão (Portugal)

*E-mail: luisconceicao@sparos.pt

Introduction

Shrimp aquaculture is considered one of the most profitable aquaculture industries. In order to respond to Whiteleg shrimp (*Penaeus vannamei*) production, hatcheries need to improve post-larvae (PL) rearing protocols. The early life-stage is a critical period in shrimp development, with the transition from live-feeds to inert microdiets (weaning) being severely influenced by diet quality. Problems related to microdiet quality have a large impact on shrimp performance in the long-term, affecting the downstream production of high-quality juveniles. Even though several commercial diets are currently available in the market, the room for optimizing a weaning diet for shrimp larvae/post-larvae is still large. This work aims to summarize the roadmap followed to develop a premium and cost-effective microdiet boosting shrimp post-larval performance. Firstly the protein requirement at the post-larval stage was evaluated. Protein sources were subsequently tested and the cost-effectiveness of 3 microdiet prototypes was finally assessed. Growth, survival and economical conversion ratio were used as criteria to select a microdiet for shrimp post-larvae with potential for market deployment.

Materials and methods

Three trials where conducted under the scope of project SHELLWIN, where white leg shrimp post-larvae (initial wet weight 3-13 mg) were reared under standard procedures in triplicate tanks (0.28 m2). Shrimp reared at RIASEARCH Lda facilities (Portugal), at 27-28ºC, and fed on microdiets ad libitum for 21 days. For the protein requirement study, 6 diets ranging from 34 to 63% crude protein were used, composed by fish meal, fish protein hydrolysate, wheat gluten, wheat meal, squid meal, fish oil, vitamin and mineral premixes and cholesterol as main ingredients. In the protein sources trial, diets containing fish meal, squid meal, krill meal or a balanced mix of these three (52% crude protein), as main ingredients where tested. For the cost-effectiveness assessment, the selected microdiets were: a standard diet (A); a premium diet with a cost around 53% higher than diet A; and an ultra-premium diet with a cost 144% higher than diet A.

Results

Protein requirement trial: a dose-response pattern was established for shrimp postlarvae (3-70 mg wet weight), with a break-point 47.1% dietary crude protein (Figure 1). No significant differences were observed for survival (above 80%) or FCR (below 1.5) in most (44-63% crude protein) tested levels, except for the lowest (34% crude protein).

Protein sources trial: No significant differences between treatments were observed regarding final body weight (Figure 2). Survival was significantly lower in the diet having fish meal as the main protein source.

Cost-effectiveness trial: No significant differences were obtained for post-larval survival, with high results being achieved for all dietary treatments (75 - 87%). Shrimp post-larvae fed the ultra-premium diet achieved a significantly higher final body weight (Figure 3) and relative growth rate (19.8 %/day) than those fed the remaining diets (A – 15.6 %/day; B – 17.1 %/day). No significant differences were found regarding ECR, even though diet B tended to have a higher value.

Conclusions

The results obtained in the SHELLWIN project show that:

1) A dietary protein requirement of 47.1% was established for shrimp postlarvae (3-70 mg wet weight).
2) Squid and krill meals proved to be good sources of protein for the early development of shrimp, as well a mixture of these two with a high quality fish meal.
3) Higher quality diets can be advantageous in early phases of production, leading to a reduction of time to reach commercial size, leading to a higher number of production cycles per year and savings in operational costs.

CONSERVATION OF THE BELUGA STURGEON (*Huso huso*) IN THE ADRIATIC AREA; DEFINING GUIDELINES BASED ON CONTEMPORARY AND ANCIENT GENETIC DIVERSITY

L. Congiu and E. Boscari

Department of Biology, University of Padua, Padua, Italy
Email: leonardo.congiu@unipd.it

The Beluga sturgeon (*Huso huso*) is one of the three sturgeon species historically present in the Italian waters together with the Adriatic sturgeon (*Acipenser naccarii*) and the common sturgeon (*A. sturio*). Since the 80ies the local population is extinct from the Adriatic area, but the species is still present in the Black, Azov and Caspian Seas and in their main tributaries. In Italy, as well as in many other countries, it is well represented in many aquaculture plants where it is reared for caviar production.

After the many restocking efforts conducted in Italy for the Adriatic Sea, the Beluga sturgeon is becoming the object of different conservation projects. The growing interest for the reintroduction of the Beluga sturgeon in the Po River basin is involving several actors who, with different methods and different strategies, act independently.

With the aim of providing informed criteria for the reintroduction of Beluga in Italian rivers we analysed its contemporary and ancient diversity based on a multi-markers approach. Genetic analyses on the mitochondrial d-Loop, 27 nuclear microsatellites and 893 SNPs isolated through the 2bRAD were conducted on 119 individuals from 3 geographical basins (Azov, Black and Caspian seas). Mitochondrial information was also used to evaluate the variability of the extinct Adriatic population by analysing a few available museum samples. The historical Adriatic sample cannot be traced back to any of the contemporary ones raising the hypothesis of the presence of a past isolated population.

More in general the genomic approach allowed us to depict for the first time a clear and supported genetic differentiation between two areas (the Black–Azov and the Caspian basins) and to identify a panel of diagnostic SNP loci suitable for geographic allocation. We provided guidelines for the upcoming proper restoration of the Italian extinct Beluga population and for any future management activity of this species in its entire distribution range.

In synthesis, this contribution has the purpose of a) briefly introducing the state of the species in its distribution area, b) reporting the results of a recently conducted analyses of the geographical pattern of genetic variability across the whole distribution area, with the aim of providing and discuss useful information for an informed planning of conservation activities; d) highlighting the need of a coordinated national and international strategy for the restoring of the Beluga sturgeon.-

HAS THE LPA SYSTEM BEEN SUCCESSFUL? SMALL-SCALE AQUACULTURE RECRUITMENT IN MAINE, USA, THROUGH THE LIMITED-PURPOSE AQUACULTURE (“LPA”) LICENSING SYSTEM

M. Conkling*

University of New England. 1075 Forest Avenue, Portland, Maine 04843 (United States)
Email: mconkling@une.edu

The system for leasing publicly owned submerged marine lands in the state of Maine in the United States for aquaculture development concerns the recruitment of ocean farmers there into marine aquaculture. Maine’s “Limited-Purpose Aquaculture” (LPA) license was designed to induce small-scale farmers to enter the industry to experiment with a variety of means for achieving economic sustainability. This study analyzed recruitment of new ocean farmers into small-scale, low-trophic level (LTL) marine aquaculture in Maine through the LPA system. Through an online survey (n = 72) and a focus group (n = 7) of LPA-holders, data was collected on holders’ experiences in sustaining their operations, which encompass costs-benefits analyses as well as issues of access to working waterfronts, equipment, expertise, and various markets. Sixty-seven percent (67%) of respondents indicated that they sold their LPA products, and 32% of those not selling their products reported that they wanted to sell them. Fifty-eight (58%) of respondents wanted to expand their aquaculture operations to scale beyond the LPA license parameters; 61% expressed discontent with the size of their farm. Survey and focus-group data demonstrated that although 85% of LPA holders felt that their experiences in the LPA system had allowed them to make informed decisions about whether to expand their farms, many were concerned about the administrative and resource barriers they faced in scaling up their operations.

DISEASES RISK ASSESSMENT ASSOCIATED TO THE MOST RELEVANT INFECTIOUS AND PARASITIC DISEASES IN SEABREAM AND SEABASS FARMING SYSTEMS IN EUROPE

[4] Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research, Attika, Greece

Introduction:
Prevention is one of the most relevant aspects to provide efficient tools for improving health management in aquaculture. However, establishing useful guidelines for this purpose is not an easy task since the development of diseases in fish are usually multifactorial. The combination and impact of different factors, such as the characteristics of the infectious agents and fish host, environmental conditions, geographical parameters, and farming systems amongst others represents the main elements that determine the risk or likelihood to be impacted by a certain disease. The knowledge of these factors allows to establish biosecurity and prophylactic measures to reduce the risks of emergence of pathogens and the susceptibility to infectious diseases.

Thus, the aim of this study is to assess the relevance of these factors in order to identify the main risk factors for the most relevant diseases in gilthead seabream and European seabass in Europe

Methods:
The relevance of the different diseases of farmed gilthead seabream and European seabass in the European Mediterranean farms was evaluated after an accurate review of the available literature and discussed amongst a panel of fish health specialists from the e PerformFISH consortium. Once diseases were selected, the risks concerning each disease were also identified by a specialist working team formed by scientists using a HAZOP (Hazard and Operability Study) evaluation system, combined with the information available from technical and scientific literature for each disease, as well as from the personal clinical experience of the members of the working team. After this preliminary internal assessment, each risk factor associated to specific diseases and relevant production phases was scored by a broader panel of experts using DELPHI techniques. Experts had to assess each risk recognized by the team of specialists from 1 to 5, depending on its relevance to face problems with the disease or to avoid them.

Results:
The main diseases of gilthead seabream and European seabass selected by specialist in the Mediterranean Sea were Viral Nervous Necrosis (VNN), Photobacteriosis and disease caused by *Sparicotyle*. The main risks selected by specialists associated to these diseases were grouped in three categories: those related to farm environment (water supply, environmental conditions, epidemiological status of the farm, location…), general management (husbandry procedures, feeding, origin and control of new fish…) and risks associated with the management to avoid a specific disease (efficient protocols to detect pathogens, treatments, vaccination…).

Based on these results, dedicated well-trained personnel and with high awareness of well-established biosafety protocols was considered the most relevant factor to avoid the appearance of VNN in a facility. This recommendation was common to all the production phases. Concerning risks, the supplementation of broodstock with wild fish was the riskiest practice for VNN in broodstock facilities, and the origin of the eggs and juveniles from an external supplier with no specific VNN-health certification were identified as the main risk factors in the other phases of the production system. However, in the case of ongrowing, the highest score on VNN sanitary risks was related to the location of the cages, considering the farms located in a VNN endemic area and with water temperatures above 25 °C the ones with highest VNN risk. On the other hand, there was an agreement that one of the most beneficial practices to avoid VNN infections in both cages and tanks production systems in ongrowing was the systematic vaccination with VNN commercial vaccines following the manufacturer's recommendations.

(Continued on next page)

Vaccination was also considered the most beneficial practice to avoid Photobacteriosis in ongrowing cages, especially if fry vaccinated with bath and IP booster, in all fish stocks, and using of autologous vaccines instead of commercial vaccines. A rapid action by feeding with medicated feeds immediately after the detection and identification of the outbreak is also considered a good practice to avoid infections in this case. The main risks considered by the experts related to Photobacteriosis are associated to the farm environment, such as the location of the farm in a Photobacteriosis endemic area and/or with frequent or sudden thermal oscillations.

Finally, similar to bacterial disease, the farm environment has an essential role in the appearance of problems with *Sparicotyle*. In this case, to place the farm in a shallow area with weak water currents and/or with a large number of seabream (escapees) around the cages are the main risk factors, but also the management of the farm, if no year-class distribution is applied. A specific management for *Sparicotyle* is strongly recommended to avoid problems with this parasite, for example periodically net changing in several cages and according to *Sparicotyle* infection levels in the farm.

Conclusion:

Taking into account all the considerations and scores by specialist and experts, seems that biosecurity is the best strategy to avoid infectious problems in broodstocks, hatcheries and nurseries, meanwhile, vaccination and management are the keys to reduce the potential impact of the disease in ongrowing stages.

BEHAVIORAL RESPONSES TO DIFFERENT FEED ADDITIVES IN ZEBRAFISH (*Danio rerio*) LARVAE: A PRELIMINARY STUDY

Introduction

Feed losses are a serious problem for the aquaculture industry, as feed represents 40–75% of production costs in this sector. In addition, the release of large amounts of organic matter into the environment leads to a significant increase of nitrogen (N) and phosphorus (P) concentration promoting eutrophication problems. As a consequence, a reduction in waste outputs is now mandatory and this goal can be achieved by a better management of feeding activities and by improving aquafeed palatability through specific feed additives.

The present study wants to explore the application of feed additives for aquafeed formulations, possibly increasing palatability and reducing, at the same time, the above-mentioned issues. A set of different products have been tested during a behavioural test performed on zebrafish (*Danio rerio*) larvae to identify those that positively attracted the fish.

Materials and Methods

Eight hundred zebrafish larvae aged 25 days post fertilization (dpf) were divided in forty groups of 20 individuals each and fish were singularly exposed (after a 30 mins acclimatization period) to a different water-soluble olfactory cue (named from P01- P40). Tests were performed in rectangular white plastic tanks (L 24 cm, H 8 cm, W 8 cm; water level: 3cm), uniformly lit by a LED stripe using a Canon LEGRIA HF R38 camera to record the behaviour of the fish during testing time. During each test, two cellulose sponges (side 1 cm), mounted on a detachable metal stand, were inserted into the tanks: one contained the olfactory cue (1 %) while the second water and served as control for object exploration. During the experiment fish were fed at different times, and behavioural tests (15 mins each) were performed one hour after each feeding to exclude foraging behaviours caused by hunger and to obtain a homogeneous result excluding behaviours due to the circadian rhythm. All video recordings were visualized and analysed using BORIS software. A two-step analysis was performed: one-way ANOVA was firstly used considering the total time of analysis (min 0-15) to evaluate whether the larvae responded differently to several olfactory cues; then, the data of the first 5 minutes (min 0-5) and the total time recorded (min 0-15) were analysed separately by computing the overall proportion of time spent close to the novel olfactory cue in these two periods of time. One-sample t-tests against the preference expected by chance (0.5) were used to test whether the preference for the novel olfactory cue was different from random choice.

Results and discussion

Considering the total time of analysis (min 0-15), the percentage of time spent by the fish in the sector with the novel olfactory cue significantly varied according to the type of odour used (ANOVA, $F_{39,724} = 2.42$, $p = <0.0001$, $= 0.12$). The average percentage of time spent in the sector with the odour are showed in Figure; the olfactory cues that showed a significant effect (one-sample t-test) are highlighted in the Figure. The two temporal analyses revealed that in some cases, same olfactory cues showed different effects in zebrafish larvae behaviour. Analysing different time slots is essential because the effects of each olfactory cue can vary during the time in relation to its chemical nature and dilution factor. As for example, novel or too much concentrated odours can initially act as alarm signals evoking avoidance or defensive behaviours. However, no one of the tested odours showed this behaviour. As regards the time effect on fish behaviour, the present study evidenced that: i) P02 and P35 odours showed a constant attractive effect; ii) P25 odour instead, showed attractive effect only during the first five minutes of test; iii) the remaining odours displayed a negative or neutral effect on fish. To reduce feed losses in aquaculture, feed has to be ingested by fish quickly and thus the search of new feed additives should be focused on the olfactory cues that have a quick and positive effect on fish during the first minutes of feed administration.

(Continued on next page)

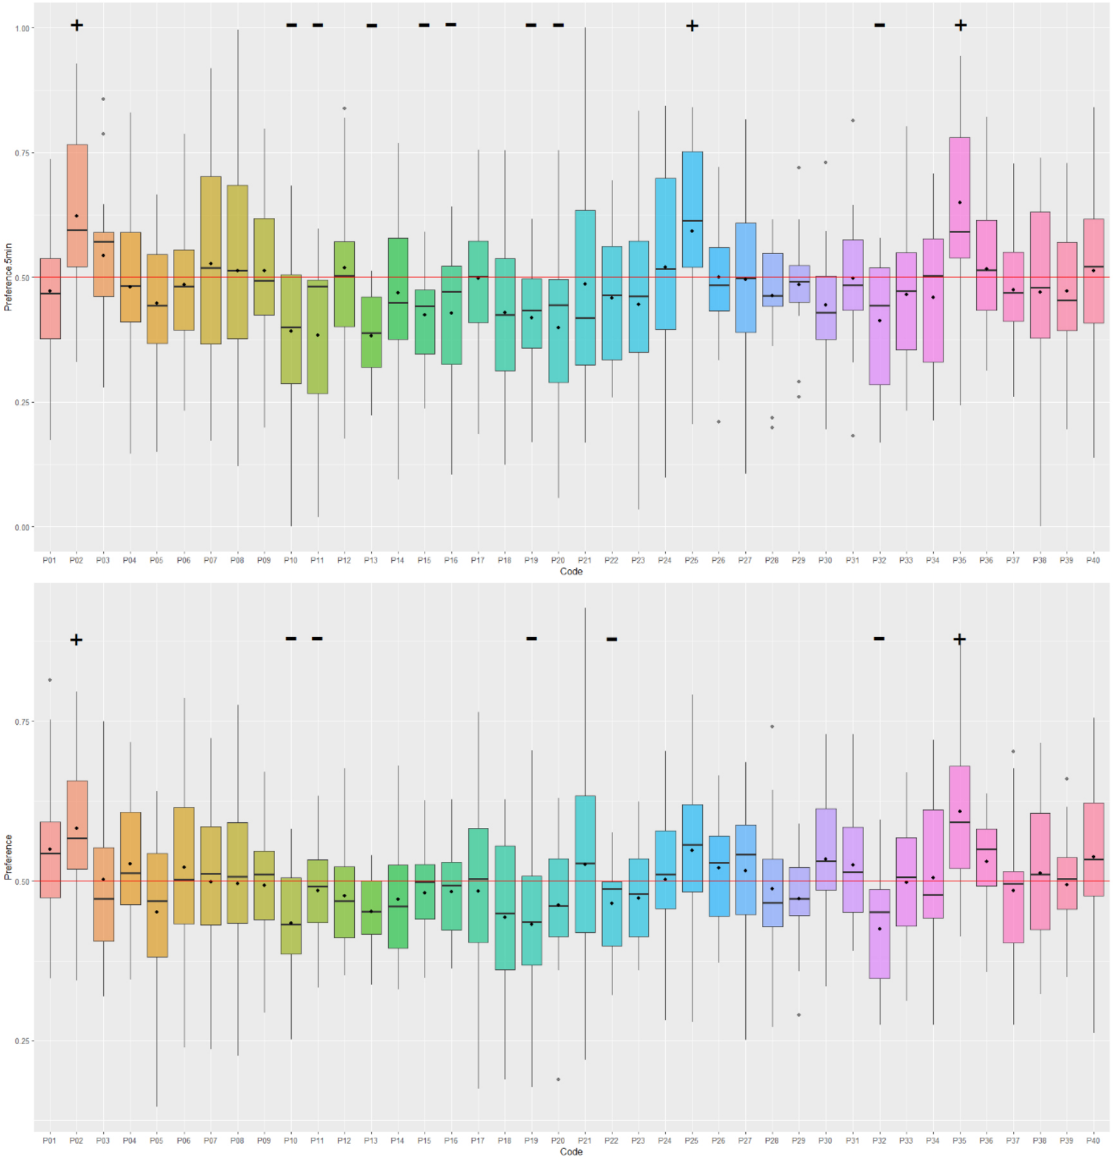

Figure - Boxplot of minutes 0-5 and 0-15 respectively, showing the average percentage of time spent by fish in the sector with the specific olfactory cue. Odours that showed a significant (positive +; negative -) effect are highlighted in the figure.

EFFECTS OF FEEDING TIME ON THE DAILY RHYTHMS OF TEMPERATURE SELECTION IN THE BLIND MEXICAN CAVEFISH (*Astyanax mexicanus)*

F. Conti (1), G. de Alba (1), J.F. López-Olmeda (1), C. Bertolucci (2), L. M. Vera (1), F.J. Sánchez-Vázquez (1)

Animals and plants live on a rhythmic planet, with regular and predictable periods of light-darkness, temperature and food. As a result, the evolution has selected the existence of endogenous circadian clocks that synchronise their physiology and behaviour with the environmental cycles.

In addition, besides the existence of daily cycles of temperature in the wild, called thermocycle, fish display a thermal preference and the ability to discriminate between different temperatures. Temperature selection in fish is connected to their biological processes and they are free to choose the best temperature in which the development of these processes will be most effective.

Over the past few millions of years, the blind cavefish *Astyanax mexicanus* has been isolated from neighbouring rivers in underground caves in Mexico. These fish have evolved and adapted to a life in complete darkness and these adaptations include the loss of eyes and pigment, as well as changes in metabolic rates, activity and the loss of sleep activity/circadian rhythms to varying degrees (Steindal et al., 2018).

The aim of this study was to investigate the existence of daily rhythms of temperature selection and the effect of feeding time on these rhythms in a fish that has evolved in an arrhythmic environment, such as *A. mexicanus*.

To achieve this objective, we used a multi-chamber aquarium and created a thermal gradient (from 20 ºC to 28 ºC) using water heaters and coolers. The fish were subjected to a 12 hours of light and 12 hours of dark photoperiod (LD 12:12 h) and fed according to 4 different feeding schedules: random (RD), feeding in the middle of the light phase (mid-light, ML = ZT 6 h), feeding in the middle of the dark phase (mid-dark, MD = ZT 18 h) and fasting. Daily temperature selection was determined by video analysis of animal behaviour. A constant temperature of 24 ºC in the whole system was used as control.

The fish showed a daily rhythm of thermal preference, regardless of the feeding protocol. Specifically, they selected warmer temperatures during the light phase and cooler temperatures during the dark phase.

In addition, during acclimation (first 3 days that preceded the experimental phase), the fish selected a higher mean temperature than that observed in the other experimental phases, showing a possible emotional fever in response to the new environment (Rey et al., 2015). Fish fed at ML tend to go to lower temperatures in the hours before feeding and warmer temperatures afterwards. During the fasting phase, the selection rhythm has a lower amplitude but still significant ($p < 0,05$).

These results show how important thermal preference rhythms can be, even in relation to feeding time, also in a species adapted to an almost totally arrhythmic environment.

Introduction: Study background

Traditional sources of protein in fish feed for salmonids, such as fishmeal, face sustainability challenges in terms of environmental and marine wildlife conservation [1]. As such, the feed industry is increasingly investing in using alternative ingredients with high protein content in future fishmeal and animal feeds. Alternative sources of protein for fish (salmonids) feed is an emerging research and commercial field. While findings in food research indicate that consumers perceive fish as healthy and natural, when new products and technologies are to be launched on the market, the degree of its success on the market depends on consumer perception, knowledge, and acceptance of the product, which influence purchase preferences [2]. As feed industry is intensively working on new possible protein sources, such as insects, microalgae, bacterial proteins, and proteins from food by-products, there is therefore a need to map consumer attitudes to these new sources to gauge consumer acceptance levels. To this end, this study investigates consumer acceptance of novel proteins in fish feed innovations. Our findings uncover Nordic consumer attitudes and preferences for types of novel protein feed for salmonids.

Data collection

Respondents were approached in three main ways, (i) via social media platforms such as Facebook, LinkedIn and Instagram messaging systems, (ii) via personal social network referrals and (iii) via face-to-face impromptu meeting requests in public spaces of various social context settings such as restaurants, grocery shops, boutiques and outdoor parks. A total of 30 respondents (17-70 years old) agreed to be part of this study. The majority (36) respondents were Swedes who resided along the Swedish West coast.

Method

The respondents were interviewed using a set of open, semi-structured questions constructed as a means of an interview guideline. The objective of the interviews was eliciting as much feedback as possible from the respondents. The respondents were encouraged to speak openly about salmon feed in farmed salmon in general, and attitudes towards alternative protein sources. The questions were designed from a systems thinking approach [3,4] to collect information along four broad dimensions, with different knowledge dimensions (i) Individual, (ii) Product, (iii) Social and (iv) Environmental. Each dimension reflects a broader context of knowledge than the previous dimension, with questions pertaining to the environmental dimension encompassing the broadest respondent perspective. The design of the interview questions aims at collecting a holistic overview of how respondents view farmed salmon and using alternative proteins in salmon feed. The interviews were on average 45 minutes long. All interviews were transcribed in accordance with the Gothenburg Transcription Standard 6.4 [5].

Findings and discussion

The subject of salmon feed and alternative proteins in salmon feed came across as a niche and unfamiliar subject for many of the respondents. Only 4 respondents out of 30, who were in the fields of higher education, research, related aquaculture activities, or hobby fly fishing, could be said to have some knowledge on farmed salmon and salmon feed. Most had no insight into salmon feed issues and remained unaware that most salmon sold on the market in Sweden is from Norway. Animal welfare was a greater concern, and some respondents said that if the salmon fared well on alternative protein feeds, that they would be fine with buying and eating the salmon. The respondents also expressed interest to have more information about salmon feed in general, and novel proteins in salmon feed. The respondents also reported to be willing to pay more for the salmon that is sustainably farmed and fed a salmon appropriate diet. The respondents were most positive towards insects as a novel protein in salmon feed. In general, all respondents are increasingly sustainability conscious, and reported clear preferences for buying the salmon or seafood that is sustainable, fed with a high quality protein, with a lower carbon footprint.

(Continued on next page)

Practical business implications

The findings indicate limited consumer knowledge about salmon feed and origin of salmon. As this information is currently not provided on product labels, providing informative product labels to consumers could be considered by the industry. Further, as sustainability is important to consumers, informing the consumers about sustainable feed could benefit product sustainability branding.

Respondent feedbacks also indicate the following potential areas of value-added exploitation for the salmon industry such as: (i) exclusive branding and marketing salmon based on higher quality, more sustainable feed based on insects instead of soya beans or other vegetable proteins; product differentiation for Norwegian salmon based on high quality protein salmon feed; (ii) introduction of appropriate labels, and making information for consumers available on Norwegian produced salmon, raised on high quality protein feeds; (iii) exploiting high quality insect-based salmon feed as a product differentiation strategy for salmon produced in Norway, together with high sustainability standards for Norwegian salmon farming; and (iv) improved research and product development opportunities for flavour and texture profile when salmon are fed higher quality protein feeds.

Future research

Two topics that arose from the respondents that were of interest for consumers were (i) need for increased information on the origin of the salmon, and what it was fed on package labels and (ii) using entire supply chain sustainability as an accounting measure of how sustainable the salmon is as a food product.

Introduction

Molluscs, mainly bivalves, represent a significant portion of our current aquaculture production worldwide accounting for over 22% of the total global harvest (FAO, 2018).The ability of mussels to disperse and settle on suitable substrates is exploited by the aquaculture industry for the seasonal supply of seeds. However, dispersal of *Mytilus spp.* larvae at present remains largely unresolved and it is difficult to measure in situ. In this study, we use an unstructured 3D hydrodynamic model to drive a particle tracking model where prediction of larvae movement and dispersal, together with simulations of spat dispersal in designated localities help to investigate potential connectivity between sites (Adams et al., 2016). These advanced approaches help to characterise broad-scale dispersal patterns and have wide implications that can be applied to evaluate the efficiency of spatial-temporal management measures.

Material and Methods

The biophysical model is based on an unstructured grid approach; modelling pelagic connectivity between aquaculture sites consists of a hydrodynamic model, a particle tracking model and post-processing module to estimate the source location of the mussel larvae. The domain for this study covers the west coast of Scotland (Aleynik et al., 2016), building upon previous work using smaller domains in the same locality (Adams et al., 2012, Adams et al., 2014, Aleynik et al., 2016, Davidson et al., 2021). The hydrodynamic model applied for this study is based on the Finite Volume Coastal Ocean Model (FVCOM; Chen, 2013). Particle tracking was carried out using the model of Adams et al. (2012, 2016). This model, originally developed to predict the dispersal of sea lice, links physical processes such as water movements with biological processes such as maturation and mortality. The movement of larvae incorporates advection due to local currents and a fixed random diffusion term.

We run the model under two different scenarios. First a single day release of particles in order to assess variability in predicted dispersal patterns. And second a tidal cycle release of particles to quantify the accumulation of particles in each target location (Shellfish farms) and to detect possible source locations seeding each target location.

Results

We have analysed the general patterns related to the connectivity between source areas and different geographical areas. The overall overview from the single day releases shows a constant pattern between years (2017 to 2021) and different depths (2 m, 6 m, and 10 m depth). Through the tidal cycle releases, we have calculated the particle dispersal accumulation and we've been able to identify possible source locations of mussel larvae seeding our target locations (Shellfish farms located on the West Coast of Scotland) (fig.1). Results were considered in context with the relevant wind roses for the simulated periods. We have produced monthly representation of the current direction for the same period. With this study we are one step closer to help mussel farmers with their site selection process, as well as to understand the larvae movements through the flow along the complex coastline and bathymetry in fjordic coastal environments.

(Continued on next page)

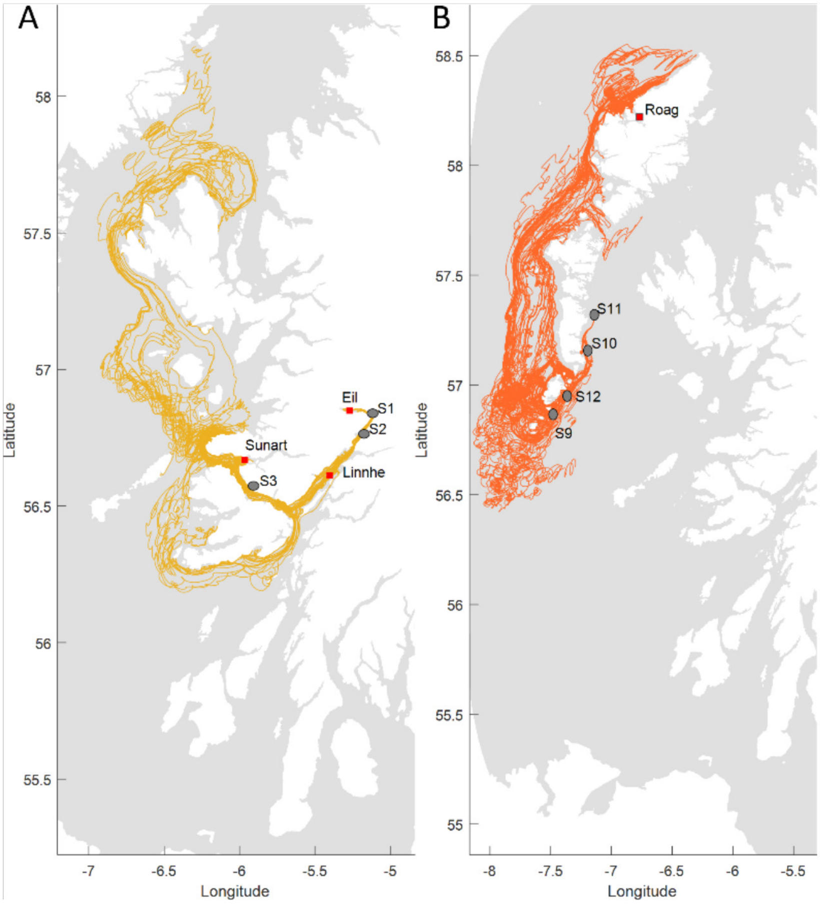

Figure 1. West Coast of Scotland; red squares are the target locations and grey circles the source locations. Figure 6A shows an example of self-recruiting where S1 is the only source location for Loch Eil. And self-recruiting and influence of external recruitment where S1 and S2 are source locations for Loch Linnhe and S1, S2, and S3 for Loch Sunart. Figure 6B shows an example of not self-recruitment for Loch Roag.

e-mail: ecortes04@cibnor.mx

In this study, the reproductive biology in the natural environment through histological and histochemical techniques that describes the gonadal development or oogenesis during the reproductive season of female river prawn *Macrobrachium americanum* in B.C.S. Mex. Specimens were collected the month July-October. Four stages of gonadal development were characterized: previtellogenesis I and *II*, vitellogenesis *I* and *II* and eight sub-stages: oogonia (Og), nucleolus chromatin (Cn),oocyte early perinucleolus (Opn1), oocyte late perinucleolus (Opn2), oocyte lipidic droplet (Old) (Li2), oocyte early vitellogenic (Ov1), oocyte late vitellogenic (Ov2) and germinal vesicle migrand (Vgm) (Fig. 1). The criterion used was the measuring oocyte size (µm), the nucleus and the characteristics of the ooplasm and the accumulation of yolk (lipids, carbohydrates, and proteins were quantified in the different stages) showed significant differences ($P<0.05$). The number of biomolecules that constitute yolk, such as triglycerides, carbohydrates and proteins showed significant differences between the different oocyte types, presenting the lowest values of triglycerides (5.42 ±1.21%) in the previtellogenesis and the highest values in vitellogenesis. This proportion is inverted in phospholipids (54.92±1.40%). Establish that the female is a partial spawners. This information might help for conservation measures in the species, as well as to establish the fishing period of the species.

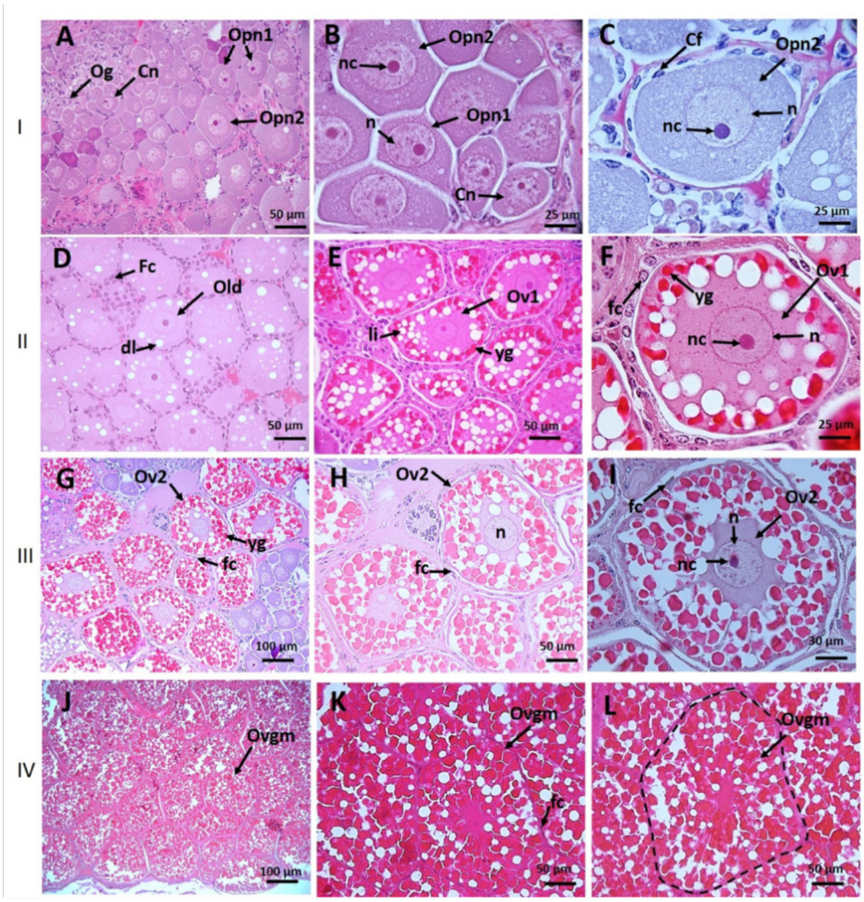

Figure 1 Stages of ovarian development of *Macrobrachium americanum*.

PHYTOBLOOM® RAS FORMULA: DEVELOPMENT OF A NEW DIET DESIGNED FOR ROTIFERS RECIRCULATION AQUACULTURE SYSTEMS

Introduction

Recirculation aquaculture systems (RAS) are more sustainable, when compared to conventional production modes, due to the reduction of water usage simultaneously maintaining the water quality. This aquaculture system started recently to be applied in intensive rotifers production. Rotifers (*Brachionus plicatilis*) production is widely constrained by degradation of the water quality and the fluctuation of environmental parameters (e.g. oxygen, temperature, bacterial load, ammonia) in the tank. Therefore, the use of RAS systems (e.g. RotiRas, IDEE aquaculture, France), allowed to improve the rotifers population densities and outputs. *Nannochlorpsis* sp. is nutritionally balanced and successfully used for rotifers nutrition. Rotifers high-density cultures require a hight daily input of microalgae and commercial microalgae products are the solution to feed rotifers in RAS systems under semi-continuous mode of production. However, the constricted filtering system do not allow the application of product that generate high microalgae agglomeration. The use of low density *Nannochlorpsis* sp. products prepared with low salinity solutions may reduced the agglomeration and avoid filter clogging. The objective of this work was to develop a new microalgae product specifically designed for rotifer nutrition in RAS systems under semi-continuous mode operation.

Material and methods

The product RAS, liquid concentrate is formulated with industrially produced *Nannochloropsis oceanica* paste prepared with a saline solution of 35ppt, to obtain a final product with 15% of dry weight. The formation of microalgae agglomerates was evaluated and the dimension of the agglomerates. The microbiological quality (PCA, TSA and TCBS media) of the product was monitored throughout storage time (1-3 months at -20ºC) and post-thaw days (3-7 days at 4ºC). The product was applied in a RotiRas (IDEE aquaculture, France) production system with a semi-continuous production mode, the target daily harvest was 500 million rotifers. The rotifers were cultured with a density of 1500 - 2000 rots/mL, at 28ºC, 20ppt of salinity, maintaining the culture pH between 7.5 to 8 and ammonia below 1mg/L. There was a daily exchange of 50% of the water of the culture. The efficiency of rotifers production of RAS formula was compared with an available commercial product (CP1). The dosage of RAS formula was 2ml of product per million of rotifers. For CP1 product the recommended daily dosage was respected. Rotifers concentration and percentage of rotifers with eggs were evaluated daily.

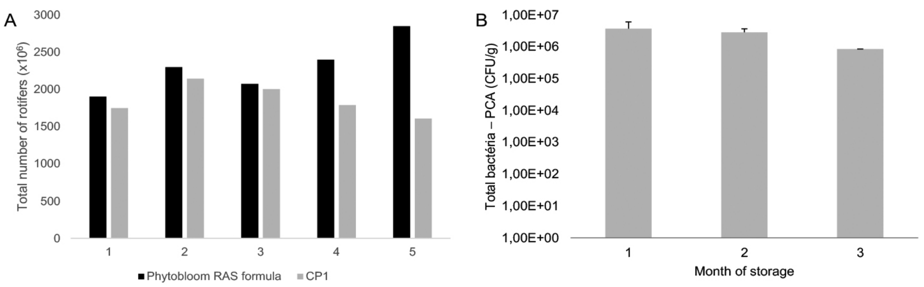

Fig 1 – Rotifers new diet Phytobloom® RAS Formula and commercial diet 1 (CP1) quality characterization in relation to A) rotifers total daily production in RAS systems with a 700 million rotifers of daily harvest and B) Phytobloom® RAS Formula total bacteria throughout storage (-20ºC) time.

(Continued on next page)

Results and Discussion

RAS formula was successfully applied in the RAS system. The rotifers concentration was maintained at 2075 rot/ml with a daily harvest of 700 million rotifers. Therefore, the total number of rotifers was maintained according to the previously established target (Figure 1A). The total bacteria of RAS formula was maintained throughout storage time (Figure 1B), therefore the low salinity of the product did not affect the product microbiological quality in the first 3 months of storage.

The RAS formula reached an average of 30±12% of rotifers with eggs and CP1 product reached an average of 33±4% of rotifers with eggs. In conclusion, the new Phytobloom® RAS Formula was successfully applied in rotifers RAS system, without filter clogging and reaching the target rotifers densities and daily harvest.

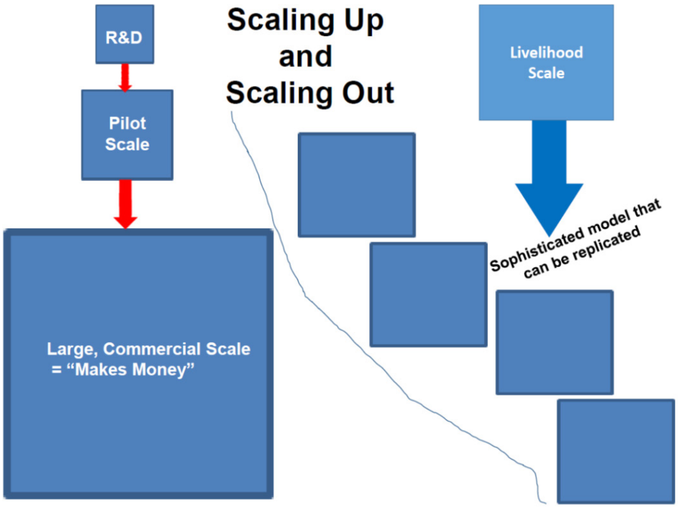
ACCELERATING THE DEVELOPMENT OF MARINE AQUACULTURE IN THE NEARSHORE: SCALING OUT IS AS IMPORTANT AS SCALING UP

Barry Antonio Costa-Pierce

Ecological Aquaculture Foundation, LLC
Maine, USA and Pico, Portugal
Kaua'i Sea Farm, LLC
Kalaheo, Kaua'i, Hawai'i 96741

Nearshore oceans with their high primary and secondary productivities, fluid logistics and close proximities to markets are excellent places to develop marine aquaculture. However, as common property resources, the numbers/diversities of user conflicts increase with proximity to shore. Conflicts result in the overuse of the precautionary approach by inadequate ocean governance which limit increases in the number/sizes of marine aquaculture operations nearshore. Sustainable system change to gain easier access to expand marine aquaculture nearshore would consider ocean engineering advances made offshore that can open large areas of energetic, nearshore oceans with less user conflicts. Governance systems would then include options for accelerated permitting in these areas as well as differentiate between scaling "out" and scaling "up". To illustrate changes needed the case study of the state of Maine USA and its contiguous sea, the Gulf of Maine (GoM), are discussed. The GoM is a productive marine basin with potential for the development of both fed and non-fed aquaculture in a bioregion that has an historical affinity for seafoods. Markets are abundant as consumers have a higher rate of seafood consumption than national averages but the region meets its seafood needs from imports. If a straight line were drawn along the outer edges of Maine's islands/bays, a distance of ~360 km to Canada and extending ~4 km from shore, ~1700 km^2 of highly energetic nearshore space is available with less user conflicts. However, scaling up in these new ocean spaces remains regulated though a leasing structure tiered by size whose upper bounds are derived more by social/political factors and a "social license to operate". Maine has the unique system to "scale out" marine aquaculture development, the limited permit access (LPA) system, which as of end 2021 attracted over 700 entrants. A new governance vision for scaling out in nearshore energetic oceans is required that can merge ocean leasing systems for businesses to scale up and scale out that can limit overuse of the precautionary approach and reform nearshore marine aquaculture policies.



DIETARY EXOGENOUS ENZYMES SUPPLEMENTATION IN PLANT-BASED FISH DIETS AFFECTS POSITIVELY THE INTESTINAL ENDOGENOUS ANTIOXIDANT AND DIGESTIVE ENZYME ACTIVITIES OF THE EUROPEAN SEABASS JUVENILES

*e-mail: ecotou@hcmr.gr.

Introduction

The European seabass (*Dicentrachus labrax*), a carnivorous marine species, is one of the most important species for Mediterranean aquaculture. As it has already been demonstrated, *D. labrax* can be fed on terrestrial plant ingredient-based fish diets (PM) without compromising its growth and feed utilization (Kaushik *et al*., 2004). However, most of these plants contain several anti-nutritional factors (ANTs) that are not heat-labile and/or inactivated by feed processing and therefore can affect the nutrient digestibility, growth performance and gut health of this species (*Torrecillas et al*., 2017). Nonetheless, an effective way of eliminating the negative effects of ANTs on this fish and improving digestibility of plant ingredient-based diets is the supplementation of exogenous enzymes in the feedstuff (Magalhaes *et al*., 2018). In omnivorous species exogenous enzyme supplementation can promote the secretion of the endogenous enzymes in fish and thus, boosting the digestibility of nutrients via raising activities of intestinal digestive enzymes (Drew *et al*., 2005; Farhangi and Carter 2007; Lin *et al*., 2007). However, data concerning the effects of supplemented exogenous enzymes on *D. labrax* juveniles' intestinal digestive enzymes is limited, while there is no information of any effects on their intestinal antioxidant enzyme system.

Materials and Methods

Four isoproteic (48%), isolipidic (16%) and isoenergetic (21%) diets were formulated and produced at our lab (IMBBC-HCMR). Briefly, a 20% fish meal-based formulated diet was stated as FM diet while a diet of 30% plant ingredients-based consisting of rapeseed, sunflower and guar meals at inclusions levels of 10% each as PM diet. Then, to the PM diet three exogenous enzyme products were supplemented to generate two more diets: a diet with a 0.05% of a solid-state fermentation supplement (SSF) which contained a heterogeneous complex of residual enzymes liberated by the action of a fungus on the substrate during fermentation and a diet with a mixture of 0.01% phytase plus 0.03 % xylanase (Phyt/Xyl mix). Following a three-month experimental feeding trial, the specific activities of the antioxidant (CAT, Se-GPx, GST) and digestive enzymes (Trypsin, Aminopeptidase, ALP) were measured in the whole intestines of the fish. Correlation was also performed with measured critical growth performance indicators (i.e. weight gain, feed intake, SGR and FCR).

Results

Table 1. Growth performance indicators of *D. labrax* fed on plant ingredient-based diets supplemented with exogenous enzymes.

	FM	PM	SSF	Phyt/Xyl mix
Weight gain (g)	40.3 ± 2.4 **a**	20.9 ± 0.4 **b**	27.2 ± 0.8 **c**	33.2 ± 0.3 **d**
Feed intake (%)	1.73 ± 0.04 **ab**	1.61 ± 0.05 **c**	1.71 ± 0.01 **ab**	1.79 ± 0.07 **b**
SGR	1.35 ± 0.05 **a**	0.88 ± 0.01 **b**	1.05 ± 0.03 **c**	1.20 ± 0.00 **d**

ALP	92.1 ± 17.6 **a**	27.7 ± 5.5 **b**	46.8 ± 8.5 **c**	33.7 ± 7.2 **b**

**the different small letters indicate significant differences at p < 0,05 level*

(Continued on next page)

Conclusions

- Intestinal antioxidant enzyme activities were induced with the SSF and Phyt/Xyl mix diets in comparison to PM diet but were significantly higher with the SSF than with the Phyt/Xyl diet except CAT. Inductions, however, did not reach the levels of the FM diet except GST with the SSF diet.
- Digestive enzyme activities were significantly induced only with the SSF compared to PM diet and were similar to FM diet except with ALP. With Phyt/Xyl mix diet the enzyme activities were significantly lower than that with the SSF diet.
- Critical growth performance indicators were significantly improved compared to PM diet. The significant differences indicated between SSF and Phyt/Xyl mix did not coincide with the growth performance indicators, thus further research is needed.

INTEGRATION OF SEA CUCUMBERS TO ABALONE PRODUCTION: LOW TROPHIC SPECIES IMTA SYSTEMS

G. Courtois de Viçose[1], C. Jones[2]

Introduction
The interest of Holothurians as deposit feeders has been demonstrated in different studies and their environmental value, through their mitigation ability, was highlighted within different IMTA systems (Hannah et al., 2013; Kang et al., 2003; Zhou, 2006) indicating that sea cucumbers can optimise the net use of wastes (Reid et al., 2013).

Given the existing research, the current studies investigated the potential for the integrated culture of the sea cucumber *Holothuria. sanctori* and *Neostichopus grammatus* with the abalone *Haliotis tuberculata* and *Haliotis midae* in order to develop an integrated Land Based IMTA production of these species.

Materials and methods

Experimental specimens
Young individuals of *H. sanctori* and *N. grammatus* were collected at a depth of 0-10 m, by scuba diving, and maintained and acclimated in experimental installations, placing them under abalone (*H. tuberculata* and *H. midae*) baskets (in which abalone were fed macroalgae and/or compound feed). After their acclimation, they were then respectively allocated to experimental IMTA units.

Adult abalone of *H. tuberculata* and *H. midae* were obtained from research and commercial facilities both at the University of Las Palmas de Gran Canaria and Wild Coast Abalone.

IMTA experimental set up
Experimental IMTA systems were designed to provide two levels compartments; one for the fed abalone and the other for sea cucumbers located below the abalone compartment. The abalone were placed in perforated baskets to allow water exchange and release of abalone wastes to reach the sea cucumbers located below.

Experimental parameters
Weight Gain (WG), and Specific Growth Rate (SGR) as well as ingestion rate, faecal production rate and water quality were analysed.

Results

The results obtained demonstrated the influence of abalone feed employed in the growth potential of the sea cucumbers and the impact on the ingestion rate. They also highlighted the potential to coculture abalone and sea cucumbers, the sea cucumber bioremediation capacity and growth under abalone as well as macroalgae production.

Discussion

The results obtained confirmed the potential to produce sea cucumbers in co-culture with abalone species as demonstrated by previous research. They highlighted the variation of sea cucumber growth potential as a function of the nature of abalone feed employed and the differences in ingestion and growth parameters according size, density and species. Moreover, the studies highlighted the potential to develop IMTA systems including only low trophic species and allowing the integration of macroalgae production in the systems. These results are of interest for the future development of low trophic species IMTA systems and the future successful integrated production of the sea cucumber species.

Introduction

White spot syndrome virus (WSSV) can cause a cumulative mortality up to 100% within 3-10 days on shrimp farms (Dey et al., 2020). Although progress has been made in the past 30 years, a better understanding of the pathogenesis and transmission route(s) of WSSV is still necessary. This work relies heavily on the establishment of standardized *in vivo* experimental infection models that can be used as a tool for studying WSSV pathogenicity and for evaluating the efficacy of WSSV mitigation strategies (Prior et al., 2003). A WSSV challenge model via per os route in which shrimp are individually housed has certain advantages over a WSSV group challenge model. It allows for accurate collection of research data in a highly controlled scientific setting, while increasing the throughput in selecting and developing infection control tools. The amount of WSSV positive inoculum consumed by each shrimp can be recorded meticulously. In addition, the clinical outcomes on the level of the individual shrimp can be evaluated in detail. On the other hand, a challenge in group simulates more closely the on-farm reality of a WSSV outbreak, as it allows for disease transmission between shrimp. This might indeed generate results that can potentially be easier to extrapolate to the field, but due to the less controllable nature of this experimental setting, results may be less reproducible and accurate data collection becomes more challenging. Nevertheless, both model types can be very useful tools in WSSV research. In the past, mortality levels after oral WSSV challenges have varied between studies, in part due to a lack of knowledge on the portal of WSSV entry (Prior et al., 2003; Domínguez-Borbor et al., 2019; de Gryse et al., 2020). The objective of this study was to develop standardized and reproducible individual and group challenge models for experimental WSSV infection studies in *L. vannamei* whereby 100% of clinical WSSV infection is induced. By testing different experimental conditions to obtain this clinical outcome, we aim to learn more about WSSV transmission.

Materials and Methods

Specific pathogen free (SPF) *Litopenaeus vannamei* were imported as postlarvae (PLs) from Global Blue Technology (USA) and Miami Aqua-culture (USA). Shrimp were housed in artificial seawater at 20 ppt salinity and 27°C ± 1°C. They were injected intramuscularly with the WSSV Thai-1 strain (Escobedo-Bonilla et al., 2005). WSSV positive solid inoculum was prepared from the resulting infected carcasses. This was used to infect PL65-72 shrimp through oral route. Briefly, during the 1st experiment, in which the effect of different doses within 24h was tested, shrimp were randomly divided into four challenge groups (A1, B1, C1, D1) of 15 shrimp each and one control group (Mock1) of 10 shrimp. Shrimp were housed individually in 10L tanks. The oral infection trial followed a procedure adapted from Van Thuong, et al. (2016). Over a period of 24h, individual shrimp from groups A1, B1, C1, and D1 each received respectively 4, 5, 6, or 7 doses of WSSV positive inoculum. Mock1 shrimp received 7 doses of WSSV negative inoculum. For the 2nd experiment, in which the effect of daily repeated inoculation of 4 doses was tested, shrimp were again randomly divided into four individually housed challenge groups (A2, B2, C2, D2) of 15 shrimp each and one control group (Mock2) of 10 shrimp. In A2, B2, C2 and D2, shrimp received respectively 4 doses of WSSV positive inoculum within one day for one, two, three or four consecutive days. Mock2 shrimp received 16 doses of WSSV negative inoculum within 96h. Finally, for the 3rd experiment, where the effect of group housing was tested, shrimp were randomly divided into six groups of 100 and housed in six 250L tanks at 1.5kg/m^3. Over a period of 24h, three tanks (+WSSV1, 2, 3) each received 400 doses of WSSV positive solid inoculum, while the three control tanks (-WSSV1, 2, 3) received 400 doses of WSSV negative inoculum. WSSV infection was confirmed by qPCR. The survival/mortality data were analysed statistically using the Log-rank (Mantel-Cox) test.

(Continued on next page)

Results

When shrimp from the individual challenge received either 4, 5, 6 or 7 doses of WSSV positive solid inoculum within 24h, this did not result in a significantly different mortality (A1 = 16.7±4.7%; B1 = 20.0±9.4%; C1 = 20.0±9.4%, D1 = 20.0±18.9%). However, in case of daily re-inoculation, a significantly lower mortality was observed in group A2 (28.9±16.8%) compared to group D2 (57.8±3.8%). When shrimp were housed in groups and received the same number of doses as individually housed A1 and A2 shrimp, the accumulated mortality reached 100%, while in the three control tanks all shrimp survived. For each experiment, WSSV infection was confirmed by qPCR in a sample of the dead shrimp. WSSV was absent in sampled survivors and negative controls.

Discussion and conclusion

The results of the 2nd experiment showed that the probability or risk of infection in the population increased when the inoculation procedure was repeated on subsequent days. Increasing the number of doses that are given within 24h on the other hand, did not significantly raise the chances of a clinical infection in individually housed shrimp. Moreover, the uptake of inoculum by shrimp slowed down after the 5th dose, possibly because the animals were sated. In the 1st and the 2nd experiment, a clinical infection of 100% was not reached. This level could only be reached during the group challenge. This was a striking result, because the individually housed shrimp in A1, A2, and the group-housed shrimp in +WSSV1, 2, and 3 consumed the same amount of inoculum. In addition, during the group challenge cannibalization of sick shrimp was virtually absent. How WSSV transmission exactly occurs remains unknown. Proposed routes include consumption of infected tissue, water-borne transmission, and entry via the antennal gland during urination (de Gryse et al., 2020). After analysis of the results, it was hypothesized that shrimp behaviours associated with cohabitation and high stocking densities, such as increased aggression and urination, play a major role in a WSSV outbreak.

CO-CULTIVATION OF *Chlorella vulgaris* AND *Streptomyces rimosus*: A NOVEL PERSPECTIVE FOR ENHANCING BIOACTIVITIES OF MICROORGANISMS

R. Čož-Rakovac*, L. Perković, G. Matijević, M. Baković, A. Martić, S. Babić, L. Čižmek, and T. Paradžik

Introduction

Microalgae-bacteria symbiosis represents commensal and mutualistic inter-kingdom relationships, that may result in stimulation of algal growth, but also in the development of new metabolites with a prominent potential for application in the industry sector (Yao et al. 2018). *Chlorella vulgaris* is a green unicellular microalga with numerous biological and pharmacological properties important for human health. Streptomycetes are the most thoroughly studied microorganisms producing biologically active compounds, such as antibiotics, anticancer agents, immunosuppressives, antifungals, etc. In the recent decade, co-cultivation, as a potential replacement for mono-culturing of various microorganisms, gained special interest due to a whole range of desirable characteristics, such as modularity, robustness, predictability, scalability, and stability (Rollié et al. 2012). However, very little is known about the significance of *S. rimosus* and *C. vulgaris* co-cultures concerning the production of high-value metabolites with anti-bacterial, anti-oxidant, and anti-aging activities.

Materials and methods

C. *vulgaris* and S. *rimosus* were co-cultivated under mixotrophic conditions, with 12:12 (day:night) photoperiod on Triptic Soya Agar (TSA) plates during 7 days. Cultivated biomass was collected and freeze dried. Freeze dried biomass of C. *vulgaris* and S. *rimosus*, as well as their mono-cultures, were successively extracted with methanol:dichlormethane (1:1) solution in ultrasonic bath. To determine the significance of their co-cultivation, a range of biological assays were performed on algal and bacterial mono-cultures, as well as co-culture. The antimicrobial activity of extracts against *Staphylococcus aureus* and *Escherichia coli* was tested using the microdilution broth method. Furthermore, the antioxidant activity was investigated by four spectrophotometric methods (reduction of the radical cation (ABTS), the oxygen radical absorbance capacity (ORAC), ferric-reducing antioxidant power (FRAP), the 2,2-diphenyl-1-picryl-hydrazyl (DPPH) assays) (Jerković et al. 2021). In terms of anti-aging properties, *in vitro* collagenase inhibition was determined spectrophotometrically according to the manufacturer's instructions. The potential toxicity of tested samples was determined by conducting zebrafish *Danio rerio* embryotoxicity test (OECD 236, 2013).

Results

Co-culture extract showed higher antimicrobial activity (against both *S. aureus* (46.06% of inhibition) and *E. coli* (72.28% of inhibition)) when compared to activities recorded on both tested *C. vulgaris* and *S. rimosus* mono-cultures. The highest antioxidant activity was obtained using the FRAP assay on algal mono-culture and co-cultivation. In terms of anti-aging properties, the highest percent of inhibition of collagenase activity was recorded on *S. rimosus* mono-culture (90.5 %, 88.8 %, 87.8 % of inhibition on 3, 1, 0.5 mg/mL of extract, respectively). Tested extracts in a concentration range from 0.6 to 0.15 mg/mL showed no negative impact on the survival/development of zebrafish *Danio rerio* embryos.

Discussion

As can be seen from the obtained results, co-cultivation of *S. rimosus* and *C. vulgaris* effectively improved bioactive compound synthesis which reflected in higher bioactive potential when compared to the one obtained in mono-cultures. The co-culture extract exerted beneficial effects such as antibacterial, antioxidant and anti-age activities, while at the same time not being toxic. It should be emphasized that observed anti-collagenase activity on *S. rimosus* monoculture and co-cultivation extracts appears to be related to oxytetracycline, which is widely known as Streptomyces product. Collectively, co-cultivation of macroalga *C. vulgaris* and bacteria *S. rimosus* has great commercial potential and opens possibilities for the discovery of novel bioactive molecules.

E-mail: silvio.cristiano@unive.it

Introduction

Environmental concerns, resource optimisation goals, costs abatement, and market competitivity all make the aquaculture sector not exempt from seeking cheaper and less impacting solutions, be them technological or organisational ones.

Although not possible everywhere, especially in dry areas, land-based fish farming systems promise to allow for resource saving for both management and transportation.

The improvement of this kind of operating systems addressed here seabass and seabream farms, selected in a convenient area of Tuscany, Italy, very close to a natural lagoon. Here, academic and business partners are involved, from the action 'New Technologies, Tools and Strategies for a Sustainable, Resilient and Innovative European Aquaculture (NewTechAqua)', funded within European Union's Horizon 2020 programme.

Their objectives are:
1) Decreasing the environmental loads of land based farming;
2) Increasing profitability by decreasing feeding costs, also applying the emerging framework of "precision fish farming" (Føre et al., 2017), with the aim of supporting operators in optimising feeding practices with respect to growth performances, fish welfare, and - indeed - environmental load.

The environmental performances of the solutions proposed to achieve these objectives are evaluated and here preliminarily presented.

Methods

The environmental performances of the land-based seabass and seabream fish farming plant at hand are appraised through well-oiled Life-Cycle Assessment (LCA), standardised and updated by the International Standard Organisation (Arvanitoyannis, 2008; ISO, 2018). Indicators are available from different calculation choices, including the Ecological Footprint (Wackernagel and Rees, 2004), the Global Warming Potential, the Cumulative Exergy Demand, the Water Footprint (Hoekstra et al., 2011), and the ReCiPe sets (Goedkoop et al., 2009).

Results

The potentials, limits, and margins for improvement of the proposed solutions are presented and discussed, bringing together trade-offs between newly invested resources and newly caused environmental impacts and expectedly saved resources and environmental impacts over time. This kind of information represents a basis for further refining of such solutions.

Introduction

The present study as a part of CLIMAQUA project aims at full utilization of seafood resources (particularly, farmed fish) for recovery of both high- and low-value products. Even though seafood raw material as a source of multifunctional peptides has already been reported in scientific literature, extraction of bioactive peptides from farmed fish for non-communicable disease prevention, is currently underexplored. Therefore, regarding the production of high-value ingredients, the current study's aim was to identify new multifunctional peptides isolated from rainbow trout (*Oncorhynchus mykiss*) which can be further used in manufacture of functional foods and nutraceuticals. Regarding low-value applications, recirculation and zero-waste re-utilization of aquaculture and fish processing side-streams (sludge after enzymatic hydrolysis of rainbow trout, fish slam and wastewater obtained from fish processing facility of Hofseth AS) as substrate for cultivation of algae (*Galdieria sulpuraria*) which can further be used in fish feed formulations, was addressed.

Methods and materials

Head-on gutted rainbow trout delivered from a local fish processing plant "Hofseth AS" (Ålesund, Norway), was used as raw material for enzymatic hydrolysis. Hydrolysis was performed in 4-litre bioreactors at 50±2°C, adding 0.05 % papain and 0.05 % (w/w) bromelain enzymes at the Department of Biological Sciences Ålesund of Norwegian University of Science and Technology (NTNU). Sludge was collected from the bottom of the bioreactor after the enzymatic hydrolysis for further use as a substrate for cultivation of algae (*Galdieria sulpuraria*). Fish slam and wastewater were delivered from the fish processing facility of Hofseth AS (Ålesund, Norway), physiochemically characterised at NTNU and sent to Germany along with the sludge for algae cultivation trials. Trout hydrolysate was freeze-dried at the Department of Energy and Process Engineering (NTNU) and sent to the Department of Pharmaceutical Sciences of University of Milano (Italy) for analysis of biological activities.

At NTNU, the obtained trout hydrolysate was subjected to physicochemical assays to assess its quality parameters (proximate analysis, degree of hydrolysis, amount of water-soluble proteins, amino acid composition, total carbonyl content, fat content and colour parameters).

A peptidomic investigation (using HPLC-MS/MS technique) was performed at University of Milano to display chemical composition of the trout hydrolysates and identify peptide sequences which are present in the hydrolysate mixture, as well as proteins to which each peptide belongs to. In addition, direct antioxidant activity of the hydrolysate by using a combination of ABTS, FRAP and DPPH assays, was measured.

(Continued on next page)

Results and discussion

The study has shown that trout hydrolysate has good quality parameters and exerts a multifunctional bioactivity through the ability of reduction of the oxidative stress induced by H_2O_2 in human intestinal Caco-2 cells, as well as inhibition of ACE and DPP-IV activities, respectively, suggesting antioxidant, hypotensive, and anti-diabetic effects. The results of bioactivity investigation indicated that trout peptide mixture is able to scavenge the ABTS and DPPH radicals, respectively. In addition, it increased the reduction of Fe^{3+} at Fe^{2+}. At cellular levels, the same peptides reduce oxidant stress induced by H_2O_2 in Caco-2 cells. The high presence of hydrophobic peptides within the hydrolysate is correlated to the antioxidant effect and other biological activities.

Regarding low-value applications, the results have shown that fish slam has a potential to be used as a substrate for the algae cultivation. However, more investigation is needed to establish the conditions for re-utilization of sludge and wastewater for the efficient cultivation of *Galdieria sulpuraria*.

Conclusion

The study has shown that peptide mixture of the rainbow hydrolysate can reduce with a dose-response trend both ACE and DPP-IV activities, suggesting hypotensive and anti-diabetic activities of the product. Thus, rainbow hydrolysate can be used as a functional ingredient in the food industry, as well as multifunctional nutraceutical.

Norway has established efficient aquaculture and fish production systems and will work further on methods for full utilization of seafood resources through zero-waste utilisation of fish processing side-streams. The cooperation between Norway and other European aquaculture actors involved in CLIMAQUA project will strengthen regional capabilities and contribute to food security and resource utilisation efficiency under climate change expected within 1.5 or 2°C until 2050.

EFFECT OF*Perkinsus olseni In Vivo* INFECTION ON *Ruditapes decussatus* CONDITIONING AND SPAWNING EFFICIENCY

Introduction

Worldwide, the major problems that clam's production faces are the lack of constant seed supply and drastic annual fluctuations of seed recruitment in wild beds. Moreover, clam's production/survival has been greatly affected by anthropogenic actions and climate changes (for instance, temperature increase, salinity drops, ocean acidification, etc.). Among the major problems is the lack of resistance to infections by pathogenic organisms such as bacteria, viruses, protista, etc. (Carella et al., 2015) leading to extremely high mortality rates (Gosling, 2008) that can reach 80-90%. This is also applied to grooved carpet shell, *Ruditapes decussatus*, a European native clam species. In the last two decades, *R. decussatus* production has declined mainly due to over-exploration of natural clam beds, pollution, significant temperature and salinity variations and pathologies caused by bacteria, virus and protozoa. In particular, new diseases like Perkinsosis caused by the protozoan parasite *Perkinsus olseni*, associated with environmental degradation, are causing abnormal mortalities (Matias, 2013).

The effects on the reproduction capacity of bivalves under pathological infections have been extensively studied, since it is a major cause of production decrease in natural marine and estuarine beds (Dittman et al., 2001; Villalba et al., 2004). The effect of *Perkinsus olseni* infection on the reproduction ability of clams has been underestimated. Although some studies found evidence of reduction of egg production and delay in gonad maturation after infection, the total effect of the infection is still unclear.

Material and methods

In this study, *Ruditapes decussatus* clams from a naïve population were injected with two different doses of *Perkinsus olseni* parasites, a low infection dose ($5{\cdot}10^3$ parasite cells per clam) and a high infection dose ($5{\cdot}10^5$ parasite cells per clam). Clams were maintained during two months for conditioning and at the end of the experiment the spawning was induced, larvae production was quantified, and mortality was evaluated during their first days of life. Also, the infection level and the oxidative status of animals were evaluated at days 0, 30 and 60 post-injection.

Results

The combined effects of *P. olseni* infection, conditioning temperature and feeding significantly increased mortality. Also, gonad maturation was delayed in infected animals but with a higher effect in the high infected animals. The reproductive capacity of the clams was impaired in both infected groups with a lower quantity of larvae produced per clam and a higher mortality rate in larvae during the first week.

Conclusion

Finally, this study showed that the production of natural beds with high prevalence of *Perkinsus* spp. could be compromised by deregulation of the natural reproduction cycle and decreased larval production by infected animals, probably due to a combination of lower egg production and lower lipid reserves in the infected clams.

Introduction and Approach

SUCCESS (System for Understanding Carrying Capacity, Ecological, and Social Sustainability) is a soil to sea modelling framework for integrated coastal management (Fig. 1). SUCCESS addresses (i) the partitioning of nutrient and bacterial loading from land; (ii) the circulation of water and water properties in receiving waters (in this case Belfast Lough) and the exchange with the ocean; (iii) aquaculture inside the system (in this case production and environmental effects of mussel aquaculture, including top-down control of primary production); (iv) system biogeochemistry and ecosystem sustainability, in particular with respect to carrying capacity for aquaculture. Each model has a number of uses *per se* and addresses different management challenges—for instance, SWAT is key for source apportionment of drivers and their connection to nutrient pressures—the linkages among models allow the whole framework to be leveraged to provide policy makers with fact-based, actionable information.

T he well-tested EcoWin ecological model (e.g. Ferreira et al, 2008; Bricker et al. 2018, and references therein) was used in the SUCCESS framework to analyse bottom-up (source control) and top-down (bivalve filtration of phytoplankton and detritus) control of eutrophication symptoms in Belfast Lough, Northern Ireland (UK).

The EcoWin.NET model divides Belfast Lough (130 km^2, maximum depth 23 m) into 52 physical compartments (boxes) with two vertical layers at mid-depth (26 boxes for surface waters and 26 for bottom waters), using a 3D formulation where the circulation is resolved by the Delft-3D hydrodynamic model. EcoWin considers 234 boundaries, of which 232 are land boundaries and 2 are ocean boundaries. Of the former, 21 are rivers and 95 are urban assets discharging directly to the lough. Nutrient discharges from the catchment are modelled using SWAT. Bivalve aquaculture in the lough consists of sub-tidal bottom culture of blue mussels. At present, ten mussel farms are active, all within Inner Belfast Lough, and there is a complementary artisanal fishery of wild mussels.

The SUCCESS framework has been applied in a joint project in Northern Ireland (the Living With Water Programme - LWWP) that brings together the water industry (i.e. supply and treatment), environmental regulators, and aquaculture and fisheries research and policy makers, in order to plan for environmentally sustainable, multi-stakeholder development of a large water body, adjacent to a major city with a population of 640,000. To our knowledge, this is the first time that this type of integrated, multi-stakeholder approach has been used to inform investment decisions at the scale of hundreds of millions of euros by applying ecosystem-based management (EBM).

Results and Discussion

Table 1 shows nitrogen load from both diffuse and point sources to Belfast Lough. The main source of sewage input to the lough is the River Lagan, and about half the nitrogen loading comes from diffuse sources (46%), where bottom-up control has significant social and economic costs.

Nutrient inputs to the lough increase primary production and potentially lead to coastal eutrophication, which would result in a degradation of water quality and ecosystem health and impact economic activities and other uses of the lough.

Table 2 shows that bottom-up control of eutrophication by pro-rata reduction of N loads is significant across all the lough but appears stronger in the southern part due to the location of urban discharge points.

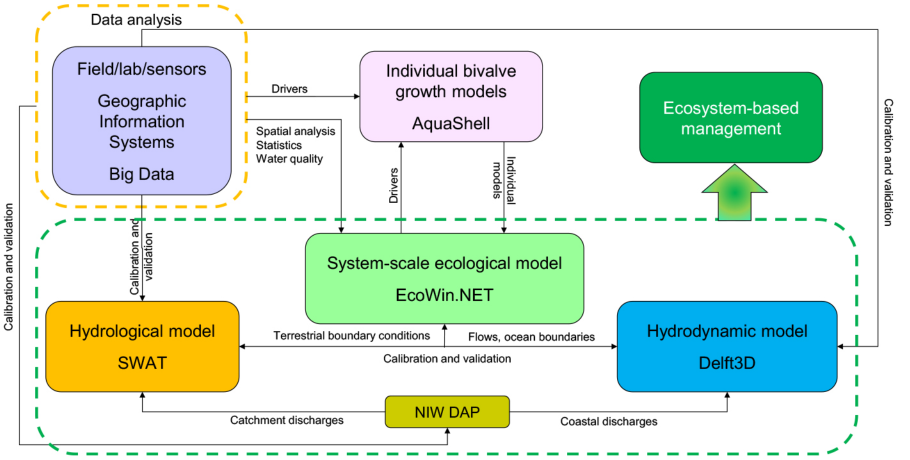

Fig. 1. SUCCESS ecological modelling framework applied to Belfast Lough.

Table 1. Partitioning of nitrogen loads from the catchment to Belfast Lough.

Parameter	**Urban (DAP + septic tanks)**	**Diffuse from land (SWAT)**	**Total**
Nitrogen load (kg y^{-1})	1,411,366	1,204,702	2,616,069
N per unit area (kg ha^{-1})	17.87	15.25	33.11
Population Equivalents (PEQ)	427,687	365,061	792,748
Percentage	54%	46%	100%

Table 2. Effect of 50% nitrogen load reduction on chlorophyll in Belfast Lough.

Chlorophyll P_{90}	**Box 7**	**Box 8**	**Box 11**	**Box 9**	**Box 10**	**Box 20**	**Box 22**	***Box 38***
Standard loading (µg L^{-1})	6.4	14.8	13.3	9.9	10.4	7.3	8.1	13.0
50% loading (µg L^{-1})	4.7	9.8	8.8	7.0	7.1	5.0	5.5	8.6
Difference (%)	-26.6	-33.5	-33.6	-29.9	-32.0	-32.1	-31.8	-33.5

Table 3. Chlorophyll reduction in Belfast Lough with top-down control. From left to right, upper boxes from head to mouth of the lough. Box 31 is the only lower box, included to show differences between upper (Box 5) and lower boxes (Box 31).

Chlorophyll P_{90}	**Box 7**	**Box 5**	***Box 17***	***Box 18***	**Box 24**	**Box 25**	**Box 26**	***Box 31***
Blue mussels (µg L^{-1})	6.4	8.2	5.2	3.9	3.0	0.9	0.8	2.7
No top-down control (µg L^{-1})	9.2	10.9	7.0	5.0	3.5	0.9	0.8	5.1
Difference (%)	-30.7	-25.1	-25.4	-22.2	-13.5	-7.9	-1.0	-47.7

When farmed blue mussels are 'turned off' in EcoWin, chlorophyll decreases significantly in all the lough, particularly in the northern part of the system and close to the mussel farms. Table 3 shows the difference in chlorophyll depending on whether bivalves are active or not and suggests that filtration of phytoplankton and organic detritus makes a significant contribution to top-down eutrophication control. Since 46% of the possible nutrient controls are related to land management (Table 1), and challenging to implement, shellfish aquaculture plays a significant role in meeting water quality standards and Water Framework Directive (WFD) targets.

The SUCCESS modelling framework is a valuable management tool for assessing different scenarios for eutrophication status and legislative compliance, from source control of nutrient emissions to complementary approaches such as shellfish farming for top-down control. If diffuse sources such as agriculture are a significant part of nutrient loading, bivalve aquaculture can play an important role in providing ecosystem services and offset eutrophication symptoms, internalising costs of meeting environmental standards and increasing social capital.

Introduction

Deposit-feeding sea cucumbers are promising candidates for integrated multi-trophic aquaculture (IMTA), not only for their commercial value, but also for their capacity to process and reduce organic matter in sediment (Cubillo et al., 2016, Chary et al., 2020). However, if fish-sea cucumber IMTA systems are to be developed, there is a need to establish a trophic link between fed and extractive species and to verify the ability of sea cucumbers to assimilate organic matter from aquaculture-derived waste. This study combines carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) stable isotope and fatty acid (FA) techniques to substantiate the ability of *Holothuria poli* to incorporate dietary organic matter from aquaculture waste in fish-sea cucumber IMTA.

Methods and Materials

This study was carried out between October 2018 and September 2019, at a commercial fish farm (MFF Ltd.), in Malta, central Mediterranean Sea. Sea cucumbers were cultured directly below a gilthead sea bream (*Sparus aurata*) fish cage at 0 m (E0), at 10 m (E10) and 25 m (E25) distances from the cage, based on particulate depositional model outputs (Baltadakis et al., 2020). Reference sites, R1 and R2, were set up over 800 m away from the fish cages. In February, May and September 2019, sea cucumbers were sacrificed from each of the three cages set up at every site to assess the isotopic and FA composition of their body wall tissue. As potential food sources, fish faeces from sea bream and fish feed administered to the farmed fish were sampled for stable isotope and FA analysis. Also, seagrass *Posidonia oceanica* was collected where present at the sites, whereas suspended matter and seafloor sediments were sampled at each site for analysis.

Results

Mass mortalities were recorded at E0 within the first month due to smothering by settled wastes. The sampled food sources at the IMTA and reference sites were characterised by distinctly different isotopic signatures that allowed organic matter pathways to be traced and distinguished. Temporal variation in food availability and quality was reflected in the sea cucumber diet. Still, farm waste (FW) was generally the dominant dietary source for *H. poli* at E10 and E25 (Fig. 1), whereas the isotopic signatures of sea cucumber tissues at reference sites were not explained by the sampled food sources.

FW and sediments near fish cages were characterised by higher abundance of oleic (OA, 18:1*n*-9) and linoleic (LA, 18:2*n*-6) acids, presumably associated with terrestrial vegetable oils in fish feeds, relative to the reference sites. Importantly, fatty acid profiling also revealed a higher abundance of these FAs in sea cucumber tissue at E10 and E25, whereas sea cucumbers at reference sites were characterised by arachidonic acid (20:4*n*-6) acid, EPA (20:5*n*-3) and DHA (22:6*n*-3) instead. These important differences in sea cucumber tissue composition were driven by aquaculture-derived waste near fish cages.

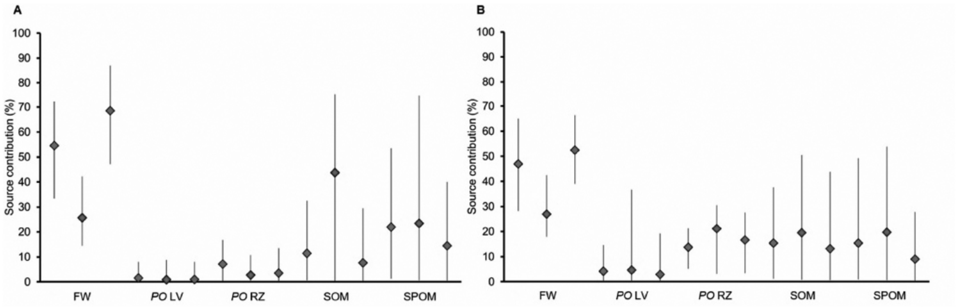

Fig. 1. Organic matter source contribution (median ± 95 credible intervals) to *H. poli* diet during the sampling times, February (in blue), May (in red), and September (in green) in A. E10, and B. E25. FW: farm waste, PO LV: *P. oceanica* leaves; PO RZ: *P. oceanica* rhizomes; SOM: sedimentary organic matter; SPOM: settling particulate organic matter.

(Continued on next page)

Discussion and Conclusions

Isotopic findings substantiated the ability of holothurians to use FW as a nutritional source (Yokoyama, 2013, Xia et al., 2015). The high relative abundance of OA and LA in sea cucumbers near fish cages, presumably linked to the terrestrial plant oil in feeds, confirms the nutritional benefits of IMTA-produced sea cucumbers. The validated uptake of aquaculture-derived organic waste could create economic value for producers to invest in sustainably farmed products. Moreover, the increasing preferences for eco-labelled aquaculture products present economic opportunities to adopt environmentally friendlier technologies and encourage diversification in the Mediterranean. Complementary evidence revealed the dietary significance of aquaculture-derived organic matter for sea cucumber production near fish cages. Findings validated the trophic link in fish–sea cucumber IMTA and the potential of sea cucumbers as value-added IMTA products.

Introduction

Successful larval settlement and metamorphosis has been linked to the recognition of specific substrates or substratum-specific biochemical signals. In many intensive aquaculture systems, the required morphogenesis-inducing substances are often absent. Sea urchin settlement and metamorphosis cues are highly species-specific and may include microalgae, natural surfaces (e.g. porous rocks), adult conspecifics, coralline and other macroalgae, specific chemicals, and bacterial biofilms, particularly those found on the surface of macroalgae. Commercial abalone and urchin farms often use biofilms that develop in the systems naturally for larval settlement (Affan et al., 2015); but this method is often highly inconsistent and seasonal and largely considered ineffective for *Tripneustes gratilla* (<2% settlement, with poor post-settlement survival) (Mos et al., 2011). Certain cues may well induce settlement but not necessarily sustain growth and ensure survival of larvae during the post-settlement phase (Mos *et al.,* 2011), because the settlement substrate is either indigestible or nutritionally poor. *T. gratilla* requires a diet capable of promoting high survival and growth during these fundamental stages of development. This study investigated settlement success, post-settlement survival and growth of *T. gratilla* during different periods of the juvenile phase fed a variety of natural and artificially created substrates/diets.

Materials and Methods

Nine settlement substrates were tested, including natural substrates of *Ulvella lens*, fresh *Ulva* and *Nitzschia,* as well as artificially created substrates using alginate with the addition of either dried *Ulva*, dried *Isochrysis galbana*, a probiotic *Vibrio midae* SY9, a combination of *V. midae* SY9 & an *Ulva* exctract, ethanol solvent (control) or no additive (control). Competent larvae were settled directly into small troughs (L:200×W:105×D:45mm) contained within a flow-through experimental system. Each treatment had 4 replicates within randomly assigned tanks. Competent larvae (n=35) were placed in each trough and the number of larvae to successfully completed metamorphosis within a 60h period was recorded. Successfully settled larvae were maintained in their respective treatments for a period of 4 weeks to assess post-settlement growth (by measuring test diameter of 10 random individuals) and survival, which was recorded weekly for each treatment using a Nikon SMZ1500 stereomicroscope. Substrates were replaced once a week when the individual troughs were cleaned. After 4 weeks, urchins from the best performing treatment (*U. lens*) were used to assess the effects of weaning urchins from post-larval feeds onto the macroalga *Ulva*. Urchins from the latter treatment were randomly divided into 2 treatments of 4 replicates each. One treatment continued to receive *U. lens* for three weeks before being fed fresh *Ulva* for an additional 3 weeks, whereas the second treatment group was offered fresh *Ulva* for the entire 6 week period.

Results and Discussion

Settlement success varied greatly between substrates. The 3 best performing treatments, not significantly different from each other, were *Ulva*, *Ulvella lens* and *Nitzschia sp.*; which induced 67, 62 and 41% larval settlement, respectively. Settlement success was less than 30% for the remaining treatments, with no significant differences between them. Survival of larvae settled and maintained on the *U. lens* substrate by the end of the 4 week growth trial was significantly higher (61%) compared with all other treatments, which had an average survival < 20%.

Juvenile urchin test diameter (TD) at week 4 was significantly greater in the *U. lens* treatment (3507μm), compared with all other treatments that had an average TD of 508μm, with no significant differences between the latter treatments. Thus, diets other than *U. lens* do not appear to be suitable post-settlement diets for *T. gratilla*, even though both *Ulva* and *Nitzschia* induce high settlement. Following the dietary change at week 4, urchins maintained on *Ulvella* were significantly larger at week 7 (6874μm; Fig 1) compared to juveniles fed fresh *Ulva* (5260μm). After 7 weeks both treatments were offered only *Ulva*, but the difference in TD did not change between the 2 treatments and urchins maintained for 7 weeks on *Ulvella* remained significantly larger at the end of week 10 (14278μm TD), compared with juveniles transferred to a diet of fresh Ulva three weeks earlier (11638μm TD).

(Continued on next page)

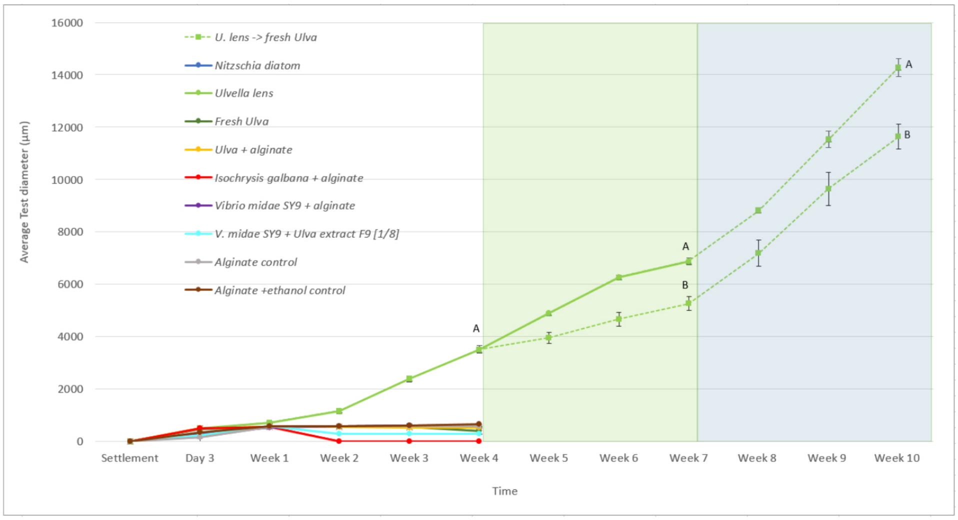

Figure 1: Average test diameter of juvenile *T. gratilla* over a 10 week period post settlement fed a variety of natural and artificial diets. Shaded areas represent dietary changes during weaning, from Ulvella to Ulva as indicated in the figure legend.

Our study suggests *Ulvella* is a superior substrate for *T. gratilla* larval production, capable of producing juvenile sea urchins of ca. 1.5cm in just 10 weeks post-settlement. These findings have important implications for the commercial production of this high value species, highlighting the importance of suitable substrates for both settlement and post-settlement feeding. The study further shows that the timing of weaning juveniles from post-settlement diets to adult feeds can have significant effects on growth and potential effects on overall production times, which could have significant effects on timelines for the production on urchins for harvest.

Introduction

Cold plasma is an emerging sanitizing technology that has been implemented in recent years to extend the shelf-life of food product (Andoni *et al*., 2022.) (Olatunde *et al*., 2021). Seafood products are among the main constituents of food diets, important for their content of vitamins, proteins and other essential constituents such as polyunsaturated fatty acids (PUFA) (FAO, 2020). The main concern associated with this matrix is the rapid deterioration of freshness and quality. The aim of this study was to evaluate the application of cold gas plasma (CP) as a non-thermal preservation technology to prolong the shelf life of sea bream *(Sparus aurata)* fillets, stored in modified atmosphere packaging (MAP).

Materials and methods

The samples were divided into three experimental groups, two of which were respectively treated in air (18 kV for 20 min), or argon (80%) and oxygen (20%) mixture (18 kV for 20 min), while the third one was not treated (control). A plasma source with an SDBD (surface dielectric barrier discharge) configuration was used for plasma generation. The samples were following packed in conventional MAP (80% N_2 and 20% CO_2), and subjected to refrigerated storage (4±1 °C) for 14 days. During this period, at different storage time, possible differences among the samples were investigated in terms of quality characteristics (e.g. O_2 and CO_2 in the package headspace, pH, water content, t-Bars, texture, colour and sensorial properties, microbes load). Experimental data were subjected to two-way analysis of variance (ANOVA) to determine the significant differences among samples during the storage and in each sampling time. Tukey HSD (Honestly Significant Difference) multiple range test, at a significance level of $p < 0.05$ was applied.

Results

Considering the physico-chemical characteristics, with the application of cold air plasma for 20 min, a reduced pH value of the product was recorded during storage, probably caused by the formation of acids (HNO_3, HNO_2, H_2O_2 and O_3) in the aqueous phase of the fish flesh, and a simultaneous slowing down of the natural increase in pH during shelf-life, promoted by the reduction of enzymatic activities. All the samples did not show significant differences in terms of texture parameters, evidencing that the applied treatments did not promote protein oxidation and/or evident structural modification, This aspect was also confirmed by the constant maintenance of the water content during storage for all the considered samples.

The major limitation of the application of cold plasma to fish matrices, or those characterized by a high proportion of unsaturated fatty acids, can be lipid oxidation, considering the 'oxidative nature' of this technology for food applications. Actually cold plasma is constituted by various reactive species, including free radicals, positive and negative ions. These species responsible of its potential sanitizing effect can also stimulate the oxidation process in food products with a high fat content, having a negative impact on their sensory and nutritional quality.

The present study showed that already by the sixth day of storage, the samples treated by argon plasma, reached the quality limit of t-Bars > 4 mg MDA/kg of fresh product compared to the samples treated by air plasma (2.4mg MDA/kg) and to control samples (1.20 mg MDA/kg). Color measurement following the application of both treatments also revealed significant changes in the red-green index colour (a*), the reduction of which can be correlated with lipid oxidation of the matrix.

The microbiological analyses conducted were evaluated for an extended shelf life (20 days). The presence of total mesophiles was evaluated, setting a limit of 6 Log_{10} CFU/g. Results showed that especially at day 10 and day 20 of storage, the treated samples had a lower total load than the control; and in particular at day 10, the control and argon group exceeded the set limit, while the data obtained from the analysis of the air-treated samples showed that the value was still below the limit. At day 20, the differences were significant, but all experimental groups were considered to be microbiologically unacceptable.

(Continued on next page)

Although the sensory analysis showed that the overall visual and olfactory acceptability by the consumer did not result in significant variations, this technology seemed to accelerate oxidative processes. For this reason, it could be useful to conduct further studies to investigate the application of the 'hurdles theory', which envisages the application of cold plasma in conjunction with other stabilizing factors, such as the use of antioxidants etc., in order to minimize the negative side effects on the food matrix of the CP treatment (e.g. lipid oxidation).

USE OF PULSED ELECTRIC FIELDS FOR MODULATING MASS TRANSFER DURING SALTING OF SALMON FILLETS

F. D'Elia, A. C. A. S. Pinheiro, S. Tappi, P. Rocculi

Department of Agri-Food Science and Technology, *Alma Mater Studiorum*, University of Bologna
Piazza Goidanich 60, 47521 Cesena (FC), Italy
E-mail: fabio.delia2@unibo.it

Introduction

Salting is one of the oldest and simplest methods for preserving large quantities of fish for long periods of time. It is often used by the industry in combination and/or as a pre-treatment to other traditional heat/mass transfer processing techniques (e.g. smoking, drying and cooking) (Birkeland and Bjerkeng, 2005).(De Jong *et al*., 2016) This processing step results in safer products with a better sensory appearance, but the salting kinetics require long times for the salt to diffuse into the product and to work properly. Among existing emerging technologies, pulsed electric field (PEF) is a non-thermal treatment that has been shown to be effective in increasing mass transfer to both plant and animal tissues, minimally affecting the nutritional value, flavour, colour and texture of the products (Sigurjon *et al*. 2014). The aim of the present study was to apply PEF to atlantic salmon tissue samples as a pre-treatment to dry salting, to test whether this technique could speed up processing time and achieve higher yields.

Materials and methods

For this study, salmon (*Salmo salar*) fillets purchased from a local supermarket were used, from which 90 samples of size 4 x 4 x 2 cm were obtained from Norwegian and Scottish cuts. The samples were divided into 10 groups of 9 replicates each. The experimental design included 5 sample groups for each salting time (3 and 6 hours). The experimental groups were control (NT) and 4 types of differently PEF pre-treated samples (PEF1, PEF2, PEF3, PEF 4). At the end of the salting times, the samples were rinsed in running water, dried and then subjected to the following analytical determinations: weight change, water activity, NaCl content change, water content change, texture, colour and the level of thiobarbituric acid reactive substances (tBars). The data were analyzed by performing an analysis of variance with one-way ANOVA. Afterwards, the Tukey HSD post-hoc test (with $p < 0.05$) was applied on the averages to reveal the presence of significant differences between the various experimental groups.

Results

The investigations conducted within the framework of this study have shown that pulsed electric fields of 0.64 kV/cm (PEF3), applied prior to the three hours of salmon salting, promoted the salt diffusion into the tissues, leading to increased NaCl retention by the muscle, probably thanks to the PEF permeabilization effect on cell membranes. These process parameters in fact generated a reversible electroporation capable of favoring a more homogeneous distribution of salt within the product, also allowing for a lower percentage of weight variation compared to untreated samples. PEF did not provide any advantages in terms of a faster reduction of the water activity of the samples, especially during the shortest salting times, but it did improve the water retention properties of the salmon with three hour salting, probably because of a more permeable structure that allowed retention of more liquid within the tissue. It is also possible that the results obtained were the consequence of a conformational change in the proteins induced by the applied treatment, which allowed greater NaCl absorption and less water loss from the samples. As far as texture, color and lipid oxidation was concerned, the treatment did not provide any difference in the treated samples compared to the control.

The result obtained may be of great importance to the salmon processing industry because the achievement of higher salt levels, in a product that simultaneously lost less water, can provide an important technological advantage. In fact, the salting process is thus more efficient as processing times are significantly reduced (to only three hours) and higher processing yields are achieved with attractive cost savings for companies, improving the performance of industrial processes.

However, further studies are needed in order to better understand the physico-chemical and biological mechanisms responsible of the obtained results, as a function of the process parameters applied, and to verify the impact of PEF treatment on the most important product quality parameters, such as texture, color and sensorial properties.

Introduction

Genomic selection (GS) models in aquaculture breeding schemes are often calibrated using single generation data. As data accumulate over time, however, it might be beneficial to use multi-generation data for training models to improve prediction accuracy. However, it is not clear how to utilize the information as difference in allele frequency, linkage disequilibrium and data structure across generations may limit prediction accuracy. The aim of this study was to examine the potential of implementing multi-trait approach to utilize multi-generation data for genomic prediction and compared it with alternative calibration strategies.

Materials and Methods

Phenotype and genotype data from two generations (i.e., YC2019 and YC2015) of MOWI commercial population were available. Body weight (BW) measurements of 2,670 individuals from YC2019 and of 3,546 from YC2015 were used for this analysis. All individuals were genotyped with the customized NOFSAL3 ~55k SNP.

Four calibration strategies were compared: ***Scenario 1***: *within generation prediction*, where breeding values of YC2019 were predicted using data only form YC2019. S***cenario 2****: Across generation prediction*, where breeding values of YC2019 were predicted using data only from generation YC2015; ***Scenario 3***: *Combined prediction*, where breeding values of YC2019 were predicted with combine phenotype and genotype data of YC2019 and YC2015, and ***Scenario 4:*** *multi-trait prediction*, where breeding values of YC2019 were predicted through fitting YC2019 and YC2015 in a multi-trait model assuming they are two different traits.

The performance of these calibration strategies was tested using Best Linear Unbiased Predictions based on pedigree relationships (PBLUP) and genomic relationships (GBLUP). Variance components and breeding values were estimated using BLUPF90 (Misztal et al., 2018) by fitting single and multi-trait mixed linear models. The single trait model was:

where is a vector of phenotypes, is a vector of fixed effect of the sex (2 levels) and year-class (2 levels, if exit), is a vector of breeding values, is a vector of random residual effects and are incidence matrices. It is assumed that and , where are genomic, and pedigree-based relationship matrices respectively, is additive genetic variance and is random residual variance. The multi-trait model was:

Where all the model components are as defined previously, except in a multi-trait model structure.

Prediction accuracy and the bias of the prediction models were assessed based on 30 replications of a cross-validation scheme. In the cross-validation, the phenotypes of 15% of individuals from each YC2019 family were masked and their breeding values were estimated using the genotypes and phenotypes of the reference population according to the calibration scenarios. The accuracy was computed as the correlation between the estimated breeding value (pedigree/genomic, PEBV/GEBV) with the phenotype and scaled by the square root of heritability of the BW for YC2019. The bias was computed as the regression coefficient of phenotypes on either PEBV or GEBV. The means and standard errors for the prediction accuracy and biases were calculated from the 30 replications.

Results and Discussion

Estimates of heritabilities and genetic correlation using single and multi-trait models are summarized in Table 1. The heritability estimates were moderate to high (0.28 - 0.46) and were within the range of what have been reported for BW (e.g., Tsai, et al., 2015), however, the heritability estimates form multi-trait model were higher for both generations. The estimated genetic correlation between YC2015 and YC2019 was 0.72 (Table 1).

(Continued on next page)

$$y = X\beta + Zu + e$$

where y is a vector of phenotypes, β is a vector of fixed effect of the sex (2 levels) and year-class (2 levels, if exit), u is a vector of breeding values, e is a vector of random residual effects X and Z are incidence matrices. It is assumed that $u \sim N(0, G/A\,\sigma_u^2)$ and $e \sim N(0, I\sigma_e^2)$, where $G\ and\ A$ are genomic, and pedigree-based relationship matrices respectively, σ_u^2 is additive genetic variance and σ_e^2 is random residual variance. The multi-trait model was:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} X_1 & 0 \\ 0 & X_2 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \end{bmatrix} + \begin{bmatrix} Z_1 & 0 \\ 0 & Z_2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \end{bmatrix}$$

Where all the model components are as defined previously, except in a multi-trait model structure.

Dataset	Single trait	Multiple traits	
		YC2015	YC2019
YC2015	0.287(0.032)	0.336 (0.025)	
YC2019	0.277 (0.032)	0.716 (0.046)	0.464 (0.032)

Table 1: Heritabilities and genetic correlation estimates for BW for YC2015 and YC2019

Prediction accuracies and bias for the different calibration scenarios are summarized in Table 2. The prediction accuracies found in this study are within the range of reported estimates for both pedigree and genomic datasets. The highest prediction accuracy was obtained when multi-trait model is used to combine the two generations of data (Table 2). Merging YC2015 and YC2019 data did not improve prediction accuracy compared to only using YC2019 data and resulted in slightly deflated estimates.

Table 2: Genomic prediction and bias for body weight in YC2019 estimated using different calibration strategies

Scenarios	**GBLUP**		**PBLUP**	
	Accuracy	**Bias**	**Accuracy**	**Bias**
YC2019 predicted with **YC2019**	0.83±0.08	1.10±0.12	0.62±0.06	0.99±0.12
YC2019 predicted with **YC2015**	0.15±0.12	0.78±0.27	0.28±0.09	0.54±0.17
YC2019 predicted using combined **YC2015** and **YC2019**	0.82±0.07	0.92±0.08	0.60±0.07	0.82±0.13
YC2019 predicted with **multi-trait** approach of **YC2015** and **YC2019**	0.88±0.07	1.01±0.10	0.63±0.06	0.63±0.06

These results demonstrate that the use of existing multi-generation data with appropriate modeling can improve prediction accuracy and could enhance cost-effectiveness of GS in practical aquaculture breeding. It also concluded that phenotyping at each generation if vital to maintain prediction accuracies.

ADAPTIVE EVOLUTION FOR OPTIMIZATION OF AN INDUSTRIALLY-RELEVANT MICROALGA

Introduction

Fish oil is currently the main source of omega-3-polyunsaturated fatty acids (ω-3-PUFAs) for the increasingly growing aquaculture feed market, and the Docosahexaenoic acid (DHA) and Eicosapentaenoic acid (EPA) global consumer markets [1]. About 1/3 of wild fish stocks are currently overfished, and the remainder of the wild fish stocks are already exploited at maximal sustainable levels [2]. This alarming decrease in wild fish stocks caused by unregulated fishing and its deleterious effect on marine ecosystem, as well as the issue of potential bioaccumulation of toxic pollutants in fish oil, have recently promoted research on alternative sources of these valuable fatty acids [1] . Microalgae are thought to be the primary producers of ω-3-PUFAs in the marine food chain and could therefore serve as a direct source of these nutrients for human and animal use [3].

Thraustochytrids are heterotrophic unicellular marine protists, very well known for their ability to accumulate a high content of ω-3-PUFAs. What makes thraustochytrids advantageous over other oleaginous unicellular microorganisms is, besides accumulation of a high PUFA content, their competency for the industrial scale fermentations due to their fast heterotrophic growth and their production of toxins-free oils [4]. They accumulate lipids in the cell as a defence mechanism against various stress factors, and therefore once triggered they activate their energy reserves and convert them into high concentrations of fatty acids [5]often considered as non-photosynthetic microalgae. They have been isolated from a wide range of habitats including deep sea, but are mostly present in waters rich in sediments and organic materials. They are abundant in mangrove forests where they are major colonizers, feeding on decaying leaves and initiating the mangrove food web. Discovered 80 years ago, they have recently attracted considerable attention due to their biotechnological potential. This interest arises from their fast growth, their specific lipid metabolism and the improvement of the genetic tools and transformation techniques. These organisms are particularly rich in ω3-docosahexaenoic acid (DHA. Thraustochytrids can produce biomass with more than 50% of their cell dry weight as lipids, in which ω-3-PUFAs account for more than 40% [4]. Considering the lack of genomic insights and detailed studies on lipid biosynthesis in thraustochytrids, as well as the complexity of stress adaptation, rational genetic engineering of these microorganisms is limited. Also, oils with high PUFA content and other valuable metabolites produced by genetically modified microalgae are still not accepted by the food and pharmaceutical industries in many countries. Therefore, Adaptive Laboratory Evolution (ALE) serves as an effective tool to study the molecular-level response of microorganisms to stress and adaptation and can aid in designing genetic engineering strategies for optimizing microbial production systems and constructing new microalgal strains [6] DNA sequencing, bioinformatics, and genetic engineering. Accordingly, Adaptive Laboratory Evolution (ALE. In this study, a combined two-stage ALE approach is proposed to obtain a non-transgenic mutant with a potentially higher cell growth/biomass production and stable lipid production (Figure 1).

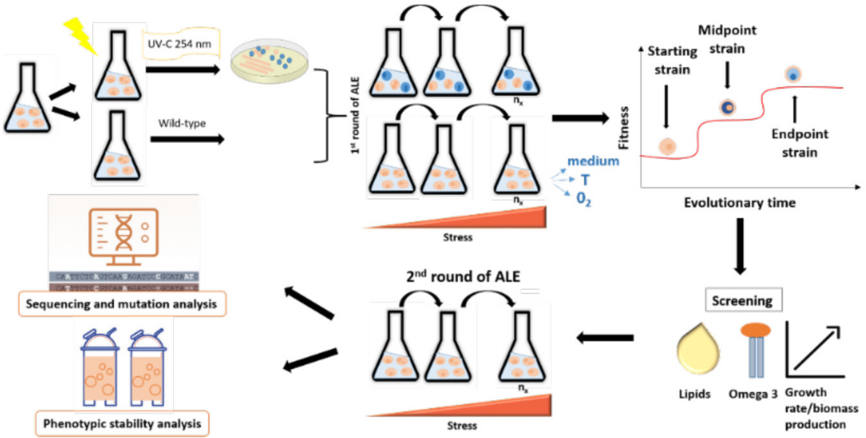

Figure 1. Schematic of a proposed two-phase ALE.

(Continued on next page)

Aim

To enhance the phenotype of a thraustochytrid strain using ALE, and to identify the possible molecular mechanisms underlying such an adaptation.

Methodology

Pre-screening and optimization of culture conditions

Various experimental cultivation systems and conditions of propagation were tested, in order to establish the starting stress parameters for ALE. Optical density was determined by measuring absorbance at 680 nm, cell density using cell counts via a hemocytometer and cell dry weight was determined gravimetrically. All of these parameters were measured daily in order to determine the cell growth curves. Lipid quantification using fluorescent dye BODIPY 505/515 was tested and will be further optimized for use in screening.

De novo whole genome sequencing and assembly

Long-read Nanopore MinION sequencing was used for the whole genome sequencing in conjunction with Illumina NovaSeq 2x150 bp sequencing. Final de novo genome assembly was conducted using a hybrid approach combining high depth Illumina short reads with Nanopore long reads.

Results and Discussion

A two-stage ALE approach was designed and starting stress parameters were determined. Initial pre-screening experiments set a baseline for future comparison with the resulting mutant strains. The Nanopore MinION sequencing run produced around 20.3 Gb of data, altogether generating an approximate 450x coverage of the genome. Around 2.5 M reads were generated with an N50 value of up to 11.7 kb. An additional 6.8 Gb of paired-end 2x150 bp Illumina reads were generated, representing approximate genome coverage of 150x. The final Illumina-polished assembly generated with Flye showed improved quality and completeness with >95% sequence identity, 91.09% of complete BUSCO genes and greatly reduced indels to 26.10 per 100 kbp.

Conclusions

A high-quality genome assembly was generated that will serve as a reference for the subsequent mutant analysis. ALE experiments coupled with further omics-based analysis including transcriptomics, proteomics and metabolomics will allow for deciphering the connection between genotype and phenotype in the evolved strain compared to the original strain.

Introduction

In shrimp aquaculture, feed can comprise up to half of total production costs (Engle *et al.* 2017). However, little is still known about shrimp reactions towards feeders, and it is unknown whether shrimp exhibit anticipatory behaviour. Large swarms (or troops) of shrimp were previously reported from SCUBA observations in ponds (McNeil 2001), but observations on the shape of swarms, size distribution, movements and triggers of such formations are yet to be published in penaeid shrimp under commercial conditions. Furthermore, it is worth noting that only a fraction of the pond is fed, irrespective of the feeding strategy. What happens to the unfed areas of the pond is yet to be investigated. The objectives of this study were therefore to understand the effects of feed distribution events, time of day and displacement of the feeding area on shrimp behaviour in a semi-industrial shrimp pond.

Materials and methods

The trial was repeated three times in the same pond (7 x 4 m, length x width) over a period ranging from July to October 2021 in Zhuhai, China; each trial lasted 6 days after an initial acclimation period of 5 days. Three cameras were positioned approximately 1.5 m apart at the bottom of the pond and feed was provided through a PVC pipe either below camera 1 or 3 corresponding to the smaller edges of the pond (with camera 2 in the middle). Feeding was performed 6 times a day, and the feeding area was moved between cameras 1 and 3 every morning. Each observation session with the cameras lasted 20 minutes ranging from 10 minutes before feed was provided to 10 minutes after distribution. Footage was then analyzed for shrimp identification and tracking using a customized software based on the image instantiation algorithm YOLACT highly optimized for this task. This deep neural network was previously trained with a comprehensive and manually labelled dataset comprising of frames of shrimp in the pond. When water conditions were too challenging or the number of shrimps too high for the software to reliably identify and track the animals, shrimp coordinates were manually obtained through EthoVision XT's manual tracking feature.

Results

The main results include a significant effect of camera location and its interaction with time around feed distribution events on the average observed density in individuals. A gradient in the density in individuals appeared just after feed dispersal, with the highest observed density around the feeding area and the lowest on the opposite side of the pond. A significant effect of feed distribution events was also found on the average individual speed, with shrimp being more active during and after feed dispersal than before. Time of day also had a significant effect on the average nearest neighbour distances, with shrimp staying further apart from each other in the observed areas in the evening (i.e. 7 pm) compared to the rest of the day (i.e. 7.30 am and noon).

Discussion

These preliminary results show that feed distribution events induce large movements in shrimp ponds, and not only around the feeding area. Further analyses (ongoing) will provide more information on how those movements are structured, investigating other metrics such as shrimp orientation, swimming direction and polarity, and shrimp size distribution around the feeding area. From previous observations (McNeil 2001), we predict that compact troops or swarms will be led by the largest individuals, with swimming directions oriented towards the feeding area likely observed immediately after feed dispersal.

Introduction

Our understanding of individual and group behaviour of penaeid shrimps, encompassing several commercially important species such as *Litopenaeus vannamei*, has grown over the past few years (see Bardera *et al*., 2019 for a review). However, most studies investigating shrimp behaviour have used clear water conditions allowing for easier observation. Little is known about the influence of water turbidity on the feeding behaviour and social interactions of penaeid shrimps even though they are commonly reared in highly turbid ponds. Therefore, the aim of this study was to provide a better understanding of the influence of turbidity on *L. vannamei* behaviour. The impact of three water turbidity treatments from suspension of kaolin clay (2.4 ± 0.4, 13.6 ± 0.4 and 30.4 ± 0.7 NTU, Nephelometric Turbidity Unit, mean ± S.E.) on juvenile shrimp group behaviour was investigated, exploring changes in key behaviours related to shrimp interaction with feed and use of the tank environment.

Materials and methods

Litopenaeus vannamei shrimp (6.42 ± 0.28 g; n=96; mean ± S.E., body mass) were used in this study, held inside two 300 L recirculation systems. After an initial acclimation period, shrimp were selected to form 24 groups of four individuals each. Each group of four shrimp was exposed sequentially to three turbidity treatments, with randomized treatment orders. The three turbidities were: clear water (CW, 2.4 ± 0.4 NTU, mean ± S.E.), medium turbidity (MT, 13.6 ± 0.4 NTU) and high turbidity (HT, 30.4 ± 0.7 NTU).

A circular experimental arena was used to observe the behaviour of the groups of shrimps, filled with 50 L of artificial sea water. Light conditions above the experimental arena were the same between trials with a light source directed away from the surface of the tank to avoid light reflection and loss of shrimp tracking. For each recording, shrimp were placed into the experimental arena and after an acclimation period of 10 min, 20 min of footage was recorded using a camera positioned above the water surface providing a top-bottom view of the tank. A known amount of feed (2 g) was added in the centre of the tank before shrimp were initially introduced. Footage was analysed automatically using EthoVision XT version 14 (Noldus Information Technology, the Netherlands) with EthoVision Social Interaction Module. Manual corrections to tracking results were applied, when necessary, particularly when occlusions occurred as individuals crossed paths or remained on the feed. Behaviours displayed by all individuals during each video were determined. To process video footage, an ethogram was developed based on known feeding responses, interactions with the test arena and social interactions.

Results

The main results included a significant effect of turbidity on the average velocity with shrimp at medium turbidity moving faster than at higher turbidity (Darodes de Tailly *et al*., 2022). Another significant effect of water turbidity was observed on the average distance between subjects with shrimp held at high turbidity being closer to each other than in clear water and medium turbidity (Darodes de Tailly *et al*., 2022). There was also a significant effect on the percentage of feed consumed with shrimp held at the highest turbidity ingesting more feed than those observed in clear water. No significant effects of turbidity were found for metrics associated with feeding behaviour (Fig. 1).

(Continued on next page)

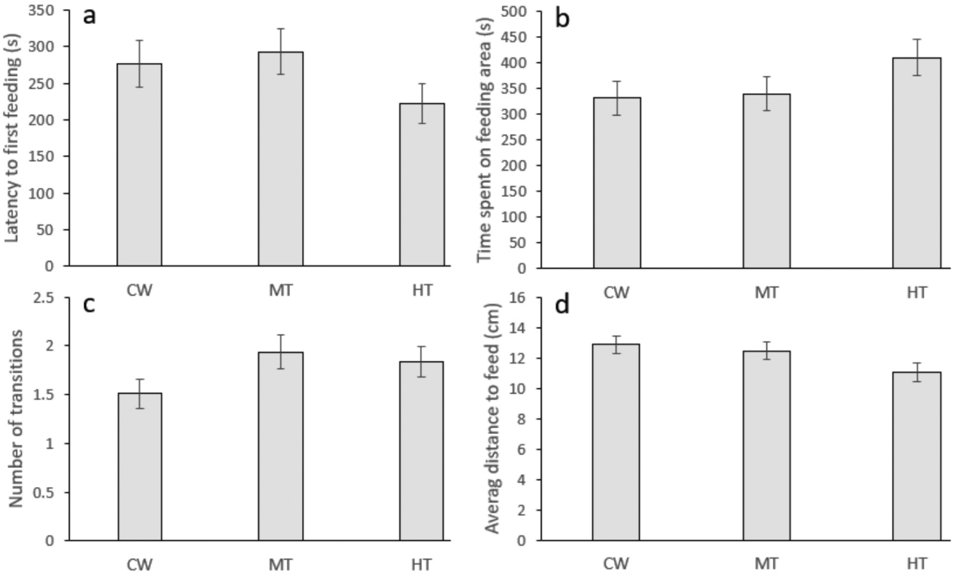

Figure 1: Latency to first feeding (a), time spent on feeding area (b), number of transitions (c) and average distance to feed (d) according to turbidity (clear water CW, medium turbidity MT and high turbidity HT) (n=4 groups for each turbidity sequence, six sequences). Results are presented as means ± S.E.

Discussion

Behavioural differences in shrimp held at different turbidities such as changes in velocity and distance between subjects may be a result of stress responses in reaction to turbidity. The significant increase in feed consumption at high turbidity compared to the clear water treatment aligns with previous observations made by You *et al*. (2006) who found that penaeid shrimp rely mostly on olfaction to detect feed and not vision. The present results therefore highlight the importance of accounting for water turbidity in the behaviour and feed intake of penaeid shrimps, and changing the turbidity conditions of a pond or tank may have a significant impact on production costs for the farmer as a result. Further studies will need to focus on the effect of water turbidity on stress in shrimp, through a combination of behavioural and physiological approaches and the use of other agents to artificially increase turbidity.

INVESTIGATING THE POTENTIAL OF HYBRID ULTRASOUND - MICROWAVE TECHNOLOGY IN GREEN EXTRACTION OF PHYTOCHEMICALS FROM FRESH BROWN MACROALGAE *Alaria esculenta*

Rahel Suchintita Das* [1, 2], Brijesh K. Tiwari[2], Marco Garcia-Vaquero [1]

Introduction

Macroalgae are increasingly being explored as a prospective sustainable food resource and a rich store of numerous bioactive compounds for use in the nutraceutical, pharmaceutical, feed, fuel and cosmetic industries. *Alaria esculenta* is a widely cultivated brown macroalgae species off the Irish coast. Significant research that is being carried out on extraction of phytonutrients from macroalgae, mainly focus on extracting these compounds from the dried and milled biomass due to their higher shelf life, stability, greater uniformity, and ease of transportation and handling compared to minimally processed macroalgae. However, the use of fresh macroalgae can be beneficial, reducing the cost and time of drying as well as reducing the time needed for re-hydration in advance of the extraction processes. This study focused on employing a hybrid ultrasound - microwave (UM) technology to extract total sugars, polyphenols and soluble protein from fresh chopped *A. esculenta* using water as a green extraction solvent.

Materials and methods

Extraction using the integrated UM equipment E200 (IDCO, France) as seen in Fig.1, investigated a set of 27 UM combinations of machine output power of ultrasound (U) ranging from 25-100 W, that of microwave ranging from 336-1340 W for time durations of 5, 10 and 20 min. These treatments were carried out at a fixed macroalgae: water ratio of 1:10. Control runs included using only ultrasound (U), and only microwave (M) at the same output power ranges. After the application of the three types of treatments, the extracts were tested for their total soluble sugar content through phenol sulphuric acid assay, total protein using the bicinchoninic acid assay (BCA), total polyphenol content using Folin–Ciocalteu reagent method and antioxidant activities through DPPH scavenging activity and ferric reducing antioxidant power (FRAP).

Results

Use of U treatment (ultrasound power: 200 W and extraction time: 20 min) yielded the highest amount of total soluble sugars (32.68 ± 2.9 mg glucose equivalents per 100 mg dried extract). UM conditions (ultrasound power: 50 W; microwave power: 1340 W; extraction time: 10 min) recorded maximum total polyphenol content (2.07 ± 0.04 mg gallic acid equivalents/ 100 mg extract) and highest FRAP (38.36 ± 3.36 μM trolox equivalents/ mg dried extract). UM conditions (ultrasound power: 50 W; microwave power: 670 W; extraction time: 5 min) resulted in extracts with the highest DPPH scavenging activity (92.38 ± 0.44 % per mg dried extract). The highest protein content in the extracts (15.62 ± 1.69 mg bovine serum albumin equivalents/100 mg extract) was achieved using UM (ultrasound power: 100 W; microwave power: 1340 W; extraction time: 20 min).

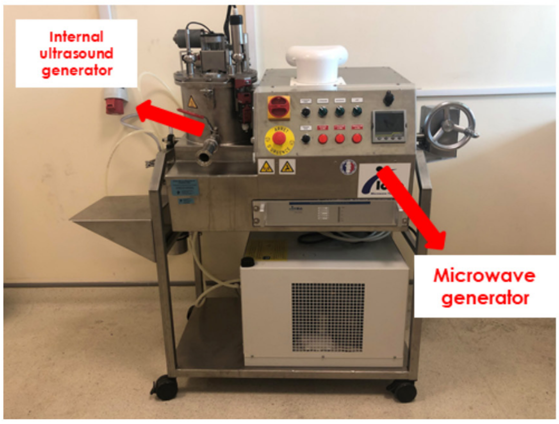

Fig 1: Integrated ultrasound and microwave equipment E200 used in this study.

(Continued on next page)

Discussion

Combining ultrasound and microwave could harness the dual benefits of each of the individual technologies. Ultrasound via its sono-chemical and sono-physical effects induced through acoustic cavitation helps in disrupting the cell wall of the macroalgae (Chemat et al., 2017) and microwave through dipole rotation and ionic conduction (Moret, Conchione, Srbinovska, & Lucci, 2019) help in increasing the diffusional mass transfer rate and thereby facilitate the penetration of the solvents into the cell, facilitating in multiple ways the extraction of bioactives. This was observed in this study, as UM aided in the maximum extraction of most phytochemicals.

Conclusion

The results of this study indicate that the use of ultrasound alone and in combination with microwave can be employed as green aqueous extraction techniques for extraction of phytochemicals and antioxidants from fresh *A. esculenta*. Further studies will be necessary in order to establish the influence of different extraction forces on individual constituents of macroalgae.

Introduction

Zebrafish is a model species used for biochemical research and as a model for aquaculture nutrition and aquactic toxicology (1). Moreover, zebrafish presents numerous technical advantages as a model species such as well-established target mutagenesis technologies, embryo transparency, rapid growth and high fecundity (2,3)but their nutrition and housing requirements continue to elude researchers. Diet and housing density were predicted to affect weight change and reproductive success in 120 days postfertilization (dpf. Due to those multiple advantages, the use of zebrafish as a model is increasing worldwide in the past decades. Zebrafish larvae are traditionally reared with live preys such as rotifers and *Artemia* sp., microdiets or using both strategies in combination in a variety of feeding protocols. At the moment, there is still a lack of consent among the zebrafish community on the establishment of a common feeding protocol. This lack of standardization results in differences in the fish weight, embryo production, and it can also impact on the age of sexual maturity. Additionaly to the the biological impacts, the lack of standardized diets also compromises the replicability of results.

Therefore, this work aimed to investigate the effects of the most used feeding protocolos to promote an adequate development and survival.

Materials and methods

Zebrafish embryos (AB wild-type strain) were obtained from an in-house breeding program. At 5 days post fertilization (dpf), larvae were selected and divided into 1-L tanks with a density of 100 larvae L^{-1} and cultured in static conditions. At 15 dpf larvae were transferred to a recirculation system in 3.5 L tanks and larval density adjusted at 35 larve·L^1 in order to maintain biomass density and promote growth. The experimental design included different feeding protocols in co-feeding with microdiet (md) and live feeds (*Artemia* sp.,Art nauplii; rotifers - *Brachionus plicatilis, rots*), a microdiet-based and a rotifer-based feeding protocol were tested for early (8 dpf) and extended transition (15 dpf) to a microdiet-based diet and at different feeding frequencies (3- or 4-times day^{-1}). In addition to influence of the duration of the co-feeding, we also evaluated the effect of the concentration of rotifers, for that we used two distinct concentrations, 50 rot/ml and 150 rot/ml. The feeding protocol started with an increment of 1mg md/day^{-1} until 15dpf, followed by an increment of 2 mg/day^{-1} until 30dpf. The growth performance was evaluated at 15 and 30 dpf.

Results

At 15 dpf it was possible to observe that larvae fed with the rotifer-based protocol showed the highest total length while larvae fed with a co-feeding with microdiet and *Artemia* nauplii, or microdiet with rotifers at 50 rot/ml or 150 rot/ml and an early transition of were the smallest (Fig. 1A). At 30 dpf larvae fed only with microdiet in a frequency of 3 or 4 times were smaller than all the other treatments, and larvae on co-feeding with microdiet and *Artemia* nauplii with an extended transition , or larvae on co-feeding with microdiet and rotifers with an extended transition and the larvae fed with a rotifer-based protocol were larger than all the other treatments (Fig.1B).

The survival at the end of the trial (30 dpf) was significantly lower in larvae on co-feeding with artemia and microdiet and early transition and in all the treatments where larvae were only fed with the microdiet (3, 4 or 5 times per day).

Discussion

The use of live prey is known to contribute to fish welfare since it triggers the natural predatory behaviour and consequently reduce stress in captivity (4,5). Based on our results it was also possible to observe that they are essential to promote better growth and survival.

(Continued on next page)

Treatment name	Composition	Brief description
Art_5_8	Art (5 art/ml) + md	2 meals of Art (until 8 dpf) + 1meal of md
Art_5_15	Art (5 art/ml) + md	2 meals of Art (until 15 dpf) + 1 meal of md
Rot_50_8	Rots (50 rot/ml) + md	2 meals of rots (until 8 dpf)+ 1 meal of md
Rot_50_15	Rots (50 rot/ml) + md	2 meals of rots (until 15 dpf)+ 1 meal of md
Rot_150_8	Rots (150 rot/ml) + md	2 meals of rots (until 8 dpf)+ 1 meal of md
Rot_150_15	Rots (150 rot/ml) + md	2 meals of rots (until 15 dpf)+ 1 meal of md
Rot only	Rots (150 rot/ml)	3 meals of rots
Md x3	Md	3 meals of md
Md x4	Md	4 meals of md

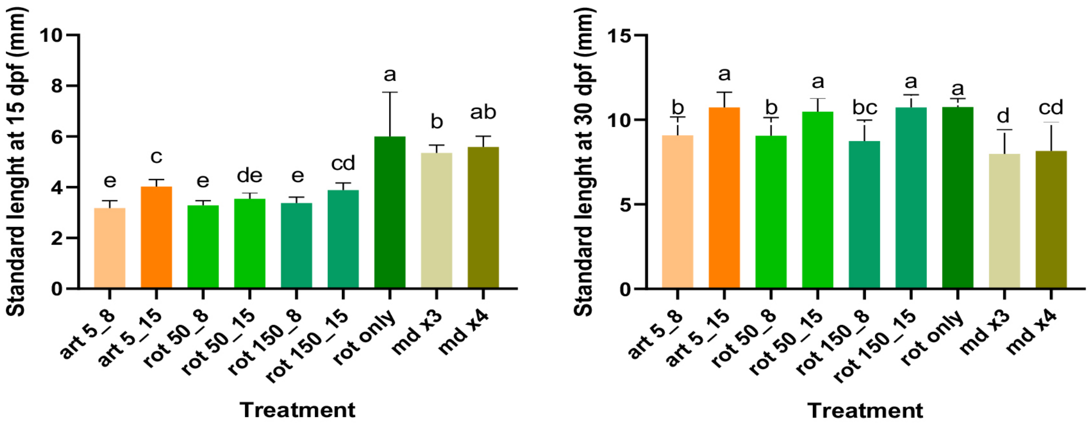

Figure 1: Effect of the different dietary protocols in zebrafish larvae length (A) at 15 dpf and at (B) 30 dpf. Data are expressed as mean ± SD. Statistical differences (One-way ANOVA followed by post hoc Tukey's test, $p < 0.05$) are represented by different letters.

Overall, our results revealed that a rotifer-based diet and extended co-feeding regime with *Artemia* sp. or rotifers until 15 dpf decreased the size dispersion among individuals and promoted larvae growth when compared to a microdiet-based feeding regime or an early transition to microdiets. Larvae survival also increased both in rotifer-based, early and extended co-feeding regimes, when compared to microdiet-based protocols where larvae are fed at least 4 times day^{-1}. In addition, the extended feeding protocol with microdiets showed to decrease the costs and labor associated with larval feeding and reduce the time spent in zebrafish maintenance when compared to microdiet-based protocols. In this work, it was possible to verify that zebrafish constitutes an important biological model for testing protocols for future applications in fish production. This work contributes to a better understanding of the impact of feeding regimes on larval growth and development and promotes the implementation of standardization procedures between different zebrafish facilities, towards higher replicability of scientific results.

Introduction

To adapt to diverse and extreme environmental conditions, marine organisms produce bioactive compounds with high potential for applications in fish farming and human health (Jha and Zi-Rong, 2004). From this large marine diversity, microalgae have received much attention recently because of their unique biochemical composition (Barbeiro, 2015) and innovative biological activities (Brillatz et al., 2018; Lauritano et al., 2020), but also because they can be easily cultivated in bioreactors. However, their potential is still largely underexplored. The diatom Phaeodactylum tricornutum is rich in eicosapentaenoic acid, monounsaturated fatty acids such as palmitoleic acid, minerals and different carotenoids such as fucoxanthin (Neumann et al., 2018) and is therefore a specied of choice for compounds with antioxidant, anti-cancer, anti-inflammatory, anti-obesity and anti-diabetic effects (Bae et al., 2020). In this work, we aimed to investigate the mineralogenic and immunogenic potential of P. tricornutum ethanolic and aqueous extracts using fish-derived in vitro cell systems.

Materials and methods

Biomass of *P. tricornutum* was produced by Allmicroalgae (Pataias, Portugal) and disrupted through exposure to high pressure at LNEG (Lisbon, Portugal). Disrupted biomass was macerated for 3 h in absolute ethanol or Milli-Q water at 100 mg/ml at four different pressures (A- cell disruption with 77.8%, B- cell disruption with 79.2%, C with 51% and D with 0%). To test the mineralogenic activity of the extracts, VSa13 cells were exposed for 21 days and mineral deposition was assessed through alizarin red staining quantification. Extract immunogenic activity was evaluated by qPCR for assessing gene expression of pro-inflammatory cytokines (*tnfα*, *il1b* and *il8*) and two enzymes with a role in the immune system (*sod* and *cox*) in SHK-1 cells exposed to extracts for 4 h.

Results

Samples A_E, B_E and D_E prepared in ethanol showed a statistically significant increase in extracellular matrix mineralization of 45%, 40% and 25%, respectively, compared to vehicle (Figure 1A). Among the samples prepared in water, only D_H exhibited a significant decrease in mineral deposition (approximately 10%), when compared to vehicles (Figure 1B). As expected, cells that were not exposed to the mineralogenic cocktail only showed residual mineralization of the extracellular matrix.

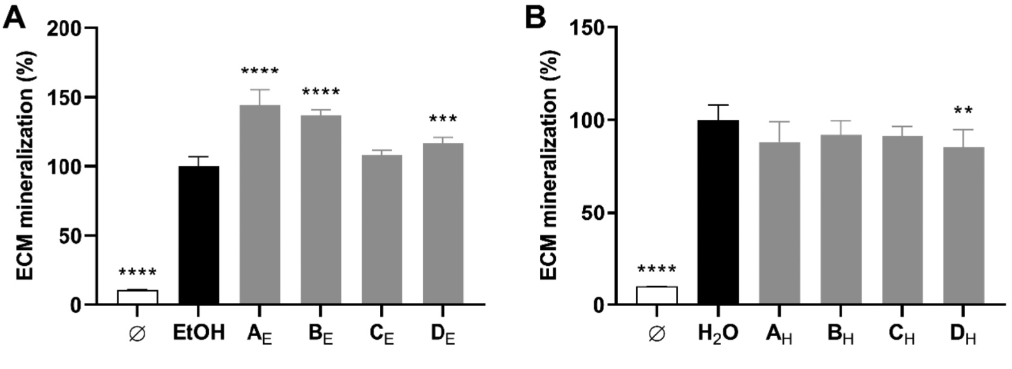

Figure 1. Effect of ethanolic (A) and aqueous (B) extracts of *P. tricornutum* on extracellular matrix mineralization. Ø, cells that were not exposed to the mineralogenic cocktail; EtOH, cells exposed to the mineralogenic cocktail and ethanol (negative control); H_2O, cells exposed to the mineralogenic cocktail and water (negative control); Statistical analysis using one-way ANOVA (**p<0.01; ***p<0.005, ****p<0.001). *n*=6.

(Continued on next page)

Exposure to extracts of *P. tricornutum* revealed that the relative expression levels of the *sod* gene was similar to the control for all the samples, while the relative expression of the other genes of interest (*il1b*, *il8*, *cox* and *tnfα*) had a slight increase, possibly indicating an increase in the immune system.

Discussion

The ethanolic extracts prepared from *P. tricornutum* led to a significant increase in the deposition of calcium phosphate crystals in the extracellular matrix of VSa13 cells, in particular extracts A and B, which were subjected to greater cellular disruption. The correlation between the mineralogical effect and the cellular disruption may indicate that bioactive compounds are intracellular and thus become accessible after an efficient disruption of the cell wall. In 2018, Grossmann et al. demonstrated that cellular disruption of *P. tricornutum* using high pressure allows obtaining extracts with molecules of interest. In general, the aqueous extracts did not show any effect on the deposition of calcium phosphate crystals despite sample D showing a small decrease in mineralization. The different mineralogenic effects of the extracts dissolved in water and ethanol can be explained by the fact that the solvents have different polarities, and thus, allow a selective extraction by solvent affinity, that is, depending on the type of solvent, the dissolved compounds will be different. Thus, the promineralogenic compounds are soluble in ethanol and not in the water, something already observed in extracts prepared from other marine sources. Ethyl acetate extracts from green marine macroalgae *Cladophora rupestris* and *Codium fragile* and from the marine plant *Spartina alterniflora* had a promineralogical effect on VSa13 cells, and this action was not observed in their aqueous extracts (Roberto et al., 2018; Surget et al., 2017). Regarding the immunogenic activity was possibly to observe an increase in the relative expression of the pro-inflammatory cytokines, important initiators of the inflammatory response (Kim et al., 2013). The fact that *sod* gene presented a different behaviour may indicates an antioxidant activity that prevents the toxic effects of oxygen radicals in cells, already observed by Wang et al(2018).

OPERATION OF RAS UNDER HETEROTROPHIC-N ASSIMILATION: CARBOHYDRATE ADDITION TO FRESHWATER RAS WITH RAINBOW TROUT

K. J. de Jesus Gregersen*, L.F. Pedersen

Technical University of Denmark, DTU Aqua, Section for Aquaculture, The North Sea Research Centre
P.O. Box 101, DK-9850 Hirtshals, Denmark
jdjg@aqua.dtu.dk

Introduction

All RAS rely on the common biological treatment process – nitrification – to avoid accumulation of ammonium. The process takes place in biofilter and has numerous assets and drawbacks. An alternative to autotrophic biofilters is heterotrophic N assimilation (HET-N) (De Schryver and Verstraete, 2009; Ebeling et al., 2006). In this process, heterotrophic bacteria consume ammonia directly for growth and thereby remove dissolved N. HET-N assimilation require a higher carbon to nitrogen ration (C:N ratio) which can be achieved by adding a bioavailable carbon source – i.e. acetate (OA) to the system. This can be done by adding easily bio-degradable carbon in the water to promote bacterial growth in the water. However, the addition of carbon and corresponding growth of heterotrophic bacteria leads to a large increase in oxygen consumption, increase in turbidity and high suspended solids loads (Crab et al., 2012). An alternative carbon source is slower releasing products like polyhydroxybutyrate (PHB) (Luo et al., 2020). These PHB pellets placed in a reactor may reduce the turbidity and suspended solids compared to direct carbon addition. The objective of this study was to compare traditional RAS with nitrifying biofilter with different modes of carbon addition to obtain heterotrophic N assimilation. The main focus included assessment of changes in water quality and implication on fish performance during a 4-week experimental period.

Materials and methods

Four different treatment groups were tested in triplicate in 1.7 m^3 pilot scale RAS:
1) RAS with biofilter (*Control*); 2) RAS with biofilter + acetate addition (*BF+OA*); 3) RAS without biofilter + addition of acetate (*OA only*) and 4) RAS without biofilter + PHB biopellets (*PHB only*).

Water samples were collected weekly during the duration of the trial and tested for different physical, chemical and biological parameters. Fish survival was compared and performance was assesses by weight gain during the trial.

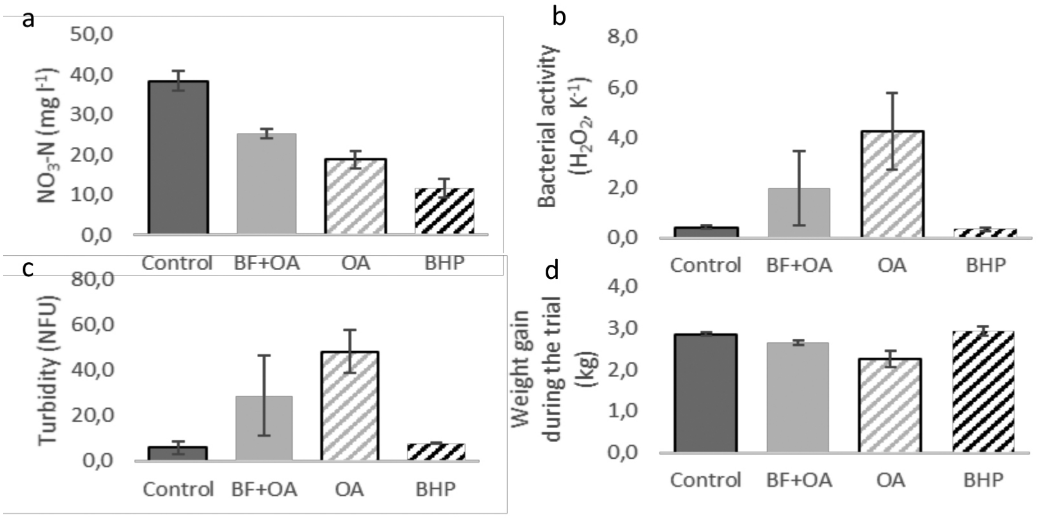

Figure 1. Different water quality and fish performance parameters at the end of the 4 week trial. (average values ± standard deviation). a) Nitrate levels b) Bacterial activity measured using H2O2 degradation method c) Turbidity d) Fish weight gain during the trial.

(Continued on next page)

Results and discussion

Control systems led to accumulation of NO_3 as predicted during the duration of the trial (Fig 1a). In contrast, all other RAS with carbon addition were found to have much lower levels of nitrate at the end of the trial, with 70% less NO_3 in the *PBH only* RAS. Despite not having any biofilters installed, both *OA only* and *PHB only* RAS maintained acceptable water quality parameters during their respective start up phases. The *OA only* RAS showed a moderate accumulation of NH_4+ during the first 2 weeks (up to 0.747 mg l^{-1} TAN), and a constantly higher level of NO_2 throughout the trial (0.834 mg Nl^{-1} vs approx.. 0.100 mg N l^{-1} in the control group). The *PHB only* RAS did not cause accumulation of TAN and only a moderate increase in NO_2- in the first week. This indicates a very fast start up time for Het-N systems, which could have important monetary implication for fish farms as it reduces start up time and allows for an increase feeding from earlier in production. The addition of acetate to the water (*BF+OA* and *OA only)* caused expected formation of bioflocs in the systems, and a significant increase in bacterial activity and turbidity (fig. 1b and 1c). While the fish in all tanks showed apparent appetite and readiness to eat, tanks where acetate was added (*OA only*) led to substantial feed spill. The feed spill may have been caused by the deteriorating water quality conditions affecting fish appetite, or could simply be due to visual impairment of the fish, reducing their ability to ingest the feed. In contrast, system fitted with biopellets (*PHB only*) remained stable and showed no changes in both physical (turbidity) and biological (bacterial activity) parameters during the trial. The absence of bacterial accumulation and no increase in turbidity in the water in *PHB only* suggests that the processes primarily occurred within the reactor, having no negative impacts on water quality.

These results translated to differences in the growth of the fish during the trial, with no differences found between the control groups and the biopellet group (fig. 1d), but a reduction in weight gained in both acetate groups (7,4% less growth in the *BF+OA* and 21 % less growth in the *OA* group). Survival was over 99%.

The results of this trial indicate that it's possible to convert a conventional RAS to Het-N assimilation through the use of different carbon sources, without compromising fish survival and reducing dissolved N and P in the water. However, the use of fast degrading carbon such as acetate resulted in deteriorating water quality and affected fish performance by significant reduced growth. In contrast, slow degrading carbon such as PHB biopellets in a reactor, resulted in reduced levels of N and P, with none to negligible effects on water quality and equal fish performance, while having a much faster start up time compared to traditional autotrophic biofilters.

Introduction

The percentage of fishmeal and fish oil used in aquaculture diets has been decreasing over the past decades. However, with the increased production volumes of the aquaculture sector, the total usage of these marine-based components hasn't decreased. Since both fishmeal and fish oil are scarce raw materials, which are considered to be expensive and less sustainable, the need to implement alternative ingredients, mostly terrestrial plant-based materials, remains critical to ensure the further growth of the aquafeed industry. One of the issues when replacing marine-based materials with terrestrial plant-based materials is the decline of important micronutrients in the diet. One of these nutrients is selenium (Se). Se is an essential trace element, involved in several biological systems in the animal body. It plays a vital role in the protection against oxidative stress but also in growth, antioxidant status and immune response of animals. Se deficiencies can therefore lead to serious problems in aquaculture, whilst previous research has shown that the increased inclusion of plant-based ingredients has led to decreasing Se contents in both feed and animal tissues. Nile tilapia farming is increasing and becoming more and more intensive, with increased stress and disease pressure as a consequence. Supplementation of Se has become crucial to maintaining fish health and productivity. Additionally, decreasing amounts of Se in fish fillets due to the replacement of marine-based ingredients by plant-based ingredients reduces the healthy image of fish and shrimp for human consumption. To date, Se can be offered to fish in various forms, inorganic, such as sodium selenite, and organic Se, such as L-selenomethionine. Although it is known that these forms differ in bioactivity, bioavailability and efficiency the effect on fish health has not been researched intensively. The objective of this study was, therefore, to assess the effects of sources and levels of Se on the antioxidant status, immune response, and disease resistance of Nile tilapia.

Material and methods

A completely randomized design involving a 2 x 3 factorial arrangement treatment was used. Seven different diets were designed, where a basal Tilapia diet was used as a control diet. Six different treatments were obtained by supplementing the basal diets with 1, 3 and 5 mg/kg Se from L-selenomethionine (SeMet; Excential Selenium 4000 by Orffa Additives BV, The Netherlands) or with 1, 3 and 5 mg/kg Se from sodium selenite (SS). After fish feed production, total Se content in the diets was analysed (Table 1). A total of 735 Nile tilapia (13.52 ± 0.5 g) were randomly assigned to one of the 21 (seven treatments, in triplicate) tanks with 1,000 L of water, with 35 fish per tank. Fish were fed by hand to apparent satiation twice a day for 8 weeks. Moreover, blood samples were collected and analysed on blood chemistry including albumin, globulin, total protein, alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), blood urea nitrogen (BUN), and cholesterol. Antioxidant enzyme activity such as catalase (CAT), superoxide dismutase (SOD), lysozyme (LZM), myeloperoxidase (MPO), glutathione peroxidase (GPx) lipid peroxidation and malondialdehyde (MDA) were also measured. Additionally, survival and growth performance during the feeding trial were measured. After the feeding trial, fish were injected intraperitoneally with *Streptococcus agalactiae*, and the 14-day cumulative mortality was calculated and compared amongst treatments.

Results and discussion

The blood serum biochemical data of tilapia fed the different treatments showed that ALT, AST and cholesterol were affected by both Se levels and source. Increasing dietary Se levels significantly decreased ALT and cholesterol ($p < 0.05$), whilst it significantly decreased the AST levels ($p < 0.05$). Next to that, it was observed that fish fed SeMet had significantly higher values of ALT were significantly higher compared to those fed SS ($p < 0.05$), whilst AST and cholesterol levels were significantly lower in fish fed SeMet compared to SS ($p < 0.05$). All three parameters are the first indicative indicators of increased resilience against oxidative stress and decreased lipid accumulation.

Fish fed diets supplemented with SeMet of 1.0 mg Se/kg resulted in higher growth performance as well as an improved antioxidant status of the fish (Figure 1). Dietary sources and levels of Se had a significant effect on lysozyme (LZM), catalase (SOD), myeloperoxidase (MPO), superoxide dismutase (SOD), and glutathione peroxidase activity (GPx) ($p < 0.05$; Figure 1).

(Continued on next page)

Table 1: Analysed Selenium contents of the experimental diets.

Diet	Se addition (mg/kg)	Total Se in diet (mg/kg)
Control	0	0.68
SeMet - 1	1	1.78
SeMet - 3	3	3.53
SeMet - 5	5	4.9
SS - 1	1	1.75
SS - 3	3	3.49
SS - 5	5	5.3

SeMet = L-selenomethionine, SS = sodium selenite

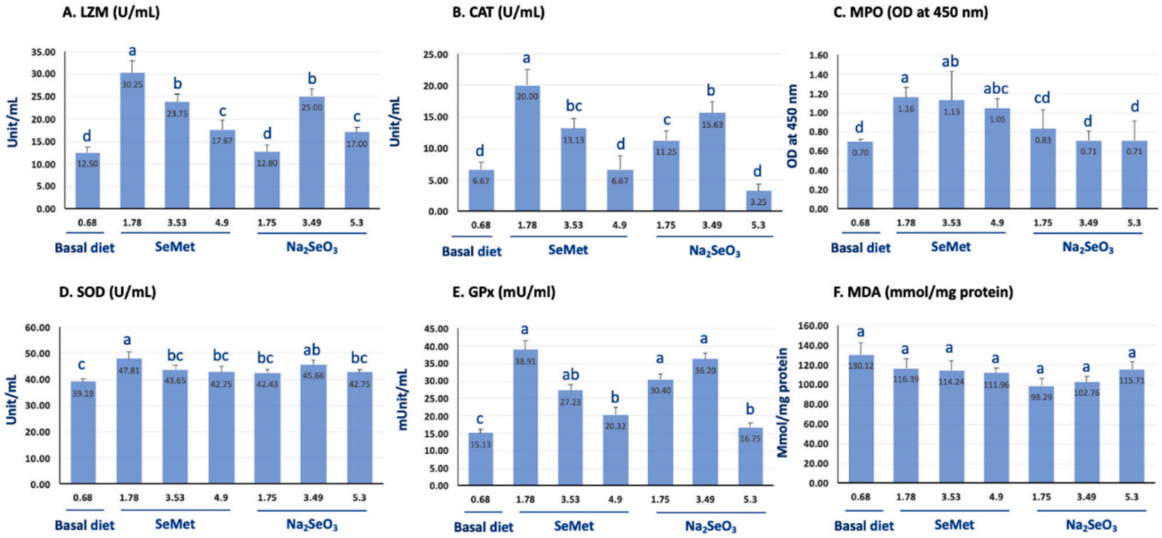

Figure 1: (A) Lysozyme activity (LZM), (B) catalase activity (CAT), (C) myeloperoxidase activity (MPO), (D) superoxide dismutase (SOD), (E) glutathione peroxidase activity (GPx), and (F) malondialdehyde (MDA) of Nile tilapia given different dietary sources and levels of mg Se/kg for 8 weeks.

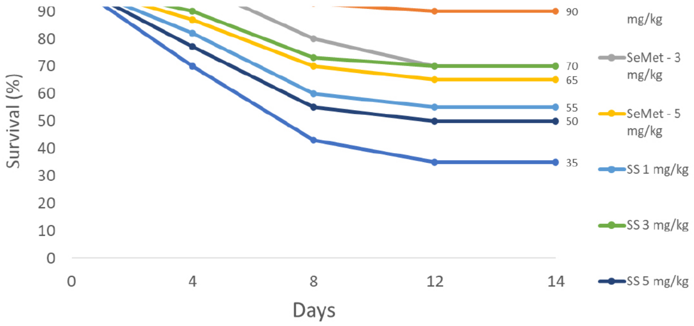
Figure 2: Survival (%) of Nile tilapia fed different sources and levels of selenium after a *Streptococcus agalactiae* challenge.



(Continued on next page)

The potential benefits of dietary sources and levels of Se on the disease resistance of fish against *S. agalactiae* were also assessed (Figure 2). These results may indicate that Se supplementation enhances the immune response, which may be related to the increased resistance of Nile tilapia to pathogenic bacteria. Additionally it could be observed that supplementation of SeMet at an inclusion level of 1 mg Se/kg resulted in the highest disease resistance. The current research results show that dietary sources and levels of Se not only improved the growth performance, but also enhanced the immune response of Nile tilapia, indicating the significant importance of Se in improving growth and immunological parameters. Moreover, Se could be used in feed additives to enhance disease resistance and increase the host immune response against *S. agalactiae* infection. Not every source of Se gives the same performance. In this experiment, it was observed that the inclusion of organic Se (SeMet) outperformed the inorganic Se (SS) regarding antioxidant status, growth performance and immune response, with an optimum supplementation of 1 mg Se/kg from SeMet.

Conclusion

In summary, Se is an essential micronutrient for improving overall fish health and growth performance by improving the antioxidant status and immune response of Nile tilapia. The supplementation level of 1.0 mg Se/kg of organic Se (L-selenomethionine) is suggested to be the optimal level to improve growth performance, antioxidant status and immune response of Nile tilapia. Therefore, the results of the present study suggest that supplementation with L-selenomethionine has high potential in the aquafeed industry.

EVALUATION EFFECTS OF HEAT WAVES ON FARMED *Crassostrea gigas* BIOMETRIC INDICES, HEAT SHOCK PROTEIN 70, 72, 90 AND P53 GENE EXPRESSION

Introduction

The whole shellfish farming sector is negatively affected by the heat waves (HWs). According to the predictive models developed by Galli et al., 2017, in the years 2041-2050 HWs will not exceed 28° C in the north Adriatic Sea, but there will be an increase in the duration of the wave up to 30 days. Knowledge regarding the effects of HWs on bivalves at physiological and molecular level is still limited. In order to fill this gap, this study tries to simulate what will happen in the future, assessing morphometric indices, *HSP70*, *72*, *90* and *p53* gene expressions in pacific oyster exposed to prolonged HW (Farcy et al., 2009)

Materials and Methods

120 specimens of farmed *C. gigas* reared into 12 aquaria were divided in two groups: the control one at temperature of 20±0,5°C and the heat wave exposed group at 28°±0,5°C. At 3, 5, 10, 30 days exposure, oysters were sampled in both groups to determine the biometric indices of whole animal weight, soft body and shell weight, the condition index (CI). At the last time sampling also hepatosomatic index (HSI) and the physiological index of clearance rate (CR) were evaluated. For each time point, the hemolymph was analyzed to determinate total protein, aspartate transaminase, ammonia, magnesium, calcium, phosphorus, and glucose concentrations. *HSP70*, *72*, *90*, (in muscle and gills) *p53* (only in gills) gene expressions levels were evaluated by real-time PCR in the heat wave exposed group as relative up- or down-regulation compared to the expression detected in the control group.

Results and Discussion

About biometric indices, significant differences were found for wet soft body weight and CI, where the lowest values were reported by the exposed group at 30 days. Also the HSI of the exposed group at the end of trial is lower than the control group, while there was no difference between groups in term of CR. Although the heat wave reduced meat yield and energy reserve of the stressed group, this filtered at the same rate than the control group. The HW affected some hemolymph biochemistry parameters like the calcium: there was a significant increase of the values in the exposed group over time, different also from the control group. The HW alters the ultrastructure of the valves, made of calcium carbonate, therefore the animals have sequestered more calcium from the environment and transported it through the hemolymph to the cells used for the shell formation (Knights et al., 2020) (Fig.1). In the muscle, *HSP70* and *HSP72* followed the same trend with the highest values at 5 days in the exposed group: these two *HSPs* induce the use of energy in response to stress (the muscle exposed to HW consumed more energy). *HSP90* in muscle and all three *HSPs* and *p53* in gills were upregulated in the exposed group at 10 days. Gills are the first organ that comes into contact with environmental stressors and, even if concave oyster has developed over time a functional adaptation to sudden environmental changes, prolonged exposition to HW caused an over-expression in *HSPs* and *p53* genes with an alteration in cellular metabolism of the tissue (Fig. 2).

Conclusion

Heat wave causes a reduction in the quality of the oyster as a food product due to the loss in pulp yield, energy reserve. Moreover, HW induces an over-expression of the genes involved in physiological stress/repair response and apoptosis altering cellular metabolism and animal welfare. In order to help farmers in mitigating the consequences of this acute climate events, it will be necessary to develop predictive systems able to warn farmers about the arrival of heat waves.

Introduction

The gilthead seabream *Sparus aurata* is one of the most produced species in Mediterranean Sea and has a great potential of expansion for other regions were the species occurs. The species have been cultivated in the Red Sea in commercial farms, and studies on nutrition in the early grow-out phase and at harvestable size are always on demand. The Kingdom of Saudi Arabia has a large coastline suitable for aquaculture with favorable conditions and environment. Aquaculture is a growing sector in KSA and nutrition is one of the key factors, since feeds are responsible for up to 60% of the total production costs. So, in order to have the optimal feed conversion ratio and high feed efficiency, in the present work we evaluate the best diets commercially available in KSA and investigated the growth performance, survival and fish incorporation of the feeds in order to understand seabream performance in different sizes under the Red Sea conditions.

Materials and methods

In the first feeding experiment at the Coastal Marine Resources Labs (CMOR) of the King Abdullah University of Science and Technology (KAUST), 20 juvenile of gilthead seabream (Run 1) with an average body weight of 119.6 ± 8.9g were randomly stocked in 600 L tanks. In the second experiment, 30 pre-adult seabream (Run 2) with an average body weight 310.3 ± 41.9g were randomly stocked in 1m^3 tanks. For Run 1, the fish were fed with four commercial diets (diet 1, 2, 3, and 4) and for Run 2, three commercial diets were tested (diet 5, 6, and 7). Fish were hand-fed until apparent satiation two times per day, sampling was conducted every 2 weeks to determine growth performance and survival, and proximate composition of the diets was performed. The parameters that fulfilled the prerequisites of analysis of variance (ANOVA) were performed with a one-way ANOVA followed by Fishers Least Significant Difference (LSD) and the parameters that did not fulfill the prerequisites were compared using Kruskal-Wallis-H test followed by Student Newman Keuls using Sigmaplot version 11.0. The level of significance adopted were P<0.05.

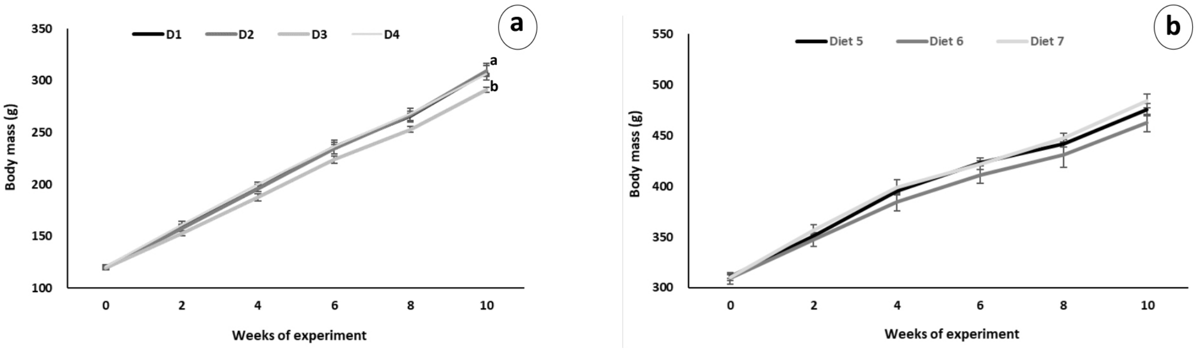

Figure 1. Average body mass of Sea bream *Sparus aurata* during the experimental period. a. Juvenile seabream fed with four commercial diets during 10 weeks. b. Pre-adult seabream fed with three commercial diets during a period of 10 weeks.

(Continued on next page)

Results

The survival of the gilthead seabream in both runs was around 98.3-100% and showed no significant difference among the different diets tested. In this study, the 119 g juvenile gilthead seabream showed a maximum daily weight gain of 2.36 g day^{-1} and an SGR of 1.27% day^{-1}. Comparing the different diets, the FCR value was significantly lower (more efficient) in diets 2 and 4 as compared to diets 1 and 3, so, the higher energy diets, showed better FCR. For the pre-adult gilthead seabream (run 2), the FCR value was significantly lower ($p<0.05$) in diet 6-fed fish (1.95) as compared to fish fed the diet 5 (2.16) and 7 (2.02). Diet 3 exhibited lower body mass at the end of the experiment ($p=0.001$) (figure 1a), while diet 4 showed the highest PER. In the pre-adult fish, diet 7 showed the highest SGR and growth gain, while, diet 6 showed the lowest FCR, but no differences was observed in the body mass (figure 1b).

In the juvenile fish, the feed intake was highest in diet 1 that has the lowest energy content while the lowest feed intake in diet 4, which has the highest energy.

Discussion

These growth results are comparable or even better to the results obtained by previous researches wherein juvenile gilthead seabream of about 105-254 g size cultured at salinity conditions lower than the Red Sea (<41 ppt) attained a daily weight gain of around 1.15-2.87 g day^{-1} and an SGR of around 0.56-0.96% (Ribeiro et al., 2015). The FCR values obtained from this study (1.57-1.7= juvenile; 1.95-2.16= preadult), were also comparable from previous reports (1.5-2.1) (Araújo-Luna et al., 2018; Ribeiro et al., 2015).

It has been observed even with other fish species that the energy density of the feed directly influences the amount of feed consumed, such that a high energy diet can result in a reduction in the amount of food eaten by the fish. In many fish species, that protein (nitrogen) retention can be improved by partly replacing dietary proteins with lipids resulting in a protein-sparing effect (Santinha et al., 1999). PER, which is a good measure of the protein-sparing effect by non-protein energy sources, showed a significantly higher PER in diet 4, suggesting that the lipid in the diet has probably spared protein. Our result for diet 4 is comparable to previous results wherein PER was highest in a lower protein (40%) as compared to a higher protein diet (55%) but with a higher energy diet (Santinha et al., 1999). However, optimum lipid content should be determined in the diet considering that a high-energy diet generally leads to fat deposition and thus can affect the fish commercial value.

Conclusions

The growth results from this study showed comparable with past researches despite the fish were grown in slightly higher temperatures (>24°C), probably due to the higher protein and/or energy in some of the diets tested. Our results suggest that gilthead seabream can attain high survival in the Red Sea with good growth performance and FCR levels showing potential economic feasibility for a commercial operation.

INFLUENCE OF DIFFERENT COMMERCIAL DIETS FROM THE KINGDOM OF SAUDI ARABIA IN SOBAITY SEABREAM (*Sparidentex hasta*) AQUACULTURE: INVESTIGATING A POTENTIAL CANDIDATE SPECIES FOR WARM WATER AQUACULTURE

P.H. de Mello [1]*, A. Mohamed[1], S. Zehra[1], R. Saleh[1], A.A. Siddik[1], E. Pantanella[1], J. L.Q. Laranja[1], J. Alarcon[1], A. Al Shaikhi[2], A.M. Al-Suwailem[1]

Introduction

The Sobaity seabream *Sparidentex hasta* also known as silver porgy is considered one of the promising fish species for aquaculture, especially in the Arabian Gulf region, because of its good adaptation in captivity, rapid growth, high market value, tender flesh and rich flavor. When compared to other sparid species, sobaity seabream is not so well studied and not informations regardins growth performance and feeding conversion ratio (FCR) nor nutritional requirements are available in order to advance in the production of the species. The Kingdom of Saudi Arabia (KSA) has a great potential for aquaculture production due to the good conditions of the Red Sea and Arabic Gulf. Therefore, knowing that nutrition is one of the key factors in fish production and represents major expenses of the total cost of production, our main goal was to study Sobaity seabream growth performance, FCR and survival fed with four diets commercially available in KSA in order to investigate Sobaity performance under the Red Sea conditions.

Materials and Methods

For the first feeding trial (Run 1) at the Coastal Marine Resources Labs (CMOR) of the King Abdullah University of Science and Technology (KAUST), 60 juvenile of Sobaity seabream (Run 1) with an average body mass of 66.0 ± 1.4 g were randomly stocked in 600 L tanks. In the second experiment, 34 pre-adult seabream (Run 2) with an average body mass of 331.0 ± 3.9g were randomly stock in $1m^3$ tanks. For Run 1, the fish were fed with two commercial diets (diet 1 and 2) and for Run 2, three commercial diets were tested (diet 3, 4, and 5). Fish were hand-fed until apparent satiation two times per day and sampling was conducted every 2 weeks. We evaluated the growth performance and survival. Data were tested for normality and equality and one-way ANOVA and Kruskal-Wallis-H test were tested according to the parametric and non-parametric data using Sigmaplot version 11.0. The level of significance adopted were P<0.05.

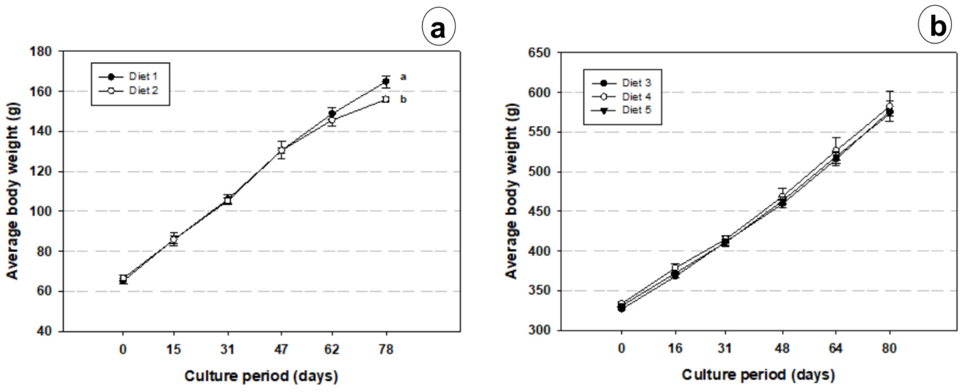

Fig. 1. Average body mass of Sobaity seabream *Sparidentex hasta* during the experimental period. **a**. Juvenile seabream fed with four commercial diets during 10 weeks. **b**. Pre-adult seabream fed with three commercial diets during a period of 10 weeks.

(Continued on next page)

Results

The survival of the Sobaity seabream in both runs was around 96-99% and showed no significant difference among groups. In the juvenile fish, the final body weight (run 1) was significantly higher ($p<0.05$) in diet 1 as compared to diet 2 (figure 1a). The growth increased from 65.3 g to 164.9 g, with a total weight gain of 99.7 g, with a daily weight gain of 1.3 g day^{-1} and a specific growth rate (SGR) of 1.2% day^{-1}. In the pre-adult (run 2), the final body weight, total weight gain, daily weight gain and SGR showed no significant difference between the three diets tested (figure 1b). The juveniles total feed intake was significantly higher in diet 1 when compared to diet 2 (134.8 g fish^{-1}), but for the pre-adult, no significant difference was observed. The FCR in the juvenile, no difference was observed and the value was around 1.5, while in the pre-adult, diet 2 group was significantly lower than the other diets and values were around 1.6-1.4.

Discussion

The present study showed that sobaity seabream is a very good candidate species for increasing aquaculture production in the Red Sea and Arabian Gulf region, since the species exhibited good growth performance that is close to past-developed research; however, improvement on the nutritional characteristics of the feed is essential to improve the growth performances of the fish. In the present study, the daily weight gain was 1.3g day^{-1} and SGR of 1.2% day^{-1} in a 66g fish, which is better than previous research where a 51g juvenile growth 0.85 g day^{-1} and 0.76% day^{-1} of SGR (Houssain et al., 2014). The species attained good growth performance and low FCR when compared to previous study where FCR obtained was 1.6-2.57 (Houssain et al., 2014). For the pre-adult, commercial diet 2 showed significantly better FCR and PER, which shows the high protein requirement of the species. However, the percentage of protein of diet 2 was 46% which is lower than the recommended for the species in previous work that mention diet with 50% protein (Mozanzadeh et al., 2017), so studies approaching lower and sustainable protein sources and alternative to fish meal can be explored in order to produce a cost-effective diet for the species.

Conclusions

Sobaity seabream is a highly recommended species to increase aquaculture production in Middle East region, especially in the Kingdom of Saudi Arabia. The species exhibited a very good growth performance, survival and if the nutritional requirements of the species is targeted in future research; sobaity can be a great potential candidate species to increase marine fish production in KSA.

Introduction

Sea urchin aquaculture (echinoculture) is an emerging industry with high potential. To facilitate production optimisation, accurate and effective methods for quantifying somatic growth of urchins are required. The method frequently utilized involves manually measuring diameter of each individual urchin test (shell) with vernier callipers. This is not only time consuming but also has potentially high measurement variance. Recently, a 3D laser scanning technique was developed (Shpigel and Erez, 2020), which provides highly accurate measurements but requires urchins to be sacrificed and is time consuming. Both methods can be applied when quantifying small sample sizes. However, these methods are not practical when measuring large quantities of urchins. As echinoculture develops to a commercial scale, methods will be required to monitor urchin size accurately and effectively. This study compared the use of callipers to a newly developed machine vision technique for measuring test diameter of two urchin species. Machine vision has been highly effective at optimising fish aquaculture (Saberioon et al., 2017), but does not seem to have been applied significantly in other aquaculture sectors.

Methods

Urchin test diameter (TD) was manually measured using vernier callipers to the nearest 0.5mm. Fifty *Tripneustes gratilla* were measured manually by three operators, with operator 1 conducting 3 measurements of the urchins and operator 2 and 3 conducting one measurement each. This allowed for measurement variance to be determined within a single operator and between operators. Twenty *Parechinus angulosus* were measured separately three times by a single operator. Each urchin was numbered to ensure the same individuals were compared. Images of each numbered urchin were captured and inputted into the machine vision model, with 10 urchins per image. Three images were taken of each set of urchins, but the position of numbered urchins was changed randomly between each image.

To ensure accessibility of this machine vision program, no specialised equipment was used. Images were acquired using a simple homemade photo box and mobile phone cameras. Specific instructions on the setup can be found in the Read.me file (Batik and de Vos, 2022). To check for instrument bias, repeated images of urchins were taken with two different mobile phones, a Samsung A52 and Huawei P30. The program was written in Python3 primarily using the OpenCV library. The machine vision model measured urchin TD by computing the contour of each urchin, using the Canny contour detection algorithm, and the corresponding minimum area bounding rectangle. An HSV filter and basic morphological operations (i.e. blur, erode, dilate) were applied to remove the spines from the measurement area. Settings for the latter used in this analysis are set as defaults; however, these can

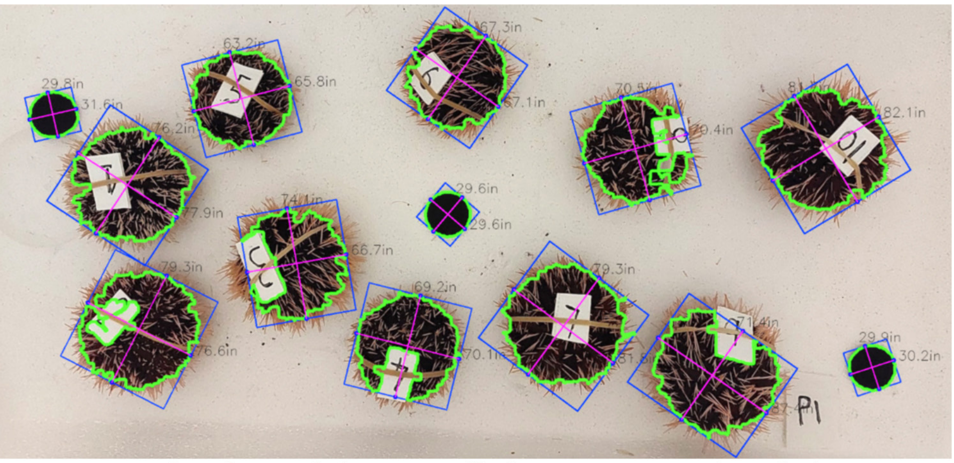

Figure 1. Results of one of the *T. gratilla* images once run through the program. Numbering system on urchins caused some issues with edge detection, measurements affected by this were excluded.

(Continued on next page)

Statistical analysis was conducted in R. To compare measurement methods, the coefficient of variation (CV) between each measurement was determined within each measurement technique. Each technique was regarded a treatment and an ANOVA and Tukey tests were applied. To compare the two different phone cameras' effects on measurements, a paired T-test was used. All assumptions were checked and met.

Results

For *P. angulosus,* the CV for machine vision measurements was 2.21% and lower than that of the manual measurements by a single operator with a CV of 2.65%, however there was no significant difference ($F_{(1,39)}$=0.791, p = 0.379). For *T. gratilla* the machine vision (Fig. 1) CV was 1.55% and significantly lower ($p < 0.001$) than that of the calliper measurements taken by multiple operators (CV of 2.41%), but not significantly different to that of a single operator (CV of 2.02%, p=0.068). There was no significant difference in measurements between phones (p=0.655).

Discussion

The machine vision program was able to provide more accurate measurements of urchin diameter than manual calliper measurements, and with much higher efficiency. It proved difficult to configure the image in such a way that only the urchin test (shell) was measured and not the spines as well. The higher accuracy of the program with *T. gratilla* than *P. angulous* was the result of colour variation between *P. angulous* individuals (colours include black, orange, red purple and white), making it difficult to fit into generalist parameters of the colour filter. While it was still relatively accurate, and now the default parameter should work for urchins of most colours, there is still much scope for refinement and optimisation of the script for specific species. There was decreased accuracy due to mobile phones not having a truly flat lens. This could be improved by using more appropriate cameras, although this would reduce accessibility. While there were no significant differences between mobile phones, it is still recommended to use the same phone and setting across all data points. A possible extension could be real time measurements to attach to a grading machine. In conclusion, this program could be a useful and accessible tool for anyone measuring the diameter of live urchins.

Introduction

Growing demand using European seas for renewable energy, food production, tourism and transportation has resulted in increasing competition for marine space with the push to move into offshore waters. The Belgian pilot within the European Union's Horizon 2020 project UNITED[1] (Multi-**U**se offshore platforms demo**N**strators for boost**I**ng cost-effec**T**ive and **E**co-friendly pro**D**uction in sustainable marine activities) seeks to combine the cultivation of seaweed (*Saccharina latissima*) and European flat oyster (*Ostrea edulis*), and the restoration of flat oyster reefs within an offshore windfarm operated by Parkwind. To do so, best cultivation and restoration practices to withstand the harsh environmental conditions were identified in the nearshore test site at Westdiep, a NATURA 2000 area five kilometres off the coast of Nieuwpoort. Only the best suited materials and methods will be applied in the offshore site in the Belwind offshore wind farm, 46 km off the coast of Zeebrugge.

Materials and methods

The installation of the four offshore oyster restoration structures was conducted early summer 2021. Four restoration structures filled with nature-inclusive scour materials were placed on the scour protection of two monopiles. At each monopile, two structures were installed. At the first monopile, adult European flat oysters (*Ostrea edulis*) were added. At the monopile downstream of the first one (with respect to the main current direction), no oysters were added. The goal of this is to verify whether settlement on the scour protection materials and reef restoration can be enhanced by adding adult oysters.

For the flat oyster cultivation, several techniques were tested, such as oysters cemented or glued to ropes and sticks, and OSTRIGA lantern baskets connected to a rope.

To identify best cultivation practices for *Saccharina latissima* (known as sugar kelp) in the highly exposed environment of the Belgian part of the North Sea (BPNS), different substrates, seeding techniques (comparing direct seeding versus the importance of a nursery period), and strains were investigated. Two types of seaweed cultivation nets (AtSeaNova) were partly pre-seeded with two different strains of *S. latissima* gametophytes and kept in a nursery setting for four weeks. The remaining part of the nets was seeded with the direct seeding method a day before being installed at the nearshore site (Westdiep) in November 2020. Biomass, density, maximum length and width of *S. latissima* were assessed upon the harvest in May 2021.

(Continued on next page)

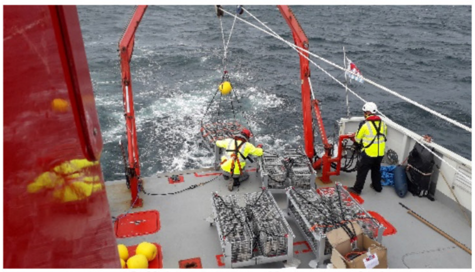

Figure 1 : Offshore installation of the oyster restoration structures filled with nature-inclusive scour protection, shell materials and adult flat oysters to evaluate success of flat oyster settlement and reef formation on the different materials.

*Figure 2 : Healthy looking sugar kelp (*Saccharina latissima*) during the spring inspection in April 2022 at the nearshore site (Westdiep, 5km off the coast of Nieuwpoort)*

Results

The offshore restoration of *O. edulis* reefs gave very promising results. Successful settlement of juvenile flat oysters was discovered on both the scour protection and the added shell materials.

Concerning oyster cultivation nearshore, the oysters cemented to ropes initially seemed to be a practical cultivation method. However, the ropes were overgrown with fouling organisms, mostly mussels once the mussel spat season had begun and water temperatures had risen. The OSTRIGA baskets on the other hand proved to be successful, although pinpointing of the amount of stacks, maze width, and depth was necessary. The other systems seemed to be unpractical (too heavy, basket loss, too much fouling) and need further tweaking before commercial upscaling and/or implementation in a wind farm can be considered.

The first seaweed cultivation trials resulted in a promising harvest of *S. latissima* in May 2021 (Figure 2). While seaweed biomass was of good quality with barely any visible epiphytes, strong biofouling especially on substrates seeded via direct seeding was observed, resulting in low biomass (0.1 kg m^{-1}). Best results were achieved with nets incubated in the nursery before deployment (1.1 kg m^{-1}).

Discussion and conclusion

Overall, the implementation of offshore multi-use activities is still in its infancy. Test pilots such as the Belgian pilot are a prerequisite before offshore multi-use can take place. While nearshore testing of systems and techniques are needed before moving offshore, the real test will come with the installation of offshore seaweed and oyster aquaculture inside an offshore wind farm. The first results of the offshore oyster reef structures in the Belgian pilot show at least that this environment is suitable for the survival, growth, reproduction and settlement of European flat oysters, which looks promising for successfully implementing oyster restoration inside offshore wind farms in the BPNS. The first seaweed cultivation trials made clear that proven cultivation protocols from sheltered locations need adaptation for the successful implementation in the highly exposed offshore environment. Future planned activities on the installation of the aquaculture structures offshore will prove possible further success.

Introduction

Shewanella putrefaciens Pdp11 was isolated from the skin of healthy gilthead seabream (*Sparus aurata*) and has been studied as a probiotic in the culture of some fish species, such as *S. aurata* and *Solea senegalensis*. These are two relevant species cultured in the Mediterranean area, but the pathogens that affect them represent a serious problem for the commercial development of their farming industry (Cámara-Ruiz *et al*., 2020). *Vibrio harveyi* is a significant pathogen of cultured marine fish, especially in southern Europe, and causes a wide variety of pathologies in its hosts (Zhang, He and Austin, 2020). Studies on SpPdp11 probiotic showed antagonistic activity against *V. harveyi in vivo* (Cámara-Ruiz *et al*., 2020), so there is an interest in understanding the mechanisms underlying the observed effects in order to enhance them. In this work, the interaction between SpPdp11 and *V. harveyi* was studied by RNA-seq to understand how SpPdp11 interferes with the pathogen through bioinformatics analysis.

Material and methods

Three types of cultures were performed for this study: SpPdp11 alone (code: Pdp11), *V. harveyi* alone (code: Vibrio) and SpPdp11 and *V. harveyi* together (code: PV). Aquafeed medium was used for all the cultures, which is composed of 160 g/L feed + M3 minimal saline medium. Liquid cultures of SpPdp11 and *V. harveyi* were brought to a known concentration of equal numbers of CFU/mL and 100 µL of the source flasks were added to solid plates of aquafeed medium. For the interaction, a 1:1000 concentration of *V. harveyi*:SpPdp11 was assumed based on previous studies of their growth curves. All cultures were incubated for 24h at 23ºC and samples were stored in TRIsure™ until processing. RNA extraction was performed with the GeneJET purification kit (Thermo Scientific™) following the manufacturer's instructions.

Sequencing libraries (paired-end, 2x75 bp) were constructed at the Ultrasequencing Service of the University of Malaga and sequencing was performed on the Illumina NextSeq™ 550 platform. Six samples of each experimental group (Pdp11, Vibrio and PV) were sequenced. Raw reads were processed using a bioinformatic pipeline including pre-processing with SeqTrimBB (v2.1.8), mapping with BWA (v0.7.5), differential gene expression with DEgenesHunter (v1.0) and functional enrichment of GO terms with in-house R scripts. GO enrichment was performed for the three ontologies: Biological Process (BP), Cellular Component (CC) and Molecular Function (MF). For the processing of Vibrio data, in addition, a de novo assembly of the genome and its functional annotation were performed, and predicted genes were searched for in the core genome of Vibrionales order (results not shown). Data processing was carried out with the computational resources of the Andalusian Bioinformatics Platform. To find out the effects of the interaction in both species, two gene expression comparisons were carried out: PV vs Pdp11 and PV vs Vibrio. Genes were considered as differentially expressed (DEG) if fold change > 2 and adjusted *p*-value < 0.05. A network analysis was performed for the most relevant functional enrichment results using Gephi (v0.9).

Results

When comparing PV vs Pdp11 through differential expression analysis, 66 DEGs were obtained, of which 31 were upregulated and 35 were downregulated. Significant GO terms (*p*-value < 0.05) were obtained in BP and MF ontologies, but not in CC. Nevertheless, due to the low number of DEGs obtained, few genes were annotated in the enriched terms and no further analysis was performed.

When comparing PV vs Vibrio, 2370 DEGs were obtained, of which 1113 were upregulated and 1257 were downregulated. Significant GO terms were obtained in the three ontologies for both upregulated and downregulated genes, but the enrichment yielded higher significance values in the case of the upregulated genes than of downregulated genes. The most relevant results were obtained in BP ontology, so a network analysis was performed in order to study the distribution of up and downregulated genes and enriched terms. Briefly, upregulation of expression was observed in genes related to motility, localization, organization and peptide metabolism, while downregulation was observed in genes related to stress response, signal transduction, transcription, transport and metallic clusters assembly.

(Continued on next page)

Discussion

A quick glance at the results shows that the number of deregulated genes as a result of the interaction is much higher in *V. harveyi* than in SpPdp11. This suggests that the presence of SpPdp11 affects *V. harveyi* to a greater extent than *V. harveyi* affects SpPdp11. Considering that *V. harveyi* is a pathogenic strain and SpPdp11 is a probiotic strain, this may be positive for its probiotic capacity, as it not only maintains its functionality almost intact, but also produces a huge imbalance in that of *V. harveyi*. Although the pathogenicity mechanisms of *V. harveyi* remain to be properly resolved, many virulence factors have been identified, as hemolysins, proteases, lipopolysaccharide (LPS), the capacity to bind iron, interaction with bacteriophages, biofilm formation and quorum sensing (Zhang, He and Austin, 2020). Interestingly, we found that genes related to metallic clusters assembly were downregulated in *V. harveyi* in the presence of SpPdp11, which could be modulating this virulence factor. Moreover, this has been found to be important for pathogenicity in fish, but not in invertebrates (Owens, Austin and Austin, 1996). As for other groups of downregulated genes, such as those related to stress response or transcription, it would be necessary to elucidate how they are related to known virulence factors. Overexpressed genes are mostly related to two major functionalities, protein biosynthesis and motility. SpPdp11 is clearly affecting motility and organization of *V. harveyi*, but the consequences of this deregulation need to be elucidated. Regarding protein biosynthesis and translation, it is well described that *V. harveyi* uses many proteins as virulence factors (Zhang, He and Austin, 2020), so an experimental study on the expression of known virulence factors under conditions of interaction with SpPdp11 would be desirable. Based on these results, new interaction experiments will be conducted to observe the behaviour of the two species at the interaction front and metabolomics and proteomics studies to explore further effects of the deregulation of gene expression.

In a context of increasing demand for food and decreasing resources availability, aquaculture emerges as a promising sector. With an annual growth rate of 5.8% since 2001 (FAO 2018), it is one of the fastest growing industry. Mussel aquaculture, in particular, is considered to be one of the least impactful food production method as it usually grows native shellfish species which take their nutrients directly from the environment, a process that makes them interesting bioremediation tools against water eutrophication. In addition, shellfish aquacultures have a potential for carbon absorption and can provide shelters for fish and marine life. Mussels also constitute a healthy source of food for consumption, further raising the attention that is being drown to it. However, while the incentives for shellfish aquacultures are increasing, the potential impacts of such farms, especially the more extensive offshore ones, should not be overlooked.

With an average consumption of 2.69 kg/inhabitant, Belgium is the third favorite market for mussels in Europe (FAO 2014). The country purchases 30 000 T of mussels each year at a high cost (83 560 000 €). Long-established purchaser, Belgium is the only main consuming country in Europe that is not also a main producer (FAO 2014). Although a few other attempts have failed in the previous decades, a new innovative longline offshore mussel aquaculture is being installed off the coast of Nieuwpoort. The first harvest of mussels is expected for 2023, and in a second and third phase, the aquaculture will also produce oysters and seaweeds, mainly aimed at the Belgian internal market.

In this poster, we present a monitoring plan in order to assess the environmental impacts of this aquaculture in the Belgian part of the North Sea for the next 9 years. While this study is integrated in a wider pluri-disciplinary research, we here focus on the monitoring of the potential impacts on the benthos as well as on the seabed and sediment dynamics and geochemistry.

Introduction

Gilthead sea bream (*Sparus aurata*) production is one of the main aquaculture industries in the Mediterranean, producing 258,754 tones of seafood in 2019 (FAO, 2021). However, in recent years uncertainty regarding the profitability and the economic losses have been inevitable for many production facilities due to rapid market expansion in the 1980s followed by an oversupply establishing a lower market value in the last two decades (Llorente et al., 2020). Therefore, a focus on increasing the production value rather than increasing production quantity would be a sustainable solution to improve profitability and adjust for long-term environmental and economic goals in the EU (Llorente et al., 2020).

The coupled application of Large Volumes (Ø =30-60m^3) and low densities (< 16 larvae/L) has been demonstrated (Koumoundourous et al., 2004; Boglione et al., 2009; Prestinicola et al., 2013) augment the survival rate and the morphological quality of gilthead sea bream and other Sparids. However, the separate effects of density or volume, decoupled from each other has not been investigated. This knowledge will help farmers to produce subadults of higher quality to be ongrown by modulating only one of these two factors, without any need for extra economic investment, high-tech solutions, or new tanks.

The aim of this study was to individuate which between ‘large volume’ and ‘low density’ is the main driver in attaining high quality gilthead sea bream during both the hatchery (from eggs to juveniles) and the preongrowing ($W_{average}$ up to ~55 g). The experimental design envisaged to test the effects at a commercial scale of A) larger and smaller tank volumes on seabream, stocked at the same density; and B) higher and lower stocking densities on seabream maintained in the same tank volume. The experimented tank volumes were smaller, and the densities higher than those tested in previous studies. The choice of the experimental tank volumes (500 vs 1000 L) was based on the ubiquity of these tanks in almost every Mediterranean farm. The densities we utilized were those indicated as interesting to be tested by API (Italian Association of Fish farmers).

Materials & Methods

Experimental rearing were conducted in the EcoAqua facilities at the University of Las Palmas, Gran Canaria (Spain) for the hatchery phase and at the Intituto Portugues do Mar e Atmosfera facilities in Olhão Portugal for the preongrowing phase. 3 different densities (Low Density (LD): 25 eggs/L and 5kg/m^3; Medium Density (MD): 125 eggs/L and 10kg/m^3; High Density (HD): 250 eggs/L and 20kg/m^3) were utilized for the hatchery and ongrowing phases respectively. Two tank volumes were tested for each density condition, in all the trials: 500L tanks (small volume) and 1000L tanks (large volume). Natural seawater was pumped into the systems and all of the rearing parameters were maintained the same for all of the conditions, save the volume or the density. Additionally, oxygen was maintained at above 70% SAT for both trials. Seabream were reared for approximately 2 months in each trial.

Juveniles from the hatchery phase were whole-mount stained with Alizarin red while the sub-adults from the preongrowing cycle were radiographed. Monitoring of skeletal anomalies was done for both studies using an adapted alphanumeric code to account for skeletal elements affected and region of body in which the anomaly was located Prestinicola et al. (2013). Data was expressed in a raw matrix in order to calculate the frequencies of anomaly types found over the total amount of anomalies and a binary matrix to calculate the frequencies of individuals affected by every anomaly types. All statistical analyses and graphs were done using Python and Past 4.02 (Hammer et al., 2001).

(Continued on next page)

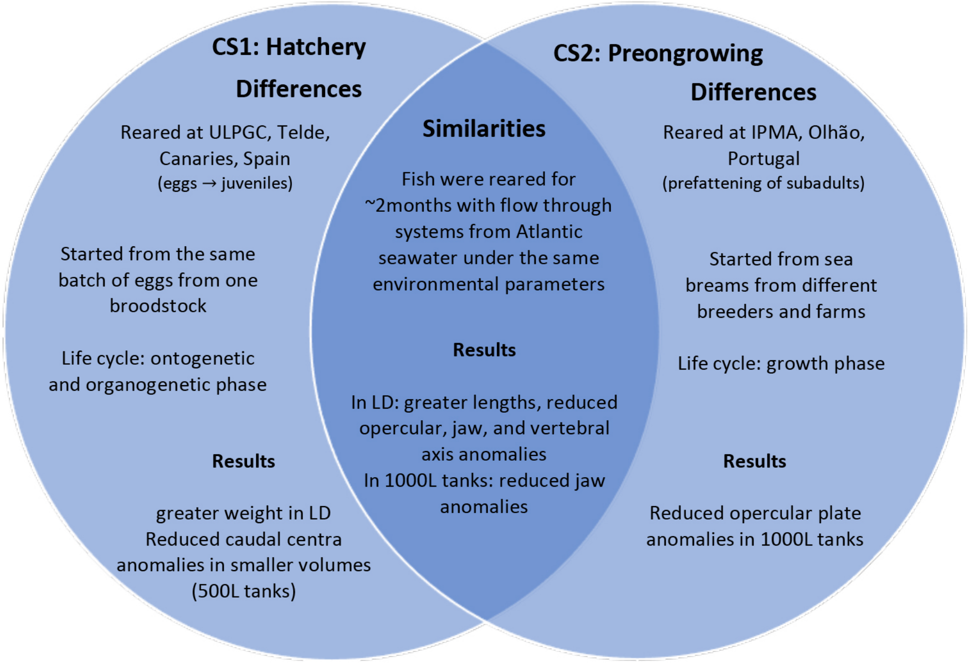

Figure 1. Venn-diagram displaying differences and similarities between the two case-studies.

Results

Strikingly the environmental parameters of varying degrees in density and volume elicited similar responses in both early juveniles and subadults.

Both experimental cycles enhanced significant greater lengths, reduced opercular, jaw, and vertebral axis anomalies in LD reared seabream, while larger volumes reduced the incidence of jaw anomalies. This outcome highlights the predominant effect of environmental drivers on skeletal plasticity in this species, regardless of notable differences in genetic origin, life-stage, and ontogenetic phases (Fig. 1).

The possible hypotheses (behavioral, chemo-physical, physiological, etc…) that can be formulated to explain this primary, more positive effect of low stocking density rather than the larger tank volume, are largely discussed.

This project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under the Marie Skłodowska-Curie grant agreement No. 766347, BioMedAqu, ETN 766347.

FINE MAPPING FOR VIRAL NERVOUS NECROSIS RESISTANCE IN EUROPEAN SEA BASS (*Dicentrarchus labrax*) IDENTIFIED BY WHOLE GENOME SEQUENCING

Introduction

Viral Nervous Necrosis (VNN) is the most impacting disease for the European sea bass industry, which can lead to mortality up to 90%. This virus develops favourably in warm waters and outbreaks may be promoted due to global change-related increase in temperature in coastal and marine environment. Identifying concrete improvements in European sea bass populations resistance to VNN is thus of utmost importance in the light of a potential upsurge in viral outbreaks. Selective breeding is a promising strategy to reduce the frequency and severity of VNN outbreaks. Several genomic regions (Quantitative Trait Loci or QTLs) have been identified thanks to SNP arrays, as involved in the variation of VNN resistance, named (Palaiokostas et al., 2018, Griot et al., 2021, Faggion et al., 2022). With the development of cost-efficient sequencing tools, the identification of QTLs can be now much more precise. This work presents a next level of the genome-wide association studies (GWAS) using whole genome sequencing and imputation in order to refine the description of the genetic architecture of VNN resistance in European seabass.

Materials and methods

A total of 5,799 European sea bass (*Dicentrarchus labrax*) from two French breeding companies, EMGi and FMDS, were used in our study. The sires and/or dams used in the crosses of the commercial populations were sequenced, on a NovaSeq sequencer (Illumina), in order to know all the genetic variants characterizing both populations. Then, to study survival to VNN, all offspring were experimentally challenged to VNN on the SYSAAF-ANSES Fortior Genetics platform (ANSES, Plouzané, France), to evaluate their resistance, and each dead or alive individual were genotyped on the ThermoFisher 57K DlabCHIP SNP chip (Griot et al., 2021). We analysed sequences with a home-made bioinformatic analysis pipeline. First, the variant calling was processed according to the DeepVariant best practice and after classical filtering steps nearly 1 million SNPs shared by both commercial populations were identified. Second, FImpute v2.2 software was used to obtain an imputed genotype for these 1 million SNPs for each of the 5,799 offspring. Then, GWAS was performed for each population separately, using a Bayesian sparse linear mixed model (BSLMM) on a dataset of these imputed SNPs for all challenged individuals, using GEMMA software.

Results and discussion

A genomic region (QTL) of 250 base pairs on LG12, common to the two commercial populations, was detected with strong evidence for association with the phenotypic trait of VNN resistance. We identified a survival rate of nearly 78% for individuals possessing the resistance allele at this QTL, vs. 40.6% for the individuals with the susceptibility allele (Figure 1).

Investigations are on their way to identify the genes and possible causal polymorphisms of VNN resistance in this region. Identification of a causal gene would be a major step towards understanding immunological and physiological mechanisms of VNN resistance, and a major advance for breeding programs, allowing for greater genetic gain by using marker assisted selection. Further research is needed to validate the association of the polymorphism with resistance in other populations, and to confirm the mechanism implied using transcriptomics, proteomics or RNA interference.

(Continued on next page)

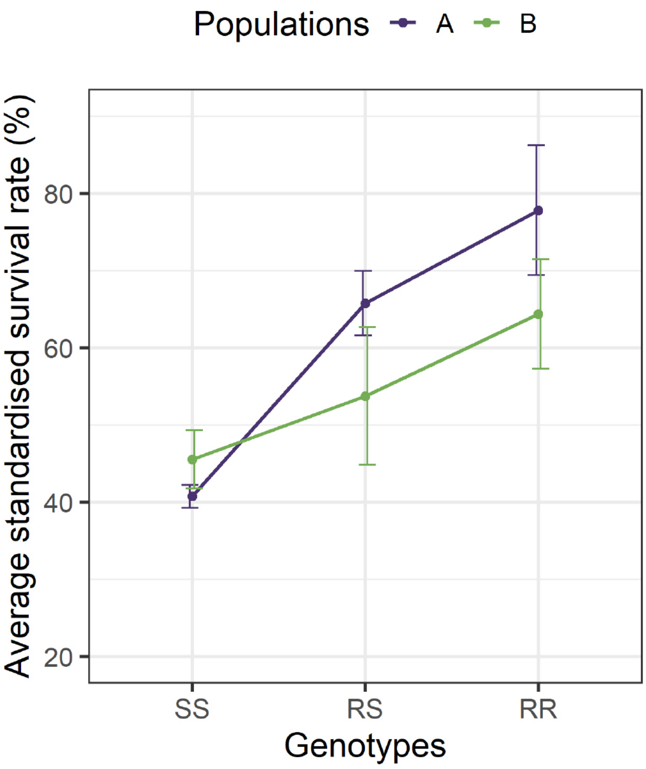

Figure 1: Average standardized survival rate for the strongest SNP detected with the BSLMM approach for the LG12 QTL. Each point is a mean of the standardized survival rate obtained in each of the commercial populations. The standard deviation was reported for each genotype in each population.

Ukraine is the one of countries of origin for a number of *Acipenseridae* species.

Some of them have been probably lost in the wild nature conditions. Such species as *Acipenser nudiventris* and *Acipenser sturio*, despite the fact that these species have been historically noted as registered for Ukrainian waters, don't occure in Ukrainian wild nature no less then three decades. At the same time wild populations of such species as *Acipenser gueldenstaedtii, Acipenser stellatus, Acipenser ruthenus, Huso huso* are stll presented in the Ukrainian marine and freshwater bodies.

Any sturgeon fishery is absolutely prohibited in Ukraine since 2000, and the all *Acipenseridae* species, historically described for the Ukrainian water bodies, have been included to the National Red Book in 2009.

An important step towards implementation of the strategy for conservation and restoration of sturgeon populations was the adoption of the «Action Plan for the Conservation of Sturgeons (Acipenseridae) in Ukraine for 2021-2030», approved by the Ministry of Environmental Protection and Natural Resources of Ukraine in 2020. This Action Plan provides implementation of number of important measures for conservation sturgeon wild populations.

Taking into account, that last decades only Danube is keeping a status of important sturgeon spawning freshawater body for anadromus sturgeon species, artificial sturgeon reproduction always had an extremely high importance for restocking sturgeon wild populations in the Azov Sea basin and in the Black Sea basin.

Historically, based on natural circumstances, Ukraine is conducting artificial reproduction of wild sturgeon populations mostly on the Black Sea basin. Here Ukraine has well functioning Dnieper sturgeon hatchery, which is producting and releasing up to 1.6 million sturgeon fingerlings yearly. Released sturgeon species are *Acipenser ruthenus* (the most in general fingerlings amount), *Acipenser gueldenstaedtii* and *Acipenser stellatus*.

Additionally to sturgeon restocking in Dnieper area, two releases of *Acipenser ruthenus* fingerlings to Danube have been done last decade: 2 thousand specimens in 2015, and 10 thousand specimens in 2021. These restocking actions have been technically realized by Ukrainian private aquculture company "Odessa sturgeonbreeding complex", and in 2021 it has occured in cooperation with the World Wide Fund for Nature Ukraine (WWF-Ukraine). About 1 thousand of released juveniles were marked with special external visual labels.

Also 2 thousand *Acipenser ruthenus* fingerlings were released in April, 2022, to Dniester river, as a result of fruitful collaboration of aquaculture company «ISHKHAN» with Chernivtsi National University, with support of Ukrainian governmental and non-governmental nature protection organisations.

Unfortunately, developing wild sturgeon populations restocking activities in Ukraine have met a strong obstacle as Russian agression against Ukraine, which has began since February, 24, 2022. Nowadays the Dnieper sturgeon hatchery is situated inside of the area of active military actions, and it excludes normal functioning of this hatchery current year.

Regading commercial sturgeon aquaculture, most developing aquaculture technologies using in Ukraine for commercial sturgeon breeding are freshwater cages farms (located at different river reservoirs) and high intensive recirculating aquaculture systems (RAS).

(Continued on next page)

Food products of sturgeon aquaculture have always been classified as a delicatessen with limited demand due to its high market value. During the USSR years commercial sturgeon farming in Ukraine was practiced in pond's, cage's and flowing pools' fish farms (about 15 sturgeon breeding farms in total). The main objects of cultivation in the ponds were Bester (*Huso huso X Acipenser ruthenus*) and paddlefish (*Polyodon spathula*), and in the cages and pools - Bester, sterlet (*Acipenser ruthenus*) and Siberian sturgeon (*Acipenser baerii*). The sturgeon production in Ukraine in 1985-1990 was ranged from 130 to 180 tons per year.

The 90s of the 20th century were a crisis for Ukrainian aquaculture and, above all, for its intensive forms. Due to a significant decline in the purchasing power of the population there was a reduction in demand for products of sturgeons. This led to the shutdown of a number of intensive aquaculture enterprises. By 2000 the number of sturgeon fish farms had fallen from 15 to 8.

With the beginning of the new century there is a gradual revival of sturgeon aquaculture. This was facilitated by the growth of demand for fish products and the emergence of full-fledged fish feeds of leading European brands in the domestic market. In 2011 there were about 10 sturgeon farms, including cage's and RAS. In 2021 were already more than 20 sturgeon farms, and at least half of this number were functioning as cage's and RAS aquaculture systems. Over the last decade, there has been a trend of increasing the number of farms that combine farming of table sturgeon products with the production of edible black caviar with use of modern methods of ultrasound diagnosis of sex and maturity of fish. Currently yearly sturgeon production in Ukraine is up to 100 tons, according to the official monitoring system.

The problems of sturgeon aquaculture development in Ukraine are, in particular:
a) There is still insufficient demand in the domestic market for an expensive table sturgeon products. Ways of solutions: the use of modern technologies and materials in sturgeon farming to reduce the cost and market price of fish and enter the markets of other countries.

b) Lack of production of quality fish feed in Ukraine. Feeds of domestic brands are still considered to be worth than imported feed at the expense of «price-quality», and starter feeds are not yet produced in Ukraine. The problem could be solved by the construction of a feed plant in Ukraine by one of the world's leading feed producers, such as BioMar, AllerAqua or Coppens. The expediency of the step is due to the fact that today in the intensive aquaculture of Ukraine for feeding fish use more than 2,000 tons of high-protein feed each year, and this amount is growing permanently.

c) The development of cages sturgeon (and not only) farms restrains the legally difficult procedure of renting part of the area of water reservours of national importance. Since the adoption of the Law on Aquaculture in 2012, only one farm has achieved to lease of part of the Kaniv Reservoir for cage sturgeon farming. However, currently the State Agency of Melioration and Fisheries of Ukraine does much efforts especially to solve this problem by implementing needed changes to the national legislation.

d) A significant number of aquaculture enterprises do not report on their activities, what causes lack in collected aquaculture data, especially in part of total production estimation. As the one of important keys to avoid this problem considered an improvement of existing responsibility rules, what is also the one of challenges for the State Agency of Melioration and Fisheries of Ukraine.

e) There are almost no subsidies from the state to support the development of aquaculture. However, due to investments in the aquaculture sector, a significant increase in production and quality of sturgeon products is possible.

f) Internal isolation of many aquaculture farms in their activities. Weak links with scientific institutions and limited access to world aquaculture practices do not contribute to the progressive development of production. One of the ways to solve this problem is to create non-governmental aquaculture joint ventures to solve common problems and gain access to modern technologies and other achievements of science and world practice.

As it should be concluded, the development of sturgeon aquaculture both restocking hatcheries and commercial sturgeon farms is an important factor of conservation and restocking wild *Acipenseridae spp*. population in natural water bodies of Ukraine and, at the same time, covering market demand on products of sturgeons. Huge water potential in Ukraine is an evident positive circumstance for sturgeon production growing. Besides, Ukrainian scientists and fish breeders have multiannual experience on sturgeon aquaculture for different nature and artificial conditions.

EFFECTS OF SPACE AVAILABILITY ON THE SKELETON AND SPATIAL DISTRIBUTION OF MEDAKA, *Oryzias latipes*

Introduction

Differently from terrestrial farmed animals, there are currently no regulations on the minimum space which is necessary to fulfil the animals' needs in aquaculture. Crowding and reduced space under intensive rearing conditions are among the causative factors of skeletal anomalies, stress, and reduced animal welfare in farmed fish. In contrast, lower rearing densities improve survival, yield larger fish, and reduce the incidence of skeletal anomalies (Boglione et al., 2014; Izquierdo et al., 2010; Koumoundouros et al., 2001; Prestinicola et al. 2013; Roo et al., 2010). Behavioral studies on rainbow trout demonstrated that high stocking density has a significant effect on swimming activity, oxygen consumption and muscular activity, with substantial effects on swimming trajectories and space utilization (Bégout Anras 2004; Cooke et al. 2020). High rearing densities increase the incidence of particular skeletal anomalies in the model species medaka, *Oryzias latipes* (Di Biagio et al., 2022) and zebrafish (Martini et al., 2020). The laboratory setup provides a convenient and easily accessible monitoring of fish behavior that can provide basic information about the consequences of crowding for skeletal development and animal welfare. Thus, it was tested whether increasing the tank volume has an impact on reducing the incidence of skeletal anomalies and affecting medaka's behavior and survivorship. The present study represents a first attempt to combine anatomical observations and behavioral parameters, such as the overall space occupation (even utilization of the available space, independently of the spatial distribution) and the distribution (aggregated *versus* non-aggregated) of the individuals over time.

Materials and Methods

Medaka were reared from 0 to 40 days post hatching (dph) in 3L (small volume, SV) or 6L tanks (large volume, LV) at high density (40 medaka/L). All the experimental trials were carried out under standard rearing conditions (T: 26°C, photoperiod: 14H light: 12H dark, fed *ad libitum* with the commercial feed ZEBRAFEED® by Sparos, Portugal). The oxygen level was maintained between 98-100%. The levels of ammonia, water hardness and pH were controlled weekly. 150 min videos of the LV and SV tanks were taken every 4 days. At the end of the experimental rearing, the individuals were euthanized, fixed and whole mount stained with Alizarin Red S. Standard length S_L and skeletal anomalies were monitored. The video analysis was performed in triplicate on videos recorded from 40-, 38- and 35-dph of both tanks (LV and SV). The algorithm was written in MATLAB®.

Results

On a laboratory scale, the increase of available space (water volume) by maintaining high rearing density conditions seemed to not rescue or mitigate the effects of high density that were previously published (Di Biagio et al.). In particular, the high-volume condition significantly reduced survival, did not affect the length nor reduced the prevalence and distribution of skeletal anomalies. As an attempt to explain these results and correlate medaka's behavior with the changes in the available space (crowding), we investigated the overall space occupation and spatial distribution of the individuals over time. A first observation of the medaka juveniles swimming in tanks of different volumes reveals that the individuals do not exploit the entire available space. They rather tend to be grouped at the water surface with a subset of individuals that gathers at the bottom. The occupation of space and the dynamic behavior over time were investigated based on the image density of the recorded videos. The section of the imaged tanks was subdivided into three regions: top, central and bottom. Next, it was tested whether the density of the picture was homogeneous in these three regions by randomly sampling the same number of subregions, calculating the average of the pixel values (i.e. the image density) and testing whether the medians

(Continued on next page)

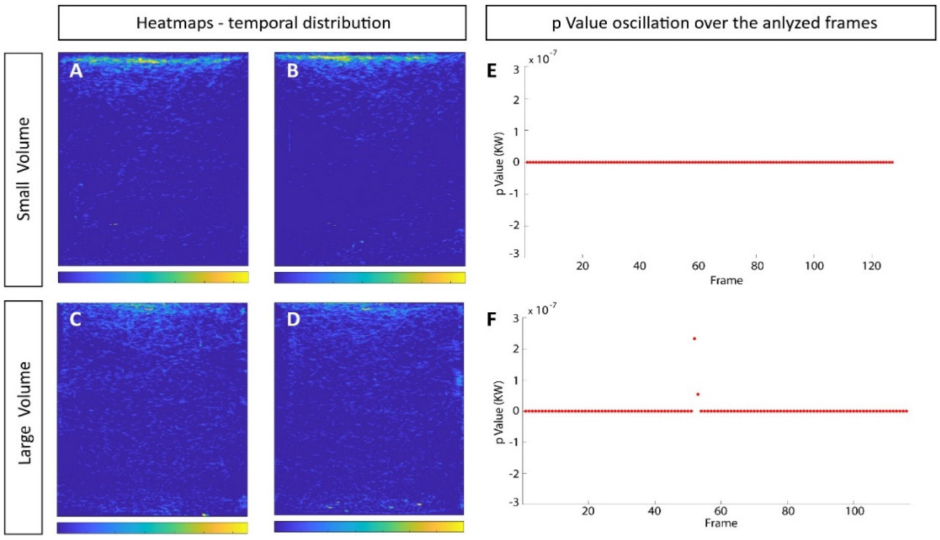

Fig.1 Representative heatmaps of the short-lived behavior of the individuals in small (A,B) and large (C,D) volume tanks. The blue-yellow range indicates the max and min pixel values calculated over 1 minute. (E-F) Scatterplots of the p-values over 90 min: 40 dph (LV) and 38 dph (SV). Each frame on the y-axis is representative of 1 minute of the analyzed video.

of the three regions were homogeneous. To evaluate the overall space occupation, all frame values were summed up in a single image irrespectively of the relative positions of the medaka juveniles. The Kruskal-Wallis (KW) showed significant differences between the medians. The calculated p-values for 40-, 38- and 35-dph indicate that the density of the top, center and bottom of the tank are not equal. Visually, the lack of uniform distribution is evidenced by the heatmaps (Fig.1 A-D). The second analysis focuses on multiple observations over time. Thus, the sequence of frames extracted from every minute of the investigated videos was examined to determine the homogeneity of pixel values distribution with the same regional approach. The KW test was applied to each group of frames (representative of 1 minute) and the oscillation of the calculated p-value was observed. None of the p-values exceeded the value of 0.05 for both rearing conditions (Fig.1 E, F). Thus, it can be assumed that the medakas are never randomly distributed in the tank, but rather grouped, confirming the visual observations.

Introduction

Recently, mass mortalities of Manila clam, *Ruditapes philippinarum*, were verified in the lagoons of the North Adriatic Sea. In summer, they could be linked to thermal stress from heatwaves (Bertolini & Pastres, 2021). High mortalities in autumn may be due to the low salinity levels, caused by extreme precipitation events and related high freshwater discharges. This study aimed at elucidating the sublethal effects of temperature and salinity on Manila clam behaviour using the valvometer "SmartShell", a system developed by the Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise "G. Caporale" (Di Giacinto et al, 2021).

Methodology

Fifty (50) *R. philippinarum* specimens were sampled in Venice Lagoon, Chioggia (VE). The first acclimatization period lasted 1 month in automated system (400 Liter aquaria) at 20 °C with artificial seawater (Instant Ocean®). Microalgae suspension of a mixture of *Tetraselmis* spp. and *Dunaliella* spp. were used for animal feeding. Experimental setting up was settled in four experimental groups composed by 2 individuals inserted in the SmartShell sensors in closed aquaria at different temperature and salinity conditions:1) 20°C ± 2 °C at 22 psu; 2) 20°C ± 2 °C at 36 psu; 3) 28°C ± 2 °C at 33 psu; 4) 20°C ± 2 °C at 33 psu (control group). The test lasted 14 days, during the first 7 days the behaviour of all molluscs was pre-evaluated at control conditions, then they were put under different salinity and temperature conditions. Four replicates were carried out.

Data were grouped in five classes of valve gapes (VG), namely: VG ≤ 20%, 21–40%, 41–60%, 61–80% and ≥ 81% (Redmond et al., 2017). Both in control and exposed mollusc groups, the average amount of time percentage spent in each VG class has been evaluated. Preliminary analysis showed some effects on periodicity, therefore Fourier analysis was used to analyse differences in periods and amplitudes of oscillations. Fourier analysis was done for each individual for both the pre-exposure and exposure periods separately.

Results and discussion

All molluscs had clearly distinguishable periods of activity and inactivity, repeated within the 24 hours. This was confirmed with the periodograms showing the highest peak around the 24h. In the low salinity group this value was slightly lower indicating a slightly higher frequency of oscillations. In the high temperature treatment, the molluscs spent more time opened than the control group, with the amplitude of oscillations significantly dampened.

In the control group, molluscs showed a flapping behaviour, spending more time at VG category of 61–80%. At lower salinity, the animals spent more time at VG of 61–80%. The most represented VG categories at higher salinity and temperature were 61–80% and 41 – 60%, respectively.

These results, first for clams, confirmed that high temperature influenced the behavioural patterns of molluscs, consistently with results for other species (e.g. mussels, Bertolini et al. 2022).

Introduction

Mussel farming takes place directly in the marine environment. So, it is strongly influenced by weather and environmental conditions. In the last years, climate changes are causing severe weather events and anomalies of chemical/physical seawater parameters (e.g., higher average temperatures). Such anomalies are responsible of product losses, structural damages and, sometimes, the closure of production areas due to hygienic conditions. In fact, during the severe rain events, the rivers can discharge faecal bacteria into the sea, that can be accumulated by bivalves posing a potential risk to their consumers (Colaiuda et al, 2020). To face these emerging threats, FORESHELL project (funded by the FLAG Costa Blu trough 2014-20 EMFF program of the Abruzzo Region) created a management tool, able to forecast the main hydro-meteorological-environmental risk factors by alerting the farmer 48 hours in advance. The general aim was to enhance the efficiency and the sustainability of shellfish farming.

Methodology

The study area was a mussel farm located in the Giulianova Maritime District (Abruzzo, Italy). The hydrographic basins of the rivers close to the farm, Vibrata and Salinello, were constantly monitored trough the hydrological model (CHyM) (Tomassetti et al, 2005; Colaiuda et al, 2020; Lombardi et al, 2021), to forecast occurrences of discharge peaks at the river mouth. A specific sampling program was conducted before and after severe weather events to determine the concentration of *Escherichia coli* in freshwater at the river mouths and in mussels/seawater at the farming area. At the same time, the predictive tool was developed by acquiring hydrological data for sanitary risk and environmental parameters (such as sea water temperature, salinity, chlorophyll a, sea currents dissolved oxygen and wave height) though satellites and in situ probe. Furthermore, the growth of mussels was constantly monitored with biometric controls.

Results and discussion

A total of 10 hydro-meteorological events were investigated. At river mouth of Vibrata River the *E. coli* concentration was higher than legislative threshold (500 UFC/100 ml) (Italian Ministry of Health, Decree of 30 March 2010) following 7 hydro-meteorological events; whereas in Salinello River following 4 events. *E. coli* concentration was higher than the legislative limit (230 MPN/100 g) (EU Regulation n. 2019/627) in mussel samples following 4 events. The value of the bacterium in sea water ranged from 0 to 67 UFC/100 ml. Finally, the mussels showed a self-purification time ranged from 3 to 6 days. During the project lifetime the mussel grew constantly.

As regards Salinello River, the analysis showed that 100% of the samplings with high concentrations of *E. coli* in both molluscs and river water occurred following a significant increase in the river flow, while Vibrata River in the 93% of samplings. Based on these results, various flow rate thresholds were defined as an alert system associated with color codes and with the identification of different alert states: early warning (yellow), moderate alert (orange) and high alert (red) in order to make the whole system easily interpretable by the aquaculture.

(Continued on next page)

A customised oceanographic model, developed starting from satellite data, to estimate environmental parameters together with flow rate data of Vibrata and Salinello rivers estimated by CHym model were integrated into AquaX platform. The infrastructure of the AquaX platform was exploited to notify through alarms sent via SMS or email the forecast of adverse weather-marine events and anomalous fluctuations of the monitored physical-chemical parameter, with a predictive capacity of 48 hours. The alarms for the area investigated were set on the basis of bibliographic data and on the basis of aquaculture farmer's experience over the time

In conclusion, the FORESHELL project supplied farmer with easy-to-use tool useful to plan daily activities to obtain a sustainable and optimized production by implementing adaptive procedure to climate changes and ensuring health product.

Introduction

Sea lice infestations represent the major damaging parasite in salmonid aquaculture. Among the sea lice treatments, the use of cleaner fish, mainly lumpfish (*Cyclopterus lumpus*) and wrasse (*Labrus bergylta*), has increased exponentially in the past few years. Lumpfish is widely used as a cleaner fish by the salmon industry in Canada, north of Norway, Scotland, and Faroe Islands due to its higher cleaning efficiency in cold water compared to the wrasse. However, although the use of lumpfish represents a green alternative against sea lice, high mortalities are reported in the weeks post deployment and while they are in the cages. They are mainly caused by poor health and welfare, infectious diseases and the lack of optimal nutritional requirements and tailored diets (Brooker et al., 2018). This study aims to assess key differences between farmed and wild lumpfish regarding welfare and nutritional status and identify nutritional deficits in the lumpfish feeds in order to formulate a new feed that improves their survival.

Materials and Methods

The lumpfish for this study were collected at salmon farming sites, lumpfish hatcheries and from the wild. Regarding the wild specimens, both coastal and pelagic lumpfish were sampled for a total of 172 fish. Coastal lumpfish were collected along the coast, shaking seaweed, and using a hand net. Pelagic lumpfish were sampled by pelagic fisheries and by a research survey conducted in the Faroe Islands. 391 farmed lumpfish data and samples were collected at Atlantic salmon farming sites across the Faroe Islands, during regular lumpfish health monitoring. Twenty lumpfish in the sea cages were harvested with a hand dip net from the pen edges. Finally, thirty pre-deployment lumpfish were collected from two Faroese hatcheries. At each sampling occasion, a suite of morphometric measurements and operational welfare indicators (OWIs) were recorded for every fish, e.g., body condition, fin damage, deformities, eyes integrity, skin status, liver colour and stomach content, using the method reported by Eliasen et al. (2020). Both livers and whole fish were frozen and stored at -80°. Further nutritional analyses were carried out on livers, such as total lipid content, fatty acid methyl esters (FAME), lipid classes, total carotenoids, and on whole fish and feeds, such as proximate composition, fatty acid, and amino acid profile. A subsample of ten livers, anterior and distal intestine, spleen was fixed in 10% neutral buffered formalin for posterior histopathological analysis and in RNAlater for gene expression studies. Nutritional and histological data were analysed in R version 4.1.2. A principal component analysis (PCA) was carried out to identify the variables that gives the highest variation among groups and the visualization using R packages, FactoMineR and factoextra. Linear models with fish origin as independent variable and nutritional or histological parameters as dependent variables, were used to identify the key differences between farmed, hatchery and wild lumpfish.

Results

Preliminary data analysis focused mainly on lumpfish <50 g from different origins. Both lipid and protein content of whole fish was significantly different between fish origins, with the hatchery fish having a higher amount of lipid (2.9%) and protein (8.94%) compared to the farmed and the wild ones (1.11, 1.59%; 7.6, 7.99%). PCA was carried out on fatty acid profile of livers and whole fish. The first two components (PC1 and PC2) accounted for 80.4% of the variation and the fatty acids that give the highest contribution to the variability were 18:4n-3, 18:1n-9, n-3PUFA, 22:6n-3 (DHA), and 20:5n-3 (EPA). Significant differences were found in almost all the amino acids in wild fish compared to the hatchery ones. Preliminary results of liver histological analysis shows that liver vacuolisation is lower in wild (37%) than in farmed fish (43%). Livers from farmed fish also have higher liver inflammation, fibrosis, and congestion. Proximate analyses on different lumpfish commercial feeds show a substantial variability in both protein (45 to 56 %) and lipid (12 to 17%).

(Continued on next page)

Discussion

Lumpfish deployed in the sea cages displayed a higher variability on body composition compared to the ones in the hatcheries and the wild ones. Deployed lumpfish have access to both salmon and lumpfish feeds, different seasonal preys and the salmon cages are exposed to different environmental conditions (Imsland et al., 2015). Fish from the hatcheries are reared in controlled environmental conditions (Powell et al., 2018) and have a higher amount of lipid and protein content, and this reflects the diets they get in the hatchery. Wild lumpfish show overall a lower amount of lipid and protein in their body and a different fatty acid and amino acid profile due to their natural diet.

Introduction

In aquatic animals, gut microbial communities shift with host development and living environments. Understanding the mechanism by which the environment impacts the gut microbial communities of aquatic animals is crucial for assessing and managing aquatic ecosystem health. Initially, fish embryos develop in a relatively constant bacteria-free environment (i.e., within the egg), although some environmental microbes quickly colonize the egg surface from the surrounding water after spawning. After hatching, environmental microbes colonize the gut and after the first feeding, new microbial communities are introduced into the gut with the diet, increasing microbial diversity. The gut microbiota further shifts with host development and with changes in diet. At an early stage, the gut microbiota is influenced mainly by the introduction of environmental microbes with water and diet; however, as the immune system and nutrition metabolism develop, gut microbes are selected and enriched gradually and can be altered with nutritional elements. For this reason, the research project aimed to explore the impact of novel ingredients on these gut communities using metabarcoding analysis of feed- and gut-associated microbial communities.

Materials and Methods

Feeding trial and sampling: the feeding trial was set at a recirculation aquaculture system (RAS) and the growth phase of the trial lasted for 84 days. Briefly, fish were fed with two isoenergetic and isonitrogenous experimental diets in triplicate (3 tanks/diet). A control diet containing only fish and plant proteins (CTRL), and an insect diet containing 10% of *Hermetia illuncens* meal (Hi10) were tested in rainbow trout (*Oncorhynchus mykiss*). At the end of feeding trial two fish per tank were sampled (6 fish/diet) and the whole intestine was aseptically removed. The fecal matter containing transient (allochthonous) intestinal bacteria were collected and the resident (autochthonous) microbiota was obtained by scraping the intestinal mucosa of whole gut length and excluding pyloric caeca.

Bacterial DNA extraction and sequencing: DNA was extracted from three samples per feed and six biologic samples of feces-mucosa per each dietary fish group. For the characterization of microbial communities, the V4 region of the 16S ribosomal RNA gene was amplified, using the oligonucleotides:

515F: 5′-GTGYCAGCMGCCGCGGTAA-3’ | 806R: 5′-GGACTACNVGGTWTCTAAT-3 ′

The amplicon library preparation and sequencing were carried out using an Illumina MiSeq platform and protocol (#15044223 rev. B). The raw sequencing data were analyzed with QIIME 2™ (v. 2018.4) pipeline at the default setting (*Bolyen et al*., 2018). The Silva database was used for the recognition and taxonomic classification of the sequences obtained. The taxonomical classification was performed down to the genus level. OTUs (Operational Taxonomical Unit) assigned to chloroplasts and mitochondria were removed from the analysis as of eukaryotic origin. The relative abundance (%) of each bacterial taxon was determined for every single sample (fish or feed) and for every experimental group (CTRL and Hi 10%). Starting from sequencing data processed by the QIIME pipeline the relative abundance of each OTU was calculated. Alpha (within a single sample) and beta diversity (between samples) have been performed using QIIME alpha-phylogenetic and beta-phylogenetic commands. The “observed OTUs”, “Shannon”, “Faith-PD”, and “Evenness” alpha diversity indices were calculated at the same level of rarefaction, i.e. considering the sample size with a lower number of sequences. Beta diversity was calculated using both the weighted (presence /absence/abundance) and unweighted (presence/absence) UniFrac distance matrix. The UniFrac distances between the microbial communities of the individual samples were visualized by means of two-dimensional scatter plots (PCoA).

(Continued on next page)

Results

Metabarcoding analysis of feed-associated bacteria showed that the microbial communities of CTRL feed differed from those of experimental feed Hi10. The microbial community structure for each feed was outlined at the phylum, class, order, family, and genus. The microbiome profile of all samples comprised 6 different phyla, 11 classes, 17 orders, 25 families, and 30 genera. The number of reads taxonomically classified according to SILVA database was 168,562. Six hundred and thirteen OTUs at 99% identity were identified in feed samples and classified into 134 different taxa. Good's coverage in all samples reached a value of 0.99, indicating that sequencing coverage was achieved and that the OTUs found were representative of intestinal microbial communities. To elaborate on alpha rarefaction analysis, samples were normalized at a sequencing depth of 3,900 reads. At the order level fish fed diet containing 10% of insect meal showed a significantly higher relative abundance of Bacillales (34%) in their intestinal microflora compared to the control group (1.7%). This important enrichment in Bacillales was due to an increased number of bacteria belonging mainly to Bacillaceae (22%) families in the intestine of fish fed Hi10 diet. Accordingly, at genus taxonomic level, Bacillus, Oceanobacillus, Virgibacillus, and Paenibacillus Corynebacterium were more abundant in Hi10 samples, while fish fed control diet showed higher percentage of Shigella and Shewanella genera, the last one practically absent in fish fed Hi10 diet.

Conclusions

In agreement with the majority of studies on the partial substitution of fishmeal with insect meal (*Terova et al*., 2019; *Rimoldi et al*., 2019; *Bruni et al*., 2018; *Antonopoulou et al*., 2019; *Huyben et al*., 2019), the experimental diet with 10% *Hermetia illucens* (Hi10) had an important effect in modulating the intestinal microbial communities of trout. In particular, Hi10 diet increased gut microbial richness (Observed OTUs index) and numerically the diversity (Shannon diversity index p=0.05) as compared to control fish. In general, high gut microbial richness and diversity are considered desired features because they are usually associated with the health status of the host. Based on the ratio of Firmicutes:Proteobacteria, fish fed Hi10 diet showed a dominance of Firmicutes that has been associated with dietary plant ingredients that are rich in fibers, whereas an animal protein-based diet usually favors the dominance of Proteobacteria (*Terova et al*., 2019; *Ingerslev et al*., 2014 a; 2014b). Dietary inclusion of insect meal influenced the microbial intestinal profiles of trout both qualitatively and quantitatively. Indeed, multivariate analysis of bacterial communities revealed a significant relationship between diet and microbiota associated with fish intestines.

A REGIONAL MULTI-TROPHIC AQUACULTURE ECONOMIC MODEL

G. Diaz*[a], S. Agnarsson[b], G. á Norði[c], J. Arias[b], U. Laksá[b]

E-mail: gerdiazb@gmail.com

In the past decades integrated multi-trophic aquaculture (IMTA) systems have been studied in several countries, potentially posing a more sustainable alternative to traditional mono-culture aquaculture. IMTA production systems involve species from different trophic levels, where the dissolved and particulate effluent produced by one species can be partially reduced through the cultivation of extracting species, such as filter feeders and seaweed (Neori *et al*., 2007). However, the many challenges related to the production of multiple species in the same operation have hampered implementation by the finfish producing industry.

Finfish farming typically occurs in arrays of suspended net pens with free water exchange ensuring the supply of oxygenated water and waste removal from the pens. The farming operations are complex, relying heavily on service ships for stocking, harvesting, cage assembly and maintenance. This means that installing structures for seaweed or shellfish adjacent to the net pens, would represent an obstacle for the day-to-day functioning of the fish farm. Additionally, regulatory constraints do not permit the installation of IMTA in relevant salmon producing countries, such as Norway. Whereas in Chile, economic considerations have hindered the adoption of IMTAs at a commercial scale (Buschmann *et al*., 2009; Ellis & Tiller, 2019).

To advance the implementation of IMTA the concept should be considered on a regional level instead of farm level (Chopin, 2017, Ellis & Tiller, 2019, Sanz-Lazaro & Sanchez-Jerez, 2020). An integrated coastal area management (ICAM) approach was proposed by Chopin (2017), with several strategies to recover nutrients. This could help untangling some of the complexities of operating IMTAs, potentially increasing adoption from the industry.

The aquaculture industry of the Faroe Islands is largely dominated by the production of Atlantic salmon (*Salmo salar*) but in the last decade, sugar kelp (*Saccharina latissima*) has been farmed in the fjords of the Archipelago. Studies carried out in the EU H2020 AquaVitae project, investigating the direct assimilation of fish farm waste by blue mussels at a commercial fish farm have shown limited effect (á Norði, 2022). However, an ICAM approach to multitrophic aquaculture can potentially limit the accumulation of dissolved and particulate effluent in the fjord, thus increasing the interest from the industry on adopting this novel strategy. Multi-trophic aquaculture economic performance is usually contrasted with monoculture, for increased acceptance, it must appear profitable (Lance et al., 2017).

Economic analyses have been developed for similar models in Canada (Carras *et al*., 2020), but financial performance and markets vary greatly between countries. The aim of this paper is to advance the knowledge on the economic feasibility of producing three ecosystem-balancing species at different trophic levels in a regional environment by introducing an economic model based on three species; the already established aquaculture operations of salmon and sugar kelp in the Faroe Islands, as well as the cultivation of blue mussels *(Mytilus edulis)*, as filter feeders to complete the system. In the Faroe Islands, the potential for establishing multi-trophic aquaculture has increased with the recent changes to aquaculture legislation which now allow farming of multiple species in the same fjord. Therefore, the model applied to the Faroese context can provide important insights to support the adoption of multi-trophic aquaculture in larger salmon-producing countries, such as Norway and Chile.

The value-chain model employed to assess the economic feasibility will take into account commercialisation and market dynamics. Profitability will be estimated using net present value and market appraisal, and the analysis will also include sensitivity analysis and risk assessment.

TECHNOLOGICAL SOLUTIONS FOR REDUCING MICRO- AND MACRO- PLASTIC FROM FISH FARMING

Hanne Digre*[ab] and Torstein Kristensen[ac]

[a] Scale Aquaculture AS
[b] The Norwegian University of Science and Technology
[C] Nord University

Introduction

Plastic is extensively used in aquaculture. Its strength, durability, flexibility, tensile and waterproof properties, in addition to the low cost of this material, make plastic optimal for diverse applications in the industry. However, Scale Aquaculture, as a technological supplier, recognise that marine litter, and especially plastic pollution, is a major environmental problem. It is important for us to work with reducing emissions of plastic in nature and increasing the recycling of our products.

In the aquaculture industry there are about 192,000 tonnes of plastic in use in sea-based aquaculture in Norway. About 16,000-29,000 tonnes of this amount is plastic waste annually (Hognes and Skaar, 2017). There is a need to increase the recycling rate of the plastic equipment and derive the most value from resources during their lifetime Additionally, the Directive (EU) 2019/904 on the reduction of the impact of certain plastic products on the environment includes i.a. requirements for producer responsibility schemes for certain plastic products, including equipment from fisheries and aquaculture industry. The directive requires equipment suppliers to have solutions for collection, reuse and recycling of plastic equipment.

Lost equipment as consequence of storms, wear and tear of plastic materials used in off-shore farms generate large amounts of plastic waste to the surrounding regions of the farm (Lusher et al., 2017). Plastic waste from fish farming has been found along the Norwegian coast. Ropes were the major polluting materials, but parts of other plastic equipment such as feeding pipes, walkways, and floating collars were also found (Vangelsten et al., 2019). In addition, weathering of plastic equipment at the fish farms can release microplastics and contribute, to another extent, to the microplastic pollution in the marine environment. Recent studies have estimated the amount of microplastics released from materials used in fish farming. In 2020, a study assessed the abrasion of feeding pipes caused by the fish feed pellets to analyse the amount of microplastics released (Gomiero et al., 2020). Results showed that aged and curved pipes had higher abrasion rates compared to new and straight pipes. Aged pipes released 2 to 3 times more microplastics than new pipes. In average, abrasion of the feeding pipes was estimated to release 0.24 g of microplastics per meter of feeding pipe and per day. Some reports estimate that up to 200 tons of microplastics per year are release from feeding pipes (Vangelsten et al., 2019).

Small microplastics (< 50 µm) can affect marine organisms like reduced food intake, delayed growth, and decreased efficiency of the immune system of the organisms affected (Abihssira-García et al., 2020). As for other equipment used in fish farming, there is no detailed information about degradation rates or microplastic release as far as we know. Though, it has been roughly estimated that the degradation rates of plastic in the Norwegian marine environment is less than 0.5% per year (Booth et al., 2017).

We will present the work that Scale Aquaculture is doing regards to reduce emissions of plastic in nature from fish farms both regards to micro- and macro-plastic. We will give examples on possible technological solutions. Results from an ongoing project called Circular plastic products for sustainable aquaculture ("SPARE") will also be presented.

Results

The main objective of the project "SPARE" is to increase the proportion of recycled plastic in several of our products used in the aquaculture industry. In 2021, we mapped out the material flows of plastics in the company's value chain, all the way to post-use in the fish farm and subsequent recycling. Our estimates show that we currently recycle around 42% of our plastic equipment, an amount we want to increase. As an extension of this study, we conducted a pilot project where we collect one discarded floating collar and produced 17 tons of recycled plastic pellets. After grinding and extrusion, the re-granulated was analysed and characterized to find the most suitable area of application. Relevant analysis like strength calculations, durability, tensile strength was carried out. We are now using these recycled plastic pellets to produce new plastic-based equipment for the aquaculture industry. Testing and documentation of full-scale pilot installation of selected products made from recycled material is now being carried out.

(Continued on next page)

In the aquaculture industry, air-based feeding is typically used, but during the last years water-based feeding is becoming more common. Water-based feeding systems represent a key solution for the reduction of microplastic emissions. At the end of 2021, we developed and launched our new barge with subsea/ water-based feeding technology. After testing subsea/ water feeding through pilots in both Tasmania and Norway, we experienced promising results on several parameters such as no microplastic emissions, less noise, reduced energy consumption and increased feeding capacity.

A more detailed presentations of the results will be given.

Introduction

During the past 50 years, mariculture has become one of the most productive industries worldwide. The most known effect of a typical aquaculture is the releasing of dissolved nutrients and particulate organic matter in the water column as well as sediment organic enrichment causing biological and geochemical changes. Integrated multitrophic aquaculture (IMTA) has been suggested as an innovative method that ensures sustainable development in agreement with the EU directions for Blue Growth and Blue Economy. It is defined as the cultivation of two or more aquatic species from different trophic levels in the same area in order to mimic the energy flow in natural ecosystems (Chopin et al., 2004). IMTA organisms may include bivalves and echinoderms that consume phytoplankton and particulate organic matter. In this study, the Mediterranean mussel (*Mytilus galloprovincialis)* and rayed pearl oyster (*Pictada imbricata radiata*) were co-cultured with fish (*Sparus aurata*). Mediterranean mussels and pearl oysters are filter-feeding organisms that feed on phytoplankton and selected particles retained after filtering the water column (Bayne, 2002). The primary objective of this study was to develop IMTA methodology suitable for use in the oligotrophic eastern Mediterranean focusing on the survival, robustness, and growth of the above mentioned species. The results can be used as a basis for setting up large scale commercial IMTA systems in Greece.

Materials and Methods

The IMTA trials were implemented in three different fish farms in the Aegean Sea with similar cultivation methods, but different eutrophic conditions. Characterisation was based on Eutrophic Index (Primpas et al., 2010). The first aquaculture farm (Aq1) was characterized as higher mesotrophic, the second farm (Aq2) as lower mesotrophic and the third (AQ3) as oligotrophic. The same IMTA cultivation method was applied in all farms.

For IMTA mussel cultivation, the traditional longline technique was used: Mussel seed (spat) was collected by hand either from hard surfaces within the farm area and put in longlines which were then submerged around the middle cage in the centre of each fish farm. The cultivation period was nine months, which is when they reached marketable size (5–6 cm) from an initial 1.5 ± 0.5 cm. Mediterranean mussels were not placed in Aq3 as they were not locally available. To estimate the growth of the mussels, 30 individuals were randomly selected from different parts of the longline and were measured on October, February, May, and June (2020-21) for total weight, as well as shell and flesh morphometrics. The measurements were used to calculate the Condition Index, Specific Growth Rate and Meat Yield (MY) (Theodorou et al., 2021). To determine Mediterranean mussel growth, our data from IMTA-mussels were compared with data from Keskin and Ekici (2021), who provide data from typical mussel farms in eastern Mediterranean.

Pearl oysters were cultivated in baskets fabricated by SEAPA© for oyster growers. Spat was again collected from natural populations in the vicinity of each fish farm. Before putting them in the IMTA system, the pearl oysters were divided into three different size classes (40 in each class) and placed in separate baskets with holes of increasing diameter. Oyster baskets were deployed around the middle fish cage in the centre of each fish farm at a depth of 3 metres for 9 months in total in all three farms. All measurements and metrics taken for mussels were also taken for pearl oysters. CI and MY data was used from Theodorou et al. (2021) to compare IMTA growth to natural populations (since pearl oyster cultivation is not yet allowed in Greece).

(Continued on next page)

Results

In Aq1, which had the highest eutrophic conditions mussels grew with an SGR of 0.4% per day to a 21.2 g. In Aq2 the grew with an SGR of 1.3% to 16 g over the 9 month period. Additionally, the CI was 42% and MY 19% in Aq1 while CI was 33% and MY 35% in Aq2. Based on the bibliographic data the CI of typical mussel farm was 35% and the MY 10%. CI comparison between the two farms showed that Aq1 had a significantly higher CI in February, May and June (ANOVA $F = 38.408$, $p<0.05$).

Pearl oysters also showed positive SGR in all the study sites. In Aq1 the SGR was 0.7% per day, in Aq2 it reached 0.9% per day, and in the most oligotrophic Aq3, it was found to be 0.4 per day. Within 9 months, in Aq1, pearl oysters grew from 6.6 g to 39.5 g, in Aq2 from 4.4 g to 48.9 g, and in Aq3 from 7.2 g to 25.5 g. CI was 53% in Aq1, 56% in Aq2, and 19% in Aq3. Bibliographic data showed that the CI of natural populations was 30% to 45%. MY was 26% for Aq1, 33% for Aq2 and 27% for Aq3, while natural MY ranged from 20 to 31%.

Discussion

The first IMTA bivalve pilot cultivation in the eastern Mediterranean was successful. The Mediterranean mussel was able to successfully grow in IMTA conditions, but not in all waters; the Mediterranean mussels have not colonized oligotrophic waters being unable to assimilate adequate food resources to ensure the survival of their population. The pearl oysters, on the other hand, is a species highly suitable for IMTA cultivation because it can grow successfully in environments with very different trophic statuses. The culture methodology applied in an IMTA system is similar to techniques used in traditional monoculture bivalve culture. This is very important since cultivation equipment and know-how is already available to fish farmers and can be easily applied.

Comparing the values of CI and MY, the IMTA mussels had higher CI and MY than reported values for traditionally farmed mussels from the North Aegean. These results indicate that when Mediterranean mussels grow in proximity to multiculture farms, they have more flesh in their shell in comparison to those growing in a typical mussel farm. As opposed to Mediterranean mussels, oysters were successfully cultivated in all locations: they grew properly at commercial size at all sites with all types of trophic conditions despite their high requirements for phytoplankton biomass. However, they they exhibited a different growth rate. They reached commercial size (5–6 cm) within a few months in Aq1 and Aq2, but in the oligotrophic aquaculture (Aq3) they needed nearly a year. In conclusion, IMTA is a dynamic system that can be adapted to the conditions prevailing in each region. Depending on the water variables, IMTA may involve cultivating different types of organisms near the fish cages.

Introduction

Traditionally, farmed Atlantic salmon stay in open net-pens throughout their sea-cage production cycle. Farmed salmonids are more frequently exposed to stressful events, such as poor environmental conditions and farm operations (e.g., sea lice treatment, splitting), which could deteriorate the well-being of fish. Poor welfare can result in low growth rate, immunosuppression, and high mortality in farmed salmon (Oliveira et al., 2021). Therefore, assessing the severity of stressors helps not only to prevent fish from poor welfare conditions, but also to improve farm operations. Plasma cortisol (PC) level is widely used as the acute stress indicator, since it increases significantly in response to different physical, chemical, and biological stressors. PC levels start to increase several minutes after fish are subjected to a stressor. Fish were sampled with large dip nets or with nets weighted bottom ropes from under commercial production cages. Capture effects are hardly avoided, and the baseline level of PC is more difficult to estimate, since fish may stay in stressful situations for several minutes before they can be anesthetized, and blood samples can be taken. Other matrices for cortisol measurements are being developed, to minimize interference from sampling procedures themselves and extend valid sampling time of using cortisol level as a stress indicator in the aquaculture industry. Based on cortisol metabolic pathway, fecal corticoid metabolites (FCMs) to monitor stress level of fish with less interference from sampling procedures is currently under development. We aim to compare PC and FCM under stress situations and the effect of sampling procedures on PC and FCM levels. We hypothesize that FCM level is in correlation with PC level and that sampling itself has less effect on FCMs level than on PC level.

Materials and methods

The experiment was conducted at the Industrial and Aquatic Laboratory (ILAB) in Bergen, Norway. After two weeks of acclimation, the salmon started its parr-smolt transformation, which was used as the stressor in this experiment. To measure cortisol stress response to the parr-smolt transformation, fish were sampled before (C1), during (S1), one week (S2) and five weeks (C2) after transfer to seawater. 18 fish were sampled from three replicate tanks. Three fish were sampled each time, and the time interval between each sampling being around 40 minutes. Blood samples were collected from the caudal vein using EDTA (ethylenediaminetetraacetic acid) vacutainers (VACUETTE® TUBE, Greiner bio-one, Austria), centrifuged for 10 min at 3040 g, and plasma was removed and stored at −80 °C until cortisol analysis. Intestinal contents were collected as feces samples in this experiment to ensure enough material for analysis. Samples were stored at −80 °C until analysis. Cortisol concentration in plasma and FCM level were measured by using a commercial EIA kit (Cortisol ELISA KIT; Neogen® Corporation, KY, USA). Data analysis was conducted in R software™ version 4.0.4. A *p*-value below 0.05 was considered statistically significant.

Results

Statistically significant increases were found between C1 and S1, C1 and S2 for both PC and FCM. For FCM. There was a significant decrease of FCM level from S1 to S2, and no statically significant difference was found between S2 and C2. The level of PC in S2 was lower than S1 ($P > 0.05$) and significantly higher than C2. No differences were found between C1 and C2 for both PC and FCM. Sampling time and stressor had statistically significant effects on both PC and FCM level. Although cortisol levels of the second sampling point were higher than the ones of the first sampling point in all samples, statistically significant differences between two sampling points were found in the C2 group for both PC and FCM, and in the C1 group only for FCM. Significantly positive correlations were identified between plasma cortisol and FCM (Spearman's $p < 0.05$) in all samples.

(Continued on next page)

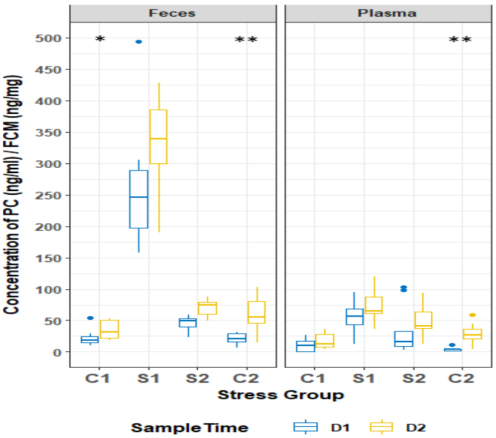

Figure 1.Concentration of PC and FCM in four sampling groups, each sampling group has two sampling time points. Asterisks indicate the degree of significance (: p <= 0.05, **: p <= 0.01) as assessed by Wilcoxon test.*

Discussion

The observation of changes in PC during parr-smolt transformation is in accordance with the regular patterns of cortisol responses in Atlantic salmon. The PC level usually stays elevated during and after parr-smolt transformation and only declines to the baseline level after the fish has stayed in sea water for about one month (Sundell et al., 2003). The 40 minutes interval between two sampling points could explain the significant increase of PC by the second sampling points. Normally, the concentration PC in Atlantic salmon reaches peak levels around 30 mins after an acute stress exposure (Fast et al., 2008). More stable values of FCM between two sampling points were expected. Because radiometabolism studies in domestic livestock demonstrated that there is a time lag between provoking stress responses and FCM, which is related to the gut passage time(Palme et al., 1996). In this experiment, the contents were collected from mid and distal intestine and fish is relatively small (wet weight around was 44.3 grams in the C1), which could shorter the time lag. Further study of the time course and FCM dynamics in the Atlantic salmon post stress exposure are essential to evaluate stress events and farm operations in aquaculture industry. To be noted, two control groups (C1 and C2) without stressors had higher increase-rates between two sampling points than their stressful groups for both PC and FCM. These findings together with recent studies, indicate that conducting a novel acute stress challenge to the fish can differentiate whether fish is chronically stressed. Significant correlation between PC and FCM were demonstrated in all samples, which indicates FCM could be used an alternative matrix to PC for measuring cortisol acute stress responses in Atlantic salmon. The results draw researchers' attention to the importance of standard sampling procedures and experimental designs to the robust and repeatable results

Introduction

The culture of rotifers (*Brachionus plicatillis*) is essential for successful marine larviculture, since altricial larvae require live feed during the first developmental stages. Despite the fact that rotifers are cultured for decades, its cultivation still presents relevant challenges. Rotifers full nutritional requirements and metabolism are still poorly understood, which difficults the dietary optimization of this cryptic species. Rotifers are microalgae grazers and *Nannochloropsis oceanica* is particularly successful for feeding *Brachionus plicatilis*. The expansion of aquaculture is rapidly leading to the reduction of labour intensive and costly activities such as microalgae production. The substitution of live microalgae to industrially produced microalgae products is the solution for this challenge. Within the available microalgae products (paste, powder, liquid concentrate), the liquid concentrates have become popular due to their easy usage, since they do not require *in situ* daily preparation steps (e.g. hydration, blending). Most of the commercially available microalgae products require improvements for aquaculture specific applications, such as the nutrition of rotifers. Some of the most relevant challenges in industrially produced *Nannochloropsis* sp. are agglomeration, decantation and bacterial load. The bacterial load can have negative impacts not only on rotifers culture but also larviculture (Turgay et al., 2020), particularly in species with susceptible larval stages. The objective of this work was to develop a premium microalgae diet for rotifers nutrition, with improved microbiological quality and rotifers growth efficiency.

Material and methods

The production of Phytobloom© ELITE formula (ELITE), *Nannochloropsis oceanica* liquid concentrate, was performed with an improved saline diluent (200ppt) to achieve 18% of dry weight. For this premium product a selection criterion of the batches of industrially produced microalgae according to bacteria load was applied. The comparison of the quality and efficiency of ELITE (n=2 batches) was performed in comparison with two microalgae commercial diets (CP1 and CP2) (1 batch of each product) commonly used in rotifers nutrition. Products quality was analysed according to the total bacteria detected through PCA, TSA and TCBS media, presence of ammonium, nitrates, pigments (chlorophyl a and total carotenoids) and microalgae agglomerates presence and dimension. All products were used in rotifers culture under batch (4 days) production system (ELITE n=13, CP1 n=40, CP2 n=4). Rotifers were cultured in cylindroconical tanks (1.2m^3), with oxygen injection and aeration with an initial concentration of 500 rotifers/ml. The water quality was daily monitored and maintained at 28ºC, pH 7.5-8, ammonia below 1mg/L. The dosage of ELITE in the first day was 3.2ml of product per million of rotifers and 2.5ml per million of rotifers in the remaining days. The recommended feeding protocol of the commercial products was applied in the culture. Rotifers concentration and percentage of rotifers with eggs were evaluated daily.

Results and Discussion

ELITE is a new formula product presented significantly lower total bacteria content in comparison to the other rotifers diets (Figure 1A). The use of an optimized saline diluent promoted a reduction of the microalgae agglomeration and dimension of the microalgae agglomerates (Figure 1B). The new productELITE significantly improved rotifers growth under batch system in comparison to the two commercial products tested (Figure 1C).

The reduction of the number and size of the particles in the water column can promote the reduction of the microalgae decantation, thus improving particle suspension on the water column. These characteristics lead to an increase of the availability of microalgae for rotifers nutrition, reduces waste formation and toxic ammonia accumulation in the tanks. The reduction of the bacteria load in the product through the new saline diluent used in the liquid concentrate, along with the selection of batches with lower microbial loads allowed the improvement of the new product microbiological quality. Altogether, these characteristics promoted significant improvements on rotifers growth performance when compared to the other tested commercial products. In conclusion, the new premium diet ELITE developed for rotifers nutrition successfully improved rotifers production under batch production mode in comparison to other commercial diets commonly used in rotifers culture.

(Continued on next page)

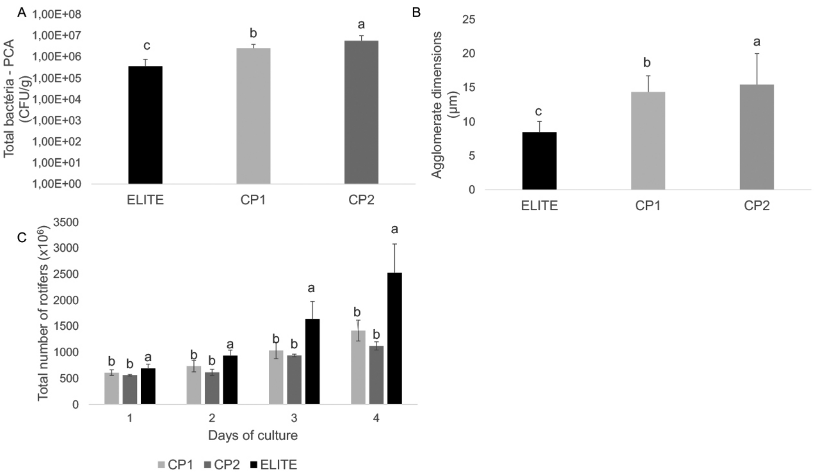

Fig 1 – Rotifers new diet ELITE and commercial diet 1 and 2 (CP1 and CP2) quality characterization: A) Products total bacteria analyzed through PCA media, B) Microalgae agglomerates dimensions and C) Total number of rotifers produced per day of batch. Data is expressed as means and standard deviation and significant differences between treatments are represented by different letters (One-way ANOVA, post hoc Tuckey, $p<0.05$).

Introduction

Perch rhabdovirus (PRV) can lead to high mortality in European perch (*Perca fluviatilis*) and pikeperch (*Sander lucioperca*). Larvae and juveniles are mostly affected. Typical clinical signs are spiral swimming movements and, later in the disease course, cachexia due to emaciation. Driven by intensive fish trade, different variants of PRV are currently circulating in European percid aquaculture.

PRV belongs to the *Perhabdovirus* genus. The perhabdovirus genome is made of a linear, negative-sense, single-stranded RNA, which codes for 5 proteins. Differences in the nucleoprotein (N) and phosphoprotein (P) genes are used to differentiate genetically close viruses (Bigarré et al. 2017). A total of four PRV infections in pikeperch and European perch are described in this report.

Material & methods

The first submission involved an import of pikeperch from France that was routinely examined after arrival in the quarantine. The second case concerned pikeperch from the same facility as the first submission, which were analysed due to clinical symptoms and low mortality. In the third investigation, a pikeperch spawner from another facility was sent for routine inspection. Finally, in the fourth case, European perch were sent for diagnostics due to clinical symptoms and increased mortality.

All animals were subjected to pathological examination and tested for the presence of PRV using conventional RT-PCR (Pallandre et al. 2020) followed by sequencing. For phylogenetic analysis, the total RNAs were sent to the laboratory of Ploufragan-Plouzané-Niort, ANSES, Plouzané, France. A new nested PCR-based method was used to amplify and sequence the complete N and P genes (Pallandre et al. 2022).

Results

Using a range of cPCR, PRV was detected in all four groups. Interestingly, the pikeperch that were examined for control purposes after importation, as well as the spawner, showed no clinical signs of PRV infection. The pikeperch sent for diagnostics due to low mortality presented few symptoms such as spiral swimming movements and lethargy. However, the animals recovered after few days and no further mortality occurred. In contrast, the European perch showed severe clinical signs, particularly spiral swimming, and high mortality. These animals were euthanized for welfare reasons.

The viruses from the asymptomatic pikeperch (quarantine, spawner) were almost identical to another virus isolated in Belgium in 2016. The virus from the pikeperch presenting low clinical symptoms was more closely related to a subgroup of viruses of different origins (France and Belgium). The rhabdoviruses found in the diseased European perch were more closely related to a subgroup of viruses isolated in France.

Discussion

This study shows that PRV is more widespread in percid aquaculture than previously assumed. The pikeperch examined in this study showed significantly less clinical symptoms than the European perch. However, the virus was also detectable in these clinically mostly inconspicuous pikeperch. The viruses detected in this study in the pikeperch cluster together with PRVs found previously in pikeperch. The viruses found by the European perch are also related to other isolates from European perch. However, all viruses documented in this report seem different from the rhabdovirus isolated in Switzerland in 2013 and the Egli virus detected in a Swiss aquaculture in 2017.

Systematic phylogenetic studies will help in future to obtain more information on epidemiology of the virus and thus optimise control mechanisms to prevent further spread of the disease.

SUPPLEMENTATION OF COMMERCIAL FEED WITH VITAMINS AND IMMUNOSTIMULANTS TO INCREASE IMMUNITY OF EUROPEAN PERCH (*Perca fluviatilis*) AND AVOID SECONDARY INFECTIONS AFTER STRESS SITUATIONS

N. Diserens[1]*, B. von Siebenthal[2], H. Schmidt-Posthaus[1]

[1] Institute for Fish and Wildlife Health, University of Bern, Länggassstrasse 122, CH-3012 Bern (Switzerland)
[2] Valperca SA, succursale Percitech, Le Grand Pâquier, CH-1373 Chavornay (Switzerland)
E-mail: nicolas.diserens@vetsuisse.unibe.ch

Introduction

European perch (*Perca fluviatilis*) is a native fish species, which is highly appreciated for its meat in Switzerland. However, most of the perch consumed in Switzerland originates from wild populations in Eastern Europe. To reduce (over)fishing and to increase the amount of locally produced aquaculture fish, the company Valperca SA started production of perch in 2007. The company is a pioneer in Swiss perch production and even worldwide. Perch aquaculture is still a relatively new branch of production. Consequently, knowledge about this fish species' needs under production conditions is still limited, including knowledge about stress-related secondary diseases. Currently, increased stress-induced vulnerability and subsequently increased disease susceptibility or even mortality due to secondary bacterial infections after transport or fish grading is one of the main concerns in perch production.

Aquavac Ergosan® is made of two brown seaweed species, *Laminaria digitate* and *Ascophyllum nodosum*. Many in vitro and in vivo studies (on various species, particularly salmonids and sturgeons) have shown the benefits of Ergosan® on fish growth, survival rate, immunity and broodstock performance. Vitamins, especially vitamin A, D, E & C, are also known as immunoregulators and immunostimulants, tested in farm animals, inclusive aquaculture animals (e.g. salmonids, cyprinids, tilapia). Both, the use of Aquavac Ergosan® and of the abovementioned vitamins have not yet been tested on perch. Immunostimulation is especially important during stress conditions, like shortly before, during and after transport, vaccination or grading of fish. At these time points, perch are especially vulnerable to bacterial infections with *Flavobacterium* sp. causing disease and mortality.

Material & methods

Perch (*Perca fluviatilis*) of 10g (approximately 100 days post hatching) will be bath challenged with *Flavobacterium columnare*. The bacterial strain used originates from a previous disease outbreak in a warm water recirculating system. The amount of bacteria required for this challenge will be determined in a preliminary pilot trial performed on a reduced number of fish (six groups of 25 fish each). In order to be able to differentiate effects of the different feed supplements, the infection should cause low to moderate mortality (approximatively 25%) in the infected groups.

The main trial will include four groups:

- Group 1: Feeding with commercial feed without supplementation (control group)
- Group 2: Feeding with commercial feed supplemented with Aquavac Ergosan®
- Group 3: Feeding with commercial feed supplemented with vitamins A, D, E & C
- Group 4: Feeding with commercial feed supplemented with Aquavac Ergosan® and vitamins A, D, E & C

All groups will be exposed to two different treatments in triplicates of 27 fish each:

- Treatment 1: The fish will be netted and subjected to two times 30s out of the water to simulate husbandry related stress (mechanical stressor).
- Treatment 2: The fish will be netted and subjected to two times 30s out of the water to simulate husbandry related stress (mechanical stressor), followed by infection by immersion with *Flavobacterium columnare*.

Mortality, clinical symptoms, histopathology and differences in expression of immune response parameters (interleukin-1β, interleukin-8 and tumor necrosis factor α 2) will be assessed.

The aim of the study will be to compare the benefit of supplementation of commercial feed with (1) Aquavac Ergosan®, and (2) with vitamins A, C, D and E to increase immune capacity of aquaculture perch. Boosting fish immune system should reduce secondary bacterial infection after husbandry related stress conditions.

BIOTECHNOLOGICAL POTENTIAL OF MICROALGAE AND PROBIOTIC STRAINS IN A CO-CULTIVATING SYSTEM

Introduction

The divergence of microalgae species is a rich source of many different metabolites with bioactivity. Many of the compounds extracted from microalgae biomass show beneficial effects on health. Recently, co-cultivation of microalgae and bacteria have emerged as a promising solution that can enhance synthesis of active compounds and induce it with new compounds not specific to the monoculture. Rich sources of nutrients like probiotics and microalgae biomass serve as beneficial food supplementation as their influence on diets is the focus of scientists. These microorganisms and their extracts have great potential to boost health and improve one's well-being. Algae are considered as prebiotics and most studies implement them as enhancers to the probiotics performance. However, a different focus to switch their roles in co-cultivation is approached. Several studies have shown that the addition of algae, along with probiotics, can influence the microbiota, and improve gut health and overall yield in fish and shrimp aquaculture. This research focused on further enhancing their benefits by combining them in a co-culture manner which showed promising results.

Materials and methods

The co-cultivation system was established with microalgae *Chlorella vulgaris* and the probiotic species *Lactobacillus plantarum*.Optimization of the inoculum ratio was done in 24-well plates which served as a base for further „scale-up“. The „scale-up“ of the co-culture system was performed in flasks for 5 days as batch cultivation with Tryptic soy broth as medium. The flasks were shaken on an orbital agitator at 125 rpm and were illuminated with warm white LED lights (2700K). To determine the bioactivity of their co-culture co-existence, a range of biological assays were performed. These analyses were performed on the biomass of the monocultures and that of the co-culture. The lipid composition was analyzed by fluorescent microscopy using Nile Red staining method. Pigment composition such as chlorophylls, pheophytins and total carotenoids of *C. vulgaris* in the monoculture was compared with the composition in the co-culture system. The potential toxicity of tested samples was determined by conducting a zebrafish *Danio rerio* embryotoxicity test (OECD 236, 2013). Metabolite products synthesized in the monoculture as well as in the co-culture biomass were analysed using quadrupole time-of-flight (q-TOF) mass spectrometry revealing the production of new compounds.

Results

Optimization of the inoculum ratio showed that the best ratio was in favor of the microalgae *C. vulgaris* with a cell number of 10^7 cells/mL while the cell number of *L. plantarum* was 10^5 CFU. Nile red staining revealed that the growth conditions were not stressful for the microbes in the co-culture (Figure 1). Chlorophyll a, b and total carotenoid compounds increased in their value through the cultivation of the monoculture and decreased in the *C. vulgaris* co-culture(Figure 2). Evaluation of the embryotoxicity of *C. vulgaris* in zebrafish *D. rerio* showed no negative impact on survival and development below the concentration of 0.025 mg/mL for *C. vulgaris*. For the monoculture of *L. plantarum* as well as the co-culture, no toxicity was obeserved at concentrations below 6.25 µg/mL. Q-TOF analysis revealed the presence of molecules with already proven antihypercholesterolemic and antiobesity activities.

Discussion

From the results shown in the previous section we can conclude that the coexistence of *C. vulgaris* and *L. plantarum* in the same medium, as well as the co-cultivation conditions, were optimal and enhanced bioactive compound synthesis. Furthermore, the co-culture system was succesfully „Scaled up“ and the parameters used for this research were not stressful for the co-culture. It should be noted that Q-TOF analysis showed many bioactive metabolites which could be essential for a balanced diet. These positive bioactive potentials and comprehensive analysis serve as a base for further implementation of the co-cultured biomass into aquaculture systems.

AQUAVIP (AQUACULTURE VIRTUAL CAREER DEVELOPMENT PLATFORM FOR THE SOUTH BALTIC REGION) SUCCESS AND FURTHER POTENTIAL

B. Dmochowska*, A. Bischoff-Lang, H. Łądkowska, N. Nika, A. Sutnikas

AquaVIP INTERREG SB project, communication: University of Gdańsk
Bażyńskiego 8, Gdańsk, 80-309, (Poland)
Email: b.dmochowska@ug.edu.pl

Introduction

After almost three years of carrying out AquaVIP – Aquaculture Virtual Career Development Platform for the South Baltic Region project, led by Klaipeda Science and Technology Park, accompanied by University of Rostock, University of Gdańsk and Klaipeda University, the partners and stakeholders along the aquaculture value chain share a great success in fostering human resources capacity through cross-border training and networking to meet the objective and boost aquaculture labor market within the South Baltic region. Recognizing the significant demand for aquaculture professionals and a need for progress in innovative technologies in the South Baltic Region AquaVIP project focused mainly on: investigating best practices, testing innovative methods and tools, exchanging knowledge and experience related to human resource capacities for the aquaculture sector, training students and professionals in innovative aquaculture methods, cooperation and networking with organizations pursuing the same mission, and promotion of sustainable and innovative solutions.

Materials and methods

AquaVIP project offers have been carried out through four pillar services, namely: AquaVIP experiments, AquaYouth, AquaProfi, and AquaTION.

AquaVIP experiments performed in partners' facilities foreseen as core activities for the training and networking included research on: recirculating aquaculture systems (RAS), artificial feed chains, aquaponics, microalgae, *Litopenaeus vannamei*, native Baltic Sea shrimps, technology optimization, new shrimp tower concept, brackish conditions in freshwater fish RAS, geothermal brine, and *Daphnia* sp. as feed for fish, and provided results crucial for academic and professional trainings, as well as aquaculture business consulting development.

To deliver crucial academic and hands-on-experience training of students and young professionals AquaYouth – "Aquaculture Youth career development" service has been developed, including summer schools on innovative aquaculture technologies such as recirculating aquaculture systems, aquaponics, and integrated systems, carried out at the University of Gdansk and the Klaipeda University. Certified AquaVIP summer schools introduced participants from the region but also from all over the world to background theoretical skills in modern aquaculture biotechnology: main types, biological and technological processes and development trends as well as practical hands-on experience on modern aquaculture technology and innovative blue biotechnology-based approaches. They were based on real ongoing AquaVIP experiments in research facilities, and partner aquaculture companies, and included students' panels and virtual visits to innovative aquaculture facilities, with farms and jobs presentations. AquaYouth service also included study visits in AquaVIP facilities (Klaipeda University and Klaipeda Science and Technology Park) which gave students and researchers a unique opportunity to have an insight into practical aspects of working with large-scale experimental shrimp and fish farms, to share professional knowledge and experience, and find aquaculture themes for further cooperation.

Noticing the necessity to support business performance and development across the modern aquaculture and seafood industry, appropriate trainings and competence building has been offered through the AquaProfi - "Aquaculture Professionals' success support" service. The Master FishFarmer Class (MFFC), a core service activity, with over one hundred forty registered participants focused on the AquaProfi community by inviting professionals and young talents from the South Baltic region. The aim of this exceptional online course, which was based at Rostock University, was dedicated on the one hand for fish farmers aiming at becoming master fish farmers, but also for aquaculture professionals who are looking for further training opportunities. The complete Master FishFarmer Class contained six different topics: RAS technology, larviculture, fish diseases & parasites, algae production, aquafeeds & nutrient requirements & feed additives, aquaculture business & marketing & product development. A seven-months course with each topic lasting approximately for one month, with four online lectures per topic, allowed interested parties to participate in addition to their regular job and gain a certification by passing a final exam and fulfilling course requirements. MFFC gave access to a wide

(Continued on next page)

spectrum of knowledge and up-to-date-information, provided by our experts, possibility to observe and evaluate familiar processes from a broader perspective, thus developing the professional career, and multiple networking opportunities. The certification was awarded to almost sixty participants from eleven different countries. AquaProfi also included onsite and virtual study visits to innovative aquaculture sites in Germany, Poland and Lithuania. What is more AquaProfi networking activities led to the development of Aquaculture Career Portal, a Linkedin group, launched to share information on courses, exhibitions, study visits, summer schools etc., post jobs and internships offers, look for job and internships possibilities, find partners for your project, business, and more.

AquaTION – "Aquaculture innovation – boosting education and business capacity" is yet a final project deliverable, an e-learning platform which will be developed on the basis of state-of-the-art knowledge and experimental and training activities of the AquaVIP project. To sum up project achievements AquaTION will offer training in skills related to innovative and sustainable aquaculture, crucial for the future employees in the aquaculture sector of the South Baltic area. The aim of the platform is to expand and promote further aquaculture as a blue and green economy sector among employers and employees already active in the labor market, willing to improve their skills, as well as aquaculture students willing to make a career in the aquaculture market in the South Baltic area.

Results

Through its research, educational and promotional activities the AquaVIP project has already resulted in the success stories, and provided a solid base for strengthening aquaculture programs in the universities, provide hands-on-experience for academic communities and create conditions for changes in the labor market. The project has already resulted in two certified aquaculture summer schools, with materials and presentations available on the project website (www.aquavip.edu.pl), where also experiments descriptions, virtual farm visits, videos on good practices, and other educational materials are available. A six-module certified Master FishFarmer Class is another project success, still to be available on AquaTION e-learning platform. Vivid Aquaculture Career Portal offering up-to-date-information and aquaculture job postings guarantees further networking cooperation among partners and stakeholders, strengthened by the development of Aquaculture Competence Centre in Klaipeda, with the plan to extend its activities on the whole of the South Baltic region to bring benefits to aquaculture and related fields students, future employees willing to make a career in the aquaculture market in the South Baltic area, employees and entrepreneurs of micro or SMEs willing to improve their skills, farmers associations, NGOs, authorities interested in improving their skills and sustainable aquaculture development, businesses in the region and society in general.

MINERAL AND VITAMIN NUTRITION IN GILTHEAD SEABREAM JUVENILES (*Sparus aurata*)

David Dominguez*, Yiyen Tseng, U. Sivagurunathan, Marisol Izquierdo

Introduction

Requirements for the major nutrients have been described for several European Union (EU) cultured species including salmonids and carps, however, information related to minerals and vitamins is still scarce for Gilthead seabream (*Sparus aurata*) despite being a major marine species cultured in the EU. Recent studies have described the effects of increasing dietary levels of selenium (Se) (Dominguez et al., 2019a), manganese (Mn) (Dominguez et al., 2020a), copper (Cu) (Dominguez et al., 2019b), zinc (Zn) (Tseng et al., *in prep*), and their sources (Dominguez et al., 2017, 2019c; Mechlaoui et al., 2019; Tseng et al., 2021); as well as vitamin A (VA) (Dominguez et al., *in prep*), vitamin D (VD) (Dominguez et al., 2021, Sivagurunathan et al., *submitted*), vitamin K (VK) (Dominguez et al., 2022, Sivagurunathan et al., *in prep*), and B-vitamins (Dominguez et al., *in prep*)) in gilthead seabream. The present abstract aims to describe the available knowledge on mineral and vitamin nutrition for gilthead seabream juveniles.

Materials and methods

A total of 8 trials were conducted in gilthead seabream juveniles with the aim of understanding the optimum dietary levels for Se, Mn, Cu, Zn, VA, VD, VK and vitamins B1, B9 and B12; an additional 4 experiments were carried out to understand the effects of several mineral sources. For the trials aimed at studying the optimum levels, a basal feed was supplemented with at least 5 different levels for each nutrient, and each feed was tested in triplicates, to give a total of 15 tanks per trial. For the experiments with the difference mineral sources, the same level of the mineral was tested using different sources. Fish were raised by natural spawning at the Aquaculture Research Group from the University of Las Palmas de Gran Canaria ECOAQUA institute, and for each trial the fish came from the same broodstock, so as to reduce the genetic variability. Samples for proximal and vitamin/mineral composition, gene expression, histology and other analyses were taken at the start and end of the trials.

Results and Discussion

Se supplementation up to 0.94 mg/kg promote growth of gilthead seabream juveniles (figure 1). On the contrary, dietary levels of 1.70 mg Se/kg were found to be excessive and caused growth reduction, increased catalase expression and hydropic degeneration in the liver. The Mn content present in the basal diet (19 mg/kg) covered the requirements in juvenile seabream, although results from oxidative status markers might point out the need to increase levels beyond this point when fish are under pro-oxidant conditions. Dietary Cu levels did not affect productive parameters, suggesting that no supplementation was needed. On the contrary elevation of dietary Cu levels up to 11.0-32.0 mg/kg reduced growth and increased the markers of hepatic damage denoting toxic effects of Cu (figure 2). Seabream fed with dietary Zn levels at 89 mg/kg of plant-based diet increased the growth. VA levels tested were several times above those described for other species, however, no effects of toxicity were observed. Increasing the VD level caused an increase in the prevalence of histological alterations in the cardiac muscle. On the other hand, VK supplementation affected growth, *grp* expression, and the reduced prevalence of skeletal disorders suggested that dietary VK levels for gilthead seabream fingerlings should be above 12 mg/kg. Moreover, in an interaction study between VK and VD showed, 0.04mg VD/kg and 12 mg VK/kg in diet reduced total anomalies by upregulating the *bmp2* and *pthr1* expression in vertebral column. Dietary B-vitamins showed no relation to productive parameters, nor were there external signs of vitamin deficiency or mortalities. After the trial, the level of vitamins in whole body had reduced in 50% for B1, 12% for B9 and 18% for B12 on fish fed the diet without supplementation when compared to the initial samples, whereas an increase in the deposition of the vitamins was observed as the dietary levels increased. The dietary increase in B9 and, particularly, B12 reduced the percentage of erythrocytes with irregular nucleus in blood. These results suggest the feeds for seabream should be supplemented with B-vitamins.

Introduction

Bacteria communicate with each other by producing signal molecules and regulating the production of virulence factors that have importance in pathogenicity. Quorum sensing (QS) is a bacterial communication mechanism based on the perception of population density and secretion of determining signal molecules called autoinducers (AI) such as the case of Acylhomoserine lactones (AHLs) (Borges et al. 2019). AHLs-mediated QS processes seem to be common in the marine environment and among marine pathogenic bacteria, which pathogenesis could be mitigated by probiotics (Kuebutornye et al. 2020), among others. Probiotics are defined as live microbial cells that confer health benefits to the host and some of their mechanisms include the production of antagonistic compounds that are inhibitory toward pathogens (Zhou et al. 2018). In this sense, Shewanella putrefaciens Pdp11, a strain described as a probiotic for use in aquaculture, has been analysed to mediate QS processes by quorum-quenching assays using synthetic AHLs.

Material and methods

The detection of AHLs was done as previously described (Torres et al. 2016). *S. putrefaciens* Pdp11 was cultured in tryptone soy agar plates supplemented with NaCl (1.5%) (TSAs) at 23ºC for 24h. Then, the probiotic Pdp11 was grown in 2 mL of tryptone soja broth supplemented with NaCl (1.5%) (TSBs) at 23ºC for 24h under agitation (120 rpm). After 24h, a stock solution of N-butyryl- DL-homoserine lactone (C4-HSL, Sigma-Aldrich), N-hexanoyl- DL-homoserine lactone (C6-HSL, Sigma-Aldrich), N-octanoyl- DL-homoserine lactone (C8-HSL, Sigma-Aldrich), N-decanoyl- DL-homoserine lactone (C10-HSL, Sigma-Aldrich), N-dodecanoyl- DL-homoserine lactone (C12-HSL, Sigma-Aldrich), N-(3-Oxodecanoyl)-L-homoserine lactone (3-oxo-C8-HSL, Sigma-Aldrich), N-(3-decanoyl)-L-homoserine lactone (3-oxo10-C-HSL, Sigma-Aldrich) and N-(3-Oxododecanoyl)-L-homoserine lactone (3-oxo-C12-HSL, Sigma-Aldrich) were added to achieve a final concentration of 2μg/mL (10μM), and incubated for further 24h. At the same time, an overnight culture of the biosensor *Chromobacterium violaceum* CV026 and VIR07, maintained on Luria-Bertani (LB) plates supplemented with 50μg/mL of kanamycin, and *A. tumefaciens* NTL4 (pZLR4), maintained on LB plates supplemented with 50μg/mL of gentamycin, was diluted to 1:10 in 5 mL of LB soft 0.7% (w/v) agar and poured respectively onto LB agar plates for CV026 and VIR07, and LB medium supplemented with X-gal for NTL4. Then, 6-mm-diameter wells were hollowed in the medium with the back of a sterile Pasteur pipette and 100 µL-aliquots of each Pdp11 culture were loaded in the wells. Simultaneously, 2mL of TSBs were incubated containing AHLs as positive control. The plates were incubated at 28ºC for 24h to check for the presence or absence of a coloured halo around the wells.

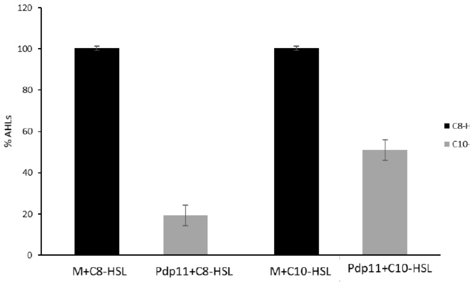

Figure 1. Percentage of synthetic C8-HSL and C10-HSL *N*-acyl homoserine lactones (AHL) measured in the cell-free culture media by degradation of the strain *S. putrefaciens* Pdp11 after 24h. Cell-free medium (M) added HSLs present 100% activity and was used as negative control. Initial AHL concentration was 10 mM. Error bars represent one standard deviation.

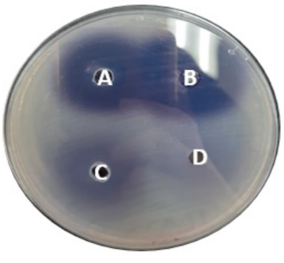

Figure 2. Recovery of synthetic C8-HSL after acidification visualized on agar plate assay by means of the biosensor strain *Chromobacterium violaceum* (CV026). Cell-free medium added with synthetic C8-HSL AB), synthetic C8-HSL extracted by pH7 C) and pH2 D). Scale bar, 1cm.

(Continued on next page)

To determine whether the QQ activity was related, C8-HSL was added as above in overnight cultures of the degrading strain Pdp11, which was incubated for a further 24h at 23ºC under shaking (120 rpm). The mixtures were then centrifuged at 10000g for 2min, one supernatants were extracted with equal volumes of acetonitrile (1:1) and another supernatants were acidified with HCl 1N to pH 2 and incubated for 24h at 23ºC on shaking. Finally, the remaining AHLs were suspended in methanol 70% (v/v) and detected by well diffusion agar-plate assays using sterile discs and the corresponding biosensor as above. At the same time, to confirm AHL degradation, the final concentration of it in the culture media was evaluated using HPLC-MS.

Results and discussion

Figure 1 shows the degradative activity of *S. putrefaciens* Pdp11 of the synthetic C8- and C10-HSL after 24h. The enzymatic activity is estimated at around 80% and 30% for C8- and C10-HSL, respectively, while the rest of AHLs tested were not degraded by the Pdp11 strain. It would be an interesting feature of the probiotic Pdp11 strain since these AHLs are related to facilitating microbial adhesion by promoting biofilm formation among other virulence factors related to pathogens (Fan et al. 2019).

On the other hand, a distinctive feature of AHL inactivated by lactonase is that it can be reactivated by acid treatment (Shaheer et al. 2021). In this way, little C8-AHL was recovered when it is extracted to pH2 (Figure 2), which indicates the enzyme activity is not derived from the hydrolysis of the lactone ring derived from the action of lactonases (Yates et al., 2002), suggesting the enzyme activity in Pdp11 could be an AHL-acylase. The potential QQ activity of Pdp11 was unknown so, these preliminary studies led to a further as another promising probiotic QQ tool for aquaculture.

ENVIRONMENTAL SALINITY REGULATES BARRIER FUNCTION IN RAINBOW TROUT SKIN

Darragh Doyle.[1]*, Bethanie Carney Almroth.[1], Kristina Sundell.[1], Nefeli Simopoulou.[1], Henrik Sundh[1]

[1]Department of Biological and Environmental Sciences, University of Gothenburg, Gothenburg, Sweden
E-mail: Darragh.doyle@bioenv.gu.se

Introduction

The skin is one of the primary barriers between the fish and the external environment. As such, the skin is a vital organ in osmoregulation, where it acts as a barrier against ion diffusion. Additionally, the health of the skin is vital in aquaculture settings, where fish may be exposed to an array of pathogens and other contaminants. However, relatively little is known about how the skin functions in relation to environmental variation.

The aim of this study was to measure barrier function and active transport in the trunk skin of rainbow trout using the Ussing chamber technique. The effects of epithelial wounding, skin region, and salinity on skin function were tested. In addition, immunohistochemistry was used to test for the presence of certain ion transporters including V-ATPase, NKA, and NKCC.

Method

The contribution of the different skin layers (epidermis and dermis) to barrier function and active transport was assessed in fully intact skin (dermis, epidermis, and scales present) and wounded skin (only dermis present). Regional differences in skin function were also assessed, as well as the response of the skin to environmental variation in the form of salinity change. To explore barrier function and active transport in long-term acclimated fish, skin sampled from freshwater (FW) acclimated fish was exposed to FW (FW-FW), while skin from seawater (SW) acclimated fish was exposed to SW (SW-SW). To explore the effect of acute salinity change on barrier function and active transport, skin from FW acclimated fish was exposed to SW (FW-SW), while skin from SW acclimated fish was exposed to FW (SW-FW). Each salinity exposure took place on the apical/epidermis side. Finally, the effect of pharmacological inhibition on potential sites of active transport in the skin was assessed.

To assess skin barrier function and active transport, the Ussing chamber technique was used. This method involved the measurement of several electrophysiological parameters from excised skin sections. These measurements included transepithelial resistance (TER), transepithelial potential (TEP), and short-circuit current (SCC). The TER mainly reflects the paracellular shunt resistance created across the tight junctions (TJs) between the epithelial cells, while the TEP reflects the net ion distribution across the epithelium as a result of the paracellular and transcellular transfer of ions. Finally, SCC is a measure of the net active ion transport across the epithelium. Skin sections were gently removed from each fish using a scalpel and locking forceps, according to Figure 1. The basal side of the skin was bathed in Ringer's solution and the apical side was bathed in either freshwater or seawater.

Results

The results of our study indicate that salinity is the primary regulating factor on both barrier function and transport in the trunk skin. At isosmotic conditions, the skin has a very small transepithelial potential, indicating little active transport. However, we found that skin permeability decreased drastically following exposure to freshwater and increased following exposure to seawater, with these changes occurring rapidly. Changes in epithelial permeability were accompanied by salinity-dependent changes in transepithelial potential (TEP) and short circuit current (SCC; Figure 2). We propose that barrier function in rainbow trout trunk skin is regulated by TJs that rapidly respond to changes in salinity. These changes are likely due to the varying expression of claudins in both freshwater and seawater. To assess the skin for active transport, we exposed to the skin to the V-ATPase inhibitor N-ethylmaleimide. This resulted in a gradual increase in epithelial permeability and changes in TEP, in both freshwater and seawater, suggesting an opening of the TJs. The presence of V-ATPase was confirmed using immunohistochemistry. However, there was no evidence that NKA or NKCC were present in the skin.

(Continued on next page)

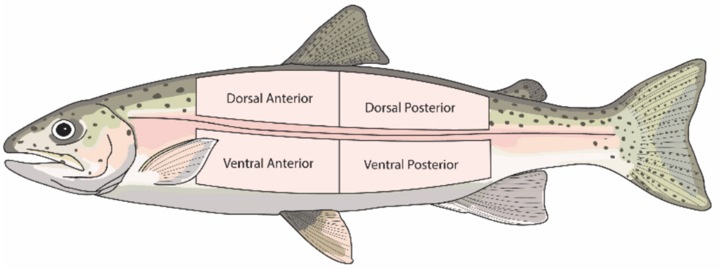

Figure 1. Diagram showing the skin regions that were sampled to assess regional differences in barrier function and active transport. The same skin regions were sampled from both the right and left side of each fish.

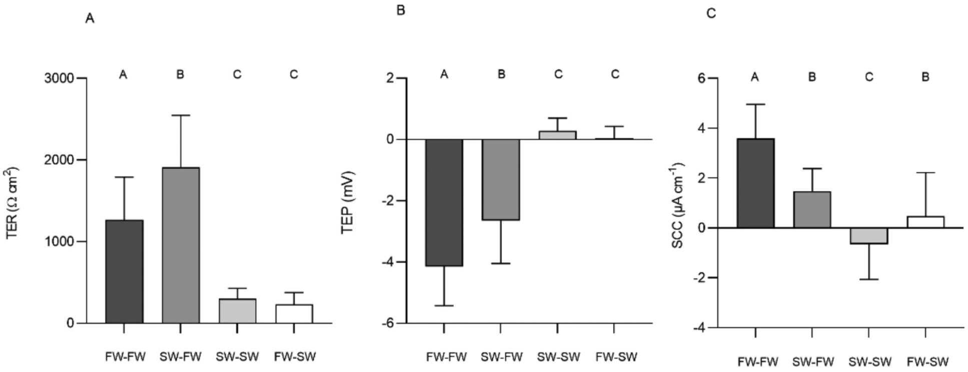

Figure 2. Barcharts showing the effect of salinity on (A) transepithelial resistance (TER), (B) transepithelial potential (TEP), and (C) short-circuit current (SCC). Bars represent means and whiskers represent SD. Groups not sharing a letter differ significantly based on the results of Welch's ANOVAs and post-hoc Games-Howell tests.

Discussion

In this study, we assessed the contribution of the different skin layers to barrier function, determined the effect of salinity, and tested for possible active transport mechanisms. The epidermis was found to be the diffusion barrier in the skin, with the dermis playing a negligible role. Epidermal barrier function was mainly determined by environmental salinity, with FW exposure resulting in a strong reduction of epithelial permeability. While the rapid salinity-dependent changes in skin function are likely related to acute changes in TJ structure and function, the exact mechanisms behind the acute changes in epithelial permeability remain unclear. However, the salinity dependent differences in barrier function observed in the current study are consistent with previous studies that have showed varying expression of TJ proteins in the skin of fish. In relation to active transport, immunostaining and selective inhibition suggest that one active transport component is an apical V-ATPase. However, further research is required to determine the exact role of this transporter in the context of the trunk skin.

RE-THINK PHOSPHORUS: HOW SALMON BONE REACTS TO LOW AND HIGH PHOSPHORUS DIETS

Lucia Drábiková*, Per Gunnar Fjelldal, Adelbert De Clercq, M. Naveed Yousaf, Thea Morken, Charles McGurk, P. Eckhard Witten

Evolutionary Developmental Biology, Biology Department, Ghent University, Ghent, Belgium
E-mail: Lucia.Drabikova@ugent.be

Introduction

The main minerals of bone are calcium and phosphorus. While teleost can obtain calcium in sufficient amounts from water they depend on dietary P supply. Dietary P deficiency is considered a risk factor for the development of vertebral deformities in farmed Atlantic salmon (*Salmo salar*). In commercial diet formulations dietary P requirements are met by addition of inorganic P compounds such as mono-ammonium phosphate (MAP) which are highly digestible (up to 90%) (Morales et al., 2018). Recent studies on early seawater stages of Atlantic salmon show that low-P diets result in the development of non-mineralised bone matrix that retains the capacity to mineralise without causing vertebral deformities (Witten et al., 2016; 2019). High P diets, on the other hand, may increase P excretion associated with waste of P resources and environmental pollution. We here present results from two studies that show the effect of low and high dietary P on freshwater stages of Atlantic salmon and the long-term effects of dietary P history at harvest. Study 1 analysed the effects of dietary P as a single factor for skeletal health. Atlantic salmon parr were fed low and high P diets and growth performance, plasma P content, and vertebral deformities were analysed. Study 2 followed individually tagged animals with low and high dietary P history from study 1 up to harvest. Progression and regression of deformities related to the animals' dietary freshwater history were analysed.

Materials and Methods

Study 1: Freshwater parr stages of Atlantic salmon (start weight 13.5 g) were fed MAP supplemented diets with a low (0.35%), regular (0.56%), or high (0.93%) estimated available P for 11 weeks (week 0 - 12). Animals were subjected to different analytical methods such as radiography, whole mount Alizarin red S staining, histology, plasma analysis, and bone mineral content analysis.

Study 2: The remaining animals from the study 1 (45 animals per diet group) were tagged and fed a commercial diet with regular P content for 66 weeks in seawater up to harvest (4.5 kg). Deformity development was monitored in individual animals by repeated radiology (at week 15, 47, 84) up to harvest. Additional analysis was done by Alizarin red S whole mount staining, histology, and bone mineral analysis.

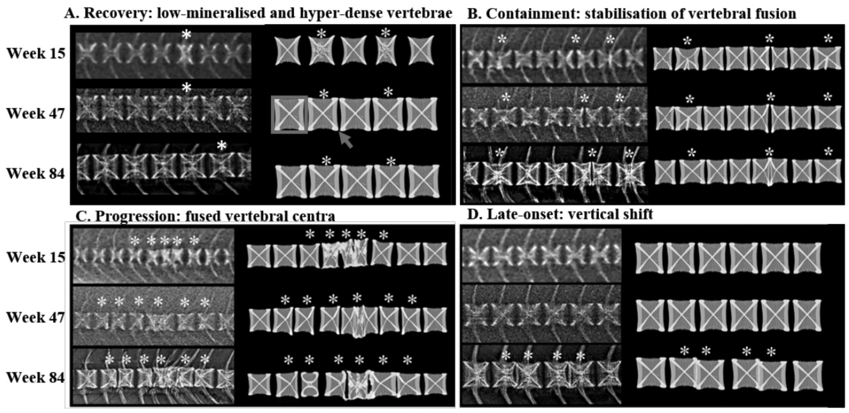

Figure1. **Development of vertebral deformities.** X-ray images and cartoons of individual Atlantic salmon x-rayed at week 15 (freshwater), 47, and 84 (seawater). Each block represents one animal. Deformities with the potential to recover (A) affected bone trabeculae of the vertebral centra (rectangle) but not the intervertebral spaces (arrow). Deformities which affected both structures were either contained (B) or progressed (C). Late-onset deformities developed in *de-novo* in seawater (D).

(Continued on next page)

Results and Discussion

Study 1 (freshwater): The prevalence of deformities in Atlantic salmon (week 12) was low and there was no effect of low or high P diet on the development of deformities. Animals fed low-P diet showed low-mineralised vertebrae characterised by extended areas of non-mineralised bone. Plasma P levels showed a 3-fold reduction in low-P fed animals. While bone formation continued, bone mineralisation was discontinued. In contrast, regular-P and high-P diet animals had fully mineralised bone. The high-P diet had no further effect on bone mineralisation. Interestingly, the growth of animals fed different levels of dietary P was comparable, no growth retardation was observed in low-P diet animals (Drábiková et al., 2021).

Study 2: Vertebral body deformities either affected bone trabeculae of the vertebral centra (rectangle in Fig. A) or the intervertebral spaces (arrow in Fig. 1A). Deformities of the vertebral centra with intact intervertebral spaces (low-mineralised, hyper-dense, compressed, and vertically shifted vertebrae) (Fig. 1A), had the capacity to recover in seawater (week 47). The prevalence of all deformities was low, except low-mineralised vertebrae and hyper-dense vertebrae that were frequent in low-P diet animals. In seawater low-mineralised vertebrae were completely mineralised and hyper-dense vertebrae recovered. Deformities which affected both the vertebral centra and the intervertebral joints, equally prevalent in all diet groups, were either contained (stabilised vertebral fusion) (Fig. 1B) or progressed over time (fused vertebral centra) (Fig. 1C). Deformities could also develop late in the seawater (week 47-84) (late-onset vertical shift and compression) (Fig. 1D). At harvest (week 84), the number of progressive deformities was low and independent of dietary P history.

In current studies the dietary P in freshwater has an immediate effect on bone mineralisation but no effect on the development of bone deformities and growth. There was also no long-term effect on the incidence of deformities at harvest. This study shows that under favourable conditions specific deformities can recover in seawater. Moreover, a high-P diet freshwater history had no effect on growth or development of deformities.

Introduction

Insect-based products are gaining in popularity as a good sustainable protein and oil alternative for animal feeds. Beyond fishmeal replacement, insect meal and oil present potential functional benefits to the farm-raised animals. In the present paper insect meal and oil, from Black Soldier Fly (*Hermetia illucens*) larvae were tested at different inclusion rates in shrimp (*Litopenaeus vannamei*) diets.

Methods and Materials

The trial aimed at monitoring zootechnical performances including growth, survival and feed conversion ratio (FCR), and immune responses in laboratory conditions of PL12 individuals for a 45 days period. A seven day challenge test with *Vibrio parahaemolyticus* was also conducted on those juveniles where mortality was recorded and hepatopancreas histology compared between the control and test diet.

Five experimental groups, each with four replicates, were studied as follows: 2% Insect meal, 5% Insect meal, 10% Insect meal, 2% Insect meal + 2% Insect oil, and a control (without the inclusion of insect meal or insect oil).

Results

After 45 days of feeding, shrimp fed 2% Insect meal + 2% insect oil, and 10% Insect meal had a significantly higher average survival rate than other groups. At the same time, shrimp provided 2% Insect meal +2% Insect oil, 5% Insect meal, and 10% Insect meal, had a significantly higher average body weight and lower FCR than other groups. Regarding the immunological study, shrimp from all groups that provided insect meal had significantly higher immune responses (the total hemocyte count, phagocytosis activity, phenoloxidase activity, superoxide dismutase activity, and bactericidal activity) than the control group. Shrimp from all groups that provided insect meal had fewer *Vibrio spp* in the hepatopancreas and intestine of shrimp than other groups.

Shrimp provided with 2% Insect meal +2% Insect oil had the best apparent digestibility of nutrients, including a percent dry matter digestibility, percent organic matter digestibility, percent protein digestibility, percent lipid digestibility, and percent nitrogen-free extract.

In the challenge test, all insect-based treatment showed a 26% better survival than the positive control (no insect ingredient). Furthermore, a noticeable reduction in the sloughing signs of the hepatopancreas was observed in the tested diets.

Conclusion

These results indicate health and performance benefits of insect meal and oil in shrimp diets in controlled conditions.

HYDROLYZED YEAST *Kluyveromyces fragilis* AS A FEED MATERIAL TO IMPROVE GROWTH PERFORMANCE AND IMMUNE FUNCTIONS OF RAINBOW TROUT (*Oncorhynchus mykiss*)

V. Eckart[1], S. Parhizkar[1], M. Norouzi[2], M. Bagheri Tavani[3], B. Keimer[1]

E-mail: veckart@biochem.net

Introduction

Functional feed materials derived from yeast are a highly valued ingredient in a wide range of animal diets. While most of these products for aquaculture are based on *Saccharomyces cerevisiae*, the use of *Kluyveromyces fragilis* (also named *K. marxianus*) has hardly been investigated. In previous studies, *K. fragilis* showed a higher nutritional value compared to *S. cerevisiae*, as evidenced by a higher proportion of fish meal replacement in Atlantic salmon diets (Øverland et al. 2013). To further improve the digestibility and efficiency of functional components such as mannans, ß-1,3-1,6-glucans and nucleotides, the product TechnoYeast – hydrolyzed *K. fragilis* (KF) – was created. The purpose of this trial was to investigate the effects of different dosages of KF on growth performance and immune parameters of rainbow trout (*Oncorhynchus mykiss*).

Material and methods

2400 fingerlings (avg. weight 16.3g) were randomly stocked into 4 concrete outdoor raceway ponds (600 each). The raceways were separated by metal mesh to get triplicates of 200 fish for each group. After two weeks of acclimatization, the 90 days feeding period was started. The control group (CON) was fed a commercial trout feed with 44% crude protein, 15% fat, 3% crude fiber and 9% ash. For the treatment groups KF (TechnoYeast, Biochem GmbH, Lohne, Germany) was added to the commercial feed via gelatin. The groups were defined by the inclusion level of KF as KF 0.5%, KF 1.0% and KF 2.0%. Feeding was performed 4 times a day according to the standard table of the feed supplier and based on 1.5% to 2% of the average body weight considering the water temperature. Due to seasonal changes, the water temperature was 10 to 13°C for the first 30 days and 4 to 8°C for the last 60 days. The pH was around 7 and oxygen level was >9 mg/l. At the end of the feeding period, 10 fish from each replicate were randomly selected for biomass measurements and to take blood samples. Blood from each replicate was pooled, separated with heparin, centrifuged at 3000 rpm, and sent for laboratory analysis. Standard statistical tests (ANOVA) were used to calculate significance values.

Table 1: The table indicates mean performance results and mean blood analysis values at the end of the 90 days feeding period of rainbow trout fingerlings.

	CON	**KF 0.5%**	**KF 1.0%**	**KF 2.0%**
Performance parameters				
Initial weight [g]	$17.2^{a} \pm 0.5$	$17.8^{a} \pm 0.7$	$17.1^{a} \pm 1.2$	$12.9^{b} \pm 2.5$
Final weight [g]	$81.4^{a} \pm 2.0$	$91.2^{b} \pm 4.6$	$94.6^{b} \pm 6.5$	$102.9^{c} \pm 5.3$
WG [g]	$64.2^{a} \pm 1.5$	$73.5^{b} \pm 5.0$	$77.5^{b} \pm 7.0$	$90.0^{c} \pm 7.3$
SGR [%BW/day]	$1.73^{a} \pm 0.01$	$1.82^{a} \pm 0.08$	$1.90^{a} \pm 0.12$	$2.31^{b} \pm 0.24$
FCR	$0.79^{a} \pm 0.01$	$0.73^{a} \pm 0.04$	$0.69^{a} \pm 0.05$	$0.61^{a} \pm 0.05$
Survival [%]	99.98^{a}	99.33^{a}	99.67^{a}	99.98^{a}
Immunity parameters				
WBC [cells/µm^3]	$13.3^{a} \pm 1.25$	$12.2^{ab} \pm 1.11$	$9.7^{bc} \pm 0.76$	$7.5^{c} \pm 0.60$
ALT [u/l]	$22.0^{a} \pm 1.00$	$16.3^{b} \pm 2.30$	$18.6^{ab} \pm 2.08$	$14.7^{b} \pm 1.15$
AST [u/dl]	$21.6^{a} \pm 0.26$	$17.6^{b} \pm 0.38$	$18.5^{b} \pm 0.61$	$13.6^{c} \pm 1.03$
LDH [u/cl]	$17.6^{a} \pm 0.79$	$10.7^{b} \pm 0.51$	$11.9^{b} \pm 0.77$	$8.6^{c} \pm 0.65$

WG: weight gain; SGR: specific growth rate; BW: body weight; FCR: feed conversion rate; WBC: white blood cells; ALT: alanine transaminase; AST: aspartate transaminase; LDH: lactate dehydrogenase; ^{abc} means with different superscripts within a row differ significantly ($P < 0.05$)

(Continued on next page)

Results and discussion

At the beginning of the trial fish of the KF 2.0% group had a slightly lower initial weight compared to other groups. However, these fish achieved the highest final weight of all treatments (Tab. 1). This compensatory growth could be related to higher feed efficiency, which is evident in all KF groups through improved FCR and increased SGR. These results are consistent with previous trials with KF in terrestrial animals, e.g., in pigs (Keimer et al., 2018). The performance data in Table 1 generally shows a scalable and significant increase in performance with increasing dietary inclusion levels of KF. Analysis of the blood samples revealed that the white blood cell (WBC) count in the fish was negatively correlated with increasing dietary inclusion of KF (Tab. 1). In previous studies, high WBC counts were associated with the influence of various types of stress (Peters & Schwarzer 1985). Consequently, all KF-groups appeared to be less affected by stressors such as pathogens or handling than the control group, resulting in better growth performance.

Further analysis of the liver enzymes lactate dehydrogenase (LDH), aspartate transami-nase (AST) and alanine transaminase (ALT) displayed the positive effects of KF on the overall health status of the fish (Tab. 1). AST and ALT are common indicators of liver condition. Elevated levels of these enzymes are often a result of intoxication (Bury et al. 1997). Besides, increased LDH levels usually occur in association with tissue damage. Thus, studies with other freshwater fish species showed an increase in LDH when exposed to sewage (Parveen et al. 2017). Herein bad water quality caused cellular hypoxia, creating anoxic condition and cell damage. A similar event occurred during the feeding period of the present study when heavy rain flushed the flow-through system with turbid water in week 6. Interestingly, all groups fed with KF had lower concentrations of the analyzed liver enzymes when compared to the control, which could be a sign for a better protection against such challenges.

In conclusion, KF positively affected immunity and health parameters of rainbow trout fingerlings. All dietary inclusion levels tested significantly improved growth performance, with the strongest effects observed at a 2.0% dosage.

Driven by product diversification and circularity of nutrients, also land-based production systems are exploring the potential of integrated aquaculture. The co-cultured species are used as biofilters, and each level has its own independent commercial value, providing both economic and environmental sustainability.

In this study, the nutrient uptake of *Caulerpa lentillifera* was evaluated together with its light preferences in view of integrated cultivation with *P. vannamei*.

The growth performance of the macro-algae and its uptake of NO_3-N, PO_4^{3-} and NH_3-N at three different concentrations of organic fertilizer (233μlL^{-1}, 466 μlL^{-1}, 932 μlL^{-1}) was evaluated for 28 days. Growth performance was best at 233 μlL^{-1} and lowest at 932 μlL^{-1} of organic fertilizer. A reduction in NO_3-N and PO_4^{3-} of 77,4% and 3%, respectively, was registered together with an increase of NH3-N of 19,2%, indicating a preference of Caulerpa for nitrate over ammonia under experimental culture conditions. In a subsequent experiment, the effect of light quality (spectra) on the growth of *Caulerpa lentillifera* was determined. The results indicated a preference for blue light, whereas the lowest growth performance was under warm white light conditions. The third and final experiment revealed a better growth performance under LED light over fluorescent light. In future experiments, the present results will serve as basis for the integrated culture with shrimp and indicate a nitrate reduction of the culture water in comparison to monoculture. The first experiment will be repeated using more accurate techniques for nutrient analysis to verify the rise in NH_3-N.

This study was realized thanks to co-funding from the Europees Fonds voor maritieme zaken en visserij (EFMZV) and the Vlaamse Visserij- en Aquacultuursector (FIVA).

AQUACULTURE FEEDS AND OFF-ODOURS COMPOUNDS IN RECIRCULATING AQUACULTURE SYSTEMS: CORRELATIONS, PATHWAYS AND MITIGATION THROUGH ALTERNATIVE INGREDIENTS

*Matteo Egiddi[1,2], Eva Ortner[1], Andrea Buettner[1,2], and Jonathan Beauchamp[1]

Introduction

The presence of off-odour compounds in fish, such as geosmin and 2-methylisoborneol (2-MIB, Abd El-Hack et al., 2022), or less commonly reported skatole, eugenol, or indole (Mahmoud et al., 2018), can drastically reduce its palatability, leading to consumer rejection and lower market demand of recirculating aquaculture systems (RAS) products. A common off-flavour mitigation strategy is to purge the fish in flow-through systems prior to harvesting while ceasing feeding. However, this procedure results in the loss of fat content and precious market weight, as well as in a far greater consumption of water. Other technological strategies utilise intense ozone and ultraviolet (UV) light, which further increase costs in RAS farms. In the last 30 years, scientific effort has been directed towards understanding and mitigating the presence of bacteria lineages believed to be responsible for the production of geosmin and 2-MIB for quorum sensing. Previously, these compounds were believed to be only absorbed by aquaculture fish from the water, yet recent work has demonstrated the presence of these compounds and other dominant off-odour taints in aquaculture feeds, indicating their potential absorption through ingestion (Podduturi et al, 2017; Mahmoud et al., 2018).

Methods

This presentation outlines a conceptual workflow to address the issues of off-odour in RAS fish in relation to feed. The present work will apply sensory evaluations combined with analytical methods (e.g., solvent assisted flavour evaporation (SAFE) technique, gas chromatography-mass spectrometry/olfactometry (GC-MS/O), aroma extraction dilution analysis (AEDA), proton transfer reaction-time of flight-mass spectrometry (PTR-TOF-MS), stable isotope dilution analysis (SIDA)) to explore correlations between dominant off-odour compounds in common aquaculture feeds and their presence in RAS water and several RAS fish species. The study will examine the pathways of production, absorption and bioaccumulation of off-odour compounds. After determining links between feed ingredients and off-odour formation, new fish feeds will be formulated and trialled. The formulations will aim to reduce off-odour presence via feeding by employing only plant/algae-based ingredients exhibiting no off-odour themselves (Garcia-Vaquero & Hayes, 2016) and then testing various chemically mediated mitigation strategies. Overall, the project aims to develop and maintain a cost-effective feed while improving digestibility and nutritional/welfare requirements of the fish.

Expected Results

The expected outcomes of this project are an understanding of the relationship between aquaculture feed ingredients and off-odour in fish, as well as the evaluation of which feed parameters impact microbial and water quality and fish health. Further, the use of plant/algae ingredients as an alternative to fishmeal will be assessed, with related strategies, to prevent the formation of off-odours in RAS fish.

Points of Discussion

Aquaculture feeds represent the focal point at which the aquaculture industry and marine environmental conservation meet. Currently, the research and development of alternative feed ingredients receives unprecedented attention from private and public investors (Naylor et al, 2021). This is motivated by a set of fundamental strategic priorities: producing larger amounts of feeds that employ cheaper and more readily available ingredients than fishmeal/fish oil; shifting away from the dependency of stagnant baitfish fishery landings; and completely lifting the fishery pressure on wild stocks to let world oceans recover from overfishing. Further, aquaculture feeds today represent the highest capital expenditure for aquaculture farmers, amounting up to 34% (Liu et al., 2016) of the total final product in RAS farms. Finally, the design of RAS depends on the feed loads, protein content and conversion ratios, which increase the dependency of RAS farmers on digestible and highly nutritional feeds. Consequently, a great research effort is required to improve aquaculture feed formulation. This

(Continued on next page)

work can provide means to reduce off-odours in the feeds by employing alternative feed ingredients, while potentially improving digestibility and promoting a healthy microflora in the animals' gut and biological filters. Such findings could promote high flavour quality product standards and improve cost-effectiveness in RAS production.

Introduction

In land-based recirculating aquaculture systems (RAS) the removal of nitrogenous waste is achieved via prokaryotic biodegradation. However, the spatiotemporal metabolic dynamics of microbial communities associated to this process in RAS are poorly understood (Letelier-Gordo *et al.,* 2020). Fast and effective top-down molecular techniques might aid into better understanding these dynamics to suggest improvements in process design and operation (Vinayavekhin & Saghatelian, 2010; Xiao *et al*., 2019).

Methods

This pilot study evaluated the applicability of untargeted metabolomics fingerprinting to describe metabolic trends in RAS bioreactors. We compared two reactor designs, a two-stage moving bed bioreactor (MBBR) and an anaerobic batch fed sludge bioreactor (BFDR), as well as different locations within each of these (i.e., inlets vs outlets).

Results

The untargeted LCMS approach highlighted a clear differentiation in metabolic fingerprints between the two bioreactors. No difference was found within the MBBR (Fig. 1). However, two distinct metabolic fingerprints were recorded within the BFDR, one in the reactor's sludge blanket and one in the supernatant.

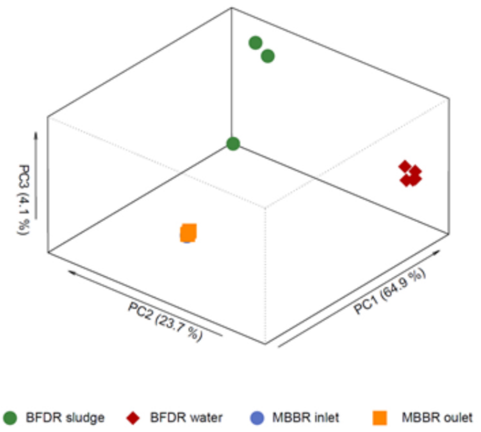

Fig. 1. PCA plot summarising 92.9% of variance in three principal components. Signals of MBBR inlet and outlet are clustered, while BFDR water and sludge are clearly distinct.

(Continued on next page)

Discussion

Contrarily to the initial hypotheses, MBBR signals clustered. Possible explanation can be identified in a vessel-wide distribution of a homogenous microbial community, influenced by substrate-limiting conditions and short hydraulic retention time (Torresi *et al.,* 2018; Yang *et al*., 2019). Unexpectedly, the BFDR showed a significant diversity in metabolome, inferring on a significant differentiation between location-specific microbial communities. We demonstrated how untargeted metabolomics can reveal metabolic dynamics in a RAS bioreactor and at the same time confirm or deny their initial design principles.

Introduction

The aquaculture industry produces enormous amounts of data every day. Data comes from sensors in the fish cages, cameras, boats, feeding barges, but also from e-mails, notes, and through conversations between the people working on the production sites. Some tools exist for gathering and displaying the produced data, and there are several initiatives for standardizing the data, but there are also challenges with today's solutions related to finding and visualizing the interconnections between the gathered data. When the data quantity is high the interconnections between data become more important. Furthermore, it is difficult for humans to navigate through millions of data points in a table and find these interconnections. A graph database [1] stores relationships and connections between data, as well as the data itself, and is therefore well suited for this particular purpose. The Aquagraph project (RCN 321422) aims to implement aquaculture data in a graph database and develop methods and algorithms that will aid the fish farmers in their daily operations as well as in their long-term planning. The project group consists of the fish farming company Eide Fjordbruk [2], one of Europe's largest ocean research organizations, SINTEF Ocean [3], and leading data scientists from the innovative company and project owner Searis AS [4].

Materials and methods

The project utilizes the Neo4j graph database software to store and structure the data [5]. The Neo4j software features extensive libraries for graph representations and multiple algorithms allowing searches, graph traversal, and clustering, amongst others.

Prior to bringing the data into a graph database the assets that belong to an aquaculture production process, and the relationships between them, need to be given a formal name and a definition in the form of an ontology data model [6]. The data model defines the general concepts in a domain context, e.g., the aquaculture fish farming operations. Once the ontology is in place one can easily add and remove assets from the graph, and the graph database will automatically ensure that the asset has the correct properties and relationships. As such, scaling and updating a graph database is fast and effective, compared to traditional databases. Figure 1 shows how some assets and the life cycle of the fish are described in the ontology, while Figure 2 shows how these are implemented in the graph database and connected to all the proper dependencies, with the correct relationships and properties. Other assets included in the ontology can be listed as sensor data, batches of fish, observations, actors, and events.

The software Clarify [4], developed by Searis, is used in the project to represent time-series data from sensors, but also as a platform for operators to communicate. Clarify serves the graph database with data in form of sensor measurements, time stamps of important events (e.g., delousing operations and feeding times), inputs from the operators, and maybe most importantly: Anomaly detections that, when represented in a graph, will make it simple for the operators to detect if something needs attention.

Results

Initial results from the project includes a complete ontology for aquaculture data structuring. Furthermore, a graph database representation of all aquaculture assets at one of Eide Fjordbruk's fish farms has been implemented in Neo4j. The graph database, and graph visualization, have been applied to new data, but historical data has also been implemented. By doing this it is possible to compare historical productions that e.g., has been very good, to new, ongoing productions, and determine if there are differences between them, and where one should focus the effort e.g., leading up to a delousing operation or when splitting and merging groups of fish.

(Continued on next page)

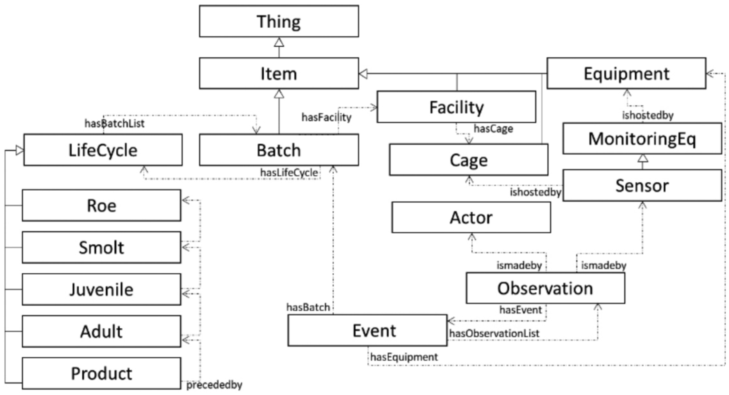

Figure 1: The ontology describing different assets in the production and the fish's life cycle.

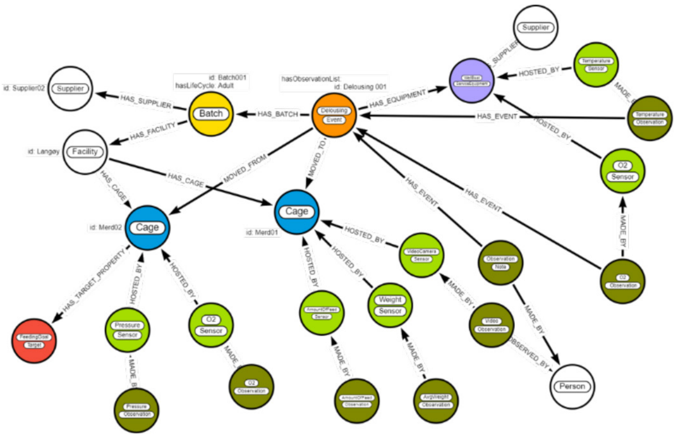

Figure 2: The ontology represented as a graph in Neo4j.

Conclusion and future work

The results from the Aquagraph project, i.e., the new way of visualizing aquaculture data and the optimization algorithms, may enable the fish farmers to learn more about the cause and effect of their actions, the significance of various environmental parameters, and may make it easier to track a group of fish throughout a production cycle, from egg to slaughter. The graph database representation can lead to the discovery of new relationships that were previously underestimated or unknown to the fish farmers. It will help put the important data in front of the right people which may secure a better foundation for decision making. The project lays the foundation for the implementation of new tools on top of the existing Clarify platform. Furthermore, machine learning can be applied to predict outcomes of production, and future relationships which were previously unknown. The project group believes that augmenting the framework with machine learning capabilities will be beneficial to the project since this opens for the use of not only machine learning plus data, which is good, but machine learning, plus data, plus context of data, which is better.

BLOOD AND MILT ANDROGENIC PROFILES OF EUROPEAN EEL (*Anguilla Anguilla*) AND CORRELATION WITH SEMINAL MORPHO-FUNCTIONAL CHARACTERISTICS

Elmi A.[*,§], Casalini A.[§], Ventrella D., Govoni N., Emmanuele P., Parmeggiani A., Mordenti O., Bacci M.L.

Introduction

In the last decades, the population of European eel (*Anguilla anguilla*) has suffered a strong decline due to overfishing, habitat reduction and pollution, and the constant growth of the market's demand [1]. As a matter of fact, the European eel population has declined by 98% since 1980 and is currently listed as a "critically endangered" species by the International Union for Conservation of Nature (IUCN) Red List [2]. In captivity, when the reproductive migration is not allowed, eels do not mature spontaneously, and long-term hormonal stimulation is necessary to promote correct gametogenesis. As a matter of fact, male specimens start producing high quality ejaculates only after 13-15 weeks of treatment with human chorionic gonadotropin (hCG) [3,4]. In fish, the principal androgen related to spermatogenesis and testis development is 11-keto-testosterone (11-keto) alongside its precursor, testosterone (T). The peak of androgens occurs some week post hormonal treatment and reaches its maximum when spermatogenesis starts [5]. The aim of the present work was to quantify 11-keto and T in both milts and bloods of male European eels and correlate them with semen morpho-functional parameters such as spermatozoa concentration, viability and objective motility.

Material and Methods

Twenty-four (N=24) male European eels were sampled at the end of the above-mentioned hormonal treatment with hCG. Upon anesthesia, 500 µL of blood and 2 mL of milt were samples from each specimen. An aliquot of milt was immediately diluted 1:10 in P1 medium added with BSA 2% w/v (4°C; ph=8.2) for the semen morph-functional evaluations while blood and the remaining milts were centrifuged (3000g x10 min). The resulting plasmatic components of both matrices were stocked at -20°C waiting for hormonal extraction and quantification. Sperm concentrations were evaluated using a haemocytometer, viability by mean of Eosin-Nigrosin staining. After spermatozoa activation with Artificial Sea water (3.7 %) at 4°C, motility was evaluated by CASA analysis.

11-keto and T were extracted in ethyl ether and quantified, respectively, using ELISA and Radio-immunological (RIA) methods. Statistical analyses were performed using GraphPad Prism 9.0 (GraphPad Software Inc., San Diego, CA, USA). Descriptive statistic included mean, SD and normal distribution by Shapiro-Wilk test. Spearman's rank correlations were performed to evaluate the correlation between androgens and sperm parameters. The statistical significance for all tests was set at $p < 0.05$ (95% C.I.).

Results

The results showed that it was possible quantify both androgens in all milts (T= 0.24 ± 0.04 ng/mL; 11-keto= 1.09 ± 0.70 ng/mL) and blood (T= 2.02 ± 0.53 ng/mL; 11-keto= 6.89 ± 3.56 ng/mL) samples. As for milts morph-functional parameters we recorded mean spermatic concentration of 1.70×10^9 spz/mL, mean viability of 94.1% and mean total motility of 52.76%. The statistical analysis did not show any correlation for the androgens between blood and seminal plasma. Testosterone and 11-Ketotestosterone resulted correlated in blood ($\rho=0,67$; $p<0,001$) but not in seminal plasma. The results of the morpho-functional evaluations showed a positive correlation between sperm viability and motility ($\varrho=0,46$ $p=0,024$), but no correlation was found between spermatozoa concentration and other parameters. No correlations were highlighted by the analysis between the level of hormones in blood and seminal plasma and the sperm quality evaluation (motility, viability and concentration).

(Continued on next page)

Discussion and Conclusion

The present study seems to be indicative of a lack of correlation between the androgen profiles of blood and seminal plasma, with the only exception of an evident relation between 11-keto and T within blood. Such study also highlights the need for a thorough evaluation of the morph-functional characteristics of milts, as assessing just one parameter such as spermatic concentration does not seem to be indicative of overall quality. Finally, it is important to mention that the lack of correlations between the analyzed hormones in seminal plasma and milts' quality suggests the need the keep on investigating the European eel's physiology of reproduction and in particular spermatogenesis, as other hormones, not fully investigated to date, may influence sperm concentration, viability and motility.

Introduction

Most freshwater teleosts lack vitamin C (vitC) or ascorbate due to the absence of L-gluconolactone oxidase, the enzyme responsible for ascorbic acid (AA) synthesis [1,2,3]. Deficit species, including carp usually require a dietary intake of vitC. AA plays a fundamental role as growth promoter and immune protective agent in freshwater fish [2,3]. Despite the vitC reputation as a robust antioxidant with anticancer capabilities, its antiviral function is poorly investigated. We examined the immune potential of AA in-vitro in brain cells and leukocytes of common carp *Cyprinus carpio* L. amid koi herpesvirus (KHV) infection as crucial cells for KHV replication and latency and carp fish immunity.

Materials and Methods

To experiment vitC influence on cell performance, naïve and mitogen (phytohemagglutinin-L) stimulated carp-derived leukocytes and carp brain cell line (CCB) were chosen as the highest cells reported to retain AA after dietary intake [3,4]. Cells treatment with sodium L-ascorbate was performed 2 hours before virus inoculation at concentrations 25, 50, and 75µg/ml of vitC solution in culture medium. A KHV strain (261) propagated in CCB cells was inoculated into the vitamin-treated cells at $TICD_{50}$ 10^{-2}. Ascorbic acid was re-administrated every next 24h throughout the experimental time (72h) for cell proliferation assessment and detection of reactive oxygen species (ROS). Cells were labeled for the activity of ploy caspases after 24h of a single administration of AA and KHV inoculation.

Discussed Results

Our results show that vitC performs a dual role both as antioxidant and pro-oxidative agent during koi herpes virus infection linked to the cell type. VitC protected the brain cells from damage induced by virus propagation via coordinated promotion of metabolic activity, ROS scavenging, and activation of caspases. In leukocytes, AA administration significantly enhanced cell proliferation with chemotaxis behavior relative to higher stimulation of ROS production for pathogen killing, and fluctuation in the caspase's activity related to cell death mechanism (apoptosis vs. necrosis) (Fig. 1, 2, 3).

Conclusion

The essentiality of vitC as an immune supplement in carp is highlited. Findings of this study reveal a selective antiviral/immune support machinery of vitC against KHV infection reflective of the disease-resistance influence reported in other teleost. An extra advantage is implementing vitC in in-vivo testing to assess its integral role against KHV and other infectious agents and stress-inducing substances in carp fish.

Introduction

Counting shrimp in a farm environment is challenging. Environmental factors may negatively affect image quality and make identification of individuals difficult, while overlapping individuals create a problem for many object detection approaches. Recent approaches such as bounding box annotation have resulted in high counting efficiencies in lab environments (<30 ind. m^{-2}) but failed in farm conditions (>80 ind. m^{-2}). The objective of the study was to test the density map approach to overcome the existing problem of object counting in real farm environments, i.e. when high numbers of overlapping individuals must be distinguished by computer vision. If successful, accurate automated counting will improve animal welfare and reduce working hours of farm staff so far dedicated to sampling and manual counting.

Material & methods

Videos were recorded with an iPhone 12 mobile camera (resolution 1920 x 1080) at Förde Garnelen GmbH & Co. KG farm at different light conditions, (dark and bright), at different heights (60cm, 100cm, 125cm, and 185cm) and with different types of nets (coarse, fine, for shrimp to rest on). To generate automated counting training examples, we extracted frames from each video with a step of eight frames, to avoid duplicates. Single point annotation was carried out in a CVAT format. Two models were used for accurate shrimp counting, FCRN (Full Convolutional Regression Network) (Xie, Noble, & Zisserman, 2018) and U-Net (Ronneberger, Fischer, & Brox, 2015). Of 887 images annotated, the total number of shrimp present in all images was 50319. The maximum number of shrimps in an image was 272 and the minimum number of shrimps in an image was 14. Truthing or accuracy testing was conducted with a unique dataset (images taken from different videos). Out of 90 test images, the total number of shrimps present in all images was 14715, with a maximum of 266 and a minimum of 66 individuals. Ground truth labels were generated by convolving exiting dot labels (x,y coordinates) with a Gaussian kernel. Models were trained on ground truth labels as a supervised machine learning problem. Density map output was a yellow dot for each detected shrimp.

Results abstracts

The mean absolute accuracy at different heights was statistically significant ($P < 0.01$, with highest accuracy (96) % at 185 cm height followed by 90 % and 71 % at 125cm and 100 cm height respectively (Fig. 1).

Discussion and conclusion

To our knowledge present results demonstrate for the first time the possibility of reliably counting shrimp in a commercial farm environment with multiple overlapping individuals. Counting accuracy factors such as object augmentation, model type, background contrasts will be presented along with a cataloguf of conditions (e.g. shrimp size, image, resolution) currently under investigation which need to be improved for successful use in commercial shrimp farming.

Introduction

Aquaculture industry is a key animal production sector to secure the future food demand. Expanding the number of raw materials will increase flexibility in the formulation of highly nutritious aquafeeds and the sustainability of the sector. The inclusion of mussel meal originated from mussel aquaculture side-streams in aquafeeds will contribute to the valorisation of aquaculture value-chains and to the circular economy approach in the industry.

The present study aimed to evaluate gilthead seabream (Sparus aurata) juveniles growth performance, feed utilisation, nutrient apparent digestibility, and nitrogen outputs to the environment when fed experimental diets with mussel meal as the main source of marine-derived protein.

Material and Methods

Three practical diets were formulated to be isonitrogenous (crude protein, ~48.6%), and isoenergetic (gross energy, ~ 21 MJ/kg). The Commercial diet (CTRL) was formulated to be similar to a commercial feed used for gilthead seabream juveniles, with fishmeal as the main source of marine-derived proteins. The other two diets were formulated to reduce dietary fishmeal inclusion in 50% (Mussel 50) and in 100% (Mussel 100) using mussel meal as the source of marine-derived protein.

Gilthead seabream juveniles (initial body weight ± 5.0 g) were acquired from a commercial aquaculture and transported to the CCMAR facilities at Ramalhete Experimental Research Station (Faro, Portugal). Triplicate groups of 90 seabream juveniles, with a mean initial body weight of 8.0 ± 0.1 g were fed one of the three diets for 8 weeks. Fish were reared in 500 L tanks, supplied with flow-through seawater (temperature: 21.8 ± 1.6 °C; salinity: 37.3 ± 0.4 psu, dissolved oxygen above 80% of saturation). Fish were fed to apparent satiety, by hand, three times a day. Feed intake was recorded, and utmost care was taken to avoid feed losses. Fish were individually weighed at the beginning, bulk weighed every three weeks and at the end of the trial, following one day of feed deprivation.

Fifteen fish from the initial stock and 18 from each replicate tank at the end of the trial, were individually weighed and measured, to calculate the condition factor. From these, three fish were stored at -20 ºC until subsequent analysis of proximal composition, in other three fish liver and posterior intestine were sampled for gene expression and microbiota analysis, and from the other 12 fish, plasma, liver and whole-fillet samples were collected for analysis of immune and biochemical parameters, antioxidant status, metabolic enzymes, proximal composition and amino acid content; liver, viscera and visceral fat were weighed to calculate hepatosomatic, viscerosomatic and perivisceral fat indexes.

The apparent digestibility coefficients of the dietary components were determined by the indirect method, with diets containing 0.02% yttrium oxide as inert tracer. Triplicate groups of fish (mean initial body weight of ± 66.8g) were allocated to cylindroconical fibre glass tanks of 100 L coupled with faeces collectors. Fish were allowed to adapt to the new conditions for ten days before starting faeces collection. During the adaptation period fish were fed by hand to apparent satiety twice a day one of the experimental diets and continue to do so throughout the trial. Tanks were thoroughly cleaned to remove any uneaten feed. Before feeding, faeces were collected daily, left to settle and water was decanted. Faeces were frozen at -20 ºC and freeze-dried prior to analysis.

(Continued on next page)

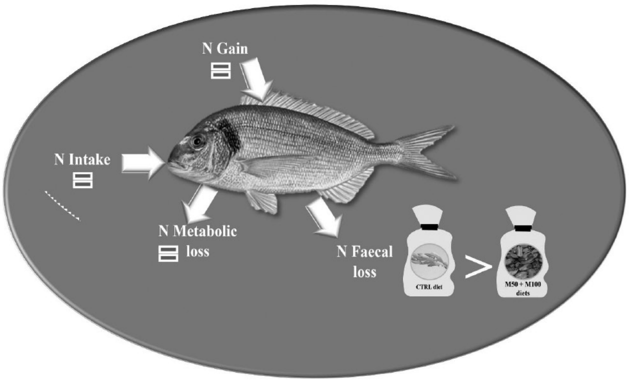

Figure 1. Daily nitrogen balance of seabream juveniles fed the experimental diets (Mussel 50 and 100) compared with fish fed the Commercial diet, at the end of the trial.

Results and Discussion

The partial or total replacement of fishmeal by mussel meal had no detrimental effect on key growth performance indicators ($p > 0.05$). All the fish (CTRL, M50 and M100) increased the initial body weight in almost 6-fold during the feeding period. Only the hepatosomatic index (HSI) presented some changes. Fish fed the diet M50 and M100 presented a higher HSI that CTRL fish ($p < 0.05$). The replacement of fishmeal by mussel meal had no impact on diets digestibility ($p > 0.05$). Fish protein, fat and energy retention were not affected ($p > 0.05$) by the dietary treatments. Phosphorous retention was lower in M100, when compared to CTRL fed fish ($p > 0.05$). Whole-body composition analysis combined with information on ADC of diets allowed the calculation of daily nitrogen and phosphorus balance. Daily nitrogen gain and metabolic losses were unaffected ($p > 0.05$) by the dietary treatments (Fig. 1).

Faecal losses were positively affected by the inclusion of mussel meal since both experimental diets (M50 and M100) presented lower values than CTRL diet ($p < 0.05$).

More parameters, such as biochemical, immune, metabolic and antioxidant responses are under analysis. Based on growth performance, feed utilization, diet digestibility, nutrient balances data, the replacement of fishmeal by mussel meal might be a viable strategy to tackle the identified technical challenge.

Introduction

Exercise promotes health in mammals (Pascoe et al., 2014). In farmed fish, the physiological effects of swimming activity are, however, overlooked. Swimming is a fundamental behavioral element contributing to the fitness of most fish species. Reduced swimming performance has been associated with lower disease resistance and poorer welfare (Castro et al., 2013). The current study aims to fulfill the lack of knowledge on swimming physiology by evaluating the impact of induced swimming activity on the welfare of gilthead seabream (*Sparus aurata*).

Materials and Methods

Forty eight seabream (total length: 13.3 ± 0.3 cm; total weight: 57.9 ± 1.8 g) were individually subjected to a 6-h exercise in a swimming tunnel on continuous or discontinuous flow patterns, as follows: i) continuous low (CL, 0.8 BL s^{-1}); ii) continuous high (CH, 2.3 BL s^{-1}); iii) discontinuous low (DL, 0.2-0.8 BL s^{-1}); iv) discontinuous high (DH, 0.8-2.3 BL s^{-1}) velocities and v) control non-exercised group (CTRL). At the end of the trial, fish were euthanized, and gills and head-kidney (HK) were sampled and frozen at -80ºC. Total RNA was extracted, purified, and complementary DNA (cDNA) was synthesized from 1 µg of RNA using reverse transcriptase enzyme SuperScriptIV with an oligodT18 primer. Expression of inflammatory (*tnf-α*, *il-1β*, *il-6,* and *nf-κb*) and immune-related genes (*igf-1*, *ctsd,* and *lyz*) were analyzed by RT-qPCR and normalized with elongation factor 1 beta (*ef1β*). Results were expressed as mean ± standard error of the mean (SEM) and data were analyzed by Two-way ANOVA followed by Tukey's multiple comparison test to determine differences between the type of flow and velocity. The level of significance used was $p < 0.05$.

Results and Discussion

TNFα (tumor necrosis factor alpha), IL-1β (interleukin 1 beta) and IL-6 (interleukin 6) are cytokines considered important components in the inflammatory response in fish and are key molecules in the immunomodulatory cascade in fish gills following an environmental challenge and regulating the host defense against pathogens mediating the innate immune response (Secombes et al., 2001). Additionally, NF-κB (nuclear factor kappa b) is a transcription factor with a fundamental role in the immediate early pathogen response and in promoting inflammation (Cheng et al., 2014). The expression of *il-1β*, *il-6,* and *nf-κb* genes in gills were up-regulated in fish swimming in DL velocity condition when compared to CTRL and DH velocity conditions. However, no significant variations were found in the relative expression of immune-related genes in the HK. Higher mRNA levels of *il-1β* and *il-6* genes in HK of fish swimming in DL and CL patterns may suggest that a longer swimming period at low velocity may be required to induce significant differences compared to CTRL. Results suggest that swimming condition at DL velocity triggers in the gills a similar response to the inflammatory process and reveals how this load may regulate the immune response in this tissue. Although the relative expression of *igf-1* and *ctsd* genes in gills were increased, they did not display significant changes between experimental groups. IGF-1 (insulin-like growth factor-I) and CTSD (cathepsin D) are involved in somatic growth and innate immune response respectively (Mommsen, 2001; Subramanian et al., 2007). It is plausible to infer that a longer swimming period may require to be applied to induce significant differences in the mRNA levels for both genes.

(Continued on next page)

Conclusions

Induced swimming activity under a discontinuous low velocity may stimulate an inflammatory response in the gills of gilthead seabream. This suggests that the gills may play a key role in the immune response in addition to the well-described functions (gas and ions exchanges). It is plausible to infer that swimming conditions, often overlooked in aquaculture, may be correlated to how farmed and wild fish cope differently with immune challenges. Considering the current results, induced swimming may be an adequate tool for improving the health and fitness of farmed fish.

Introduction

The use of dietary tributyrin (TB) supplementation in land-farmed animals has been well studied, showing the potential to improve animal performance and productivity. In contrast, its applicability in aquafeeds is less studied. Previous studies have shown that TB supplementation in fish and shrimp diets seems to alleviate some of the negative effects of high inclusion levels of plant ingredients. The beneficial effect appears to be associated with the release of butyric acid, a short-chain fatty acid composing TB, into the intestine (Abdel-Latif et al., 2020). Assessing the effects of dietary TB supplementation on plant-based diets is key for optimizing feed formulations, as TB could be used to enhance fish production and animal welfare. This will be particularly interesting for carnivorous species such as rainbow trout (*Oncorhynchus mykiss*), requiring a high substitution of fishmeal by plant-based proteins aiming to implement sustainable diets. This study investigated the potential use of TB supplementation in rainbow trout diets at different levels, aiming to improve fish performance, and studying changes in several parameters related to the innate immune and antioxidant responses.

Materials and Methods

Four hundred eighty juvenile trout (19.0±0.4 g, mean±SD) were randomly distributed in 12 tanks (210 L, 40 fish per tank) connected to a RAS system under controlled conditions and daily monitored (16±1oC; 0.30±1‰; pH 7±1; >95% air saturation; 12 h:12 h photoperiod). Water ammonium and nitrite levels were below 0.05 mg mL-1 and 0.5 mg mL-1, respectively.

Four experimental diets were formulated and manufactured by Sparos (Portugal), consisting of a basal diet (control) including 10% fishmeal and 70% plant-based ingredients (44% crude protein, 18% crude fat, gross energy 21.8 MJ kg^{-1}) with increasing inclusion levels of 0.1, 0.2 and 0.4 % of a product containing 55% TB (Lucta S.A.) in replacement of silica. Each diet was randomly assigned to triplicate tanks. Fish were hand-fed twice a day to apparent satiety at 9:00 h and 16:00 h. Fish performance was evaluated after 44 days. Nine fish per treatment were sampled after 3 h or 24 h of feeding (absorptive or post-absorptive states, respectively) to evaluate the impact of dietary TB supplementation on innate immune parameters in plasma and antioxidant response in the liver.

Results and Discussion

Experimental diets had no significant impact on final body weight (g), weight gain (g), daily growth index (%), feed intake (g), or feed conversion ratio of rainbow trout after 44 days of feeding ($P>0.05$, One-way ANOVA). Similarly, experimental diets had no significant impact on body proximal composition (dry matter, protein, lipid, and ash contents) at the end of the growth trial ($P>0.05$, One-way ANOVA).

Regarding immune-related parameters analyzed in plasma, lysozyme activity was higher at 3 h post-feeding in the group fed the 0.2% diet compared to fish-fed control or 0.4% diets (P=0.021, two-way ANOVA). In addition, plasma antiprotease activity was higher at 24 h post-feeding in the groups fed the 0.2% and 0.4% diets compared to fish-fed the control diet ($P=0.010$ and 0.013, respectively, two-way ANOVA). Other immune-related parameters investigated in plasma, including peroxidase and protease activities, were not affected by the diets ($P>0.05$, two-way ANOVA).

(Continued on next page)

Increased hepatic catalase activity was detected in the group fed the 0.4% diet compared to trout fed the control or 0.2% diets at 3 h post-feeding (*P=0.016* and *0.019*, respectively, two-way ANOVA), suggesting an improved antioxidant response. The remaining parameters investigated in the liver of trout, including lipid peroxidation, total and oxidized glutathione levels, as well as glutathione-S-transferase, glutathione reductase, and glutathione peroxidase activities remained similar between dietary groups (*P>0.05*, Two-way ANOVA).

Conclusions

Although the supplementation of a TB product in diets of rainbow trout under the levels investigated did not improve growth or feed efficiency, it did not reduce feed intake. The results suggest that dietary supplementation with 0.2 and 0.4% (corresponding to 0.11% and 0.22% TB) could result in improved immune and antioxidant responses in trout, respectively.

Introduction

Exercise causes a systemic effect and promotes several biochemical and enzymatic adaptations, with a major impact on the liver and skeletal muscle functions. In mammals, the generation of reactive oxygen species (ROS) by exercise modifies cell-signaling pathways (Bouviere et al., 2021) and plays a beneficial role in the immune response (Scheffer and Latini, 2020). In fish, however, excessive ROS formation may lead to increased pro-oxidants and free radicals which damage cells and tissues, resulting in oxidative stress (OS) (Chowdhury and Saikia, 2020). Therefore, induced swimming activity may have positive (eustress) or negative (distress) outcomes depending on the conditions applied, a fundamental aspect to improve the welfare of cultured fish. The current study aims to fulfill the lack of knowledge on the impact that different swimming conditions may have on OS in the liver and muscle of gilthead seabream (*Sparus aurata*).

Materials and Methods

Forty eight gilthead seabreams (total length: 13.3 ± 0.3 cm; total weight: 57.9 ± 1.8 g) were individually subjected to a swimming trial for 6 h on continuous or discontinuous flow patterns, as follows: i) continuous low (CL, 0.8 BL s^{-1}); ii) continuous high (CH, 2.3 BL s^{-1}); iii) discontinuous low (DL, 0.2-0.8 BL s^{-1}); iv) discontinuous high (DH, 0.8-2.3 BL s^{-1}) velocities; and v) control non-exercised group (CTRL). Fish were euthanized at the end of the trial. Liver, white and red muscles were sampled and immediately frozen at -80ºC. The OS parameters in liver and muscle, including lipid peroxidation levels (LPO), superoxide dismutase (SOD), catalase activity (CAT), glutathione S-transferase activity (GST), glutathione reductase activity (GR) and both oxidized glutathione (GSSG) and total glutathione levels (tGSH) were determined. Results were expressed as mean ± standard error of the mean (SEM) and data were analyzed by Two-way ANOVA followed by Tukey's multiple comparison test to determine differences between the type of flow and velocity. The level of significance used was $p < 0.05$.

Results and Discussion

The glutathione system (GPx, GST, tGSH, and GR) and enzymes including SOD and CAT are key components of the antioxidant system in fish tissues (Kabel, 2014). A significant reduction of GR activity in the liver was observed across all swimming conditions compared to the CTRL group. In addition, the tGSH level in the liver increased in the CH group compared to the CTRL. In white muscle, GR activity increased significantly in both high swimming velocity groups (CH and DH), but tGSH increased only in the CH group compared to the CTRL group. On the other hand, discontinuous velocity (DL and DH) triggered an increase of CAT activity in red muscle compared to CTRL, although increased LPO level was evident only in the DH group. Even though various tissues may contribute to exercise-induced ROS production, it is expected that active muscle fibers will be the main source of ROS (Powers et al., 2020). White muscle in teleost fish is regarded as being used mainly for burst sprints, as it can contract quickly by using (anaerobic) glycolysis, whereas aerobic red muscle is used during sustained swimming (Davison and Goldspink, 1984). In this study, an increased CAT activity in red muscle was linked to a discontinuous swimming, which may indicate a need for H_2O_2 removal in this tissue, which was accompanied by a higher LPO level (DH condition). Nonetheless, an opposite pattern of CAT activity was observed in the white muscle in the discontinuous swimming, revealing that similar swimming conditions can result in different OS responses, depending on the muscle type. Finally, a reduction on hepatic GR activity across all the swimming conditions showed that exercise in fish acts as an important factor in modifying the antioxidant balance in liver.

(Continued on next page)

Conclusions

Induced swimming activity triggered different responses of antioxidant enzymes between white and red muscles, indicating that optimal swimming conditions shall be applied in this fish species to avoid OS. Thus, swimming conditions should be subjected to increasing attention in aquaculture, as it may influence fish welfare.

Introducion

Utilization of by-product as an aquaculture-feed ingredient has high relevance not only from a circular economy point of view but also considering that the demand for such ingredients is growing. BSG is rich in fibre and but also in protein (up to 30%) and certain phytochemicals with many biofunctions, such as antioxidant, antiatherogenic, and anti-inflammatory activities (Rachwal et al., 2020). Biotechnological processes, such as solid-state fermentation (SSF), can be effective approaches to improve BSG nutritional value and antioxidant potential by promoting the lignocellulosic cell-wall disruption and dietary nutrient/phytochemicals availability. Our preliminary results demonstrated that BSG can be incorporated at 20% in aquafeeds for carnivorous fish, namely European sea bass (Dicentrarchus labrax), after a biological treatment with SSF, without negative effects on fish growth performance (Estevão-Rodrigues et al., 2022). The focus of the present study was to assess the effect of dietary inclusion of untreated and biological-treated BSG on hepatic oxidative status of European seabass.

Materials and Methods

BSG was fermented using tray-type bioreactors for 7 days at 25°C with spores of *Aspergillus ibericus* (MUM 03.49) at a concentration of 10^6 cells mL-1. A practical diet (45% crude protein and 18% crude lipids) was used as a control and formulated to be challenging, with 15% fishmeal and a mixture of plant ingredients Four other diets were formulated similarly to the control diet, including 10% and 20% unfermented (10BSG and 20BSG diets) or fermented BSG (10BSG-SSF and 20BSG-SSF diets). The test ingredient was included in the diets at the expense of a mixture of agricultural ingredients in the control diet. Sixteen juvenile of European bass (initial body weight 49 ± 1g) were randomly distributed to each tank and each experimental diet was assigned to triplicate of these groups. Fish were manually fed, until apparent satiation, twice a day, 6 days a week, for 68 days. After the experimental period, lipid peroxidation(LP) and antioxidant enzymatic activities were assessed in the liver. The test diets were all compared to the control (orthogonal contrast) and the interaction between the incorporation levels (BSG) and the bioprocess (SSF) (orthogonal contrast) was also verified.

Results

Compared to unfermented BSG, the application of SSF to BSG contributed to increase
the crude protein content by 21% and reduce the fiber levels by 34%. Results of the feeding trial were not the aim of this study and are presented elsewhere (Estevão-Rodrigues et al., 2022). In brief, growth erformance was significantly lower in fish fed diets including unfermented BSG. However, fish fed the fermented BSG had similar growth performance (20BSG-SSF) or superior to the control (10BSG-SSF). The 10BSG diet promoted an increase in hepatic LPO, whereas control diet and the other experimental groups (20BSG, 10BSG-SSF and 20BSG-SSF) exhibited similar LPO levels (Table 1). No effects on activities of GR and CAT (except in 10BSG-SSF group that was lower) in relation to control diet were observed in the liver of fish fed the BSG-based diets. Except for 10BSG group, the G6PDH activity was significantly lower in fish fed diets with unfermented or fermented BSG than with the control diet. Among the BSG-based diets, the biological treatments (SSF) led to a decrease in all the antioxidant enzyme activities, while dietary incorporation level promoted a decrease of G6PDH activities and LPO contente.

Values are presented as means ± standard error of the mean (SEM) (n=9). Glutathione reductase[1]; glucose-6-phosphate dehydrogenase[2]; lipid peroxidation[3]. Orthogonal contrast: ∗ denotes a significant effect ($P<0.05$).

Conclusion

Although no alterations were observed in hepatic LPO content of fish fed the BSG diets (except in 10BSG diet) in relation to control group, the lack of induction of the antioxidant enzyme mechanism may be regarded as a sign of lower risk to oxidative stress. In addition, we cannot discard that putative beneficial effects of BSG on LPO content might have been masked due to antioxidant constituents/components present in PF of control diet. Althought further studies are required, the antioxidant compounds' bioaccessibility seemed be more modulated by the level of BSG incorporation than by the biological treatment applied to BSG as only lower LPO content were recorded in 20%BSG-based diets. Overall, the results of the present study indicate that BSG can be incorporated at 20% in aquafeeds without detrimental effects on hepatic lipid oxidative damage of European sea bass.

Introduction

The significant inclusion of plant ingredients in the diet of carnivorous fish species can compromise growth performance, digestibility, intestinal homeostasis, immunological parameters, and disease resistance (Oliva-Teles et al., 2015). This happens due to the anti-nutritional factors and the absence of enzymes and microbial capable of degrading the plant cell wall. The solid state fermentation (SSF) process produces enzymes such as xylanase and cellulase, degrading the cell wall and making nutrients available inside the cell. The present study's focus was to assess the effect of dietary inclusion of untreated and biological-treated SSF of brewer's spent grain (BSG) on growth performance and hepatic oxidative status of meagre (*Argyrosomus regius)*.

Materials and Methods

BSG was fermented using tray-type bioreactors for 7 days at 25°C with spores of *Aspergillus ibericus* (MUM 03.49) at a concentration of 10^6 cells mL^{-1}. A practical diet (45% crude protein and 18% crude lipids) was used as a control and formulated with 15% fishmeal and a mixture of plant ingredients. Three other diets were formulated similarly to the control diet, including 10% unfermented (10BSG diet) or 10% fermented BSG (10BSG-SSF diet). The non-fermented and fermented BSG was included in the diets at the expense of the control diet plant ingredients mixture. A growth trial was performed in a RAS system with 9 tanks of 300 L. Nine meagre (initial body weight 83.1 ± 1.03g) were randomly assigned to each tank, and each experimental diet was assigned to triplicate of these groups. Fish were manually fed until apparent satiation, twice a day, 6 days a week, for 68 days. After the experimental period, growth performance, feed utilization efficiency, and hepatic oxidative status were evaluated.

Results and Discussion

BSG proximal composition was meaningly modified by the SSF process. Protein content increased by 21%, and lipid content decreased from 6 to 3%, while the lignin, cellulose and hemicellulose decreased by 7, 30, and 34%, respectively. Moreover, cellulase and xylanase activity were also detected, averaging 109 and 282 U/g of fermented BSG.

At the end of the growth trial, it was observed that the inclusion of 10% unfermented BSG significantly reduced final body weight, weight gain, daily growth rate, and feed efficiency compared with the control diet. Feed intake was also reduced by about 13%, although not significantly. Contrarily, the dietary inclusion of 10% of fermented-BSG restored these parameters to levels similar to the control diet (Table 1).

Hepatic catalase, glutathione peroxidase; and lipid peroxidation activities were not affected by the dietary treatment. G6PDH activity of fish fed the 10BSG diet was lower than that of the other diets (Table 2).

Conclusion

SSF of BSG improved its nutritional profile. As a result, fermented BSG can successfully replace 10% of a mixture of agriculture-based ingredients without compromising meagre's growth performance, feed utilization, and liver oxidative status, contrary to the non-fermented BSG.

CHANGE AND RACE FISH MACHINE INTERACTION – EXPERIMENTAL RESULTS ON THE REACTION OF ATLANTIC SALMON *Salmo salar* WHEN EXPOSED TO EXTERNAL INFLUENCE FACTORS

L. D. Evjemo, E. Eilertsen, E. Kelasidi, N. Blöcher

Department of Aquaculture Technology, SINTEF Ocean
E-mail: linn.evjemo@sintef.no

Introduction

In this abstract, results are presented from the study of the behaviour change of Atlantic salmon (*Salmo Salar*) in an industry scale fish farm when exposed to different influence factors. Data is gathered to study the fish behaviour change when exposed to structures with varying shape, movement, and sound. The fish reaction to the structure has been studied during static and moving case studies to identify and quantify the distance that the fish keep from the different structures and how the fish reacts when the structures are moving. Furthermore, to study how sound affects the fish behaviour, underwater speakers have been places inside the structures, exposing the fish to frequencies between 100 and 1000 Hz.

This work was financed by the Research Council of Norway through the project: CHANGE and RACE Fish Machine Interaction [1].

Methods

Two yellow structures (cube and cylinder) with diameter/side length of 0.6 meters was equipped with cameras and echo sounders and lowered to eight meters depth. The cameras and sensors were GOPros and BlueRobotics Ping360 echo sounders, which have a sampling rate of 9 seconds per 360° swipe when set to a distance of 2 meters. Four replicates of videos and echo-sounder data have been obtained from two cages in an industrial scale fish farm which is part of SINTEF ACE [2] during field trials in 2021.

When studying the fish reaction to moving the structure, the structure was manually pulled 10 meters over approx. 20 seconds using ropes, with 10 minutes between each movement. During the audio tests, sounds were played for 60 seconds at a time with a 10-minute interval in between. Sounds of 100 Hz, 200 Hz, 400 Hz, 600 Hz and 1000 Hz were played in a random order, and each frequency was played several times.

Results

The sonar data shown in Figure 1a show fish presence in a radius of 5 meters around the stationary structure over a period of 10 minutes. Based on sonar data from the field trials, the fish seem to keep a distance of approx. 2 meters to the structure when the structure is stationary. Similar results were obtained from the movement tests without audio, with the fish still keeping approx. 2 meters distance, see Figure 1b. These results were similar for the cylindrical structure, which was also tested.

The videos from the audio experiments have been analysed to observe and document the behavioural change of fish. From viewing the data it seemed evident that the fish showed no reaction when playing audio of 100 Hz, 600 Hz or 1000 Hz. For 200 Hz and 400 Hz, however, the fish react differently. Before the audio is played the fish can be seen swimming past the structure at a distance. The fish then has a clear reaction, as shown in Figure 2: When the audio starts playing, the fish swims away and disappears from the view of the cameras. Most fish stay away for the duration the frequencies are playing and do not resume undisturbed schooling behaviour until after the sound has stopped. An exception to this is if the audio is played during feeding: if this is the case the fish exhibit no response to the signal, seemingly only focused on feeding. Because of the relatively low sampling rate of the echo sounders, it is difficult to use this data to analyse the immediate reaction of the fish to the frequencies.

Conclusion

In conclusion, Atlantic salmon seemingly change behaviour when exposed to audio signals with a frequency between 200Hz and 400Hz. The fish stays away, slowly returning only after the signal has stopped. The presence of a static structure, and a structure moving in the environment without sound, does not seem to trigger this immediate response. The fish keep an average distance of 2 meter from this structure when static and move gradually out of its path when the structure is moving. The distance kept from the structure may relate to the structure size, but more tests need to be executed to confirm this. In addition, the results indicate that the salmon did not react differently to structures of different shapes when the size and colour stayed the same.

(Continued on next page)

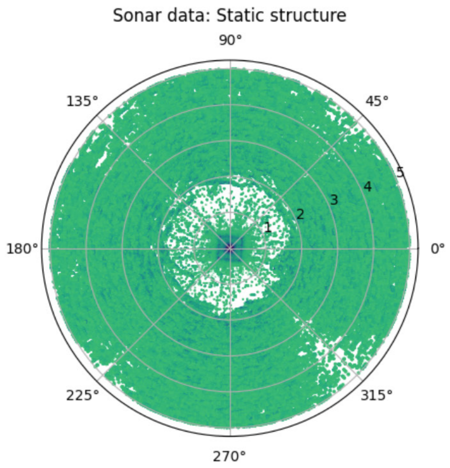

Figure 2a: *Sonar data of stationary, cubic structure. The fish seem to keep a fixed distance of approx. 2 meters.*

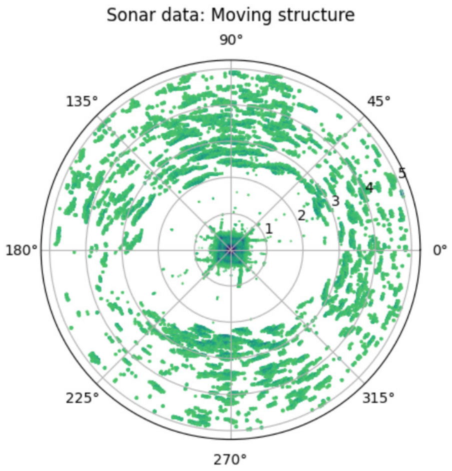

Figure 2b: *Sonar data of moving, cubic structure. The fish seem to keep the distance of approx. 2 meters even during movement.*

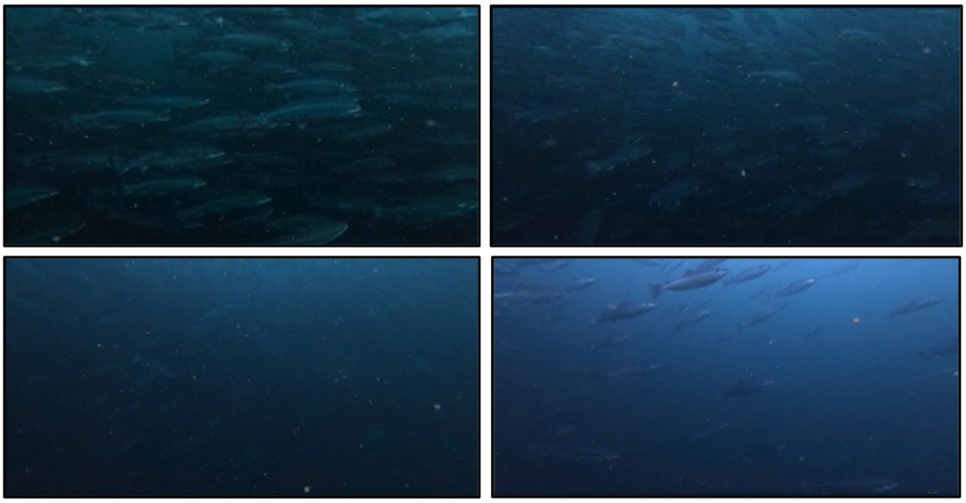

Figure 2: *Images from video when playing sound of 400 Hz for 60 seconds. From top left to bottom right: Still photos taken 2 seconds before sound started playing, the moment the sound started, 4 seconds after audio started playing, and 30 seconds after audio started playing. Fish reacts strongly when audio starts playing, and most of the fish stays away as long as the audio is still playing.*

GENOMIC RELATIONSHIPS BETWEEN TRAINING AND TESTING SETS AFFECT GENOMIC PREDICTION ACCURACY OF NODAVIRUS RESISTANCE IN GILTHEAD SEA BREAM

S. Faggion*, P. Carnier, V. Bonfatti, L. Bargelloni

Department of Comparative Biomedicine and Food Science, University of Padova (Italy)
E-mail: sara.faggion@unipd.it

Introduction

Gilthead sea bream (*Sparus aurata*) has been reported to be susceptible to a reassortant betanodavirus strain (RGNNV/SJNNV), posing a new threat for sea bream industry (Volpe et al. 2020) and raising the attention to selective breeding as a plausible disease prevention action. Genomic selection might be beneficial for traits, such as disease resistance, characterized by difficult, expensive and time-consuming routine individual phenotyping. Genomic models are trained firstly using a reference population of full- and half-sibs of the future breeding candidates, but, in a long-term view, the prediction of the genetic merit of future breeding candidates should be satisfactory even when the reference population consists of distant relatives of the animals to be predicted. In this sense, the genomic predictive accuracy provided by random k-fold cross-validations might be unrealistic. In this study, we assessed the accuracy of a genomic prediction model for VNN symptomatology pseudo-phenotypes (estimated breeding values, EBV) in gilthead sea bream in three different validation settings: 1) a random cross-validation; 2) a cross-validation based on genomic clustering; 3) a leave-one-family-out (LOFO) validation focused on the parents of the fish subjected to the VNN challenge test.

Materials and methods

The experimental fish were produced at a commercial hatchery in three independent full factorial matings (10 sires × 12 dams; 10 sires × 7 dams; 10 sires × 5 dams). At the age of 19 d post-hatching, 972 larvae were subjected to a challenge test by tank immersion using the RGNNV/SJNNV strain; the symptomatology was recorded as a binary trait. The experimental fish and their parents (22 dams and 28 sires) were genotyped using the Med_Fish SNP array (Peñaloza et al. 2021; 26,591 SNPs after quality check and imputation). The SNP genotypes were used as predictors of EBV for VNN symptomatology by means of a Bayesian Ridge regression (BRR) model. The accuracy of the model was assessed in three different validation settings: 1) a 4-fold random cross-validation; 2) a 4-fold cross-validation based on genomic clustering, where four groups (336, 177, 328 and 133 individuals, respectively) were created using K-means clustering based on genomic relationships to reduce the relatedness between training and testing populations (relatedness between one group and the others: -0.07, -0.06, -0.03, -0.04, respectively), while maximizing the relatedness within each group (genomic relatedness within group: 0.12, 0.24, 0.04, 0.26, respectively); 3) a LOFO validation, where the BRR model was trained on the EBV of all animals except the offspring of the sire (or dam) used one-at-a-time as an independent test set. The Pearson product-moment correlation (r) between the observed and predicted values was computed as a measure of prediction accuracy for the three validation procedures.

Results

Genomic predictions of EBV for VNN symptomatology showed high accuracy in random cross-validation ($r = 0.90$; Figure 1a). The predictive accuracy decreased when genomic relatedness between training and testing sets were minimized ($r = 0.53$; Figure 1b) and resulted very low in the LOFO procedure ($r = 0.13$; Figure 1c).

Discussion

In gilthead sea bream, the genomic prediction of the EBV as pseudo-phenotypes for VNN symptomatology led to a very high accuracy in a random 4-fold cross-validation setting; however, to obtain a more realistic insight, a 4-fold cross-validation based on genomic clustering and a LOFO validation were developed. The accuracy obtained in the validation procedure based on genomic clustering was lower than that of the random cross-validation, but still satisfactory, suggesting that in a scenario where the reference population consists of distant relatives of the animals to be predicted, the predictive performance of such model would be acceptable. This is of great interest in an applicative context, particularly when considering traits phenotyping difficulties and complexity. Conversely, in the LOFO procedure, the accuracy dropped remarkably (-85.6%), suggesting that the training of the genomic model was based on data of animals weakly related to the target individual. In fact, the parent contribution to offspring was rather unbalanced, with 3 dams out of 22 producing almost 67% of the individuals, and 6 sires out of 28 producing almost 48% of the individuals.

EVALUATION OF IMTA-PRODUCED MACROALGAE (*Ulva lactuca*) MEAL AS DIETARY INGREDIENT IN FEED PELLETS FOR SOUTH AFRICAN ABALONE (*Haliotis midae*)

A E. Falade*, P J. Britz, and CLW. Jones

Introduction

Abalone is one of the most valued and highly sought-after seafoods globally with South Africa being the largest producer of farmed abalone outside Asia. They are cultivated in flow-through raceway tanks in South Africa and fed fish and soy meal protein-based pellets or a combination of pellets and live macroalgae until they reach market size. Research is underway to substitute the fish meal component with a less expensive and more sustainable protein sources. The seaweed *Ulva* is cultivated as part of an intergrated multi-trophic aquaculture (IMTA) in the effluent water of several commercial abalone farms, where it acts as a biofilter to remove dissolved waste nutrients and harvested as a fresh abalone feed supplement. Effluent-grown *Ulva* can be an excellent source of vitamins, minerals, alanine, glutamic acid, iron, soluble fibers and with protein levels of up to 40%. In the present study we evaluated the inclusion effect of nutrient-enriched macroalgae (*Ulva species*) meal in a pelleted abalone diet.

Materials and methods

Ulva meal, experimental diets preparation

U. lactuca was cultured on a commercial abalone farm for 30 days using a 308.57 m3 (36.735 x 8.4 x 0.70 m) D-ended paddle-wheel biofilter pond which received effluent from abalone production raceway tanks upstream. The abalones supplying the effluent were daily fed a combination diet of commercial feed pellet (Abfeed™ S34, i.e., 34% protein, 4.5% lipid) and fresh macroalgae (*Ulva* and *Gracilaria sp*). At the end of the production cycle of the *Ulva*, it was harvested, rinsed in fresh seawater, and dried at 40 °C in a locally fabricated drier. The *Ulva* meal was subjected to biosecurity measures before being included as a feed ingredient in pelleted diets manufactured by at a commercial abalone feed company (Marifeed Pty Ltd, South Africa). Six isonitrogenous experimental diets containing 34% protein were prepared to contain graded levels of IMTA *Ulva* meal ranging from 0% – 12% of the dry mass. The *Ulva* meal replaced protein from fish and soya at 0% (basal diet), 0.75%, 1.5%, 3%, 6%, and 12%.

Feeding trial

The diets were fed daily to triplicate groups of grow-out (35-45g) *H. midae* for 244 days (December 2020–August 2021). Randomly selected abalones per treatment (n=90) were sampled for shell length and weight at stocking, after 4 and 8 months of intensive feeding. Triplicate samples of abalone for each dietary treatment were collected at the end of the trial and analysed for their proximate compositions. The daily increase in shell length, weight, specific growth rate, body weight to shell length ratio, feed conversion ratio, protein efficiency ratio and the energy efficiency ratio of cultured abalones were measured and calculated at the end of the experiment.

Results

After eight months of feeding, the weight and shell length of abalone across the various feed treatments had improved substantially as their growth and nutrient utilisation were influenced by the dietary inclusion of IMTA *Ulva* meal in the diet. Feed consumption significantly improved ($p<0.05$) with an increasing level of *Ulva* meal in the pellet ($F_{(5, 12)} = 10.242$, $p= 0.0005$). The best apparent feed conversion (1.18 ± 0.11) was recorded for abalone fed 1.5% IMTA *Ulva* inclusion diet while the lowest (2.12 ± 0.28) recorded at 12% inclusion. There was no significant difference ($p>0.05$) in the final weights, shell length and weight gains of the animals up to 12% inclusion of *Ulva* meal in the diet. However, the highest weight gains were recorded at 3%-6% inclusion of *Ulva*. The results obtained in this study suggest that the use of IMTA-produced *Ulva* meal in the diet for South African abalone (*H. midae*) could be promising as no adverse effect on growth or body composition was observed.

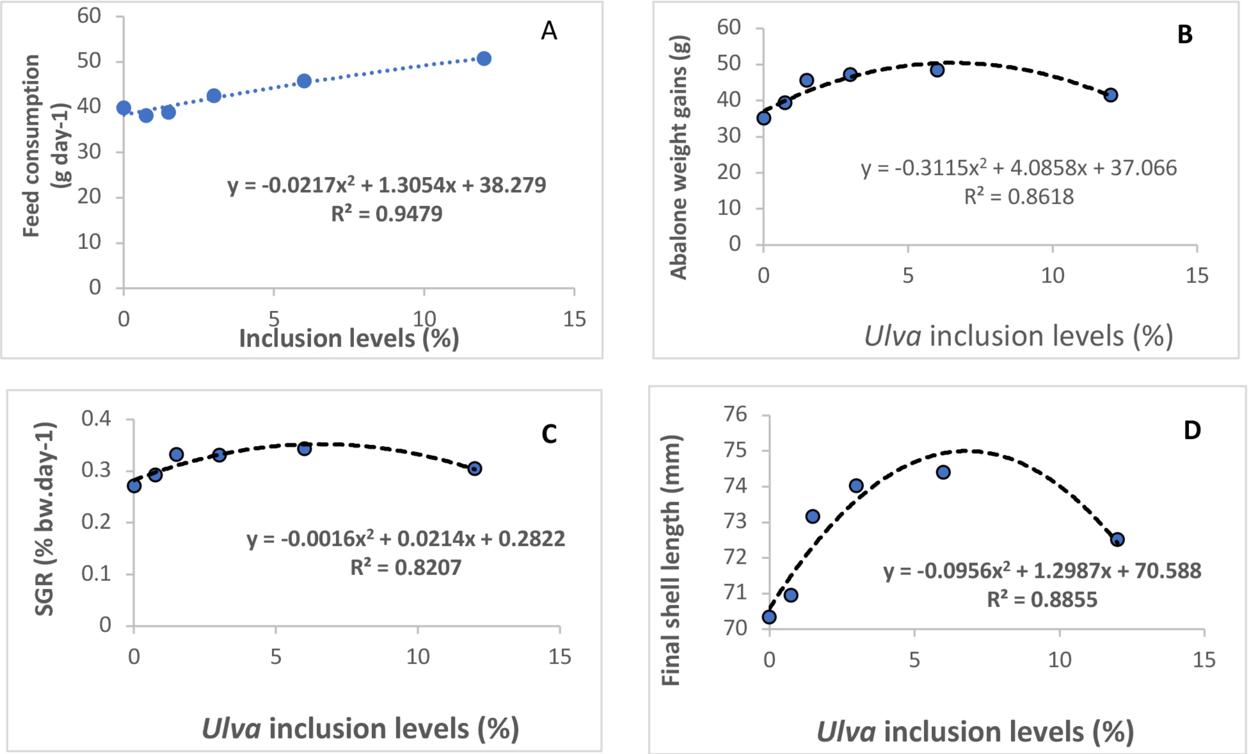

Figure 1: Polynomial regression of abalone feed consumption (A), weight gain (B), specific growth (C), and final shell length (D) against inclusion levels of IMTA *Ulva* in commercial pellet fed to the animals.

CLIMATE CHANGE AND AQUACULTURE: WORKING ON A PUZZLE WITHOUT ALL THE PIECES

Lynne Falconer*, Solfrid Sætre Hjøllo, Elisabeth Ytteborg

Institute of Aquaculture, University of Stirling, Stirling, Scotland, FK9 4LA
Email: lynne.falconer1@stir.ac.uk

Introduction

Climate change has, and continues to have, widespread negative impacts across the world. Some effects are now irreversible, and there are situations where loss and damages are unavoidable, but there is still potential to reduce exposure and vulnerability to aspects of climate change through adaptation (IPCC, 2022). Aquaculture has a range of adaptation responses that could be implemented, each with their own advantages and disadvantages. However, therein lies the question – how can we identify the most appropriate adaptation responses for aquaculture? Unfortunately, there is no simple answer.

There are many uncertainties about the future, and information is lacking on how different specific locations, species, and farming systems will be affected. The aquaculture industry and policymakers will need to make decisions on future strategies despite incomplete and missing information, which may lead to the wrong decisions being made. At the same time, waiting for impacts to occur before making any strategies is also dangerous. Many adaptation responses require time to plan, develop, and implement. Reactionary approaches would leave many parts of the sector vulnerable and unable to respond effectively, threatening aquaculture production.

This may seem overwhelming, and some may perceive this as an impossible challenge. However, whilst it is very difficult to accurately predict the future, there are ways that researchers, industry, and other stakeholders, can work together to establish supporting knowledge that can increase the confidence in decision-making. Here we present a structured approach to support optimisation of existing knowledge, prioritisation of new knowledge generation, and knowledge translation towards improved decision-making. Salmon aquaculture in Norway is used as a case study.

Methods

The first step involved developing a knowledge base with information on how climate change may affect Norwegian salmon aquaculture (Falconer et al., 2022). The scope covered the production stages from breeding to harvest and processing, as well as components of the wider supply chain such as transportation and feed. The next step involved framing the knowledge base within local-scale assessment. Models and *in-situ* data were used to provide context for more site-specific analysis.

Results and Discussion

In the knowledge base, 7 climate stressors, 45 impacts, and 101 adaptation responses were identified, as well as knowledge gaps where further research was needed. Identified impacts included damage to land-based infrastructure and transport routes, health challenges, product quality issues, and changes in availability of feed ingredients. Most of the impacts were linked to multiple stressors, highlighting the need for further research into their interactions and combined effects. This knowledge base provided a starting point that was then used to guide the local-scale assessment. There were some challenges in moving towards more detailed local-scale assessments, particularly around data-availability. However, it was still possible to integrate contextual information that enabled an overview of what potential future challenges could be.

Conclusion

Climate change and aquaculture is a puzzle, but it is one that cannot be ignored. There are many complexities, and generalisations can be misleading. Broad-scale assessments are a starting point but need to be distilled to local-scale using contextual information. This then provides a more realistic overview of the climate change puzzle at farm-level and a route forward to support long-term decision making.

EVALUATION OF APPLYING ENVIRONMENTAL ENRICHMENT ON STERLET (*Acipenser ruthenus* L.) IN EARLY LIFE STAGES

Georgina Fazekas*, Jelena Stanivuk, Dorottya Fazekas, Uroš Ljubobratovič

Hungarian University of Agriculture and Life Sciences, Institute for Aquaculture and Environmental Safety,
Research Institute for Fisheries and Aquaculture, H-5540 Szarvas, Anna-liget street 35, Hungary

Introduction

Nowadays, nature conservation programs are ongoing to maintain sturgeon populations through ex situ interventions that place great emphasis on artificial reproduction. Despite the partial recovery of populations due to annual restocking and improving water quality of upper and middle Danube and some of its tributaries, the sterlet *Acipenser ruthenus* is still considered Vulnerable by the IUCN (Kubala et al. 2021). Generally, restocking programs mainly focused on the impact of genetic processes on wild populations, however, the conditions of the rearing environment of fish for restocking purposes is a subject raising attention. Rearing fish in a commercial aquaculture manner may lead to decreased post-release survival due to artificial rearing environments that may induce behavioral responses different from those considered normal in wild fish (Williams et al. 2009; Johnsson et al. 2014). Manipulation of the rearing environment may have an impact on neural plasticity and cognition (Salvanes et al. 2013), and also on growth parameters and survivorship of fish and subsequently, it can improve welfare and fitness-related traits (Carrera-García et al. 2016; Lee et al. 2018). The aim of the current experiment was to evaluate the effect of environmental enrichment on the growth and survival of sterlets in early life stages.

Material and methods

Fish specimens used in the trial were obtained via artificial propagation of pond-reared sterlet breeders of Research Center for Fisheries and Aquaculture, MATE HAKI, Szarvas, Hungary. At 24 day post-hatch (DPH) fish were randomly divided into duplicated plain aquaria – control group (C) and duplicated aquaria with small gravel (0.5–2 cm) on the bottom – enriched group (E) for 44-day-long rearing. In total 272 fish were stocked per aquaria. Rearing conditions were tested in duplicates under natural photoperiod. Random subsamples (n=31) were collected from the aquariums and were measured for weight and total length. In total, four samplings (30, 37, 51, and 64 DPH) were conducted till the end of the rearing. Larvae were initially fed with freshly hatched *Artemia salina* nauplii and frozen bloodworms. Weaning to dry starter (BioMar Larviva 300 and BioMar Larviva 500) was initiated at 29 DPH co-fed with Chironomus sp. until the end of rearing.

Results

Significant differences were found in final body weight of fish at 64 DPH being significantly smaller in the E group (Fig.1). Likewise, the two experimental groups significantly differed in coefficient of variation in final body weight being higher in the C group. Finally, significantly higher survival (72.24 ± 2.9 % vs 89.15 ± 1.8 %) was noticed in the E group.

Discussion

Overall, our results show that environmental enrichment might play important role in the growth and survival of sterlet in the early life stage. The fish from environmental enriched groups were significantly smaller than fish from control aquariums however without influencing negatively the condition factor, implying that enriched-reared fish were perhaps forced to swim more searching for food among the gravels while in bare tanks the food was available for the fish without making a big effort. Furthermore, the mortality was significantly lower in E groups respectively indicating that the gravels might serve as a shelter for the fish during the experiment. Similar to our outcome higher survival rate was obtained in enriched groups in zebrafish (*Danio rerio*) larvae (Lee et al. 2018). In contrast with our result, the study of Carrera-García et al. (2016) in European sturgeon (*Acipenser sturio*) shows that fish in enriched conditions were bigger than fish reared in the traditional way and there was no difference in mortality between the two groups. Thus, the rearing conditions for sterlet early stages should be considered due to the potential benefits in terms of survival, and perhaps the fish may show enhanced exploratory behavior which is beneficial for stock enhancement in wild. Further studies should address the effect of environmental enrichment on stress response and anxiety-like behavior, behavioral plasticity, memory, and learning ability in sterlet.

Introduction

The sterlet is the only sturgeon species in the Hungarian section of the Danube and Tisza rivers, that is still present, and has a stabile population. The *ex-situ* sturgeon live gene bank of MATE (the Hungarian University of Agriculture and Life Sciences) and HAKI (Research Centre for Aquaculture and Fisheries) has a significant role in the preservation of this vulnerable species by its conservation management practice and conservation-based restocking programs. The individuals of the species are kept in earthen pond conditions in the gene bank of HAKI. Broodstock's collection of sterlet in the gene bank started in the '80-is, by capturing wild individuals primarily from Danube, Tisza, and Körös Rivers. This collection formed the basis of the recent broodstock of the sturgeon live gene bank. In the last decade, with the aim of compensate the fish stock of the locally habitat in Hungary, were no regular stocking activities. However the restoration of genetic diversity were taken into account considerably by the recent stocking programs. The goal of our research was to assesse the genetic patterns, and relationships of the recent wild population and captured stocks.

Materials and methods

For the analysis to detect, we assessed the genotype of individuals with 12 microsatellites (DNA) markers from a wild population. The examined wild fish originated from Hungary parts of river Tisza and Danube, from *ex-situ* gene bank and two fish farms. The fish of the gene bank was marked with individual tags, this way we could collect genetic data on the individual level. For the analysis, we took samples from the tissue on the caudal fin. DNA isolation was conducted using the E.N.Z.A. kit tissue DNA (Omega Bio-tek Inc.) method, following the instructions set by the producer. We used 100 ng DNA per sample for the PCR reaction and 12 microsatellite markers for the genetic analysis into six PCR multiplex sets. Composition of PCR reaction based on the protocol of producer (Multiplex PCR Plus Kit, Qiage). The amplified products were determined using ABI 3130 sequencing (Applied biosystems, USA). The allele number and size were identified by the Gene Mapper (Applied Biosystem) software. The standard population genetic calculations were delivered by the GenALEx 6.5 statistical software package, and the discriminant analysis by R-program.

Results and discussion

As a result of the genotyping, we detected 126 alleles on the 12 loci. The population genetic values were calculated including the number of alleles, the number of effective alleles, the observed and expected heterozygosity, the fixation index (Table 1). The average allele numbers for the group varied between 5.33 and 9.8. The average values of fixation index per population were close to zero in all populations, in the Tisza population this value was even negative. The average expected heterozygosity (He) were between 0.52 and 0.59, while the observed (Ho) values were between 0.47 and 0.60. However, the differences were small, statistically significant differences were observed in the case of the most alleles. The gene bank group reached, the highest genetic diversity, we conclude it likely represents the population of the Middle Danube and its tributary Tisza river.

Introduction

The Pacific oyster (*Magallana gigas*) is the most produced oyster species worldwide, with France leading the European Union producers (86% of total production) (FAO, 2022). Due to its economic value, ecological role (e.g. filter feeders, reef-builders) and worldwide distribution, it is critical to assess the risk of emerging contaminants in this species. Titanium dioxide nanoparticles (TiO_2 NPS) appear as the most relevant NPs as regards human and environmental exposures, and their reprotoxicity is still scarcely addressed in oysters. Improving knowledge of oysters' reproductive biology, namely gonadal energy-related parameters and susceptibility to oxidative stress, is vital for population maintenance, stocking and predicting possible effects on other bivalve species.

Materials and Methods

The present study evaluated the effects of TiO_2 NPs on the oxidative stress profile and energy-related parameters of oysters' gonads. To accomplish that, juveniles (n=36) were exposed via water to environmentally relevant concentrations of TiO_2 NPs (10 and 100 µg/L of TiO_2 NPs) for 3 and 7 days. After exposure, the sex of the gonads was identified, and the antioxidant response (CAT, GPx, SOD, GR, GST and GSHt), lipid damage (LPO), the energy available (total carbohydrates, proteins and lipids content) and energy consumed (Electron transport system (ETS) activity) were assessed in female and male gonads.

Results

In male gonads, no alteration of the antioxidant responses and LPO occurred on day 3, while after 7 days of exposure, the activity of GPx increased in the 10 µg/L concentration concerning control, as well as the levels of LPO in both TiO_2 NPs concentrations. On the contrary, in female gonads, the activity of CAT decreased in the 10µg/L concentration and SOD in the 100µg/L relative to control, but no LPO appeared. After 7 days of exposure, no alteration occurred in the antioxidant responses and damage. Regarding the energy-related parameters of males, increasing lipid content at 100µg/L concentration and decreasing ETS at 10µg/L concentration occurred after 3 days of exposure, while after 7 days total carbohydrates content diminished in the 100µg/L concentration of TiO_2 NPs. Contrary to males, no alterations emerged for females after 7 days of exposure. However, decreasing carbohydrate content occurred at 100µg/L of TiO_2 NPs.

Discussion

Male gonads seemed to be protected against oxidative stress after 3 days of exposure to TiO2 NPs, while ETS activity decreased, suggesting impairment of its metabolic activity. Plus, lipid content increased in high TiO2 NPs concentration, which can alter membrane constitution and carbohydrate metabolism, a crucial energy source for gametogenesis. After 7 days of exposure, oxidative stress occurred in male gonads (LPO increased in both TiO_2 NPs concentrations), despite the significant increase in protection against oxidative damage (GPx increase) at lower TiO_2 NPs concentrations. Simultaneously to the enhancement of GPx and LPO, carbohydrates decreased, suggesting gonadal investment in detoxification mechanisms and less energy available for spermatogenesis. These findings suggest that male gonads are impacted differently, depending on the time of exposure. While after 3 days of exposure, the metabolic pathways were affected, after 7 days oxidative stress toxicity was also evident. Female gonads showed depletion of the antioxidant after 3 days of exposure (CAT and SOD), but with no oxidative stress, as no damage occurred. Similarly, the total content of carbohydrates also decreased, reinforcing gonadal investment in detoxification processes and less energy source for oogenesis. On the contrary, after 7 days of exposure, no alterations emerged in gonads. Apparently, females seem less vulnerable to TiO_2 NPs and show recovery ability after 7 days of exposure.

(Continued on next page)

Conclusion

The present results suggest that males and females have a different vulnerability to environmentally relevant concentrations of TiO_2 NPs and that females can cope with the challenge induced by these NPs. The effects of TiO_2 NPs in males may be enhanced with the exposure time, impairing gametogenesis. Further studies should evaluate the possible impacts of TiO_2 NPs in gonads of M. *gigas*, seeking to understand the potential mechanisms that interfere with reproduction, continuity of the species and impairment of production.

Introduction

Growth of the aquaculture sector in Europe and North America is a priority for food security, particularly as the world population increases and production from Asia and elsewhere becomes more accessible to domestic markets in those regions. The strategic aim of growing aquatic production in the West is sharpened by the policy goal of increasing per capita fish consumption, widely seen as key to dietary improvement, obesity reduction, and improved health and well-being.

The anecdotal distinction of quality between farmed and wild-caught fish is at least partly based on fallacious arguments and should not be the basis for consumer choice; however, there is a deficit of consumer information—at fresh fish counters, labelling typically provides the common name for a product, sometimes the scientific name, and origin. In the European Union, the provenance of wild-caught fish is reported only as a broad region (e.g. NE Atlantic), while cultivated products refer the country of origin.

This paradigm must shift towards significantly better consumer information, presented in an appealing way, that helps buyers understand what they purchase and why—in essence, what defines a good fish.

Concept and approach

A good fish can be defined through the following four categories, each with a corresponding set of descriptors or indicators:

1. Consumer experience (taste, texture, etc);
2. Nutrition and well-being (composition, including key factors such as Omega-3 or calcium content, and health benefits, such as neo-natal cerebral development or anti-inflammatory properties);
3. Environmental sustainability (e.g. associated to ecological carrying capacity, see Ferreira et al., 2012);
4. Animal welfare (metrics on environmental thresholds, stocking and harvesting, etc).

This classification does not distinguish between aquaculture and capture fisheries, but instead uses an evidence-based categorical approach in the definition of what constitutes a good fish. The implementation of the GoodFish methodology required (a) a well-established scientific basis for extracting and providing relevant information; and (b) a simple and effective means of communication of this information to the consumer, using an actionable, two-way approach. These requirements will be reviewed in turn.

Sourcing and processing of information

Organoleptic qualities were sourced from hospitality industry databases and interviews with chefs, and included ancillary data (e.g. product suitability for preparation of specialty presentations such as sushi or ceviche). The composition of cultivated aquatic products was analysed by means of well-established food composition databases from both the US Food and Drug Administration (USA) and Public Health England (UK). From these sources, a cloud-based relational database was developed containing detailed data on proximate composition, inorganics, vitamins, saturated and unsaturated fatty acids, and a number of other constituents.

Human health information was collected from the literature, as was data on environmental thresholds and animal welfare conditions (see e.g. https://meta.longline.co.uk/, which compiles data on 500 thresholds sourced from about a thousand scientific publications).

(Continued on next page)

Communication and feedback

A smartphone application was developed, accessible via a QR code integrated in the labelling of fish and shellfish sold fresh at supermarkets and fishmongers or prepared in specialty restaurants. The GoodFish platform differs from other offerings—it does not present a score or ranking of particular products i.e. it does not make recommendations or attempt to make decisions on behalf of the consumer. Instead, the emphasis is on displaying information in a clear, simple, and appealing way, allowing consumers to make up their own mind, and providing a means for three-stage feedback on products. This feedback uses the ACT[1] metaphor: Acquire – Cook – Taste. After scanning a product QR code or set of codes, consumers are invited to classify their purchasing experience using the usual five-star scheme. Subsequently, the consumer can score the product in terms of ease and enjoyment of preparation (confection), and finally with respect to the experience of eating the resulting dish.

The app is supported by a web-based platform (http://goodfi.sh) that operates the databases and allows consumers and businesses to manage various options. For supermarkets and restaurants, this includes product management, access to scores, and other business intelligence data.

The deployment and refinement of the GoodFish app is currently being discussed with a major retail group, with the aims of providing consumers with a much richer experience in their relationship with aquatic foods, increasing understanding, and stimulating *per capita* consumption. Retail outlets currently have little grasp of the actual consumer experience—once a fish fillet or a bag of mussels is sold, there are no mechanisms to provide feedback on the way a product was prepared and whether the resulting meal was forgettable, enjoyable, or delicious. As an increasing number of consumers provide their own ACT scores for aquatic products, the resulting information can be leveraged to understand patterns of consumption, species preferences, and relevance of factors such as traceability and local sourcing, and help aquaculture producers tailor their offerings to better meet consumer expectations.

Introduction

The population of Sub-Saharan Africa is growing at an estimated 2.7% per year, more than twice that of South Asia and Latin America. This growth rate will lead to a doubling of the region's population by 2050, which poses a significant challenge with respect to food security.

Capture fisheries in the whole of Africa are well above aquaculture production, which contrasts sharply with the global situation (FAO, 2020)—since 2013, over half of the seafood for direct human consumption is sourced from aquaculture. Contrary to world fisheries, which are flatlining, African wild catch is still increasing, but the share of aquaculture in production of seafood has tripled since the year 2000. In parallel, *per capita* fish consumption in sub-Saharan Africa is very low, generally below 5 kg ind^{-1} y^{-1}. Out of the three nations bordering Lake Victoria, only Uganda consumes over 10 (10-20) kg ind^{-1} y^{-1} (FAO, 2020).

The decline of capture fisheries in the Great Lakes due to overfishing and other factors has been ongoing for several decades (Ogutu-Ohwayo et al, 1997), and catches of Nile perch (*Lates niloticus*) and Nile tilapia (*Oreochromis niloticus*) in Lake Victoria have decreased markedly since the 1990s (Katunzi, 2019).

The dual challenges of collapse of capture fisheries and population growth—the population of the Kenyan catchment of Lake Victoria is expected to double by 2050, in line with the rest of Sub-Saharan Africa—mean that aquaculture is one of the potential solutions to allow expanding human populations to have access to food security over the next thirty years and beyond.

Tilapia, due to its high growth rate, well-established husbandry, and low trophic status, shows great promise as a high-quality protein source, and Lake Victoria has appropriate conditions for its cultivation. However, in order to ensure that aquaculture expansion in this region is achieved in a sustainable manner, a development framework is required to address the challenges of environmental sustainability and ecosystem carrying capacity.

In order to illustrate the underlying issues, and in particular the challenges in the implementation of the Ecosystem Approach to Aquaculture (EAA - Soto et al, 2008), taking into account ecological sustainability, social balance, and harmonization of multiple uses, a well-tested framework for zoning and carrying capacity assessment is being applied in Lake Victoria. The rationale is that models of this kind can be used to support industry development and help managers make informed decisions about sustainable expansion of aquaculture.

Approach

The framework used for carrying capacity assessment builds on a combination of various models, which together are used to understand the different components of the system (*Fig. 3)*. These include individual growth models, local-scale carrying capacity models, farm footprint models for both organic and inorganic waste, models for land use in order to partition nutrient loading, and spatial analysis tools.

This complex framework is being developed as part of the Sustainable Activities in Water Areas (SAWA) project, developed by Kenya, which aims to build an aquaculture governance framework that improves decision-making and addresses the challenges of multiple lake uses in the Kenyan part of Lake Victoria.

(Continued on next page)

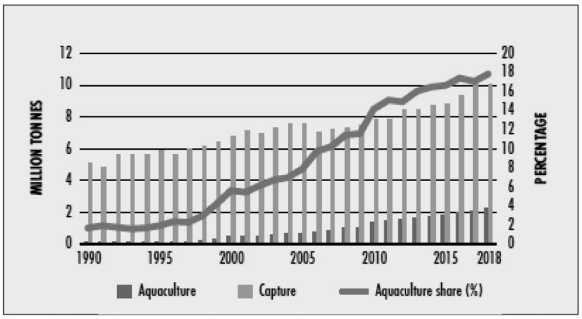

Fig. 1. Wild capture & aquaculture in Africa (FAO, 2020).

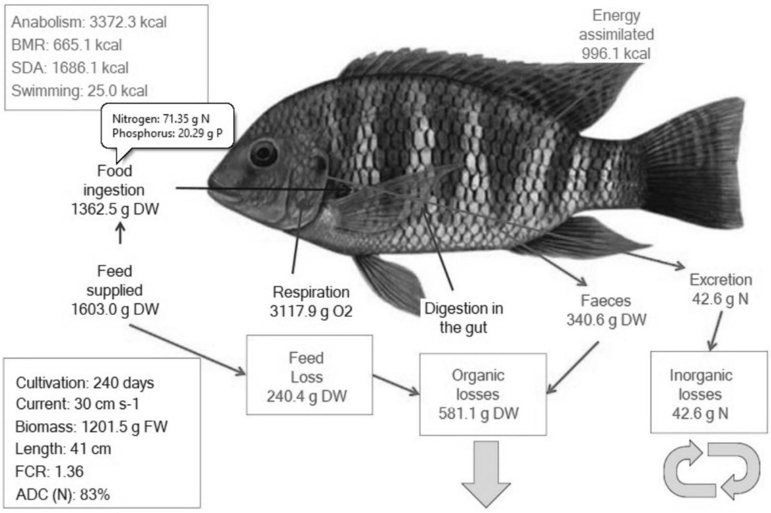

Fig. 2. Individual model for Nile tilapia. The AquaFish models are used to drive local-scale carrying capacity models such as FARM.

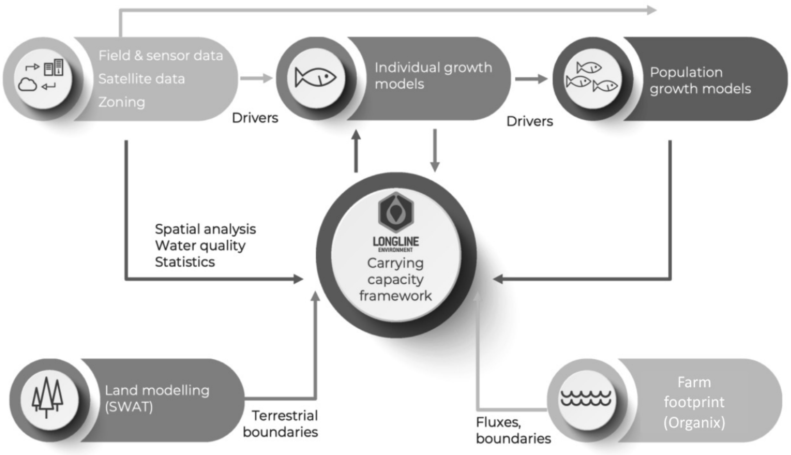

Fig. 3 –General modelling framework, showing the different types of models and respective interactions.

(Continued on next page)

In parallel to the modelling framework, a full stakeholder consultation and engagement programme is developed within SAWA. The results obtained from the natural sciences components of the work will help to inform factually-based discussions and promote consensus among aquaculture businesses, fishers, management agencies, and the wider community.

The application of the EAA for the Kenyan area of Lake Victoria will create conditions for industry growth, contemplating both artisanal cultivation practiced by local communities associated to Beach Management Units (BMU) and more sophisticated operations that include full vertical integration from farm to fork.

Results and discussion

A mass balance for individual growth modelling for Tilapia, using the well-tested AquaFish model (e.g. Ferreira et al, 2015) is shown in Fig. 2. The model will be tuned for Lake Victoria, where production of market-sized tilapia takes longer than in Thailand or China, which may be related to feed quality or to other husbandry aspects. The model forms the basis for local-scale modelling of tilapia farms, which in turn will be used to drive simulations of organic deposition and enable the assessment of ecological carrying capacity.

Results for organic loading to the sediment from commercial tilapia farms using the ORGANIX model suggest that at present, finfish aquaculture developed sustainably has significant upside for increasing food security and meeting targets for consumption of aquatic products in Kenya.

Fieldwork and stakeholder consultation showed that both local communities and larger businesses are committed to work within SAWA to provide data and improve the knowledge base essential for the successful application of EAA to Lake Victoria, and fully expect to benefit from the project outcomes. A frequent stakeholder concern was to ensure that the results of SAWA have the necessary buy-in from policy makers as a condition for success.

We hope that the implementation of a successful aquaculture framework for the Kenyan water area, taking into account the uses of the associated catchment, will exemplify how this participative governance model can be extended to Lake Victoria as a whole, a transboundary system that must be managed holistically.

Introduction

Finfish aquaculture is a source of dissolved nutrients which can affect water quality in the wider environment (Howarth et al. 2019). Therefore, the potential effects of dissolved nutrient loading must be considered if management is to transition towards an Ecosystem Approach to Aquaculture (EAA). Understanding the extent and effects of dissolved nutrient plumes emanating from fish farms has been identified as one of the largest knowledge gaps in transitioning towards the EAA (Jansen et al. 2018). In this study, the dispersion of dissolved nitrogen from a rainbow trout farm in Port Mouton (Nova Scotia, Canada) was investigated using a fully spatial hydrodynamic model. The ecosystem level effects were evaluated as the potential for dissolved nitrogen toxicity on a foundation seagrass species, particularly given that seagrass has declined in Port Mouton over time.

Material and Methods

Dissolved nitrogen loading was calculated by applying nutritional mass balance model to growth estimates from a Thermal Growth Coefficient model. Both models were parameterized for the observed conditions in Port Mouton. The spatio-temporal dynamics of dissolved nitrogen was simulated by coupling a tracer sub-model to a hydrodynamic model constructed in FVCOM (Finite Volume Community Ocean Model). The tracer submodel was restricted to advection-dispersion dynamics, omitting any chemical and biological processes. These conservative tracer simulations maximized nitrogen levels, and consequently, were considered a worst-case scenario to inform ecosystem level effects under a precautionary approach. A range of scenarios were applied for different stocking densities, background conditions and aquaculture practices.

Results and Discussion

The aquaculture scenarios simulated in Port Mouton suggest that the maximum concentration of dissolved nitrogen would not exceed 6 μM in the center of the farm under the most adverse conditions (2 μM background nitrogen, 500,000 fish, peak of production, and no uptake of nutrients by primary producers). This concentration would drop to < 5 μM for the most common scenario taking into account the aquaculture practices at the farm (Fig. 1). These values are below the toxicity threshold for seagrass reported in the literature. To the best of our knowledge, the lowest value tested in the literature for ammonium toxicity was 9 μM (van Katwijk et al. 1997). These authors reported that toxicity for *Zostera marina* occurs at ammonium concentrations between 9 and 25 μM, with no effects at 9 μM and evident necrosis at 25μM.

Models are simplifications of the real-world and this is not an exception; however, the assumptions to simplify the model were directed to simulate the worst-case scenario and would maximize the buildup of dissolved nutrients, and consequently, toxicity for seagrass. First, the model did not distinguish between chemical forms of nitrogen, which represents the worst-case scenario to define toxicity for seagrass, given that the toxicity is specific to each nitrogenous compound (e.g. van Katwijk et al. 1997). Second, only background concentration of dissolved nutrients and the contribution of the farm were used as sources of nitrogen, and more importantly, no sinks were included in the model in the most stringent scenarios. This approach implies that dissolved nitrogen can only leave the system through the exchange with the open ocean, which increases the residence time of dissolved nitrogen in the system, increasing potential for toxicity. Third, background concentration of dissolved nitrogen exceeded observed values in adjacent waters (Johnson et al. 2018), which accounts for uncertainty. Fourth, the biomass of fish was overestimated in some scenarios, and it was simulated during peak of production, which represents the worst-case scenario in terms of excretion of nitrogenous products. These four considerations ensure a precautionary approach when evaluating the model's predictions for dissolved nitrogen in the context of potential toxicity for seagrass.

The simulation of dissolved nitrogen as a conservative tracer using a fully-spatial hydrodynamic model suggests that the maximum concentration of nitrogen caused by a trout farm is unlikely to be toxic for seagrass in Port Mouton Bay. This conclusion is grounded in the analysis of precautionary worst-case scenarios that aim to maximize the buildup of dissolved nitrogen in the bay. This outcome suggests that the decline of seagrass reported in some parts of the bay are unlikely to have been triggered by dissolved nutrients discharged from the farm.

Introduction

Fish is an important source of macronutrients, vitamins and minerals, being our primary source of omega-3 fatty acids, namely EPA and DHA. This characteristic associates the ingestion of fish with cardiovascular, intestinal, and neural benefits, with aquaculture playing an essential role since it contributes to nearly half of the global fish consumption. However, the sector´s sustainability raises questions, leading the aquaculture industry to reduce the inclusion of fish oil (FO) in fish feed, and replace them with other more sustainable oils like soybean oil (SO) but devoid of omega-3 fatty acids (Kriton et al., 2018). Here, one of the biggest challenges is to find more sustainable ingredients that equally provide the demands of omega-3 to the final consumer and recommend by WHO. Another challenge is to maintain the organoleptic characteristics of the fillet since the increase in fatty acids content can lead to a more perishable product. Therefore, the aim of this study was to address if the substitution of FO and SO with sustainable marine sources rich in EPA and DHA – salmon oil (a coproduct from the salmon industry), algae oil and algae blend - in sea bass feeding could result in quality alterations during a 14 day storage period in ice.

Materials and methods

European sea bass (*Dicentrarchus labrax*) (initial body weight 71.1 ± 13.2 g) were fed for 116 days with two experimental diets (Marine 1 and Marine 2) and compared to counterparts that received a commercial-like diet (control). All diets were isoproteic (45% dry matter, DM) and isolipidic (18% DM) with different lipid sources (Table 1): Control diet is a commercial-based diet with a blend of sardine and soybean oil as primary lipid sources; Marine diets 1 and 2 were completely devoid of SO: in diet 1, FO was partially replaced by salmon oil (a coproduct from the salmon industry) and a blend of micro and macroalgae; in diet 2, FO was totally replaced by a blend of salmon and algae oil. All the diets were tested in quadruplicate. By the end of the trial, all fish were individually weighed and 4 fish per tank were sampled for flesh quality evaluation over a 14 day storage period in ice. Fish fillets were evaluated for colour, pH, water holding capacity (WHC) and texture at days 0, 3, 7 and 14. Previous reports indicated 14 days as the sea bass shelf life, so this was selected as the end point of the experiment (Kılınc et al., 2007; Özden et al., 2007). Muscle samples were also collected for antioxidant activity and lipid oxidation at days 0, 3, 7 and 14 (ongoing).

Results

In the present study, sea bass fed with diets in which FO and SO was partially (Marine 1) or totally replaced (Marine 2) by alternative marine sources, grew equally well as fish fed with the control diet. No significant differences could be observed in fish survival, growth performance, and feed efficiency.

The evolution of pH throughout time is presented in Figure 1a. For all diets, an increase in pH during storage was observed, which is in agreement with other previous studies that reported a rise in pH associated with volatile bases production due to the degradation of protein to ammonia and trimethylamine by microbial or endogenous enzymes (Monirul et al., 2019). The maximum value for pH was at day 14 with 6.65, 6.62 and 6.60 for control, Marine 2 and Marine 1 diet, respectively. The experimental diets did not significantly affect flesh pH. Also, no differences were observed for either water holding capacity (WHC) (Figure 1b) and colour among fillets from fish fed with the various experimental diets.

Regarding the textural properties, no significant differences were observed for hardness between the control and the experimental diets. The average values for springiness and resilience displayed significant changes at day 7 with sea bass fed with Marine 2 diet, which exhibited the highest values. In addition, fish fed with Marine 2 diet presented significantly higher values for cohesiveness in comparison to the control diet at the end of storage (day 14).

(Continued on next page)

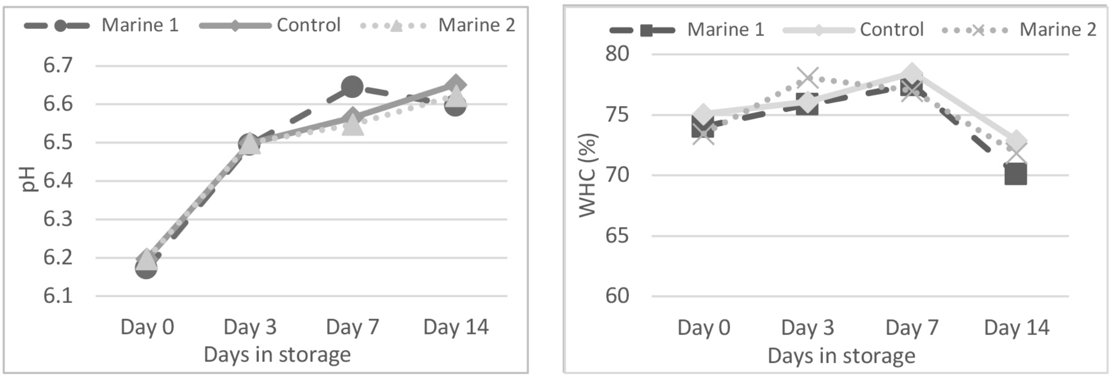
Ingredients (%)	Control	Marine 1	Marine 2
Fish oil	9.0	6.7	-
Soybean oil	4.4	-	-
Salmon oil	-	6.2	10.1
Algae oil	-	-	3.3
Blend of algae	-	2.0	-
Total dietary EPA+DHA (%)	3	3	3

Figure 1. pH and water holding capacity (WHC) of the sea bass fillet over the 14 days storage period.



a)

b)

Discussion and Conclusion

The fact that the type of feed had no negative effect on the muscle textural parameters studied suggests that marine lipid sources rich in omega-3 could be an excellent sustainable alternative to FO in aquafeeds, whilst assuring fish nutritional quality and consumers' health. Moreover, sea bass fed with salmon oil combined with algae oil improved flesh cohesiveness, suggesting an improvement in fish muscle integrity in comparison with sea bass fed with control diet, and therefore, the potential to facilitate the shelf life of sea bass fillets during 14 days of storage at refrigerated temperatures.

Introduction

With the ban on ethoxyquin and concerns about the use BHT and BHA in the European Union, novel alternatives of antioxidants for aquaculture have become an issue. The most promising replacements for these synthetic antioxidants are natural antioxidants primarily present in plants. A source of high amounts of natural antioxidants can be found within by-products from the olive-mill and winery industries, with are prominent in the EU. However, antioxidants bioavailability may be compromised due to the lignocellulosic matrix of these by-products. Solid-state fermentation (SSF) is a sustainable bioprocess that can utilize agro-industrial by-products as a substrate for microbial growth in low water activity conditions, producing enzymes that hydrolyze the cell wall and release antioxidants into the substrate. After SSF, these important bioactive compounds are recovered with different applications, including feed additives for aquaculture. Dietary fortification with antioxidants can be beneficial in reducing fish's oxidative stress status and delaying lipid peroxidation. This work aimed to study the antioxidant potential of extracts from olive mill and winery by-products, unfermented or fermented, in European Sea Bass.

Materials and methods

An optimized mixture of olive mill and winery wastes (Filipe et al., 2019) was fermented by SSF with *Aspergillus ibericus* (MUM-01.29; Micoteca od the University of Minho (UM). After fermentation, an aqueous extraction was performed (1:5 solid/water, w/v) for 30 minutes with constant stirring. Another extract was also prepared from the same mixture but without the fermentation process. The recovered extracts were then lyophilized (FWO and UWO, fermented and unfermented extracts, respectively). Four isolipidic and isoproteic diets (18% lipids, 50% protein) were formulated with 0 (control diet), 0.34, and 0.68% of FWO or with 0.19% of UWO to reach an antioxidant activity of 0 (control diet), 683 (FWO1 diet), 1365 (FWO2 diet) and 683 (UWO diet) μmol Trolox kg^{-1} of diet. A growth trial with European sea bass (IBW= 21.5g) testing each experimental diet in triplicate was performed for 66 days. At the end, the liver and intestine of 9 fish from each diet were sampled, immediately frozen in liquid nitrogen, and stored at -80º C. Samples were then homogenized in Tris–HCl buffer at a pH of 7.8, centrifuged at 30,000×g for 30 min at 4 °C and supernatants were recovered. Superoxide dismutase, glutathione peroxidase, glutathione reductase, glucose-6-phosphate dehydrogenase, and thiobarbituric acid reactive substances were analyzed in both tissues.

Results and discussion:

In the liver (Table 1), there is a general decrease in specific oxidative stress-related enzyme activity without affecting liver peroxidation with the dietary supplementation with FWO or UWO extracts. Antioxidant compounds present in these diets may have had a direct action on preventing or neutralizing the reactive oxygen species (ROS) production, modulating the activation of oxidative stress enzymes.

In the intestine (Table 2), a general increase in specific oxidative stress-related enzyme activity, together with a decrease in lipid peroxidation, was observed with the dietary inclusion of FWO1 or UWO extract. Besides their direct ROS scavenging activity, dietary inclusion of FWO1 and UWO extracts also activated the antioxidant enzymes system. Compared to the FWO1 diet, the FWO2 diet induced lower activity of the antioxidant enzymes and increased intestinal lipid peroxidation.

Conclusion

Present results showed that dietary inclusion of FWO and UWO extracts at a level corresponding to the antioxidant activity of 683 μmol Trolox kg^{-1} diet improved the intestine's antioxidant status, increasing its ability to cope with ROS production and decreasing the lipid peroxidation. In the liver, these extracts reduced the overall antioxidant enzymes activity without compromising the hepatic peroxidation

Introduction

The use of dietary supplements in the form of antioxidants is already commonplace in aquaculture diets. Antioxidants are used to reduce aquafeed lipid peroxidation and to improve fish oxidative status. Furthermore, antioxidants are vital for protein turnover as they reduce oxidative damage in the skeletal muscle thus promoting long-term growth performance. As synthetic antioxidants like diphenylamine and ethoxyquin were banned in Europe due to food safety concerns, novel antioxidants made from natural sources are becoming predominantly researched. By-products from olive mills and wineries are important agroindustrial industries in the Mediterranean region and are a good source of natural antioxidants. However, the bioavailability of these antioxidants may be impaired by the lignocellulosic matrix of these by-products. Solid-state fermentation (SSF) is an economical and ecological bioprocess that can be applied to extract the highest amount of antioxidants from these by-products. SSF uses fungi to hydrolyze the aforementioned lignocellulosic matrix and release phenolic compounds, which become available to be recovered, concentrated, and added to the diets. This work aimed to evaluate how extracts obtained from fermented and unfermented wine and olive oil by-products affected the growth and feed utilization of fish maintained under non-stressful or chronic handling stressful conditions, using Zebrafish (*Danio rerio*) as a biological model.

Materials and methods

An optimized mixture of exhausted olive pomace, vine-shoot trimmings, and exhausted grape pomace for increased enzyme production and antioxidant recovery (Filipe et al., 2019) was fermented by SSF with *Aspergillus ibericus* (MUM-01.29; Micoteca of the University of Minho (UM). After fermentation, an aqueous extraction was performed (1:5 solid/water, w/v) for 30 minutes with constant stirring. Another aqueous extract was prepared from the same mixture but without the fermentation process. The extracts were lyophilized and the final products were labeled as FWO (fermented extract) and UWO (unfermented extract). Three isolipidic and isoproteic diets (8% lipids, 40% protein) were formulated: a control diet, without extracts, and two diets with fermented (FWO diet) and unfermented (UWO diet) extract included at 1 mg gallic acid equivalents per g of diet.

The trial was performed with zebrafish (*Danio rerio*) with an IBW of approximately 96 mg. Diets were tested in quadruplicate for 24 days under non-stressful conditions. Then, fish were weighed, and in the following 5 days, 2 of the 4 replicates were exposed to daily stress by air exposure for 3 minutes, while the other 2 replicates were not stressed. During this period, stressed and unstressed fish were fed the same diets. Then, fish were weighed, and weight gain, specific growth ratio, feed intake, and feed efficiency were determined.

Results and discussion:

During the non-stress period of the trial, corresponding to the first 24 days of the trial, no effect of dietary supplementation with FWO or UWO extract on growth performance and feed utilization efficiency was observed. During the last 5 days, corresponding to the stress period, relative to the control, the diet supplemented with the FWO extract led to significantly higher weight gain, feed efficiency, and specific growth ratio.

When evaluating the whole trial, from day 1 to day 29 (**table 1**), including unstress and stress periods, relative to the control, the diet supplemented with the FWO extract led to a significantly higher weight gain and specific growth ratio. Both diets supplemented with FWO extract or UWO extract led to a significantly lower feed intake and higher feed efficiency. Stress did not affect growth performance and feed utilization.

Conclusion

The FWO diet promoted growth performance and both the FWO and UWO increased feed utilization and decreased feed intake, relative to the control diet.

Introduction

The importance of the fish hatcheries' microbial communities to fish health and welfare has been long recognized and several studies have been conducted to map these communities during healthy rearing conditions but also during disease outbreaks. Most studies focus on the intestinal and epidermal microbiome of the developing fish, which is mainly shaped by the live feeds (microalgae, rotifers and copepods) used at the rearing process. The microbiome of live feeds, however, has not been investigated thoroughly so far.

Objective

We have analyzed the microbiome of one research and two commercial fish hatcheries producing Mediterranean fish species with emphasis on their live feed sectors. The aim was to compare the microbiomes of hatcheries with different characteristics (water source, production intensity and practices) and provide baseline information about their structure with focus on putative pathogenic bacteria.

Materials and Methods

The hatcheries were sampled seasonally over one year. Sampling involved 5 stations: inlet, microalgae, rotifers, artemia and outlet. Water samples were filtered using a vacuum filtration system and DNA was extracted from filters. 16s amplicon Novaseq sequencing was conducted. Bioinformatics included amplicon sequence variant analysis (ASVs).

Results

More than 162.859 good quality sequences per sample were generated in a total of 129 samples. 46.745 ASVs were annotated with 362 average ASVs per sample. Opportunistic fish pathogens like *Vibrio alginolyticus* and *Vibrio anguillarum* are abundant in the Artemia sections of the commercial hatcheries. The genera of *Vibrio* and *Tenacibaculum* are abundant and diverse in all hatcheries with the incoming water contributing significantly to the presence of important taxa that constitute presumptive pathogens. Alpha diversity analysis revealed a relatively stable microbiome between seasonal samplings for every hatchery. Nevertheless, a diverse microbiome between sampling stations was discovered. A core microbiome for every hatchery was catalogued, which included important putative fish pathogens belonging to *Vibrio* and *Tenacibaculum* genera. Mapping of the microbiome in the live feeds through metagenomics is the first step towards an efficient microbial control in the fish hatcheries.

Introduction

Some byproducts of the dairy industry, such as the exhausted whey from Bovine Ricotta cheese production (scotta), do not have real ways of valorization as the bovine whole whey but, being still rich in nutrients, need to be disposed of for not impacting on the environment. Current conventional treatment technologiesare of hard management and feature high costs. Among the possible and more sustainable solutions, microalgae-based bioprocesses could be a valid alternative (Gramegna et al., 2020). *Euglena. gracilis* is a microalga able to grow under heterotrophic and mixotrophic conditions, accumulating higher amounts of paramylon than under photoautotrophic conditions (Lewis et al., 2020). Paramylon can be used in many fields of commercial interest. Some studies also indicated biostimulant properties of this polysaccharide (Barsanti et al., 2019).

In this work, the ability of *E. gracilis* to grow on diluted ricotta exhausted whey was verified. The obtained biomass was than characterized for protein, paramylon and lipid content and used for evaluation of its biostimulant effects.

Materials and methods

A sample of ricotta whey, coming from an Italian dairy, underwent a preliminary treatment consisting in thermocalcic precipitation (Bosco et al.,2018), in order to remove the lipid fraction and obtain a clarified phase. This phase had a significantly lower COD (from 55 g L^{-1} to 35 g L^{-1}). A part of the clarified phase was then, in turn, subjected to microfiltration, in order to reduce its bacterial count. Three growth media were tested with *E. gracilis* (1224-5/25): i) Standard Cramer-Myers medium (SM, Cramer & Myers, 1952) with glucose, used as control (SMG); ii) clarified whey, diluted 1:3 with water (TCW1); iii) microfiltered clarified whey diluted 1:3 with water (TCW2). Growth tests were performed in 100-L bubble-column photobioreactors; each medium was tested in duplicate in batch mode, at a temperature of 20-25° C and an irradiance of 80 μmol photons m^{-2} s^{-1}, with a dark/light cycle of 12/12 hours. At the end of the growth-phase, the biomass was harvested, analyzed for biochemical parameters and tested to assess seed germination on cress (Lepidium sativum L.) by a phytotoxicity test (Ronga et al., 2019).

Results

The best growth was found in TCW2, where the maximum cell density at day 10 was 0,88 ± **0,04** Mcell mL^{-1} and COD was removed by about 75%. The inorganic nitrogen was removed by 90-95% in both TCW1 and TCW2 and fully depleted in the control (SMG). The culture tests of *E.gracilis* on exhausted whey showed a content of proteins almost 2-fold higher than the control (SMG: 25.4 ± 0.6%; TCW1: 49.8 ± 8.4%; TCW2: 49.5 ± 3.4%). On the contrary, the content of paramylon (% of dry matter) was 2-time higher in the control compared with the tests (SMG: 21.9 ± 0.9%; TCW1: 9.7 ± 1.4%; TCW2: 12.0 ± **2.1%). The results of phytotoxicity test revealed an interesting** biostimulant effect on cress seeds of the TCW2 extract, with an average germination index of 150.9 ± 17.6% (with respect of water, control thesis), while the extracts of the SMG (108.9 ± 9.2%) and TCW1 (96.8 ± 2.0%) revealed neither biostimulant nor phytotoxic effects.

(Continued on next page)

Discussion and Conclusion

This study showed the ability of *E. gracilis* to grow on a pre-treated and water-diluted exhausted whey without additional nutrient supplementation.

The biochemical composition of the *E. gracilis* biomass grown on the dairy byproduct was found to be significantly different from the one grown on synthetic medium. In particular, the microalgae biomass grown on dairy byproduct, thus with lactose as source of carbohydrate and whey proteins and peptides as additional organic and nitrogen sources, showed a higher protein content, at the expense of paramylon and lipids. On the contrary, the *E. gracilis* biomass grown on synthetic medium, thus with glucose as the only organic source, showed a low content of protein and higher content in lipids and paramylon. The only microalgae biomass showing a biostimulants effects was that grown on microfiltered exhausted whey (TCW2).

In the context of expanding fish production and complex distribution chains, food safety assessments and the development of traceability tools become increasingly important. Here, the elemental fingerprints of gilthead seabream (*Sparus aurata*) muscle from four sources in the Northeast Atlantic were assessed, namely from two Portuguese locations, representing three production methods: from Olhão (Mainland Portugal) captured in i) wild, ii) semi-intensive aquaculture in earth ponds, and iii) intensive sea cage aquaculture; and from Madeira Island captured in iv) intensive sea cage aquaculture. The concentrations of elements with regulatory thresholds (Cu, Hg, Pb, Zn) were evaluated and this biochemical signature demonstrated potential of tracing production method of this species. Among these elements, only Pb presented concentrations consistently above the recommended limit for human consumption, particularly from will caught and earth pounds production. Using a chemometric approach based on multi-elemental signatures, sample origin was determined with an overall accuracy of 90%. Furthermore, a classification model was developed with samples from Olhão, and when applied to classify samples collected in Madeira Island it correctly allocated 27 of the 30 samples to its original production method (intensive sea cage aquaculture).

These results contributed to the development of traceability tools and their applicability in real case scenarios, as well as, regarding food safety, to raise attention to the potentially toxic concentrations of Pb for human consumption in fish from all origins and the high concentrations of As in wild-caught *S. aurata*. Thus, to our knowledge, the present study is the first that allowed to efficiently distinguish the production method of *S. aurata,* while additionally shedding light on its food safety features.

METABOLIC RESPONSES OF JUVENILE MEAGRE (*Argyrosomus regius*) REARED UNDER HYPO OSMOTIC CONDITIONS TOWARDS AQUACULTURE REFINEMENT

The aquaculture of Meagre *Argyrosomus regius* an important commercial fish species, is still under development towards its full potential and optimized production Although the species main strengths are well known in fish farming namely high growth rate and feed conversion ratio, flesh quality, nutritional value, size, and husbandry techniques additional scientific research might generate rearing opportunities This species is migratory, spending their first months in estuaries, and then moving to coastal and offshore areas, constantly facing environmental differences that strongly determine their feeding activity, reproduction, and trophic migrations Nonetheless, meagre production has been restricted to sea cages and land salt based tanks Considering its high tolerance to a wide range of factors such as salinity, the present study aimed to assess the stress and biochemical costs associated with the rearing of juveniles under hypo osmotic environments, to better profit from this species characteristics and potentially settle them on diverse locations without productivity loss Organisms were reared for 28 days at salinity of 5 10 20 or 30 ppt, resembling estuarine and lagoon conditions. Growth rate was calculated, and biochemical responses associated with oxidative stress, oxidative damage, and energy metabolism were measured in muscle, liver and heart tissues, with limited effects detected in meagre for any of these conditions These results confirm the euryhaline characteristic of this species early life stages at the biochemical level, which are further on related to organism fitness, improving knowledge on future aquaculture techniques towards reduction of production costs and spread under diverse environmental conditions and practices, such as integrated multi trophic aquaculture or aquaponics.

SHORT-CHAIN FATTY ACIDS AS FUNCTIONAL INGREDIENTS TO BOOST EUROPEAN SEA BASS *(Dicentrarchus labrax)* GROWTH PERFORMANCE AND HEALTH STATUS

Introduction

Novel aquafeeds usually include high levels of plant feedstuffs (PF). However, most PF has antinutritional factors (ANF) that may jeopardize nutrient digestion and metabolic utilization, increasing fish susceptibility to oxidative stress, intestine inflammation, and disease susceptibility. Recent evidence showed that short-chain fatty acids (SCFA) improve animals' digestive function, immunological and oxidative responses and modulate intestine microbiota. However, there is a lack of knowledge regarding single use or potential synergetic effects of SCFAs in fish fed with PF-rich diets. Therefore, the main goal of this work is to evaluate the potential of using SCFAs as functional ingredients in PF-rich diets on growth performance, immune status, and disease resistance of European sea bass, one of the most important fish species in the Mediterranean aquaculture.

Material and Methods

European sea bass juveniles (initial body weight 15.2g) were randomly distributed into twenty-one tanks (25 fish per tank) and fed in triplicate each experimental diet. Seven isoproteic (44% crude protein) and isolipidic (18% crude lipids) diets were formulated, including different short-chain fatty acids and different percentage supplementation: control diet with no supplementation and test diets with 0.25 or 0.5% of sodium acetate (SA), sodium propionate (SP), and sodium butyrate (SB). At the end of the growth trial, three fish per tank were sampled to evaluate their immune status.

After the growth trial, fish were relocated to the challenge room. Six fish per diet were randomly selected, and intraperitoneally (p.i) injected with 100ul of *Vibrio anguillarum* (1.2x10^{7} CFU/ mL^{-1}). Four and twenty-four hours after the p.i infection, fish were sampled to assess the hematological profile and innate immune parameters.

To assess the survival, fifteen fish per tank (thirty per diet) were also injected as previously described. These fish were fed the growth trial assigned diets, and the mortality was recorded for 3 weeks.

Data were analyzed for normality and homogeneity of variance and, when necessary, transformed before being treated statistically. Statistical analysis was performed with a three-way ANOVA, with time, fatty acid, and levels of supplementation as the main factors. When significant interaction occurred, one-way ANOVA for each factor was performed. The significant differences among means ($p<0.05$) were determined by Tukey's multiple range test. Non-orthogonal contrasts between control and other treatments were performed in each sampling time. All the statistical analysis was performed in the SPSS version 27.0 software package (IBM® SPSS® Statistics, New York, USA).

Results

At the end of the growth trial, dietary treatments had no effects on the growth performance and feed utilization efficiency of European sea bass juveniles.

During the challenge trial all blood parameters, decreased with time regardless of fatty acid or its level of supplementation comparing to time 0 (prior infection), except for mean corpuscular hemoglobin concentration (MCHC). All parameters showed a tendency to recover at 24h.

Mean corpuscular volume (MCV) is higher in fish fed sodium butyrate diets than in fish fed sodium acetate diets.

(Continued on next page)

In innate immune parameters, a time effect was found. Lysozyme and peroxidase activity decreased at 4 and 24h post-infection, compared to the other sampling times, regardless of the diet. This decrease may be related to the lower WBC values at 4h compared to time 0 and 24 h after p.i.

Peroxidase activity recovered at 24h in sodium acetate at 0.25 and 0.5% and at sodium propionate at 0.25% to similar values found in fish at time 0.

Lysozyme activity was higher in fish fed sodium butyrate when compared with sodium acetate, despite the inclusion level but was not different from the values found in fish fed sodium propionate diets.

Even though no significant differences in fish survival were observed between the tested and the control diets. Nevertheless, despite not being statistically different,fish fed the 0.5% sodium butyrate diets had the highest survival (93.3 % vs. 66.7% sodium propionate (SP) 0.25%).

CHROMOSOME ANALYSIS OF EMBRYONIC AND LARVAL STAGES OF STERLET *Acipenser ruthenus*

D. Fopp-Bayat*, M. Kucinski

University of Warmia and Mazury in Olsztyn, Oczapowskiego 5, 10-719 Olsztyn (Poland)
E-mail: foppik@uwm.edu.pl

Introduction

The aim of the present study was to develop a routine cytogenetic method for the identification of ploidy level or chromosome aberrations in sterlet (*A. ruthenus*) embryos and larvae.

As chromosome engineering is the fundamental biotechnology tool that enables improvement and sustainable aquaculture of fish, including sturgeons, new analytical techniques are still required, especially for the early life stages of fish, including embryos (Chandra and Fopp-Bayat 2021; Fopp-Bayat and Kucinski 2022).

The presented procedure can be applied during chromosome manipulation in sturgeon fish with the efficiency of chromosome extraction ranging from 70 to 100% and the average number of recorded metaphases per slide ranging between 9 to 15. This protocol can be applied as a reliable tool in genome manipulations effectiveness or to check the correctness of the ploidy of experimental individuals.

Materials and methods

In the present study four age variants of sterlet were used: embryos 24 hours post-fertilization (HPF) (blastula stage), 4 days post-fertilization (DPF), 6 DPF (before hatching), and larvae with a yolk sac up to 7 days post-hatching (DPH). The experimental chromosome preparation procedure comprised several main steps, where all variables were optimized in a stepwise manner. The experimental variants of immersion of live embryos and larvae in 0.025% colchicine for 5 different time periods and different times of embryo hypotonization were experimentally tested. Chromosome slides were prepared in accordance with the standard splash procedure (Fopp-Bayat and Woznicki 2006).

Results and discussion

The developed rapid chromosome preparation protocol enabled the isolation of chromosomes from embryos and larvae of sterlet. The quality and quantity of chromosome slides were determined by tissue type, and the slides prepared from heads (gill cells) produced the most satisfactory results. Our results show that chromosomes can be isolated from every developmental stage of *A. ruthenus*, but the overall quality and quantity of the extracted chromosomes can vary. The most satisfactory metaphase plates were obtained from embryos at 6 DPH and larvae at the age of up to 7 DPH. In these groups, the quality of chromosomes supported counting and karyotyping. Chromosomes isolated from embryos of 24 HPF and 4 DPF were characterized by the weakest quantity and quality and could be applied for chromosome counting only. The optimal hypotonization period was 5-15 minutes for embryos at 24 DPF, 40 minutes for embryos at 4dpf, and 50-60 minutes for fish at 6 dpf-7 DPF.

Introduction

The fast growth of aquaculture in recent decades has relied on several innovations (Asche, 2008; Kumar & Engle, 2016). Today, the need to achieve environmental sustainability is a strong driver for technological innovations (Osmundsen et al., 2020). To promote sustainable aquaculture and encourage relevant technological innovations, the Norwegian government launched free "development licenses" for salmon (*Salmo Salar*) production in 2015 (Norwegian Directorate of Fisheries, 2016). The industry responded by suggesting many different new farm concepts, providing a highly interesting insight into which directions the industry believes marine salmon production may take in the future (Føre et al., 2022).

Materials, methods and results

A systematic content analysis was performed to establish a base for investigating the technological directions proposed in the development license applications. The main material applied in the content analysis was the response and decision letters from the Norwegian Directorate of Fisheries (NDF) and the Ministry of Trade, Industry and Fisheries to the 104 applications for in total 884 development licenses.

By September 2021, 23 applications had been awarded, 78 had been rejected, and three applications had not received a final decision by the NDF. The awarded applications corresponded to 111 production licenses with a total maximum allowed biomass of 84,134 tons.

Categories of farm concepts were established based on observations in the applications for development licenses, including (listed by descending number of registered applications): Closed sea-based fish farms, conventional PE-rings, semi-submersible platforms, and rigid floaters. As many as nine closed farms concepts were awarded (39% of total awards), but only two PE-ring concepts (9%). Semi-submersible platforms and rigid floaters were the two concepts with the highest success rate in the allocation process: In both these categories, five of nine applications were awarded, representing 61% of the total allocated biomass.

Most suggested innovations were concerned with the prevention of sea lice infections, and all awarded concepts had measures against sea lice. According to the response letters, 70% of the applications and 87% of the awarded concepts involved specific measures against escape. 20 out of 23 were considered to contribute to the use of previously unsuitable locations (very sheltered and open ocean sites), or the increased sustainable utilisation of existing areas for aquaculture (coastal).

Some of these awarded concepts have been realized, followed by both success stories and challenges. Fish farmers report that they experience less parasitic sea lice on their fish, high water quality and optimal temperatures. This has for some resulted in good growth numbers, feed conversion factors, fish survival, and product quality. On the downside, fish escapes, demanding operational conditions (HSE-issues), and suboptimal water quality has also been reported. Time will tell which concepts will succeed in the long term, and if any will be able to compete with the currently dominating PE-rings. The development indicate that the future may include a variety of different concepts that are specially designed for environmental and biological conditions at the given sites.

Introduction

Natural products rich in polyphenols have gained particular interest because of their plethora of biological activities and related health benefits for a wide range of farmed fish (Ahmadifar, et al., 2020). Over the last decade, protein hydrolysates from the microalgae *Spirulina (Arthrospira) platensis* containing bioactive peptides with biological activity are being studied as potential novel ingredients in functional foods for humans (Lafarga et al. 2021). The most important effects of polyphenols concern fish growth performance parameters and feed utilization, and overall fish health in intensive fish farming, while those of the bioactive peptides are still unknown in fish.

The aim of the present study was to evaluate the supplementation of different olive oil by- compounds rich in polyphenols and bioactive peptides from Spirulina, on growth performance, feed utilization, and fish health in European sea bass and Gilthead sea bream juveniles after they have been fed on a commercial like diet enriched with different % of these nutritional supplements versus a non-enriched diet. In the present abstract it is presented part of a more extensive study on the use of these bioactive compounds.

Materials and methods

European seabass (~9.1g) and seabream (~7.5g) juveniles, were fed three experimental diets each for 71 days at 24^{0}C water temperature, *at libitum*. All diets were isonitrogenous and isolipidic (54/16 protein/fat). Diets differed in their % of the supplements included, leading to 3 different diets per species: Diets 1, 2, 3 for sea bream, Diets 4, 5, 6 for sea bass and one control diet without any inclusion for each species of fish. The nutritional supplements added were olive leaf extracts or enzymatically treated with increased antioxidant hydroxytyrosol content, (Stymon Oliva & Stymon oliva treated), while the olive-pomace oil was enriched with hydroxytyrosol. Protein preparations of *Spirulina platensis* were enzymatically hydrolyzed to produce putatively bioactive peptides with molecular mass >30 kDa. Supplement % added in each diet are presented in Table 1.

Results

After 71 days of feeding, fish improved growth performance in diets 1 and 4 for sea bream and sea bass, respectively (Fig. 1). The same was observed in feed Efficiency although differences were not significant. The antioxidant status expressed as the activity of the enzyme Superoxide dismutase (SOD) of the fish, showed to be improved by the addition of the bioactive compounds combination in diet 1 for sea bream and 4 for sea bass.

Conclusions

In the current study, from the preliminary results it can be concluded that the addition of the combination of Stymon oliva, Stymon treated and olive oil pomace in combination with peptides derived from Spirulina, as in diets 1 for sea bream and 4 for sea bass, resulted in growth performance improvement of both species as well as in a better antioxidant status as the results of the antioxidant enzyme SOD showed.

Introduction

Due to its delicate meat, high consumer acceptance, and a possible high reproduction rate, pikeperch is a new focus species in aquaculture (Policar *et al.*, 2019). However, several bottlenecks prevent the economically successful culture. In particular the early developmental stages between hatching and the larval development proved to be problematic and still difficult to rear, as they commonly exhibit high mortality levels. Early fish stages go through a sequence of developmental processes, which needs to be timed and balanced with endogenous resource use (Franz *et al.*, 2021; Franz *et al.*, 2022; Rombough, 2011; Wieser, 1995). The correct development of several tissues can hereby influence the survival success. In this context, muscle tissue development is crucial for early locomotion and ingestion abilities, as well as other physiological processes that may influence the specimens survival (China *et al.*, 2014; Muller *et al.*, 2000; Singleman *et al.*, 2012). Despite this, muscle development during this difficult early rearing, was not yet in focus for pikeperch.

Therefore, in this study, we analysed the expression levels of selected myogenic and developmental genes with the aim of providing a basis for future research on pikeperch muscle development.

Materials and methods

Commonly known gene markers for myogenic progenitor cells, myoblasts, and myofibres were selected (Watabe, 2001). In addition, developmental genes including skeletal markers were selected as they may influence muscle development (Sefton *et al.*, 2019). In this way, a total of 19 genes were examined at eight different developmental stages, ranging from early embryonic to larval stage (26 dd to 325 dd). Hereby, near-naturally reared specimens from a wild population were used. Each stage was analysed in triplicates with pools of 15 specimens using a nanofluidic qPCR approach. Relative gene expression was analysed using ANOVA procedure followed by a Tukey-Test to compare gene expression in between stages. The results were compared to the specimen development and previous literature on pikeperch ontogeny.

Results

The observed morphological development of the sampled pikeperches was consistent with previously present descriptions (Bastl, 1978; Güralp *et al.*, 2017). While the expression for myogenic marker genes generally varied, it tended to be elevated during three periods at the 53 dd (early embryonic), the 127 to 157 dd (before hatching), and the 280 dd stage (early larval stage) (Peňáz, 2001). The expression of developmental markers (e.g. MYH6 and EN2) was connected to ontogenetic processes. Furthermore, skeletal gene markers timed with skeletal development (Franz *et al.*, 2021; Franz *et al.*, 2022; Löffler *et al.*, 2008; Ott *et al.*, 2012) and corresponded with the observed second and third phase of elevated myogenic marker expression

Discussion

Analysis of the gene marker expression revealed the timing of three phases of increased myogenic gene expression. They occur around the somite formation (53 dd), before hatching (127-157 dd), and after the completed switch to exogenous feeding (280 dd). Specific levels of elevated marker expressions were found for each of these three phases, indicating initial basic muscle formation before the hatch and stronger growth and differentiation of muscle tissue during the last two analysed age groups. At the same time, two coinciding phases of skeletal marker expression were detected before the hatch and during the observed larval myogenic phase. The observations may support follow-up studies and help to improve muscle development and survival for pikeperches in aquaculture raise.

BROWN SHRIMP *Crangon crangon* PROCESSING REMAINS ENHANCE GROWTH OF WHITE SHRIMP *Litopenaeus vannamei*

E. Fricke*, M. Slater, R. Saborowski

Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research
Am Handelshafen 12, 27570 Bremerhaven, Germany
Email: enno.fricke@awi.de

Introduction

Brown shrimp, *Crangon crangon,* present the major coastal fishery in the southern North Sea with annual landings of up to 40,000 t (ICES, 2022). While only the abdominal muscle fraction is used for human consumption, the unused processing remains account for up to 60 % of the shrimp biomass. Incorporation of the remains into aquafeeds for high-valued species like *L. vannamei* would create by-product value, reduce waste, and promote circular economy approaches. This study aims to assess the suitability of brown shrimp processing remains (BSPR) as a sustainable feedstuff for *L. vannamei* to replace fishmeal. A detailed biochemical characterization was made and key apparent nutrient digestibility coefficients of BPSR examined. Controlled feeding trials with juvenile *L. vannamei* were conducted to determine effects on growth performance, feed utilization, digestive enzyme activities, and immunological parameters.

Materials and Methods

Frozen remains of mechanically peeled brown shrimp were obtained from a shrimp trader in northern Germany, dried at 60 °C, and ground to a homogenous meal. A detailed biochemical characterization of the meal was made using established methods (AOAC, 2010; Folch et al, 1957; Percot, Viton and Domrad, 2003) and by certified laboratories. To measure apparent nutrient digestibility coefficients, a reference and test diet was prepared using yttrium as inert marker. A 40-day feeding trial with 192 juvenile shrimp (6.5 ± 1.3 g) was conducted using pelleted diets replacing 0, 50 and 100 % of the fishmeal content with BSPR. Survival, molting frequency, growth, digestive enzyme activities, and muscle proximate composition of *L. vannamei* was determined. Based on the first trial, a second feeding trial with 720 shrimp (4.31 ± 1.0 g) was performed with six extruded feeds replacing the fishmeal content in steps of 20 % from 0 to 100 % to obtain an estimate for the optimal substitution level. The high water stability of the extruded pellets allowed for accurate measurements of feed intake and assimilation efficiency. Hemolymph was analyzed for phenoloxidase and prophenoloxidase activities and protein content.

Results and Discussion

Brown shrimp processing remains contain substantial amounts of key nutrients (521 $g\cdot kg^{-1}$ crude protein, 74 $g\cdot kg^{-1}$ total lipid, 15 $MJ\cdot kg^{-1}$ gross energy), minerals (phosphorus, magnesium, copper, manganese, selenium, zinc, and valuable functional ingredients (cholesterol, astaxanthin, chitin). Apparent digestibility coefficients of energy, protein, methionine, lysine, and copper exceeding 80 %, demonstrated excellent nutrient bioavailability of BSPR.

In the first feeding trial, shrimp showed best growth with diets containing a mixture of 50 % fishmeal and 50 % BSPR. No negative effects on muscle quality (moisture, protein, lipid) appeared and digestive enzyme activities were not affected by diet. The daily molting ratio increased with higher BSPR inclusion levels and a higher molting synchronicity was observed. The second feeding trial showed significantly enhanced growth when the BSPR substitution level exceeded 60 %. Based on the polynomial regression of the BSPR substitution level and shrimp weight gain, best growth is expected at 85 % inclusion level (Figure 1.). Different crustacean meals have been shown to stimulate growth in penaeid shrimp (Cordova-Murueta & Garcia-Carreno 2002; Williams et al. 2005; Nunes et al., 2019). This has been attributed to well-balanced nutrient profiles, increased palatability and even unknown growth promoters. Yet it remains unclear what the underlying mechanisms are. The shrimp hemolymph parameters (protein, phenoloxidase, prophenoloxidase) and digestive enzyme activities were not affected by the diets. Therefore, the enhanced growth performance might primarily be related to superior nutritional value and not immunological or digestive enzymatic improvements. We observed a reduced feed intake at concomitantly improved growth with diets containing 80 – 100 % BSPR. This supports the hypothesis that inherent component(s) of BSPR may promote growth in *L. vannamei*. Since the molting behavior of shrimp was also affected by the dietary treatment, it is possible that chitin-oligomers or chitin-protein derivatives in the BSPR are beneficial for shrimp growth. Good bioavailability and supply of key dietary nutrients further underline the suitability of BSPR as excellent feedstuff for *L. vannamei*.

SOIL-BASED AQUAPONICS: THE EFFECTS OF SOIL ADDITION AS INVESTIGATED IN NINE DIFFERENT EXPERIMENTS

L. Fruscella*, B. Kotzen, S. Milliken and M. Paradelo Perez

School of Design, University of Greenwich, Park Row, London SE10 9LS
l.fruscella@gre.ac.uk

Introduction

Under the new Commission Regulation (EU) 2018/848, which has entered into law in January 2022, aquaponic produce cannot be certified as organic in the European Union. Given the multiple components of an aquaponic system, which involve growing plants in hydroponic conditions, recycling of fish waste, and raising fish in artificial conditions, the achievement of organic certification for aquaponic produce is a complex matter dictated by many parameters. In the EU, aquaponics is considered a type of hydroponics, and mainly because of the lack of soil in its systems it is excluded from organic certification. This exclusion is considered to hinder the development of aquaponics, as it makes it difficult for producers to increase their earnings and effectively market their products. The research undertaken explores ways through which different soil substrates and potting mixes can be included in coupled and de-coupled aquaponics, and aims at helping aquaponics with its marketability, commercialisation, public acceptance, and popularity by bringing the technology one step closer to organic certification. The research was done through nine different experiments, which took place between April 2021 and August 2022. The experiments aimed at investigating the effects of soil inclusion on the health, growth, and quality of the plants and the fish, whilst examining how the soil microbiome is affected by the use of aquaponic water and aerobically-processed sludge. This presentation will include results, analyses, and conclusions for all the experiments. The experiments are listed below, with a short overview, results and conclusions for each.

Experiments 1&2: Coupled aquaponics of basil and Nile tilapia

Experiment 1 investigated the effects of aquaponic water on the growth and quality of basil (*Ocimum basilicum*), as well as potential effects of soil addition to fish health. The plants were grown in soil-filled pots placed in trays on top of fish tanks, creating full-recirculation, coupled aquaponic systems. The growth of the plants in soil-based aquaponic systems was compared to that of conventional, soil-less aquaponics ones. Two types of soil potting mixes were used, one with compost, and one without. The design of the systems was inspired by conventional coupled aquaponics, however the plant units were designed to allow the plant roots in soil-filled pots continuous access to fish water.

Experiment 2 was a continuation of the previous one, with a few modifications: compost amount was reduced, and the soil-less treatment was substituted by another soil-based treatment.

In experiment 1, the inclusion of soil was shown to be advantageous, as it prevented the appearance of nutrient deficiencies that instead showed in the soil-less treatment; in both experiments, compost produced higher yields than fish water, and the combined effect of compost and fish water produced the largest yield among all the treatments.

Experiment 3: De-coupled aquaponics of basil in pots

This experiment investigated the effects of aquaponic water and processed sludge on plant growth and quality, as well as soil microbiome composition in basil (*Ocimum basilicum*) grown in pots. The effects of the use of the different substrates and water types on plant health, quality, growth, as well as soil microbiome composition were investigated. The use of fish effluents as fertilisers was shown to be as effective as compost use, producing comparable yields.

Experiment 4: De-coupled aquaponics of onions in raised beds

This experiment investigated the effect of watering onions (*Allium cepa*) cultivated in raised beds and watered with water from different sources; the aim of the study was to compare the effects of manure, currently allowed in organic production, and fish effluents used as fertilisers on the growth and quality of the plants. Four outside raised beds were divided into four sub-units, and each subunit was devoted to the cultivation of onion sets. The four treatments were the following: onions watered with tap water, onions supplied with horse manure and watered with tap water, onions watered with aquaponic water, and onions watered with aquaponic water with sludge. Fish effluents were more effective than manure as fertilisers, producing larger yields.

(Continued on next page)

Experiment 5: De-coupled aquaponics of bok choy in certified topsoil

This experiment investigated the effect of watering bok choy (*Brassica rapa* subsp. *chinensis*) cultivated in detached containers in UK-certified topsoil and watered with water from different sources. The aim of the study was to compare the effects of manure, currently allowed in organic production, and fish effluents used as fertilisers on the growth and quality of the plants. The four treatments, each replicated three times, were the following: plants watered with tap water, plants supplied with horse manure and watered with tap water, plants watered with aquaponic water, and plants watered with aquaponic water and sludge. Fish effluents were more effective than manure as fertilisers, producing larger yields.

Experiment 6: De-coupled aquaponics of turnip in certified topsoil

This experiment investigated the effect of watering turnip (*Brassica rapa* subsp. *rapa*) cultivated in detached containers in UK-certified topsoil and watered with water from different sources. The methodology followed was identical to the methodology of experiment 5. At the time of writing, results had not been analysed yet.

Experiment 7: Use of barley for nutrient uptake of soil treated with fish effluents

This experiment investigated the use of barley (*Hordeum vulgare*) grown in the same raised beds where the onions from experiment 4 grew, in order to measure the uptake and retention of nutrients that would otherwise be washed off by rain by a cover crop. At the time of writing, the experiment was still ongoing.

Experiment 8: Coupled aquaponics of chilli peppers and Nile tilapia

This experiment investigated the effects of aquaponic water on the growth and quality of chilli peppers (*Capsicum annuum*) grown in soil-filled pots, placed in trays on top of fish tanks, creating full-recirculation, coupled aquaponic systems. Two types of soil potting mixes were used, one with compost, and one without. At the time of writing, the experiment was still ongoing.

Experiment 9: De-coupled aquaponics of chilli peppers in pots

This experiment investigated the effects of aquaponic water and processed sludge on plant growth in chilli peppers (*Capsicum annuum*) cultivated in pots. The effects of the use of the different substrates and water type on plant health and growth, and fruit quality were investigated. At the time of writing, the experiment was still ongoing.

SEASTAR MEAL AS AN ALTERNATIVE PROTEIN SOURCE IN DIETS FOR WHITELEG SHRIMP *Litopenaeus vannamei*

Vanessa I. Fuchs*, Matthew J. Slater

Alfred Wegener Institute - Helmholtz Center for Polar and Marine Research
Am Handelshafen 12, 27570 Bremerhaven, Germany
* E-Mail: vanessa.fuchs@awi.de

Introduction

The global shrimp industry continues to grow revealing a farmed shrimp production of 6.0 Mt in 2018. *Litopenaeus vannamei* was the most produced species with 82.7% (FAO, 2020). Consequently, the requirement for formulated feeds globally increased to more than 8 million metric tons (Tacon, 2018; Boyd et al., 2022). The need to find more sustainable and low prized alternatives to fishmeal (FM) in shrimp diets remains a central challenge for the industry. Sea stars as a source of by-catch or by-product, harvested around mussel farms, offer an opportunity to improve the sustainability of formulated feeds. Sea star meal (SM) revealed a promising nutrient composition (van der Heide et al., 2018b) and was already used as a feed ingredient in pig and poultry diets (Afrose et al., 2016; Sørensen and Nørgaard, 2016; van der Heide et al., 2018a). However, there is no study about using SM in shrimp diets. Therefore, the aim of the present study was to determine the suitability of using meal of *Asterias rubens* to partially replace FM in diets for *L. vannamei*.

Materials and methods

Sea stars *A. rubens* were harvested in the Kieler fjord (Germany) and their nutritional profile was evaluated before formulating the diets. Shrimps were fed with four different diets including 0%, 5.4% (20% FM replacement), 13.5% (50% FM replacement) and 21.6% (80% FM replacement) SM for 42 days in a recirculating aquaculture system (Table I). All diets contained the same basal ingredients and were formulated according to an isonitrogenous and isocaloric content. Survival, growth performance and feed intake of *P. vannamei* were determined at the end of experiment. Additionally, haemolymph samples were taken to evaluate the health condition measuring metabolic parameters (glucose, total protein, triglycerides), number of haemolymph cells and the phenoloxidase activity.

Results

Sea stars showed an acceptable nutrient composition containing up to 44% crude protein and 9% crude fat. All experimental diets were accepted by the shrimps. Shrimps fed the 80% diet with highest SM content (21.6%) achieved even significantly higher growth performance (One-way anova, $p<0.05$) than shrimps fed the 0% diet or commercial control diet (Table II). Overall, growth of shrimps and feed intake were significantly higher in the formulated diet groups (0, 20, 50, 80%) compared to the performance of shrimps fed the commercial diet. Results of survival (Table II) and health performance, analyzed by the phenoloxydase acitivity, haemolymph cell counts, glucose, triglyceride and total protein levels in the haemolymph, showed no significant difference between shrimp groups fed the experimental diets.

Conclusion

Sea star biomass very efficiently replaces FM in diets for *L. vannamei* providing high-level protein and fat sources. In the current study, the inclusion of SM to a dietary level of 21.6% resulted in excellent growth and shrimp health. Future studies may test a 100% replacement of FM with SM. As the shrimp aquaculture industry continues to expand globally, sea star biomass joins a growing list of sustainable alternative protein and fat sources to replace FM. The authors encourage the application of this neglected marine biomass resource in aquafeeds.

DUCK-AND-COVER AQUACULTURE, THE FUTURE OF MEDITERRANEAN AND MIDDLE EAST AQUACULTURE

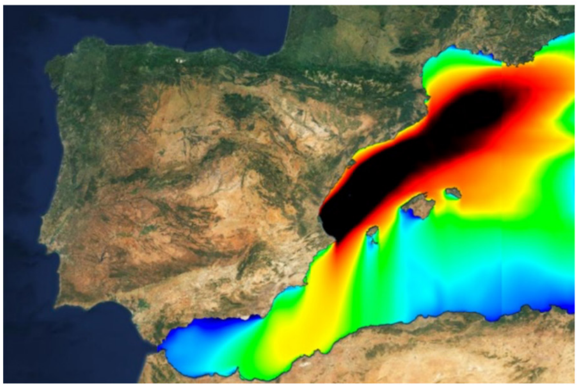
Langley Gace*, Felipe Ramirez

Innovasea Systems
266 Summer Street
2nd Floor
Boston, MA, 02210 United States
LGace@innovasea.com

The growth of aquaculture in sheltered ocean waters has all but stalled due to issues such as environmental impact, stakeholder conflict, and available locations. As a result, open ocean aquaculture has grown significantly in the past 20 years. This expansion has fueled disruptive technologies that enable farmers to successfully produce fish in challenging conditions. A third and underdeveloped type of location stands to benefit from the breakthroughs in open ocean technology.

There are areas of opportunity throughout the globe where oceanic conditions require less robust equipment day to day yet still occasionally experience seasonal storms. These aperiodic events have proven to be catastrophic to producers every few years. A recent occurred on the Mediterranean Coast of Spain when storm Gloria devastated the industry in January 2020. Farmers reported a loss of more than 40% of sea bass and sea bream production and 60% of their Corvina yield.

Innovasea has been developing equipment suited for this market for the past five years. Based on more traditional equipment such as HDPE circular pens, the new line of equipment combines the functionality well known to farmers in these areas with the added ability to submerge during aperiodic storms such as Gloria. Essentially the equipment can "duck-and-cover" during the storms. The lower-cost offerings integrate with Innovasea's submerged feeding and remote mortality collection functions developed for the open ocean. Initial testing in Mexico shows promise for this technology in areas such as the Mediterranean and the Middle East.



EVALUATION *in vitro* OF PROTEIN BIOACCESSIBILITY OF MICROALGAE AND CYANOBACTERIA BY *Sparus aurata* DIGESTIVE ENZYMES

A. Galafat*[1], M.I. Sáez[1], A.J. Vizcaíno[1], T.F. Martínez[1] & F.J. Alarcón[1]

E-mail: agd056@ual.es

Introduction

Microalgae, including some species of cyanobacteria, have the potential for reducing the dependence on conventional ingredients for aquafeeds, as they are a more reliable and less volatile source of protein. Overall, microalgae protein display well-balanced amino acid profile comparable to those of regular ingredients (Guedes *et al*., 2015). Despite that advantage, there are several drawbacks limiting the practical use of microalgae in aquafeeds. For instance, the presence of recalcitrant cell walls acting as protective barrier which hamper fish enzymes to access intracellular nutrients (Teuling *et al*., 2019). The efficiency of fish enzymes to hydrolyse microalgae cell walls relies on composition and branching of polysaccharide. In this regard, scarce research has been done to address how fish digestive enzymes hydrolyse microalgal protein (Tibbetts *et al*., 2017). The aim of this study was carry out a characterization of the protein nutritional profile and the *in vitro* protein bioaccessibility of marine (*Dunaliella salina*, *Nannochloropsis gaditana*) and freshwater (*Anabaena* sp., *Arthrospira platensis*, *Chlorella vulgaris*, *Spirogyra* sp.) microalgae and cyanobacteria, for assessing their potential as dietary ingredients for gilthead seabream (*Sparus aurata*) juveniles.

Material and Methods

Microalgae and cyanobacteria were evaluated in terms of total protein content and amino acid composition. In addition, protein bioaccessibility was estimated by means of a species-specific *in vitro* assay using *Sparus aurata* digestive enzyme extracts. To carry out the test, freeze-dried biomasses of six species of microalgae and two Cyanobacteria were used. Algal protein characterization was performed by elemental analysis (C:H:N). In addition, *in vitro* amino acid bioaccessibility was determined following the methodology described by Alarcón *et al*. (2001). At the end of the hydrolysis process, samples were withdrawn to carry out the quantification of total released amino acids and the determination of the specific amino acid profile by means of ion exchange chromatography with post-column derivatization with ninhydrin (Biochrom 30+ amino acid analyser, Biochrom LTD, UK) according to the manufacturer's protocol.

Results and Discussion

Overall, all the microalgae showed high protein content ranging from 25% to 61%. The highest values were found in *Anabaena* sp. and *D. salina* with 60.9% and 52.3%, respectively, whereas *Spirogyra* sp. showed the lowest (25.3%). All biomasses showed similar amino acid profiles, and although *Anabaena* sp. and *Spirogyra* sp. presented the highest and lowest absolute values, respectively, however, in relative terms, the proportions of amino acids were similar to that found in the rest of the species (Figure 1A). The *EAA/NEAA* ratio ranged from 0.91 to 0.95, which were higher than that of soybean meal (0.7), and within the range of fishmeal (0.92). The essential amino acids released after 90 min of *in vitro* proteolysis are shown in Figure 1B. The profile of amino acids released was clearly different among biomasses tested. Specifically, *Anabaena* sp. and *D. salina* showed the highest values of arginine released, whist the lowest values for this amino acid were obtained in *Spirogyra* sp. Moreover, *A. platensis* and *C. vulgaris* yielded relatively high levels of glutamic acid after the hydrolytic process, reaching, in the case of *A. platensis*, values up to four times higher than those observed for the rest of microalgae and cyanobacteria. Furthermore, *Anabaena* sp. had the highest tyrosine values, while *D. salina* showed high values of essential amino acids such as valine, leucine or lysine.

Conclusions

In the spite of the fact all the microalgae and cyanobacteria evaluated presented an adequate protein content and a balanced amino acid profile, the results obtained revealed differences in bioaccessibily of their protein to be hydrolysed by *S. aurata* digestive enzymes, and therefore in their bioavailability. Particularly, *A. platensis*, *N. gaditana* and *C. vulgaris* seem to be good candidates for feeding gilthead seabream.

Introduction

Aquaculture faces changing and growing demands, among them the diversification with new species for satisfying market needs and improving economic performance of the sector. In this sense, turbot (*Scophthalmus maximus*) is an option for aquaculture farming systems owing to it is a carnivorous marine flatfish showing high growth performance and excellent fillet quality, which lead high commercial value (Wiriduge *et al*., 2020). However, turbot aquafeeds require a high protein content, which supposes up to 50% in the formulation. In this context, the research related to the use of new alternative ingredients for the aquafeed production has been increased. Algae have been positioned as interesting alternative to reduce the use of fishmeal in feeds for carnivorous fish (Geada *et al*., 2021). However, the effects derived from the dietary incorporation of different species of micro and macroalgae rely on the fish species considered, so each case should assessed specifically. Therefore, the main objective of this study was to evaluate the effect of the inclusion of *Ulva rigida* or a blend of microalgae on growth performance, feed utilization and digestive functionality in *Scophthalmus maximus* juveniles.

Material and Methods

The feeding trial was carried out at the Marine Culture Plant of the Spanish Institute of Oceanography (IEO, Santander, Spain). Experimental diets were elaborated at the Ceimar-Universidad de Almería facilities (Service of Experimental Diets, https://bit.ly/3wdO03h, Almería, Spain). Three experimental feeds **U5** and **M5**, containing 5% of *Ulva rigida* and 5% of a blend of microalgae, respectively, and a **CT** feed, which did not contain any algal biomass, were formulated. In addition, a commercial feed (**CTC**) was also tested. All diets were offered in triplicate to juvenile turbot during 60 days, and after that, nine specimens of each dietary treatment were sacrificed in order to extract the gastrointestinal tract. Intestine samples were obtained and processed for the study of digestive enzyme activities (trypsin, chymotrypsin and total alkaline protease, leucine aminopeptidase and alkaline phosphatase), and to analyse the ultrastructure of the intestinal mucosa by transmission electron microscopy (TEM).

Results and Discussion

The study of digestive enzymes can provide useful information about the nutritional status of fish (Alarcón *et al*., 1998). Figure 1 shows the results obtained after performing the analysis of the digestive enzyme activities. Overall, fish fed on U5 diet showed a general decrease in the enzyme activity levels compared to CT-fed fish, while fish fed on M5 showed the highest values. These results pointed out that the use of a blend of microalgae improves the intestinal digestion and absorption capacities in turbot juveniles. The morphology of the intestinal mucosa also plays a key role both in the absorption of nutrients and in providing a physical and immunological barrier against potential pathogenic microorganisms (Wilson & Castro, 2011). In this case, TEM images obtained showed a healthy mucosa in all the cases, without signs of damage or inflammation.

Introduction

Among the bacterial pathogens affecting farmed European seabass (*D. labrax*), *Vibrio harveyi* and *Tenacibaculum maritimum* are recognised as noxious emerging agents, being responsible of frequent outbreaks and high mortality rates in the Mediterranean commercial farms. The infections are currently controlled by administration of antibiotic formulations and preventive measures including good aquaculture practices. Several studies have been dedicated to the *in vivo* evaluation of autologous vaccines efficacy against both pathogens, but none of them brought, up to now, to the development of patented commercial formulations (excluding a commercial vaccine against *T. maritimum* specifically addressed to turbot). The present study has been finalised to the tailoring of novel autologous vaccines against V. *harveyi* and *T. maritimum* to be tested within “in lab” and “in field” facilities, aimed at mitigating the disease impact on farmed European seabass.

Materials and Methods

Autologous vaccines against both pathogens were prepared at the Croatian Veterinary Institute of Zagreb starting from two bacterial strains recently isolated from spontaneous outbreaks of disease affecting local marine aquacultures. Preliminarily, the selected strains were submitted to phenotypical analysis and genome sequencing in order to identify/allocate them in the proper taxonomic position. Bacteria were cultured in Trypton Soy Broth and Marine Broth up to the log phase, respectively, then fixed with 0,4% formalin in order to get a whole-cell vaccine (bacterin). Formulations were subjected to sterility and safety test prior to the experimental use.

The **“lab” scale trials** were carried out using sea bass juveniles weighing approximately 10 grams divided in six experimental group (n=10) in triplicate, kept in fiberglass tanks, and subjected to the following treatments:

***V. harveyi* vaccination.** 1. Immersion for 1 min in 100ml vaccine (1.1x109 CFU/mL) + 900 mL sea water; 2. Intraperitoneal injection (IP) 0,1 ml/fish (1.1.x109 CFU/ml); 3. Untreated control groups (sea water as placebo for immersion and PBS for IP). ***T. maritimum* vaccination.** 1. Immersion for 2 min in 100 ml vaccine (3.75 x106 CFU/mL) + 900 mL sea water; 2. Intraperitoneal injection (IP) 0,2 ml/fish (6.0.x107 CFU/mL); 3. Untreated control groups (sea water as placebo for immersion and PBS for IP). After vaccination fish were submitted to organs and serum sampling for gene expression and immune response insights (ELISA for specific IgM), respectively. Moreover at 36 days post vaccination they were intraperitoneally or immersion challenged by the two bacterial pathogens in order to assess the relative percentages of survival (RPS) (vaccines efficacy testing).

The **“in field” scale trials** were carried out using sea caged sea bass juveniles (about 13 grams, n =1250/cage, 4 cages), and included the following treatments:
1. Vaccination by immersion for 1 min in the vaccine (3.3 x10^8 CFU ml^{-1}) against *V. harveyi* (dilution 1:10);
2. Vaccination by immersion for 2 min in the vaccine (7.4 x10^6 CFU ml^{-1}) against *T. maritimum* dilution 1:10);
3. Vaccination by immersion for 2 min in a mixure of both vaccines (dilution 1:10);
4. Untreated control group (PBS as placebo for immersion). After vaccination fish were submitted to serum sampling for immune response insights (ELISA for specific IgM). Moreover they were periodically surveyed in the field (sea cages) in order to assess their susceptibility to *V. harveyi* or *T. maritimum* natural exposure.

Results

Concerning the **“lab” scale** experiments, the potency testing (specific challenges) underlined the effectiveness of the proposed formulation. A better protection (highest RPS) was achieved after the intraperitoneal administration of *V. harveyi* bacterin, as well as after the immersion administration of *T. maritimum* bacterin. The ELISA based evaluation of immune response revealed a significant increase of specific IgM after the immersion vaccination with *V. harveyi* bacterin and a significant increase of specific IgM after the intraperitoneal vaccination with *T. maritimum* bacterin. The gene expression

(Continued on next page)

study allowed to observe significant upregulation of the genes coding for humoral immunity (IgT, p35) and also upregulation of some genes coding for cellular or non-specific immunity (IL1b, IL10). As regards the **"in field" scale** experiments, the ELISA based evaluation of immune response did not highlight specific findings to be correlated with the vaccinations performed. Still the fish submitted to the vaccinations with both autologous formulations or with the cocktail of them revealed an "in field" survival rate of 98%. Episodes of vibriosis and tenacibaculosis were reported only in the control unvaccinated sea cage, whereas in the vaccinated cages no outbreaks were recorded, and the periodical bacteriological samplings for the detection of *V. harveyi* or *T. maritimum* were always negative.

Discussion and Conclusions

The presents study, carried out within the AdriAquaNet project entitled "Enhancing Innovation and Sustainability in Adriatic Aquaculture" (INTERREG ref. number 1004516), allowed to set up a new and applicable protocol for the formulation and *in vivo* administration of immersion/intraperitoneal vaccines to *V. harveyi* or *T. maritimum*. The vaccination trials specifically targeted to sea bass juveniles showed that the novel autologous vaccines are safe and non-toxic and might be safely used in farm conditions. The vaccines also showed promising levels of protection against the two bacterial pathogens, both within experimental facilities and in farm conditions.

Introduction

Stranding of macroalgal wracks that regularly appear on coasts from offshore seaweed beds play a key role in beach ecosystems. However, this clumping natural biomass is often interpreted as an indicator of beach poor quality by bathers, and it is usually removed and discharged under considerable economic costs. On the other hand, alternatives to fish oil and fish meal for aquafeeds must be found in order to improve aquaculture sustainability. The inclusion of algae in fish feed has been described to produce several physiological benefits such as an improvement in growth performance and lipid metabolism (Moutinho et al., 2018). Gilthead seabream (*Sparus aurata*) is a marine species with high commercial value and easy adaption to captivity whose production has increased in the last few years. Nowadays it is the most important finfish aquaculture product in the Mediterranean with a total production of 136,000 tons in 2020 (Savoca et al., 2021). The use of Macaronesian macroalgal wracks as a supplement in aquafeeds from a feasible ecological perspective is proposed in the present study.

Material and methods

For acclimatization, 228 juveniles of *S. aurata* (initial weight: 18.63 ± 1.00 g) were fed with the commercial control diet for 1 week. Then, fish were randomly divided in 12 tanks (1000 L) and fed three times per day with 3-5% of their total biomass, with one of four different diets in triplicate: (1) an extruded diet for gilthead seabream (Skretting) (CD, control diet); (2) CD supplemented with a 7% of a wind dried powder (1 mm) product of multispecific (MU) macroalgal wrack (30.9% *Lobophora* sp.; 21.9% *Dictyota* sp.; 19.6% *Asparagopsis* sp.; 17.5% *Cymopolia* sp.; 1.8% *Hypnea* sp.; 0.3% *Laurencia* sp.; 0.1% *Stypocaulon* sp., and 8.0% undetermined); (3) CD with a 7% of monospecific macroalgal wrack of *Lobophora* sp. (MOL) (>85%); (4) CD with a 7% of monospecific macroalgal wrack of *Dictyota* sp. (MOD) (>85%). After 93 days of feeding, 5 individuals of each treatment were slaughtered and specific growth rate (SGR), fish body indexes, hepatosomatic (HSI), viscerosomatic (VSI), and visceral-fat index (VFI) determined. Muscle samples were also collected for the analysis of proximate composition, lipid class (LC), fatty acid (FA) profiles and peroxides index (PI). TBARS and the activity of antioxidant enzymes were also measured in both muscle and liver. Finally, gut was removed in order to analyse the activity of digestive enzymes.

Results

Survival was 100% in all treatments. Fish growth was not compromised by the dietary inclusion of macroalgal wracks (SGR= ~1.40% day^{-1}). Proximate composition, HSI, VSI and VFI were similar regardless of the treatment. Muscle lipid composition was only affected in its higher content of monoacylglycerols in MU (1.43±0.30%) and MOD-fish (1.15±0.24%) *vs*. the other treatments (0.84-1.35%) and higher saturated FA (SFA) in MOD (26.36±0.55%) and MOL-fish (26.13±0.92%) compared to the other fish groups (24-25%). Antioxidant enzymes catalase (CAT), superoxide dismutase (SOD) and glutathione-S-transferase (GST) did not vary between treatments. Contrarily, glutathione reductase (GR) in muscle, presented the highest activity in MOD-fish (0.71 ± 0.09 *vs.* ~0.40 U mg protein^{-1}). Finally, digestive enzymes activities and oxidation status (PI and TBARS) of muscle remained unchanged regardless of dietary treatment.

Discussion and conclusions

Macroalgae are known to have anti-nutrient compounds that can reduce digestibility and nutrient absorption, possibly giving rise to reduced fish growth. Nonetheless, low seaweed inclusion (2.5-10%) can even improve growth and health performance in several species (Moutinho et al., 2018). It was expected that the lipolytic activity described for some brown macroalgae (Bourgougnon, 2014) caused a lower fat deposition in fish among other effects. However, growth, body indexes, proximate composition and digestive activities were unaffected by the different seaweed inclusion. This suggests that the basic composition of experimental diets may have met the nutrient requirements of gilthead seabream juveniles

(Continued on next page)

at the same level as the CD specifically designed for *S. aurata.* FA profiles did not vary, except for SFA, which increased in MOL and MOD-fish, as it has been previously described in *S. aurata* with a 5% of seaweed inclusion (Guerreiro et al., 2019). The lipolytic activity reported in macroalgae may be removing SFA from triacylglycerides in the liver for their subsequent storage in muscle. Seaweed supplementation may mitigate stress responses. However, it also increased lipid peroxidation in *S. aurata*, which the authors attributed to lipid layer degradation (Guerreiro et al., 2019). GR catalyzes the reduction of GSSG to GSH, representing the antioxidant restoration potential. Thus, the increment of GR activity in muscle of fish receiving the MOD supplementation suggests a higher capacity to mold the glutathione metabolism state by MOD treatment (Peixoto et al., 2016).

In summary, the inclusion of the MU, MOL and MOD in aquafeeds for *S. aurata* did not show negative effects on fish growth, perivisceral or liver fat deposition, proximate composition, main lipid profile or digestive capacity. A potential capacity to better restore the antioxidant status of the organism was detected with the MOD supplementation. As a result, the inclusion of a 7% of macroalgal wracks in diets for *S. aurata* may be feasible without apparent detriment in fish performance. Besides, it will contribute to the sustainable use of ocean resources and might empower the sustainable blue economy strategy in islands.

Introduction

The early sexual maturation in the sea is a significant problem in cultures of *Salmo salar* and cause serious economic losses associated to low fillet quality among others. This phenomenon can be largely controlled, but not completely, by manipulating the photoperiod, being necessary to look other controls and recently it has also been possible through the identification and selection of genetic markers. Lochy is a domestic strain with rapid growth in cultures in the sea but that has reported with higher incidence of early maturation especially in males. According to recent studies the genomic signals between genotype and phenotype of maturation in Atlantic salmon (SNPs) are present even in 28 of 29 chromosomes and some maturation genes are *vgll3* in Ssa25 which has a great effect on the trait and other as *akap11, six6, maggi2 and picalm* (Ayllon et al. 2015; Sinclair-Waters et a. 2020). The objective was to identify QTLs associated with early sexual maturation in the Lochy strain of Atlantic salmon under the hypothesis that the trait is polygenic. For that we worked with data of 714 males obtained from 2 marine culture centers, genotyped with a microarray of 50k SNPs to later perform a genomic association analysis – GWAS, with the purpose to select them and reduce the negative effects of early maturation.

Materials and methods:

714 fishes, 80 mature and 634 immature males of the Lochy strain of *Salmo salar* were selected from two culture centers of “Salmones Camanchaca” company by a directed sampling focus on maturation and sexual secondary characteristics, in the processing plants located in the south of Chile. The culture was subjected to a continuous photoperiod of 24L: 0N from the transfer to the sea until the harvest, to prevent the early maturation. The samples were genotyped with a customized microarray of 50k SNPs and after we perform a genomic association analysis - GWAS using statgenGWAS of R. The ICSASG_v2 genome in the NCBI database was used to identify genes associated with maturation.

Results:

The sexual maturation observed in the targeted sampling varied between 2 (6/333) and 19% (74/381) in each center. The mature fish had a gonadosomatic index of 4.14 ± 1.67% and the immature ones 0.11 ± 0.33%. The GWAS revealed 34 significant SNPs for maturation in seawater (figure 1), which were distributed mainly in the chromosome 25 harbouring in the akap17A gene and nearly to *vgll3, chmp2b genes*. In contrast, only one or two QTLs were found linked to early maturation in Atlantic salmon on the other chromosomes. High variance explained for early sexual maturation was associated with two QTLs on chromosome 15 and 9. Candidate genes in these QTLs were associated a testicular development in male and cellular proliferation of embryonic cells in the presence of estrogen.

Conclusion:

With the QTLs detected in this study, the genetic architecture of sexual maturation in *Salmo salar* is deepened. These genomic regions of influence of sexual maturation in Lochy strain, allow us to select individuals that could be used to reduce the negative effects of early maturation.

INFLUENCES OF THE DESIGN AND MANUFACTURING OF VARIOUS BIOCARRIERS ON THEIR PERFORMANCE IN MOVING BED BIOFILM REACTORS (MBBR'S) IN RECIRCULATING AQUACULTURE SYSTEMS (RAS)

William Nowell, Giovanni M. Cusimano*, Jui-Che Chiang, Natalie E. Panasiak, Michele Gallo, Dannie O'Brien

AquaBioTech Group, Research Development and Innovation, Naggar Street, Targa Gap, Mosta, Malta
Email: gmc@aquabt.com

For optimal water quality management in RAS, a primary design concern is to provide the biofilter capacity required to control the total ammonia-nitrogen (TAN) concentration in the culture tanks. An optimal biocarrier will have a short start-up time- the time between when the biocarrier is added to the system and when the bacterial population can support the welfare of the needed biomass of aquatic species to be produced- and a high total ammonia nitrogen (TAN) removal rate during operation. The most challenging of these start-ups are in cold water systems, due to the slow development and metabolism of bacteria at lower temperatures. It is additionally challenging to 'cold start' a biofilter in a new system, where there is no existing 'mature' biomedia to be used for inoculation or seeding of the biological community. Experiments assessed the start-up time of five different designs of biocarriers in 14°C fresh water and, once nitrifying activity was established, their TAN removal capacity.

Five biocarriers of different designs, differing specific surface area (SSA) and protected surface area (PSA), sourced from 5 different suppliers were compared. SSA varied between 700 and 5500 and materials included virgin and recycled polyethylene, HDPE, and polypropylene. Experiments were carried out in 300L round tanks with an operational volume of 200L to ensure no exchange between tanks or loss of biocarriers through overflow and maintained at 14°C. Each biocarrier type was stocked at 50% of the operational volume (0.1m^3 per tank) in triplicate and hydrated for 48 hours before the trial start. Aeration was set at 20L/min/tank using blowers in the tanks. Following initial dosing to start biological activity in the tanks (NH_4CL (3.8g); $NaHCO_3$ (43g); $NaNO_2$ (0.4g); Na_2HPO_4 (0.08g) per tank) tanks were "fed" with calculated quantities of NH_4Cl and $NaHCO_3$ according to observed conversion rates, to promote ongoing nitrifying activity.

Over 10 weeks, DO; temperature; salinity; pH; KH; NH_4; NO_2; NO_3 data were collected at regular intervals using either probes (DO, temperature, salinity) or standard drop test kits, easily available to aquaculture producers, and with spectrophotometric titration.

There was found to be variation between hydration time required for the different biocarriers. Faster hydration times were related to faster start-up times. Start-up of bacterial development differed between biocarriers (2 weeks to 4 weeks) as did cumulative TAN conversion performance after start-up (week 4-10). Maximum daily conversion rates reflected the cumulative trend. Consumption of bicarbonate was found to be proportional to conversion of TAN and was higher than the typical values considered for a mature system, likely due to increasing conversion demand during the start-up phase. Start-up time and TAN conversion performance were not found to be correlated with SSA, contrary to common industry assumptions. Additionally, PSA was not related to rates of TAN conversion. Degassing affecting CO_2 levels; SSA vs. PSA; mixing rates; and the shape of holding tanks may have a greater influence than either SSA or PSA alone.

Selection of biocarrier for optimal cold start-up of RAS systems appears to be more complex than selecting that with the greatest SSA. Additionally, users should consider their production method and harvest strategy (e.g., continuous, batch all in/all out) when considering optimal biocarrier selection, as some may be more suitable where fast cold start-up times are needed, where others may take longer to start up but provide better and more stable continuous performance.

DEVELOPMENT OF A RAINBOW TROUT INTESTINAL PLATFORM FOR PROFILING THE ABSORPTION OF AMINO ACIDS AND SMALL PEPTIDES OF AN *IN VITRO* DIGESTED FEED

Introduction

The generation of an artificial fish intestine could minimize the use of *in vivo* trails, which are presently necessary for testing each new feed, and are lengthy, expensive and require the use of many animals. Furthermore, although *in vivo* screening allows for a precise evaluation of the final effect of each feed, it does not improve our basic knowledge of the cellular and molecular mechanisms that determine the end-results obtained. This, in turn, severely limits our ability to understand and predict the biological value of a single ingredient and of their different combinations. To circumvent these constrains, we previously derived and characterized two novel stable cell lines from the proximal (RTpi-MI) and distal intestine (RTdi-MI) of the Rainbow trout (RT), demonstrating that the two cell lines retain the main properties of the tracts of origin. In the present work, we used these cells to set up a barrier developed on a commercial permeable (PET) membrane support, to profile the absorption of dietary amino acids of an in vitro digested fish feed.

Materials and methods

In vitro digestion

A commercially relevant RT feed was produced by Skretting Aquaculture Innovation with crude protein and lipid level of 46 and 23%, respectively. In order to expose the feed to the gastric and intestinal digestive conditions, in vitro digestion (IVD) was performed using either RT stomach or intestinal enzyme extracts at either acidic or alkaline conditions. After preparation, the *in vitro* digested samples (IVD) were lyophilized for 24 hours and stored at -20°C until performing cell assays.

In vitro cell assays

The intestinal epithelial cell lines RTpi-MI and RTdi-MI were seeded at 250.000 cells/cm^2 onto cell culture inserts (Greiner BioOne, ThinCert cat. No. 665640) and cultured at 20°C under ambient atmosphere. Trans epithelial cell resistance (TEER) was measured using an EVOM2 Epithelial Voltohmmeter with STX2 electrode (World Precision Instruments). TEER was calculated by subtracting the values without cells from the values with cells. Four combinations were tested: 50% and 25% (vol/vol) of IVD diluted in Hanks′ Balanced Salt solution (HBSS), with or without 4 mg/mL Bovine Serum Albumin (BSA), all spiked with 100 μg/mL 4 KDa FITC-Dextran. 500 ul of each combination was pipetted in the apical compartment of the inserts, and 1.2 mL HBSS was pipetted into the basolateral compartment. After 6- and 24- hours of incubation, 0.1 mL samples were collected from the apical and basolateral compartments of the PET membrane support. FITC-Dextran was quantified using a Synergy HT Multimode microplate reader (BioTek EX) to assess the integrity of the epithelial barrier during the experiment. Thereafter, epithelial barriers were rapidly fixed using 4% paraformaldehyde and stained with hematoxylin and eosin to evaluate cell morphology and for endogenous Alkaline Phosphatase (AP) activity to detect fully differentiated enterocytes.

Biochemical analysis

Amino acid and small peptide profiles were evaluated by targeted and untargeted approaches in a single run by hydrophilic interaction liquid chromatography tandem Exploris-Orbitrap®- high resolution mass spectrometry (HILIC-Exploris-HRMS). The following 14 amino acids were quantified: L-Alanine, L-Arginine, L-Glutamine, L-Isoleucine, L-Leucine, L-Lysine, L-Asparagine, L-Methionine, L-Phenylalanine, L-Threonine, L-Tryptophan, L-Tyrosine and L-Valine. The

(Continued on next page)

amount of each amino acid in the apical and in the basolateral compartments was compared to the control IVD (sample not incubated with cells). Absorption of each amino acids was expressed as the percentage of the amino acid found in the basolateral compartment/amount quantified in the control IVD.

Results and discussion

At day 7 of culture, both RTpi-MI and RTdi-MI cells formed an effective epithelial barrier, as indicated by reaching plateau values of TEER (RTdi-MI: 30.5 ± 1.6 Ohm*cm^2; RTpi-MI: 28.9 ± 1.9 Ohm*cm^2).

After exposure to 25% and 50% IVDs with and without BSA, the integrity of the epithelial barrier was not affected in both cell lines, as indicated by the constant TEER values. In agreement with these results, after all treatments, both RTpi-MI and RTdi-MI cell barriers retained Dextran 4KDa in the apical compartment of the inserts at a significantly higher rate than the inserts without cells. Morphological analysis confirmed the presence of an intact cell monolayer on the membrane, further confirming that IVD incubation did not alter the epithelial barrier functionality after 6- or 24- hour incubations.

Biochemical analysis showed that all 14 amino acids were detected in all 4 combinations tested (25% and 50% IVD HBSS, with and without BSA) in the apical and in the basolateral side of both RTdi-MI and RTpi-MI cell barriers after 6- and 24- hour incubation, confirming the ability of cell lines to absorb different categories of amino acids. Absorption of all the amino acids after 24-hour incubation was higher compared to 6-hour incubations with all the media combinations tested. After 24-hour exposure to 50% IVD without BSA, the amount of arginine, glutamine, histidine, valine, methionine and threonine in the apical side of the RTdi-MI cell barrier significantly increased compared to the apical amount quantified in any other experimental group, while no differences among groups were recorded for the remaining amino acids. Consistent with these results, small peptides enriched with arginine, glutamine, histidine, valine, methionine and threonine were present in the apical compartments of both cell barriers after 6-hour incubation of all the media combinations. Whereas these peptides were not present after 24-hour exposure of RTdi-MI cell to 50% IVD HBSS without BSA, suggesting that the amino acid increase was likely due to the digestion of the small peptides in this treatment. Furthermore, these amino acids reached the equilibrium between the apical and basolateral compartments after 24 hours only when 50% IVD was supplemented with BSA implying that this protein may have a functional role in their absorption.

We also observed that RTdi-MI cells were more differentiated towards mature enterocyte than RTpi-MI cells, as shown by the detection of a higher alkaline phosphatase activity.

Conclusions

Overall, our results indicate that both RTpi-MI and RTdi-MI cells can absorb the amino acid components of pelleted feed digested *in vitro*, though with some difference between them. RTdi-MI cells, 50% IVD HBSS and 24 hour- incubation seems to be the most efficient combination, although the role of BSA needs to be further investigated. Moreover, this cell line showed the ability to cleave some small peptides increasing arginine, glutamine, histidine, valine, methionine and threonine availability for further absorption. In conclusion, the simple platform used here represents the initial step towards the generation of a more complex alternative that may improve the differentiation of the RT cell lines, thereby leading to a better reproduction of the physiological environment distinctive of the *in vivo* native tissue.

Supported by European Union’s Horizon 2020 research and innovation programme under grant agreement No 828835

EFFECT OF MACROALGAL POLYSACCHARIDES ON IMMUNE RESPONSE & SUSCEPTIBILITY TO EDWARDSIELLA TARDA IN OLIVE FLOUNDER (*Paralichthys olivaceus*)

M. Garcia[1]*, M. Rodriguez[1], D. Marzin[1], M. Gallissot[1], B. Gunathilaka[2]

[1] Olmix S.A., ZA du Haut du Bois, Bréhan, France; [2] Department of Marine Life Sciences, Jeju National University, Jeju, Korea
Emails: mgarcia@olmix.com

Introduction

Polysaccharides are well-known for their range of biological activities, such as antibacterial, antiviral or prebiotic properties and immune-stimulant effect on animals and humans (Hindu *et al*., 2019; Ngo and Kim, 2013). Sulfated polysaccharides from green macroalgae modulate the transcription of immune mediators involved in defense mechanisms within the innate and the adaptive immune response (Berri *et al.,* 2016). Hence, they could be of interest to enhance the resistance of fish to pathogenic diseases that are frequent in modern production, such as *Edwardsiella tarda*.

Materials and methods

Diets and feeding trial

Four hundred and eighty juvenile Olive flounder (26.51g ±0.02) were acclimatized in 300L polyvinyl circular tanks supplied with filtered seawater at a flow rate of 10L/min and aerated with air-stones to maintain sufficient dissolved oxygen at the Jeju university experimental facility. After two weeks of acclimation with a commercial diet, fish were fed with 3 different experimental diets to apparent satiation twice a day (08:30h and 18:00h) for 12 weeks: a basal diet (CON); and a basal diet with two inclusion rates of mix of macroalgal polysaccharides: 3g/kg (AL3) and 5g/kg (AL5). All experimental diets were extruded and using sardine fish meal (55%), soybean meal (12%), wheat flour (19.7%), wheat gluten, soy protein concentrate, tangkage meal, poultry by-product, fish oil, vitamin and mineral premixes. The bacterial challenge was conducted between day 86 and day 101 in 120 L acryl tanks. Fish were intraperitoneally injected with a *E. tarda* strain at LD50 (1×10^5 CFU/ml) and mortality was monitored and recorded every 2 hours for 21 days.

Sample collection and analysis

Fish performance: feed conversion ratio, average body weight and survival rate were recorded after 6, 9 and 12 weeks before challenge. Immunological parameters were analyzed before challenge by collecting blood samples from three fish per tank: total immunoglobulin (Ig) according to the method described by Siwicki and Anderson (1993), lysozyme activity by turbidometric method described by Hultmark (1980), antioxidant parameters (superoxide dismutase (SOD) and catalase using kits from Sigma-Aldrich 19160 and Biovision, Inc. California, USA). Intestinal health was evaluated through counting of mucus-secreting goblet cells (GC) in the whole intestine from two fish per tank after 24h of starvation. Results were analyzed by ANOVA and the differences in mean values were compared using Tukey's HSD test ($P<0.05$).

Results

In the current study, the growth performance of fish was not significantly affected by the additive.

Dietary supplementation of algae extract improved the survival of fish challenged with *E. tarda*, which likely resulted from the enhanced innate immunity and activities of antioxidant enzymes. Survival percentages in CON, AL3 and AL5 groups were 48.9 ± 3.85, 73.3 ± 0.00 and 80.0 ± 6.67 respectively (*Figure 1*).

Lysozyme is one of the well-known enzymes of the innate immune response representing the bacterial killing-activity of immune cells through hydrolysis of peptidic bonds in the bacterial cells. SOD and catalase are well-known antioxidant molecules produced to prevent the deleterious effect of stressors (pathogenic or environmental). The use of the mix of macroalgal polysaccharides significantly increased these values compared to control at both concentrations *(Figure 2).*

Additionally, both dietary groups supplemented with algal polysaccharides improved intestinal morphology and led to an increase in goblet cell counts (*Figure 3*).

Conclusion:

The findings in this study indicate that in-feed macroalgal polysaccharide supplementation modulates immunity and strengthens gut barrier function which resulted in a better fish resistance and finally strongly improved the survival of fish exposed to *E. tarda* (up to 63% survival rate 21 days post challenge)

Introduction

Dietary seaweeds and their bioactive components have positively affected some fish species' health parameters and growth performance (Thépot *et al.,* 2021). Recent work has pointed out the potential of in-feed marine macroalgal polysaccharides as reliable agents for the modulation of the immune function and the reinforcement of the intestinal barrier function of animals. Sulfated polysaccharides from green macroalgae modulate the transcription of immune mediators involved in defense mechanisms within the innate and the adaptive immune response (Berri *et al.,* 2016). Hence, they could be of interest to enhance the resistance of fish to pathogenic diseases that are frequent in modern production, such as *Photobacterium damselae* sbsp. *piscicida*.

Materials and methods

Diets and feeding trial

A total of two hundred and forty juvenile gilthead seabream (6.00 ± 0.03g) were randomly separated into 12 tanks (400 L, 20 fish per tank) distributed in four replicates and reared in a recirculating system. For the 30-day feeding trial and the 14-day post-bacterial challenge period, feeding was done three times a day, seven days a week at 3% body weight (Morning: 1.4%, Midday: 0.6%, Evening: 1%). The three quadruplicate treatments received an experimental diet with different inclusion levels of Algimun®: Control (C), AL0.3, and AL0.5 with Algimun® at 0, 0.3 and 0.5 g kg^{-1} diet, respectively. All experimental diets were extruded. The diets were formulated with dietary fish meal, plant ingredients, fish oil and vitamin-mineral mix. After 30 days of the feeding trial, all fish from each group were injected intraperitoneally with 100 µL PBS containing 1×10^7 CFU *Photobacterium damselae* sbsp. *piscida* strain cells. *P. damselae* sbsp. *piscida* was re-isolated to confirm the mortality due to the bacterial infection. Mortality was recorded for eight days until mortalities had ceased, and the observation of surviving fish was extended to 2 weeks.

Sample collection and analysis

Fish performance: Feed conversion ratio, specific growth rate and survival rate were calculated. Immune response: At 10, 20 and 30 days of the feeding trial (pre-challenge), blood samples were collected for total myeloperoxidase (MPO) quantification and lysozyme activity (LYS). The total Myeloperoxidase (MPO) content was measured on plasma according to the method described by Quade and Roth (1997) and lysozyme activity was determined according to Ellis (1990).

Results

The final mean weight (FMW), specific growth rate (SGR), and feed conversion ratio (FCR) of fish fed with AL0.3 and AL0.5 diets were significantly improved compared to fish fed with the control diet ($P<0,05$). However, there was no statistical difference between the marine sulphated polysaccharide groups (*Table 1*).

TABLE 1. Growth performance and economic parameters of gilthead seabream fed with different doses of Algimun®.

Survival against *Photobacterium damselae* subsp. *piscicida* was numerically increased in both seaweed-based dietary groups compared to the control group (>20%) (*Figure 1*). The higher survival rate in the treatment groups, especially the AL0.5 group, is in line with the improvement of the innate immune responses (*Figure 2 and Figure 3*).

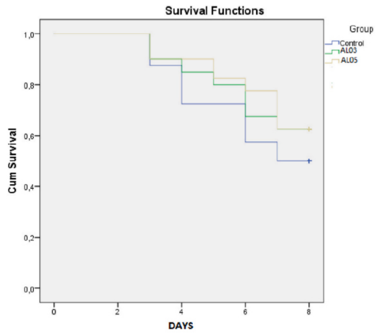
FIGURE 1. Long-range and survival rate (%) of gilthead seabream fed control (C) and diets containing Algimun® (AL0.3 and AL0.5).

Myeloperoxidase is produced by neutrophils and triggers a release H_2O_2, which is highly toxic for pathogens. The myeloperoxidase activity (MPO) was significantly higher in AL0.5 compared to other dietary groups on each sampling time ($P < 0.05$) *(Figure 2)*.

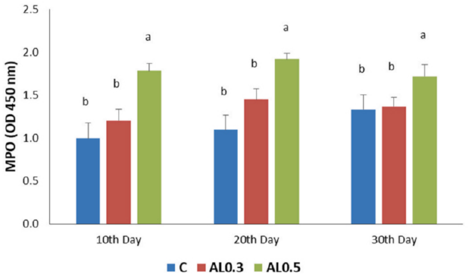
(Continued on next page)

	C	AL0.3	AL0.5
Initial mean weight (g)	6.00 ± 0.03	6.01 ± 0.05	6.03 ± 0.06
Final mean weight (g)	10.86 ± 0.05^b	11.38 ± 0.01^a	11.50 ± 0.04^a
Feed conversion ratio	1.65 ± 0.01^a	1.49 ± 0.04^b	1.47 ± 0.06^b
Specific growth rate (%/day)	1.98 ± 0.03^b	2.13 ± 0.03^a	2.15 ± 0.04^a
Economic conversion ratio ($/kg)	1.82 ± 0.01^a	1.64 ± 0.04^b	1.63 ± 0.06^b
Economic profit index ($/fish)	43.25 ± 0.15^b	45.79 ± 0.14^a	46.31 ± 0.37^a

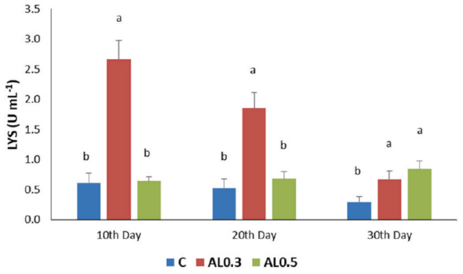
Different superscript letters indicate significant differences between groups ($p < 0.05$).



Overall comparisons of test of equality of survival distributions for the different levels of the group were performed with Log Rank (Mantel-Cox) test (Chi-Square: 2.077, df: 2, and Sig. 0.354).



Different superscript letters indicate significant differences between groups ($p < 0.05$).



Different superscript letters indicate significant differences between groups ($p < 0.05$).

FIGURE 2. Myeloperoxidase activity (MPO) of gilthead seabream fed with experimental diets containing different levels of Algimun® as 0 (C), 0.3 (AL0.3) and 0.5 (AL0.5) g/kg.

Lysozyme is an essential enzyme that lysis the pathogenic bacterial cell wall. In the present study, lysozyme activity (LYS) was significantly higher, when compared to the control group in the AL0.3 group at all sampling times and in the AL0.5 group at day 30 ($P < 0.05$).

FIGURE 3. Lysozyme activity (LYS) of gilthead seabream fed with experimental diets containing different levels of Algimun® as 0 (C), 0.3 (AL0.3) and 0.5 (AL0.5) g/kg.

Conclusion:

Dietary marine macroalgal polysaccharides increased growth performance, decreased FCR and improved the resistance of fish leading to an increase in the survival rate against *Photobacterium damselae* sbsp. *piscida*. This in-feed strategy acted as an immunomodulator and proved its efficiency in protecting and defending aquatic animals' health.

Introduction

It is recognized that nutrition is a key modulator of fish digestion and gut integrity. The structure and function of the intestine play a vital role in fish digestive capacity and efficiency. However, the digestive system is affected by different biotic and abiotic external factors (e.g antinutritional factors of the feed ingredients, stress situations during farming). Innovative and sustainable production strategies are required to assist the growth of the aquaculture industry. Functional diets can be defined as those that when supplemented confer specific benefits such as physiological functions or enhance fish health. Studies of low inclusion levels of micro-and macroalgae promoted fish growth, feed utilization, and physiological functions (gut microbiota, antioxidant activity, and stress response). In this study, we evaluated the effects of the inclusion of *Phaeodactylum tricornutum* and *Gracilaria gracilis* in gilthead seabream (*Sparus aurata*) diets to study fish intestine recovery after provoked intestinal inflammation. Physiological responses to the inclusion of micro-and macroalgae species were assessed through the integration of data from nutrient absorption and utilization and enzyme activity.

Material and methods

- *Diets*

A control diet (CTRL) was formulated to be like a commercial feed for gilthead seabream juveniles. The remaining experimental diets were formulated by supplementing the CTRL diet with microalgae (*Phaeodactylum tricornutum*; PHA) or macroalgae (*Gracilaria gracilis*; GRA) at 2.5%, or a blend of micro- and macroalgae at 5% (50:50; BLEND). Experimental diets were manufactured at SPAROS Lda. (Olhão, Portugal). *Phaeodactylum tricornutum* was obtained from Necton S.A (Olhao, Portugal) and *Gracilaria gracilis* from Alga+ (Ílhavo, Portugal).

- *Fish rearing*

Experiments were carried out in compliance with the Guidelines of the European Union Council (Directive 2010/63/EU) and Portuguese legislation for the use of laboratory animals. Gilthead seabream juveniles were obtained from Atlantik Fish Lda. Portugal and the experiments were conducted at the Ramalhete Experimental Research Station of the Centre of Marine Sciences (CCMAR, Faro, Portugal).

- *Assisted-feeding with saponins*

To study the intestine recovery after an insult in gilthead seabream juveniles, and the possible recovery through nutrition, the treatments were: a positive control (PCTRL) where fish were assisted-fed with two empty jelly capsules, afterwards fed with the CTRL diet. For the remaining treatments, fish were assisted-fed with two jelly capsules filled with soy saponins (n = 2; 850 mg saponins). Fish from negative control (NCTRL) were fed the CTRL diet during the trial. Fish from PHA treatment were fed the diet containing *P. tricornutum* at 2.5%. Fish from GRA, were fed the diet containing *G. gracilis* at 2.5%. In the fifth treatment BLEND, fish were fed the diet with micro- and macroalgae at 5%. Gilthead seabream juveniles with a mean body weight of ±176.06 g were distributed into 15 cylinder-conical 500 L tanks at an initial density of 9.8 kg/m^3 (28 fish per tank). After 24 h of fasting, fish were anaesthetized and transferred, using a fish net, onto a dry plastic tray. Two jelly capsules were inserted into the fish's stomach and gently pushed directly into the oesophagus using a solid piece of plastic. After the assisted-feeding each fish was placed into airflow and clean water and monitored for eventual capsule regurgitation. Once recovered, the fish was transferred into their respective tanks. After a period of 72 h without feeding the fish, each experimental diet was randomly assigned to triplicate tanks and fed for 20 days. Fish were fed by hand to apparent satiety twice a day from Monday to Friday and once a day on Saturday.

(Continued on next page)

- *Sample collection & analysis*

At the end of the trial, after 24 h of fasting each tank was bulk weighed and counted. Five fish from each tank were euthanized and individually weighed. Blood was withdrawn individually from the caudal vein of five fish. For histology analysis, approximately a 1 cm sample of the anterior intestine was dissected. Samples for intestine histology are under analysis.

- *Blood plasma enzymes analysis*

The activities of enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP) were determined in plasma. Samples were run at 30ºC in duplicates using a multimode microplate reader (BioTek Instruments, Inv. USA) and commercial kits (SPINREACT, S.A, Spain).

Results and Discussion

Blood plasma enzymes analysis

Alanine and aspartate aminotransferases were not affected by the dietary treatments ($p>0.05$). The ratio ALT:AST that could indicate a possible liver damage or the ratio AST:ALT that could identify a possible disorder in other organs were also not affected by the treatments. The fish fed the BLEND diet presented a significant ($p<0.05$) lower ALP when compared to fish from remain dietary treatments. A higher ALP could in some cases indicate an anti-inflammatory response situation. This result could indicate a possible positive regulation of the BLEND diet in gilthead seabream gut health. The results from anterior intestine histology could shed some light on intestine recovery responses in gilthead seabream juveniles.

Introduction

The need for species diversification in Mediterranean aquaculture has promoted the culture of omnivorous and herbivorous species. Within this context, it is worth noting the high potential presented by the species of the family Mugilidae (mullets), which is considered a priority within the current strategies of European aquaculture (Alexander et al. 2015). One of the mullets with potential for use in aquaculture is the thick-lipped grey mullet (*Chelon labrosus*), due to its great adaptability to different culture conditions, omnivorous profile, high osmoregulatory capacity, and resistance to environmental variations (Pujante et al., 2018). However, there is a lack of information regarding the composition and functions of its intestinal microbiota.

Documenting the bacteria present in healthy individuals is the first step to understanding the impacts of microbial manipulation in aquaculture systems (Tarnecki et al., 2016). In this sense, the knowledge of bacterial diversity from healthy wild fish in their natural environment is essential. Furthermore, the study of the functionality of the intestinal microbiota of wild fish provides information on its capacity to adapt to different culture conditions. Thus, this study aimed to characterize the intestinal microbiota of wild *C. labrosus* and explore its potential functionality on the host.

Material and methods

Eight wild thick-lipped grey mullets (average weight and length: 115.3 ± 5.0 g and 20.3 ± 0.6 cm, respectively) were caught in May 2021 with a net in the Port of Velez Malaga, (36°44’54.9”N 4°03’57.6”W, Malaga, Spain), kept alive and transported to the Centro de Experimentación de Ecología y Microbiología de Sistemas Acuáticos Controlados Grice-Hutchinson (CEMSAC) of the University of Malaga facilities within one hour. Animals were euthanized by immersion in water with a 2-phenoxyethanol overdose (1 mL L^{-1}). Specimens were then individually weighed, and intestinal samples were extracted. Then, each tract was divided into two major sections, anterior and posterior sections, and kept at −80 °C until the subsequent analysis.

Intestinal contents of anterior and posterior sections from wild fish were collected, and DNA was extracted. Subsequently, the V3-V4 regions of 16S rRNA were sequenced using the Illumina technology and results were analyzed by bioinformatics pipeline. The functional profile of the microbial community was analyzed using PICRUSt software.

Results and discussion

Shannon and Simpson diversity indices were significantly higher in the posterior section of wild specimens. The overall taxonomic composition suggests certain homogeneity in the anterior section of the intestine and heterogeneity in the posterior section (Figure 1). Due to this, no statistical differences were detected at any level among both intestinal sections. The intestinal microbiota of wild *C. labrosus* was dominated by the *phylum* Proteobacteria, whereas Tenericutes, Spirochaetes, and Cyanobacteria appeared in the posterior section with low relative abundance. This is consistent with previous studies on wild fish (Liu et al., 2016; Ramírez and Romero, 2017).

Predicted functions of intestinal microbiota showed the most abundant those related to amino acid metabolism, carbohydrate metabolism, energy metabolism, membrane transport, and cell replication and repair. Furthermore, the analysis revealed microbial functional genes related to the elimination of environmental toxins. These functions of intestinal microbiota might provide beneficial effects for the host.

(Continued on next page)

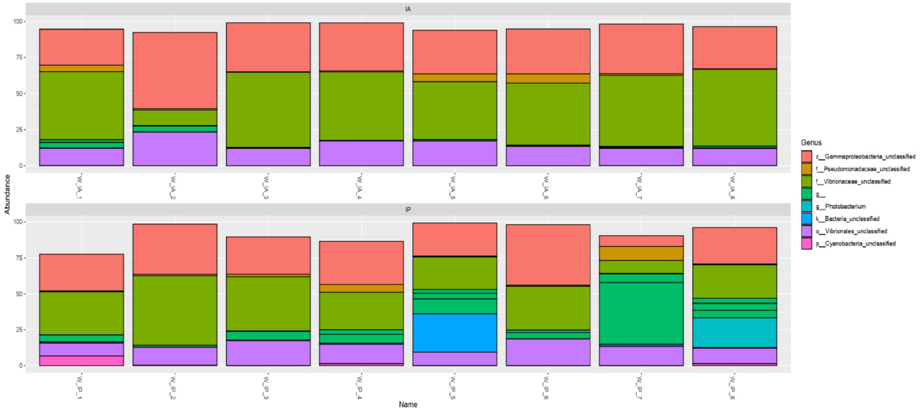

Figure 1. Relative abundance (percentage) of the top 10 genus level for each sample of intestinal microbiota from anterior and posterior section of wild *C. labrosus*. In the figure, W_IA corresponds to the anterior intestinal section of wild fish, and W_IP corresponds to the posterior intestinal section of wild fish.

Introduction

Probiotics have been established as a potential tool for improving gut health and environmental quality in aquaculture. However, despite the proven health benefits of probiotics, recent evidence suggests that bacterial viability is not necessary to attain the beneficial-promoting effects (Ang et al. 2020). In this way, postbiotics have emerged providing a potential opportunity in the field of functional foods. They are soluble factors resulting from the metabolic activity of a probiotic or any released molecule, including short-chain fatty acids, enzymes, extracellular products, endo- and exo-polysaccharides, organic acids, etc. that can have interesting properties related to hydrolytic and antagonistic capabilities inducing biological responses on health similar to probiotics while avoiding the necessary administration of live microorganisms (Balthazar et al., 2022). Interestingly, its production can be affected by different factors such as the components of the culture media (Chang et al., 2021) among others. Information on this type of postbiotic activities is very scarce, especially in the case of aquaculture (Mora-Sánchez et al., 2020), so the evaluation of the nutraceutical use of postbiotics to improve health management in fish and other cultivated aquatic organisms is an emerging area of research in aquaculture.

In a previous work, we characterized four potential probiotics (UMA 140, UMA 143, UMA 169 and UMA 216) that were isolated from the gastrointestinal tract of *Sparus aurata* specimens fed with a diet containing a blend of microalgae. This diet involves a selection pressure on the intestinal microbiota of the fish that will be used to achieve enrichment in bacteria with a set of extracellular enzymatic activities capable of metabolizing and mobilizing the components of the diet enriched with microalgae. Here, we investigate the postbiotic potential of the extracellular products (ECPs) obtained from the four candidate probiotics grown on different microalgae-supplemented medium, and evaluate its enzymatic and antibacterial activity, and its cytotoxicity against the SAF-1 cell line. Our objective is to select different ECPs with a variety of activities that help the digestive process of seabream, with the aim to be included in aquafeeds.

Material and methods

The four strains (UMA 140, UMA 143, UMA 169 and UMA 216) were grown on tryptic soy agar supplemented with NaCl (1.5 %) (TSAs) at 23º C for 24 h. Then, one to two colonies of each strain were cultured on 50 mL of tryptic soy broth supplemented with NaCl (1.5%) (TSBs) at 23ºC for 36h (10^9 UFC mL^{-1}, start of the stationary phase) on shaking at 80 rpm. Then, 1 mL of each culture was spread on solid medium plates under the following conditions: i) TSAs (control medium); and solid medium (1.5% agar) supplemented with ii) 5% *Spirulina*; (iii) 5% *Chlorella*; (iv) 5% *Nannochloropsis*; and v) 5% mix of 25% of each algae (*Spirulina*, *Chlorella*, *Nannochloropsis* and *Isochrysis*). *Isochrysis* was not included as a condition because inhibited the culture growth of the four strains. Plates were incubated at 23ºC for 24h and ECPs were obtained by the technique described by Liu (1957). The collection was carried out by adding 2 mL of sterile saline phosphate buffer (PBS). The obtained suspension was centrifuged (10,000 xg, 20 min, 4ºC) and the supernatant was filtered through membranes (0.22μm, pore diameter), and kept at -80ºC until use.

The ECPs were screened for different enzymatic and antibacterial activities. Proteolytic, collagenolytic, lipolytic and amylolytic activities were assayed according to Chabrillon et al. (2005). Phytase, tannase and cellulose hydrolysis were assayed according to Kumar et al. (2010). Antibacterial activity of the ECPs against fish pathogenic bacterial strains *Vibrio harveyi, P. damselae* subsp. *piscicida*, and *Tenacibaculum maritimum* was performed using the agar-well diffusion assay as described by García-Márquez et al. (2021). The hemolytic activity of the ECPs was tested on blood agar plates. In all cases, 50 μL of ECPs were inoculated into 6 mm-diameter wells made in the plates and incubated at 23ºC for 24-48h. The plates were observed for the presence of a clear zone around the wells. Finally, the absence of cytotoxicity of the ECPs on fibroblast SAF-1 cells from marine gilthead seambream was verified, exposing the cells to different doses of the ECPs. After exposure, the viability of the cells was determined by MTT assay according to Espinosa et al. (2018).

(Continued on next page)

Results and discussion

Only one condition (TSAs 169) was not capable of hydrolyze gelatin, and only two (TSAs 169 and Chlorella 169) did not hydrolyze milk. None of the ECPs had starch, lipase, phytase and tannase hydrolytic activity. Furthermore, only six of the obtained ECPs were capable of hydrolyze the cellulose. In terms of the antibacterial activity of the ECPs, all of them were able to inhibit *P. damselae* subsp. *piscicida*, and only one condition (TSAs 216) inhibited *T. maritimum*.

According to the European Food Safety Authority (EFSA), the evaluation of hemolytic activity is strongly recommended if the isolated bacteria intended to use in food products. In this study, the ECPs obtained from bacterial strains UMA 169 and UMA 216 showed no hemolytic activity. However, ECPs obtained in TSAs medium from strains UMA 140 and UMA 143 showed β-hemolytic activity. Accordingly, due to safety concerns, we discarded from further experiments the ECPs recovered from strains UMA 140 and UMA 143. In view of the results, 5 conditions were selected for further analysis of cytotoxicity: Nanno 169, TSAs 216, Chlorella 216, Nanno 216 and Spirulina 216. The results showed that Spirulina 216 is cytotoxic over the SAF-1 cell line, so its use for addition to feed is not advisable. Further analysis in relation to the contribution of ECP in *in vitro* algae hydrolysis under simulated digestion conditions of seabream enzymes will determine the ECPs candidate with the best potential to be included in aquafeeds.

Introduction

Diseases caused by viruses are one of the main causes of economic losses in the aquaculture sector. It is therefore necessary to search for new antiviral compounds that can mitigate these losses. The aim of this work is to evaluate the antiviral potential of four Mediterranean plant extracts against two viruses of great importance in aquaculture, the viral haemorrhagic septicaemia virus (VHSV) and infectious pancreatic necrosis virus (IPNV). The extracts chosen were *Melissa officinalis*, *Lippia citriodora*, *Cistus salviifolius* and *Rosmarinus officinalis*. These four plants were chosen because their antiviral potential had been previously described.

Materials and Methods

We evaluated the antiviral activity of these extracts *in vitro*, in wo cell lines, EPC (epithelioma papulosum cyprini cell line from Pimephales promelas) susceptible to VHSV infection and CHSE (Oncorhychus tshawytscha embryo cell line) susceptible to IPNV infection, were used for this work. We evaluated the viricidal capacity of the extracts as well as the antiviral activity before or during the course of infection. Viral loads were evaluated by means of qPCR or FFC/mL. Cell fusion inhibition capacity assays were also performed to evaluate the viricidal capacity of the extracts. In addition, the possible immunostimulatory activity of the extracts was also studied.

Results

The results obtained showed that two of the compounds exhibited viricidal and antiviral activity against VHSV, since the treatment with the extracts could diminish the viral loads *in vitro*. The effect of the extracts was observed on the viral particle and before or during the course of the infection. On the other hand, none of the extracts showed viricidal or antiviral activity against IPNV. This work presents promising results for the development of new eco-sustainable antiviral compounds based on plant extracts as therapeutic antiviral treatments in the aquaculture sector.

MOOC “AQUAPONICS – THE CIRCULAR FOOD PRODUCTION SYSTEM“

Zurich University of Applied Sciences, Switzerland

Course description

Aquaponics

Wondering, what fishes have to do with lettuce, kale, basil, tomatoes, aubergine or even vanilla or bananas? Aquaponics is a polyculture that combines aquaculture with hydroponic cultivation, i.e., connects fish farming with soil-independent food production, in a circular system with the aim of recycling nutrients and reusing water from fish farming.

Aquaponic technology continues to attract attention around the globe, especially in the context of urban farming. It is a circular technology requiring a broad knowledge base: from water chemistry, fish welfare, and plant physiology, to engineering and microbiology. Therefore, aquaponics serves also as a learning model for inter- and transdisciplinary thinking and acting.

“*Aquaponics – the circular production system*“ offers a new approach to edX courses. The novelty lies in introducing “real world” experience and skills development into a virtual world of learning. The participants acquire essential knowledge about the Aquaponics, combined with most relevant skills to successfully plan and design a sustainable aquaponic system and ensure the welfare of organisms growing in such as system.

The Aquaponics is the first edX MOOC produced at Zurich University of Applied Sciences ZHAW (Figure 1). It was developed by the Institute of Natural Resource Sciences and supported by the Center for Innovative Teaching and Learning. It is also the first course from any university of applied sciences on edx.org.

Figure 1: Impressions of the aquaponic systems at the Zurich University of Applied Sciences, Institute of Natural Resource Sciences in Wädenswil, Switzerland

Target audience

The MOOC “Aquaponics” is aimed at broad audience with at least an undergraduate level knowledge of the natural sciences (biology, chemistry and physics). However, it is also suited for aquaculture, hydroculture, and aquaponic professionals who wish to deepen their understanding and gain additional insight on specific topics, like for example pest management. The MOOC can be very well included by educators into their own curricula, for example Bachelor’s and Master’s studies.

(Continued on next page)

Course instructor and experts

The students are guided through the course with introductory videos featuring course instructor Nadine Antenen at the beginning of each new section. The sections of the course are guided by experts (Figure 2) in the field of aquaponics, hydroponics, aquaculture, horticulture, and engineering, who are actively involved in research and teaching at ZHAW.

Nadine Antenen, MSc
Researcher in Aquaponics & Course Instructor

Prof. Dr. Ranka Junge
Ecotechnology Consulting & Expert in Aquaponics

Fridolin Tschudi, MSc
Researcher in Aquaculture (RAS)

Dr. Zala Schmautz
Researcher in Aquaponics & Hydroponics

Dr. Linda Tschirren
Researcher in Aquaculture (fish welfare)

Florentina Gartmann, MSc
Researcher in Aquaponics & Hydroponics (plants cultivation)

Figure 2: MOOC Aquaponics team consists of experts actively involved in the field of aquaponics, hydroponics, aquaculture, horticulture, and engineering.

Course content

The interactive material included in the MOOC (Figure 3) provides instructional scaffolding for the students throughout the learning process. The use of interactive tools and the different edX features combined with a clear thread through the course supports a robust experience for learners. This is probably the reason for the very low dropout rate in the course.

The course content alternates between instructional videos, practical examples and exercises, and excellent visualizations. In addition, a variety of course literature and a course reader in each section support the learner's immersion in the topic. Practical exercises, individual assignments, and quizzes are designed with both, verified and audit students in mind. In the last week of the course, participants also learn how to size and design an aquaponic system.

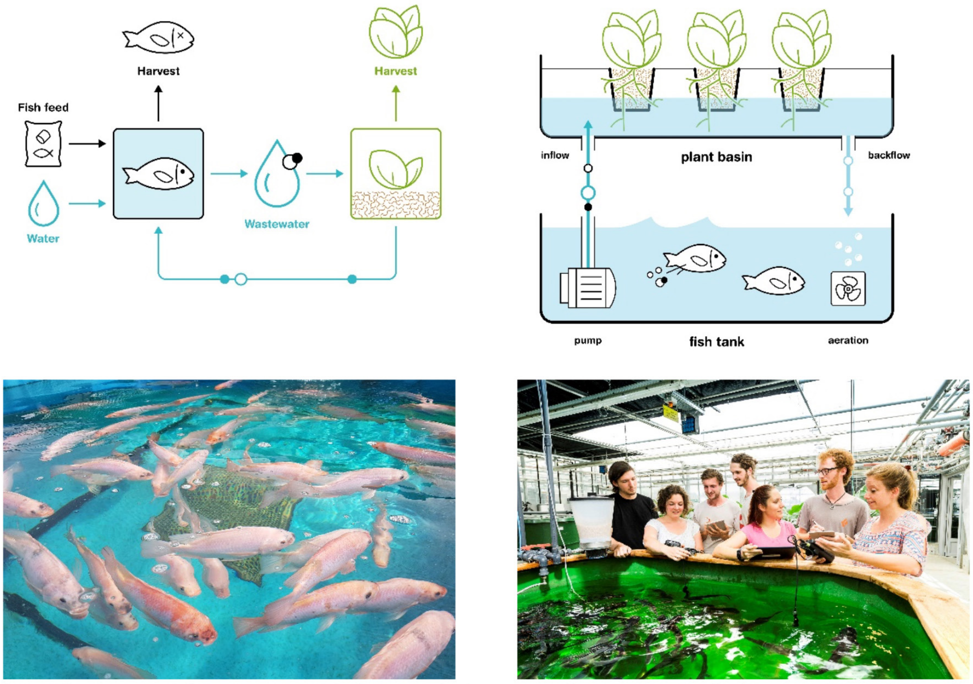

Figure 3: The participants are guided through the course in a very practical way using animated graphics and many photos and videos from our systems.

(Continued on next page)

The course offers expert knowledge, gained at ZHAW over more than 20 years, to all, with the most important literature being included in the course catalogue. The students are guided to work independently on a variety of tasks, exchange knowledge in discussion forums and evaluate each other in open-response assignments.

Course structure

The course lasts 6 weeks containing a main topic with a workload of 4-6 hours per week (Figure 4). In the first section, the general aspects of aquaponics are introduced (Basics of Aquaponics; Opportunities, Risks, Challenges, and Limitations of Aquaponics; Aquaponics - A Circular Food Production System). Aquaculture topics are presented in sections 2 (Fish Anatomy and Physiology; Fish Feeding and Growth; Fish Health and Welfare in Aquaculture), and 3 (Recirculating Aquaculture System (RAS) Engineering; RAS Management; RAS Calculations). Hydroponic (soilless cultivation) topics are presented in sections 4 (Hydroponic Systems; Plant Anatomy, Physiology and Growth Requirements; Nutrient Supply) and 5 (Plant Varieties; Monitoring Plants; Integrated Pest Management (IPM)). In its final week, the focus is on implementing what has been learned (System Design and Planning; Calculating the Dimensions of an Aquaponic System) in a practical example (Design and Calculate your own Aquaponic System).

Figure 4: Course overview consisting of 6 main topics (weeks) with a workload of 4-6 h/week

Each section starts with an introductory video as an overview of that course week. Focus videos address specific topics, such as How to dissect a fish.

The evaluation path (Figure 5) (units marked in pink color) is specifically designed to offer tailor-made evaluation for both, audit and verified learners. Through many interaction possibilities within the different sub-sections, the participants are repeatedly encouraged to become active themselves. This is probably the reason for the high number of active participants.

FIGURE 5 HERE

(Continued on next page)

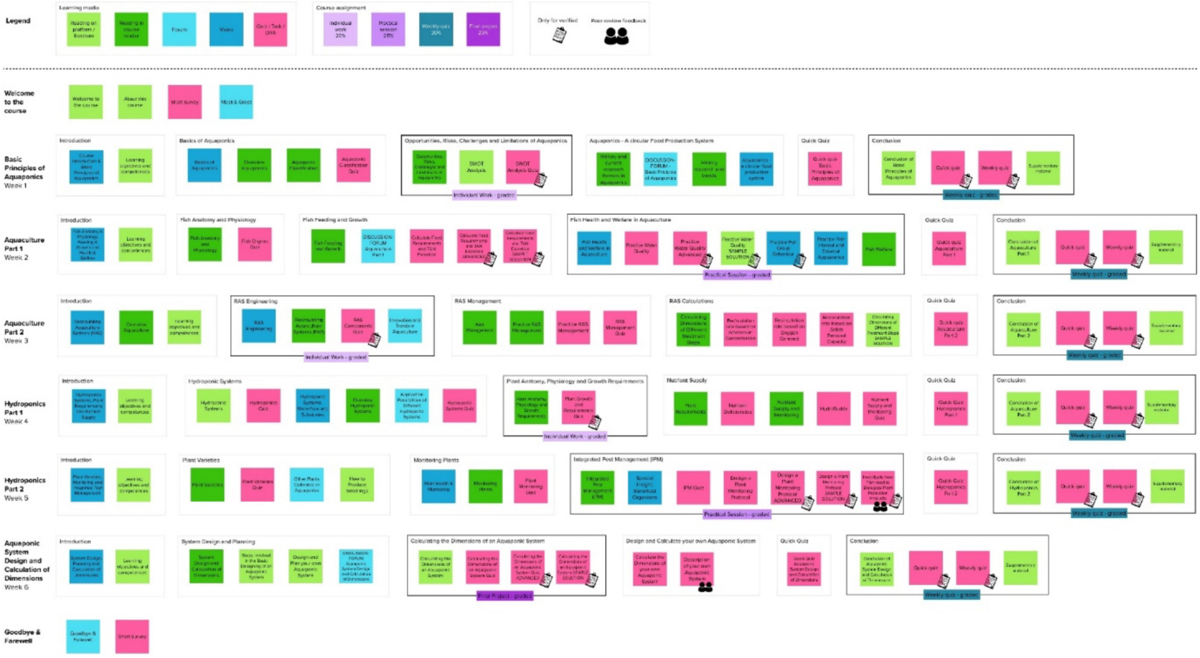

Figure 5: The course structure of MOOC Aquaponics consists of 6 sections. To support the learner's progress different learning media are deployed: Readings on platform/literature (bright green), readings in the course reader (dark green), forums (bright blue), and videos (dark blue). A cleverly done evaluation path (pink) guides both, audit and verified learners, through the course sections and sub-sections.

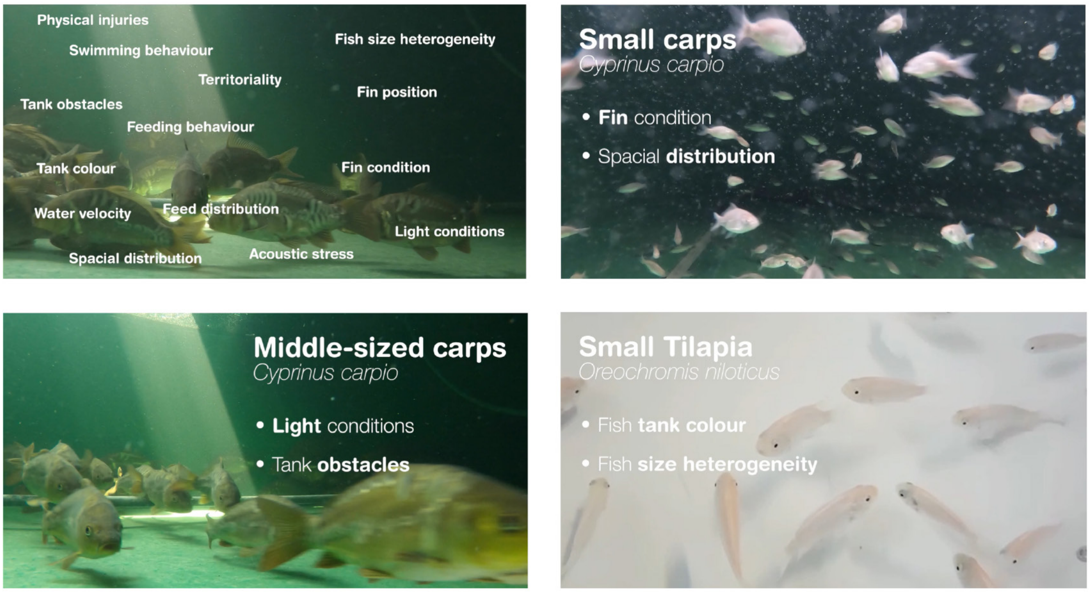
The practice-oriented learner guidance motivates students to actively participate during the course. Most course materials are available for both audit and verified learners. However, very valuable materials (usually containing the most recent models and examples from our research) are available exclusively to verified students. For example, in the session Practice fish group behavior, underwater video recordings of different fish species in recirculating aquaculture systems are collected. Under the guidance of fish welfare expert Dr. Linda Tschirren, participants (verified track) learn how to observe fish themselves (Figure 6).



(Continued on next page)

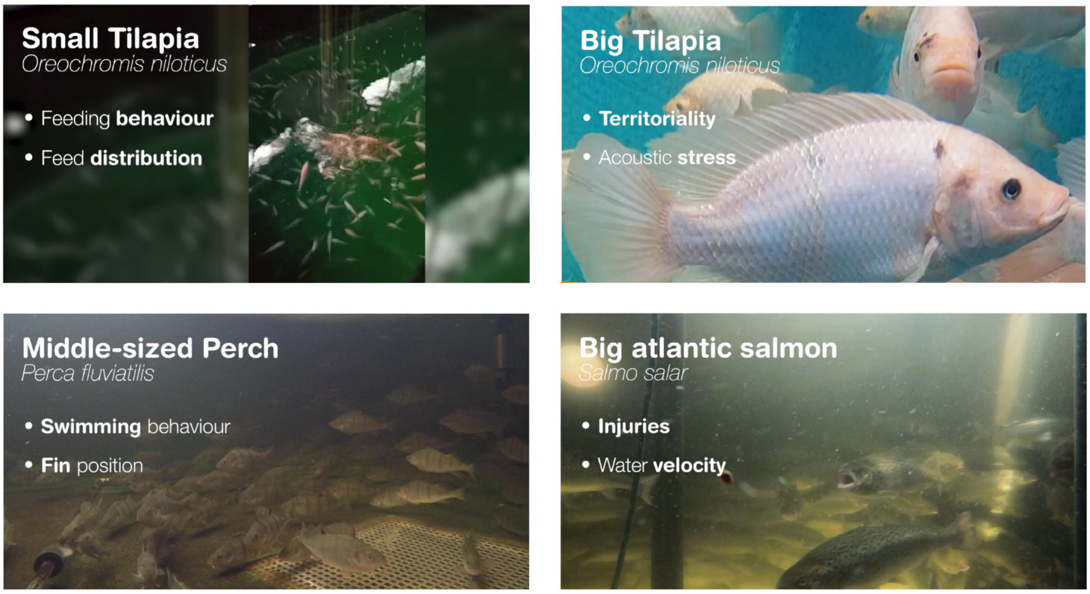


Figure 6: Insights into the practical session Practice fish group behavior guided by a fish welfare expert.

Grading path

This MOOC activates both audits and verified students throughout the course. For this purpose, tasks (individual work, practical sessions, weekly quizzes, final project) are also accessible for audit participants who choose to work only on individual sub-sections. The weekly quizzes consist of a quick quiz (for audit and verified track) and a more detailed final quiz (only for verified track).

In two Open Response Assignments (peer evaluation) on the topics of plant protection in aquaponics and the planning and dimensioning task of their aquaponic system, the participants immediately apply the knowledge they have learned and are encouraged to think further. The participants must gather information, make calculations and be creative by planning a system.

Course support

To ensure adequate support, general discussion forums invite the student to ask for advice on a variety of technical and weekly topics. The participants help each other and where necessary the MOOC team offers support. Several section-specific discussion forums promote the exchange of knowledge among students. For example, in the meet & greet forum, the participants introduce themselves and report about their relation to aquaponics and/or why they attend this course. In another forum, they describe the advantages and disadvantages of different hydroponic systems, and in a task in sections 4 they post about exotic plants which can be grown in aquaponics.

The MOOC team visits the discussion forums several times a week and responds to unresolved, adds clarifications and contributes to discussions. Also, after the first feedback, targeted information material was added to the course to support learners with insufficient knowledge of chemistry.

In addition, during the first instructor-paced course, course communication via email was actively carried out on a weekly basis. In the self-paced course communication is carried out via weekly emails containing the weekly highlights.

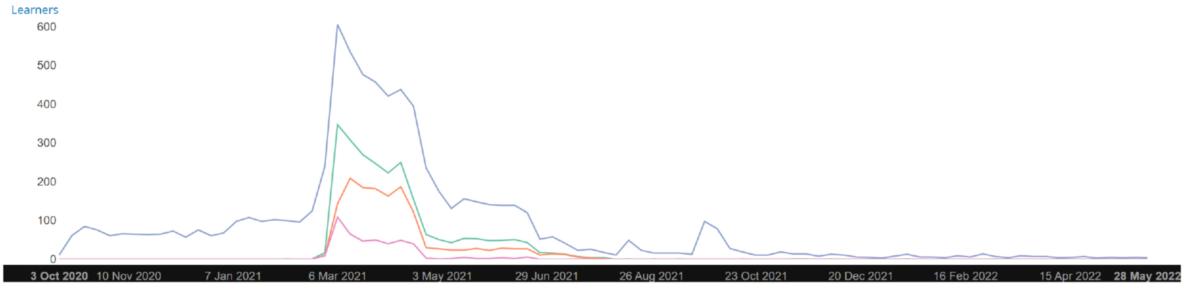
Course analytics and interaction

As the first edX course published by the University of Applied Sciences, the MOOC Aquaponics went live in spring 2021 as an instructor-paced course and attracted 2144 participants (5.3 % as verified students) from 128 countries. The re-run 1 in autumn-winter 2021/2022 was self-paced, and 2194 participants were enrolled (5.9 % as verified students). We were pleased to see that the activity of the participants remained high over time (Figure 7).

(Continued on next page)

During current course run 929 people (5.4 % as verified students) participant the course.

1st Run instructor-paced



Re-run1 self-paced

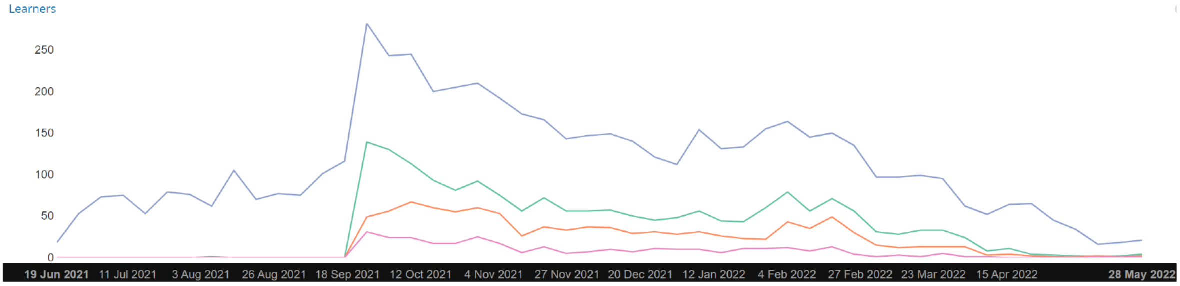


Figure 7: Weekly learner engagement of 1st run as instructor-paced and Re-run 1 as self-paced course.

In the discussion forums, the participants actively exchanged ideas and gathered interesting information. It is really noticeable how the participants are also interested in exchanging knowledge and networking.

Course availability

Because of continuously high interest, this course is now offered twice a year (April-August and October-February) for 5 months each as a self-paced course. In April 2022 re-run 2 has started.

Course feedback

This MOOC is the first one on aquaponics and it attracted very high participation. The reasons for this response are manifold: (i) since 2015, when Aquaponics was proclaimed to be one of the "ten technologies that can change our lives"[1], this topic continues to be relevant in an array of contexts: urban food production, circular economy, research, education, and social work; (ii) The Aquaponics research group at ZHAW is internationally renowned, with several high quality and widely cited papers. It has been found to be the top influential institution in this field in a recently published systematic review[2]; (iii) the Aquaponic community is tightly knit, also due to the COST Action "FA1305 - The EU Aquaponics Hub - Realising Sustainable Integrated Fish and Vegetable Production for the EU"[3], and the word about the high quality of the course spread quickly. Indeed, we received several oral feedbacks from the colleagues from the industry, for example from Michael Reuter aquaponic manufaktur, Sebastien Stoll LinkedIn, Ragnheidur Thorarinsdottir SVINNA-Engineering Ltd., Ulrich Hirschmüller Urban Lab gUG, and Raffael Känzig Phoster GmbH to name just a few.

It is great to see how much positive feedback this course is receiving, which is mostly related to the practical, varied, and open teaching style. The participants enjoyed the diversity and very much appreciated the practical relevance of this course, with contributions of experts and the different, practice-related tasks.

In addition, this course motivates people from different backgrounds to become active in the field of sustainable food production. Many participants reported that they would like to build their aquaponic system in the future or get involved in aquaculture or hydroponics. For example, an airplane pilot started to consider food value chains and interdependencies during the Covid pandemic. After completing the course, he plans to build his own aquaponics farm and produce vegetables and fish for his family.

(Continued on next page)

Further plans
MOOC «*Aquaponics – the circular food production system*» will be offered twice a year (April-August and October-February). A new MOOC «*Recirculating Aquaculture Systems (RAS)*» will be offered from summer 2023 on. These two courses will be offered as the Professional Certificate «Circular food production systems». In the long term, the MOOC «Hydroponics» should also be offered as a part of this Professional Certificate program.

Learners absolving the professional certificate in circular food production systems will acquire a unique combination of technical engineering skills, biological understanding of the circular systems and the organisms produced as well as the know-how and the inspiration needed to market the end-product. This combination of skills makes the learners fit for the growing markets of urban agriculture, vertical farming, and consulting in aquaponics, aquaculture, and soilless production.

3. Nominee(s) curriculum vitae

Nadine Antenen is a research associate in the Ecotechnology Research Group, where she works towards the water, nutrient, and energy self-sufficiency, with a focus on natural processes in water cycles. She is also an expert in E-Learning.

Florentina Gartmann is a research assistant in the Ecotechnology Research Group. Her expertise is in organic farming, horticulture, vertical farming, integrated pest management as well as sustainable solutions to produce plants and fish in recirculating systems.

Prof. Dr. Ranka Junge (emerita), Institute of Natural Resource Sciences at ZHAW School of Life Sciences and Facility Management. Her expertise and research interest include nature-based technologies involving water and nutrient recycling, such as aquaponics, hydroponics, aquaculture, building-integrated agriculture, and zero-emission buildings.

Plocamium cartilagineum AND *Sargassum vulgare* EXTRACTS MODULATE DIFFERENT SPERMATOZOA TRAITS IN SENEGALESE SOLE

F. Félix[1], N. Silva[1], C.C.V. Oliveira[1], E. Cabrita[1] and P.J. Gavaia[1,2]*

[1]Centre of Marine Sciences (CCMAR), University of Algarve, Campus de Gambelas, 8005-139 Faro, Portugal

Introduction:

As the search for novel feed ingredients increases in the aquaculture sector, micro and macroalgae are being widely explored. The three main categories of macroalgae, green, brown and red, already demonstrated to have a diversity of bioactive compounds with considerable prophylactic and treatment potential (Naiel et al., 2021). *Plocamium* and *Sargassum* are two macroalgae genus with proven positive impact on fish health (Carson et al., 2018), mainly due to their antioxidant proprieties (Wang et al., 2019). However, the information regarding the effects of dietary macroalgae in fish reproduction is scarce. In Europe, production of Senegalese sole (*Solea senegalensis*) still faces some constraints in terms of reproduction. The broodstock born and raised in captivity (F1) do not spawn naturally and males present lower sperm quantity and quality (Cabrita et al., 2006), which has been shown to be highly affected by oxidative stress. Our hypothesis is that incorporation of *Plocamium cartilagineum* and *Sargassum vulgare* in fish feeds could confer extra protection against oxidative stress and therefore enhance spermatozoa traits in F1 Senegalese sole males.

Material and Methods:

During the feeding trial, Senegalese sole F1 broodstock was kept under controlled temperature (19 ºC) to ensure the optimal conditions for spermatogenesis. Fish were fed with four different formulated diets for 60 days: Control (Ctrl), Vitamin K1 (VK1), Ctrl supplemented with 5% *Plocamium cartilagineum* (*Pc*), and Ctrl supplemented with 5% *Sargassum vulgare* (*Sv*). Every 15 days fish were sampled to evaluate different parameters of sperm motility, such as total motility (TM), progressive motility (PM), curvilinear velocity (CLV), straight line velocity (SLV) and linearity (LIN), using Computer Assisted Sperm Analysis (CASA) software. Spermatozoa viability and Reactive Oxygen Species (ROS) were assessed by flow cytometer. On the final sampling, 6 fish from each treatment were sacrificed with a lethal dose of anesthesia and gonads were extracted to determine the relative expression of anti- and pro-apoptotic genes (*bcl-2, bcl-x, mcl-1, bad, bax, bok*), and genes involved in fish antioxidant system (*sod, cat, gpx, hsp70*). Specific growth rate (SGR) and feed efficiency were evaluated at the end of the experiment. Statistical analysis was performed on GraphPad 8.0 software.

Results:

Significant differences on sperm quality parameters were evident after one month of trial (2nd sampling) (Figure 1), with *Pc* treatment showing 75 % of spermatozoa TM (A) and the highest viability (B). In turn, *Sv* treatment revealed to have a higher percentage (41 %) of live cells (C). At the end of the trial, males fed with *Sv* diet revealed to have upregulated the gene responsible for the activity of glutathione peroxidase (*gpx)* in gonads (D). Gene expression of anti- and pro-apoptotic genes (*bcl-2, bcl-x, mcl-1, bad, bax, bok*), and genes involved in fish antioxidant system (*sod, cat, hsp70*), was not influenced by dietary supplementation with VK1 or dry algae, as well as SGR and feed efficiency.

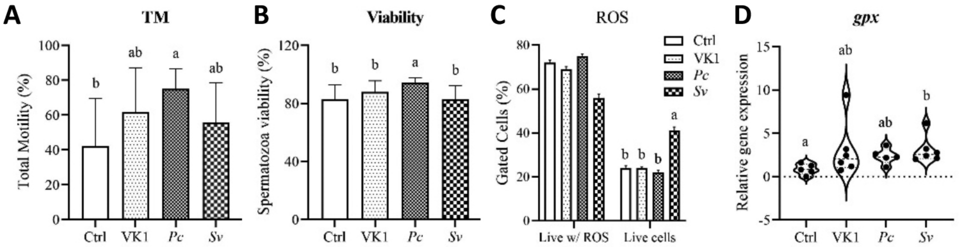

Figure 1. Results from 2nd sampling of feeding trial. A) spermatozoa total motility, B) cell viability, and C) Reactive Oxygen Species are expressed as mean ± SD, and D) gpx gene expression, is relative to the housekeeping genes ubiquitin and elongation factor1a. Differences between treatments were significant when p<0.05. Different letters show significant differences using 1-way ANOVA followed by non-parametric Kruskal-Wallis comparisons (A), (D); and Tukey post-hoc test (B), (C).

(Continued on next page)

Discussion:

In this study, we have considered four different diets to analyze their antioxidant potential effect on reproductive performance of Senegalese sole F1 males. The VK1 diet was used due to the known effect of vitamin K in many physiological roles, including fish reproduction by increasing testosterone levels (Fernandez et al., 2019). However, the most interesting results obtained here were with the macroalgae supplemented diets. *Plocamium* seems to improve the reproductive performance of spermatozoa, while *Sargassum* upregulated genes involved in gonadal antioxidant system. European seabass fed with *Gracilaria sp*. extracts also revealed higher antioxidant capacity (Peixoto et al., 2019). Further research is needed to uncover the macroalgae bioactive compounds capable of modulating fish reproductive traits and antioxidant system.

[*] rgebauer@frov.jcu.cz

Introduction

Aquaponics, i.e. a synergistic connection of hydroponics and aquaculture, is a young industry in the Czech Republic. The prominent research infrastructure in the country is the Aquaponic hall of the Faculty of Fisheries and Protection of Waters, University of South Bohemia. The Aquaponic hall comprises six recirculating aquaculture systems (5 m^3 each), six big-scale mineralization units (1 m^3 each), and four types of hydroponic systems (DWC, Media bed, Drip, Aeroponics) with at least six repetitions. The research group is mainly focused on improving the nutrient efficiency of aquaponics through the development of tailored aquaponics feed, integrated pest and diseases management in aquaponics, effective aquaculture sludge valorization, and knowledge transfer to aquaponic adopters. Further research is focused on changes in the amino acid, fatty acid, and sensory characteristics of fish fed with alternative sustainable feedstuffs.

Research fields

For improvement of nutrient efficiency through the development of tailored aquaponic feed, we used a sophisticated multistep approach based on:

a) Modeling the nutrient efflux from aquafeed with different ingredients with a developed inventory entitled Tilafeed (Roy et al., 2022),
b) Making the aquafeed in-house with the extruding machine,
c) In-house digestibility and nutrient retention and losses studies in the Guelph system (Fig. 1.; Roy and Mráz, 2021),
d) Applied studies in an aquaponic system with mineralization of sludge.

Integrated pest and disease management and its bottlenecks in aquaponics were reviewed (Folorunso et al., 2021). Further experiments are focused on the runoff of pesticides into aquaponic water and its effects on fish and nitrifiers in the biofilter. Moreover, since numerous biocontrol agents are commercially available against insect pests, further research aims to develop novel bioagents against common fungal diseases, which are hard to tackle with natural fungicides. These bioagents include several entomopathogenic fungi, which are first tested *in vitro* (Fig.2.). The best candidate is then tested *in situ*.

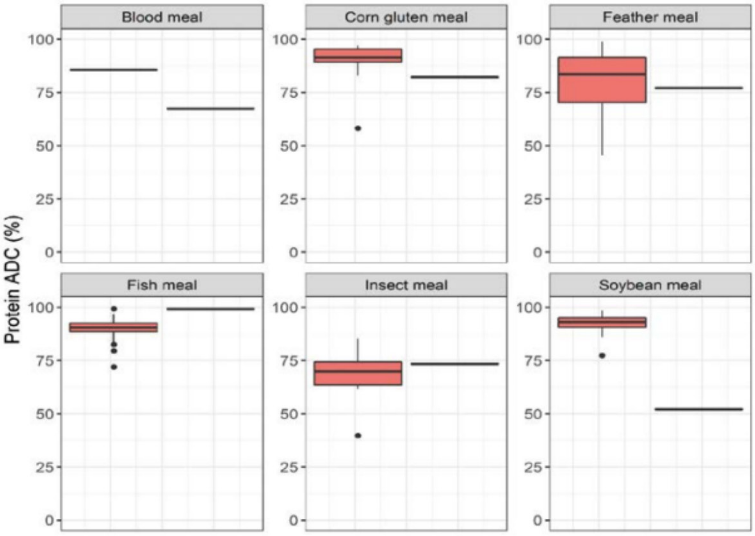

Fig. 1. Comparison of digestibility of protein sources using the in-house technology (black line) with global metadata on the same protein feedstuffs (pink boxplot) for tilapia.

(Continued on next page)

Fig. 2. Efficacy of a novel bioagent against powdery mildew on cucumber leaves. (A) leaves treated with 0.05% tween 80 solution, and (B) leaves treated with the novel bioagent.

We use several approaches for valorizing aquaculture sludge, including aerobic digestion in continuous big-scale mineralization units or lab-scale batch reactors, vermicomposting aquaculture sludge (Kouba et al., 2018), and/or/or biofloc technology.

Knowledge transfer to aquaponic adopters is based on regular meetings with aquaponic farmers. As most of the aquaponic farms in the Czech Republic were installed by the same company, they all suffer from the same flaws, i.e. undersized water and air pumps and mechanical and biological filters. With the help of national funding agencies, the technologies of two of the farms were already improved, and these farms are profitable.

Since the sustainable feedstuffs in aquafeed can substantially alter the composition of fish flesh, the final product is analyzed for amino acids, fatty acids, and sensory characteristics by certified panelists.

TOWARDS A SUSTAINABLE AQUAPONIC FARM MODEL IN BELGIUM: PRODUCTIVITY AND ECONOMIC ANALYSIS OF TWO CONTRASTING FISH PRODUCTION MODELS (TILAPIA VS PIKEPERCH)

*E-mail: vgennotte@uliege.be

Thanks to its key strengths such as water use efficiency and nutrient recycling, aquaponics is considered as a sustainable food production method and is still getting growing interest in the scientific community, producers and a broad general public. It meets commonly shared consumer expectations toward food production such as: local production, fresh, healthy (pesticide-free), diversified products, environmentally friendly and low CO_2 emissions. It is also in line with the EU strategy to promote sustainable food systems, specially fish farming. However, commercial aquaponics production remains in its infancy as regulations and profitability weakness act as a serious brake on further growth (Turnsek et al., 2020; Fruscella et al., 2021).

With the aim of creating robust foundations for the development of an aquaponic farm in Belgium, we set up an aquaponic pilot production system designed to test and compare different agronomic and economic models, sizeable to a commercial scale.

This coupled aquaponic system (total volume: 18 m^3) presents a 8 m^3 fish production capacity and 50 m^2 of crop production in raft and NFT, equipped with LED lighting. The two fish production models were tilapia (*Oreochromis niloticus*), a tropical fish species, highly productive, with a relatively low market price, and pikeperch (*Sander lucioperca*), a temperate fish, less productive but with an added commercial value. Vegetable production included lettuce, basil, coriander, parsley and rocket salad.

Data covering biological production (growth and survival), energy and water use, and physico-chemical functioning were collected during 1 year for tilapia and during 2.5 years for pikeperch production, supporting a deep analysis of fish-vegetable productivity, and operational costs.

A market analysis targeting distribution of aquaponic products was also carried out to quantify the local demand and sale prices, define the distribution channels and their capacity. First results show that, even if tilapia is 3-fold more productive than pikeperch, associated vegetable production was relatively higher with pikeperch and economical balances are similar for both models, as the high value of pikeperch offsets its lower production.

Finally, production, economical (investment and operational costs) and market data will be evaluated together to come up with recommendations on operational marketing (targeted products and markets) and more technically, on farm sizing and design. The ultimate output will be the production of a business model integrating all these data and proposing a reliable aquaponic farm model.

TRACKING AND ANALYSIS OF THE SWIMMING ACTIVITY OF EUROPEAN SEABASS *Dicentrarchus larbax* IN SEA CAGES AND ITS RELATION TO FEEDING

Dimitra G. Georgopoulou[1] *, Charalabos Vouidaskis[1], Nikos Papandroulakis[1]

1. Institute of Aquaculture, Hellenic Centre for Marine Research, AquaLabs, 71500, Gournes, Heraklion, Greece
E-mail: d.georgopoulou@hcmr.gr

Introduction

Feeding is the primary factor determining efficiency and cost in aquaculture and requires optimization to decrease feed loss and maintain fish health. Monitoring of individual and group swimming patterns in response to external factors such as feeding can provide useful information for improving production management. For this reason, intelligent feeding control based on the detection of behavioral changes and growth status has gained increasing attention and efforts are being made to define behavioral indicators to detect satiation levels and control feeding for different species. Here, an automated routine that enables individual fish tracking in sea cages as well as the detection of different swimming patterns is developed. Its potential applications on the detection of the swimming behaviour around feeding times are also presented.

Materials and methods

A group of E. seabass fish of 200 g body weight was reared in a circular polyester cage (40 m diameter, 9 m depth) located at the pilot scale netpen cage farm of HCMR at Souda bay, Crete (certified as an aquaculture facility from the national veterinary authority; code GR94FISH0001). A submerged network camera (Fyssalis V3.1) capturing at 10 fps was used for monitoring and video recording during daylight hours in April 2022. The camera was positioned at 4 m depth using a gyroscopic gimbal stabilizer to ensure it pointed upwards. Manual feeding was performed once daily, between 08:00 to 10:00. A machine learning model for tracking people (DeepSort) was trained and adapted to track fish individually (using OPENCV/Python) and extract their speed and direction. In addition, computer vision techniques that can detect feeding events and group polarized movement were incorporated into the model.

Results

The system is capable of distinguishing between three different movement patterns related to feeding (figure 1). The polarized motion seen before feeding is realized (figure 1 left), motion that resembles feeding behavior but lasts for a limited time period and could be an indicator of feeding or other warning situation (figure 1 middle) and the feeding event where the fish shoal swirls around the feed (figure 1 right).

The system is also capable to detect variations in the activity of the fish. Extraction of the group speed for two consecutive days showed significant variations of the fish speed during the day, suggesting that the fish start being more active during and after feeding and less active in the afternoon. More specifically, the group's speed increased from 0.2 bd/s to 1.1 bd/s during the feeding window (i.e. from 08:00 to 10:00, figure 2), and it remained at maximum levels until 12:00, two hours after feeding. Then it started decreasing until it reached a minimum speed of 0.2 bd/s at midnight. This pattern is repeated also in the second day.

Conclusion

The presented system can successfully capture speed variations and different swimming patterns related to feeding or other external factors and can be used to provide useful information on the dynamics of the movements and possible critical values that indicate a transition from hungry to satiated states resulting in the better control of the feeding process. Changes in speed can successfully be captured, suggesting that fish start increasing their activity just before feeding something that would indicate anticipation for feeding and decrease their activity in the afternoon. Further studies are required to help us understand the contribution of other factors such as the human presence, or the internal circadian rhythm on the variation of the activity.

(Continued on next page)

Introduction

Sturgeons in Eurasia are under increased pressure of extirpation and, as a result *ex situ* measures including the safeguarding of remaining genetic heterogeneity and supporting the recovery of the populations in the wild, are essential.

Since it is widely accepted that the targets and rearing practices between commercial rearing and conservation rearing do differ substantially in terms of fitness, this presentation attempts to describe those practices using three study cases in comparison with commercial sturgeon aquaculture. The Adriatic sturgeon (*A. naccarii), the American or Baltic sturgeon (A. oxyrinchus),* and the European sturgeon *(A. sturio*) all are critically endangered and face the threat of (local extinction) in the recent past. The three species currently are subject to regional restoration programs that differ substantially with regard to the organization of the recovery projects.

Materials and Methods

The analysis will summarize and compare the approaches taken, experiences made and the results obtained in an attempt to emphasize practicable yet safe results for the restoration programs. The analysis comprises not only rearing practices but also looks more deeply into the administrative background, the strategic approaches taken, the solutions for establishing *ex situ* stocks as well as rearing and release programs, funding and regional integration.

Results and Discussion

Since Adriatic and European sturgeon recovery programs were established in the 1980s based on the remaining populations of the species in the Po and Gironde rivers, the prerequisites differed from the reintroduction of the Baltic sturgeon that was extirpated when the project came to life. All three projects established captive (*ex situ*) broodstocks in an attempt to save the species from extinction and to provide a basis for the subsequent reproduction and release of the offspring. The comparison addresses the strategic and administrative background of the projects, analyzing the involvement of governmental agencies in funding and in accompanying the process of the recovery/reintroduction.

The means of broodstock development, reproduction and rearing are investigated and the practices of the releases are compared from the technical as well as from the administrative point of view. The strengths and weaknesses of the projects are illustrated and discussed.

As such, the presentation aims at providing a baseline for the planned follow up discussion to identify the options for a closer collaboration between commercial farms and recovery projects. The essential prerequisites, the benefits and the drawbacks in the framework of such a strategic collaboration as well as the possible options for its implementation will be assessed.

ENVIRONMENTAL QUALITY IMPROVEMENT AFTER THE CONVERSION OF A MARICULTURE PLANT INTO AN IMTA SYSTEM

Introduction

Mariculture activities strongly affect the surrounding environment (Gentry *et al.,* 2017). Wastes deriving from these activities are the main cause of negative environmental impacts influencing water quality and benthic communities (Wang *et al.,* 2020). Within the project Remedia life, a fish mariculture plant (Maricoltura Mar Grande of Taranto) was converted into an Integrated Multi-Trophic Aquaculture system (IMTA), utilizing a new set of very efficient bioremediating organisms (polychaetes, porifers, mussels and macroalgae). To investigate the restoration effect occurring after the conversion of the plant, an environmental monitoring program was performed at the beginning of the project (Giangrande et al., 2022) and repeated after two years of the IMTA system establishment. In order to obtain a detailed description of the environment, both water column and sediment were sampled.

Material and methods

The study area is located on the south-west side of the Mar Grande of Taranto (40°25′56″ N; 17°14′19″ E) (Ionian Sea), which is a semi-enclosed basin connected to the Gulf of Taranto. The investigation was performed in the aquaculture plant "Maricoltura del Mar Grande (MMG)", partner of the Remedia-Life project. Two sampling areas were identified around the fish farm, with 4 stations located at the four corners of the plant. Samples were collected one year before (2018) and two years after the realization of the IMTA system. Physical-chemical and microbiological parameters and TRIX index were measured in the water, whilst microbiological parameters and macrobenthic analysis were conducted in the sedimentary environment, considering the AZTI's Marine Biotic Index (AMBI) and microtox bioassay. Moreover, the changes in biodiversity of hard substrates present under the cages were also investigated.

Results

The ex ante analysis allowed to asses the more impacted station due to the aquaculture activities. By comparison, the other three stations were characterized by a higher environmental quality, therefore the more impacted station was chosen to experiment the bioremediating activity and considered as the Treatment station (T). Another station, without bioremediators, was utilized as Control (C). An amelioration of the Treatment station was observed after the conversion of the plant. By contrast the Control station remained quite similar throughout the years, leading to conclude that the bioremediating activity determined a similarity of the environmental condition in the investigated stations, towards an amelioration of T station at the end of the project. The changes observed over time in T station of both water column and sediment parameters are reported in the following figure (Fig. 1).

Discussion

In the realized IMTA system the bioremediating organisms grew without adding any feed other than the fish one. The synergistic action of all the bioremediators reared around the fish cages restored the water column by transforming the waste into biomass that can be utilized as a by-product of aquaculture. More in particular, macroalgae avoid the eutrophication of the water surrounding the fish cages, whilst the filter feeders, such as worms, sponges and molluscs remove bacteria and particulate organic matter, improving the microbiological quality of the water as well as the transparency. Our results indicate that the marine environment benefits from the eco-sustainable potential of this method. The values of the parameters selected as indicators of environmental quality, such as TRIX index, AMBI microtox bioassay, microbiological analyses and hard bottom biodiversity evaluation, have significantly showed an amelioration of the Treatment site. This was particularly true for the indicators related to the sediment compartment which represents the biological memory of the system. In fact, the environmental quality under the cages, once highly degraded, was recovered with a remarkable increase in local biodiversity. Our results are noteworthy since for the first time the bioremediation effect was *in situ* measured.

Introduction

Intensive tilapia culture is often affected by a wide range of bacterial infections, some of them exhibiting similar clinical presentations that are difficult to differentiate even for the most trained eye. In these cases, histological techniques presents a valuable diagnostic tool, not only to detect infectious and parasitic agents, but also to understand the clinical context, the pathogenesis and to identify possible concomitant agents sometimes difficult to detect by other diagnostic techniques. This work summarises findings and diagnostic criteria of granulomatous lesions associated to different bacterial agents.

Material and methods

Symptomatic fish were sampled, necropsied and organs were immediately fixed in 10% buffered neutral formalin on site during farm visits. Fixed organs were embedded in paraffin in our laboratory. 4 μm-thick sections were performed, mounted on glass slides and stained using Haematoxylin & Eosin (H&E) standard protocols. Additional histochemical staining techniques including Gram, Giemsa and Ziehl Neelsen were also used to better identify bacterial agents.

Results and conclusions

Macroscopical examination of internal organs revealed multiple whitish granulomas. These lesions were especially prevalent in kidney and spleen.

Histological examination presented with variable impact of granulomatous reaction including:

Focal necrosis and macrophages aggregates containing intracellular, long rod-shaped, gram-negative bacteria were detected (Fig. 1) consistent with *Francisella sp*.

Well-defined granulomas, with a thick peripherical layer of epithelioid cells and a core formed by abundant cellular debris and high counts of free and phagocyted gram-negative cocci bacillary bacteria (Fig. 2) consistent with *Edwardsiella sp*.

Well-defined granulomas, with a thin fibrous capsule, high numbers of melanised macrophages and high counts of acid-fast stained fine bacilli (Fig 3) consistent with *Mycobacterium sp*.

Given the similarity of lesions, routine H&E-stained sections and additional use of histochemical stains allow us to fully characterise the lesional pattern and and provide a morphological diagnosis. Obtained results also help to stablish a diagnostic approach, especially in those cases where microbiological analysis fails in its attempts or theis is not available. Specific techniques, such as immunohistochemistry or polymerase chain reaction are often necessary for confirmatory diagnosis.

Introduction

Nowadays, coastal pollution monitoring consists in study environmental media, such as sediments, water or/and biological samples, as mussels. A new challenge started in 2009 with the International Pellet Watch (IPW), proposing the use of resin pellet as no-living passive samplers, in order to avoid long and high-cost preparation samples of coastal environmental media. Positive correlation (Fig. 1) between POPs concentration in mussels and in resin pellet has been proved during IPW [1].

Resin pellets are the small virgin plastic particles of different polymeric types from which all plastic objects are made. During plastic production processes, industries and factories disperse resin pellets in the environment and most of them arrive in the ocean standing there for a lot of time. Due to their specific weight almost the same of salt water, many of types of pellet floats in the marine microlayer, and many of them and many of them end up on the beaches.

As the main POPs (persistent organic pollutant) and linear hydrocarbons absorption takes place in the microlayer where pollutants are most concentrated than in the water column. In this way pellets can sorb hydrophobic substance [2], [3].

The environmental pollution mapping methods proposed within the IPW is based on Endo et al. (2005) observation regarding a correlation between the degradation state of resin pellets (especially the PE ones) and their POPs content. They sustain that a more pronounced coloring (yellowing) of the pellet should indicate a longer residence time in the sea of such particles, and therefore a greater degradation of their polymeric matrix; the longer time spent in the sea also means a greater probability of having absorbed pollutants dissolved there, from which should follow a correlation between more intense coloration and POPs penetrated. This means that, by selecting the darkest pellets present at different sites, it is possible to get an idea of the degree of pollution in that particular area [4, [5].

As Endo et al. (2005) considerations are supported by a very small number of sampled pellets, we decided to undertake an “Italian pellets survey” in order to investigate, with a greater sample number and so a major statistical accuracy, the structural characteristics of beached pellets, trying to understand if exists a correlation between physical/chemical degradation state, their color (yellowing) and the organic pollutant concentrations.

Materials and methods

We sampled pellets distributed in all the Italian peninsula during spring/summer of 2019, thanks to the contribution of volunteers of Italian NGO Legambiente. Then, we selected sites presenting a high pellets density (more than 100 pellets for site) and, following the prescription reported in Endo et al. 2005 [1] and Ogata et al 2009 [4], we separate them in 3 “yellowing” classes. So, we investigated their polymeric structure and degradation characteristic with infrared analysis, and finally we proceeded to extract POPs from them.

Polymeric structure was identified with ATR analysis. Spectra were registered using a Fourier Transform-InfraRed Jasco 6200 (Jasco, Tokyo, Japan) equipped with a PIKE MIRacle (Madison, WT, USA) accessory, in the Laboratory of Istituto per i Processi Chimico-Fisici of Consiglio Nazionale delle Ricerche (IPCF-CNR), in Pisa. Each sample underwent 64 scans from 4000 to 650 cm^{-1}, after the collection of background data.

(Continued on next page)

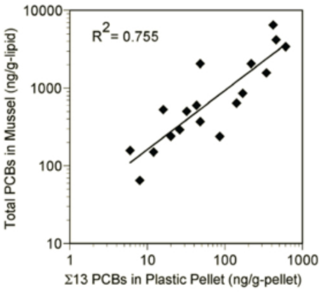

Fig. 1. Correlation between of ΣPCBs in mussels (ng/g-lipid) and in plastic pellets (ng/g-pellet) [1].

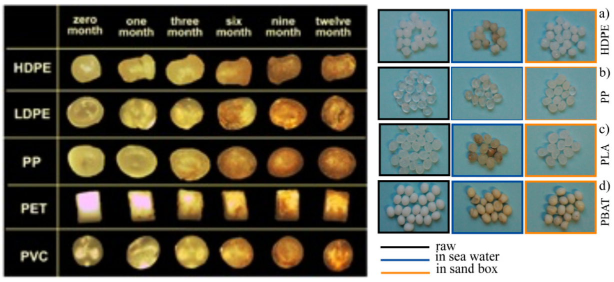

Fig 2. On the left: Discoloration of different polymeric matrix of pellets over time [3]. On the right: Digital photos of the raw pellets of standard of bio-plastic (in black), 6 months-aged in seawater (in blue) and 6-months-aged in sandbox reproducing beach conditions (in orange) [5].

The Istituto Zooprofilattico Sperimentale del Piemonte, Liguria e Valle d'Aosta (IZS PLVA) developed POPs (PCBs and PAHs) extraction and analysis. Sample preparation consisted in a vigorous extraction in n-hexane in ultrasonic bath for 30 minutes at 50°C. No purification step was applied. PCBs analysis was performed in GC-MS/MS ThermoFischer (Waltham, MA, USA) SCIENTIFIC TSQ 8000 Evo equipped with autosampler Thermo SCIENTIFIC AI 1310 hyphenated with spectrometer QqQ Thermo SCIENTIFIC TRACE 1300 with EI ionization mode. The column utilized was a Zebron ZB-SemiVolatiles (30m x 0,25mm x 0,25μm) with a 5m Guardian End Phenomenex and injection temperature has been set at 260°C. Injection was operated in splitless mode with a 2 μL volume. Acquisition was operated in SRM (Selected Reaction Monitoring) mode. As mobile phase was used He at 1.2 mL/min. PAHs analysis was performed in HPLC-FLD 1100 Series quaternary pump (Agilent Technologies, Santa Clara, CA, USA). Data acquisition and analysis were performed using ChemStation® software. Fluorescence $\lambda_{ex}/\lambda_{em}$ was 294/404 nm, gain 12x and injection volume 1 mL. Stop time at 36 min; and column temperature 25 °C. Chromatographic separation was performed using a reversed-phase column Envirosep pp (125m x 4.6mm x 5μm). The eluents were: water (A) and acetonitrile (B). The flow rate was 1 mLmin^{-1}.

Results

At the moment the results are still preliminary and under elaboration, but we hope to have them ready for presentation at the Conference "Aquaculture Europe 2022". In this way we will be able to discuss the validity of this method compared to the more standardized method using mussels as "sentinels" for environmental pollution in coastal areas. Pellet watch could certainly have some advantages (easier sampling and analysis of such inorganic samples), but it must be considered their greater mobility compared to that of mussels, which are sedentary organism. Moreover, although this method has been used for many samplings worldwide, starting from the one proposed by Ogata et al. [4] onwards [5], [6], [7], no accurate assessment has yet been made (supported on a statistical basis greater than that of the work of Endo et al. [1]) to support and corroborate the validity of the supposed correlations between pellet color, degradation status and pollutant content.

Introduction

Hundreds of millions of salmonid fish are tagged annually by removing the adipose fin before release, for example for recapture statistics and fishing. Previous experiments showed that the resection of the fin decreased swimming performance, particularly of juvenile fish. Recent research suggests that adipose fin clipping conflicts with animal welfare (Reimchen & Temple, 2004; Templ & Reimchen, 2008; Buckland-Nicks, 2016). The adipose fin is not only a useless body appendage that consists of fat cells. Microscopic analyses of the adipose fin identified a complex network of nerve fibers. Our gene expression studies support the hypothesis of nerve activity in the adipose fin. Our preliminary data together suggest a sensory function of the fin that may allow fish to align optimally with the water flow and swim more efficiently. We therefore began a targeted study to generate data that support the hypotheses of the acute and chronic stress and the potential pain response due to fin resection and furthermore the expected mechanoreceptive function of the adipose fin. As part of a multiparametric approach, we performed comprehensive gene expression analyses, conducted holistic transcriptome studies over time, plotting behavioral responses, and recorded stress hormone activity.

Results

We profiled the specific expression of 20 neuron- and glial cell-marker genes in the adipose fin and seven other tissues (including dorsal and pectoral fin, brain, skin, muscle, head kidney, and liver) of the salmonid species rainbow trout *Oncorhynchus mykiss* and maraena whitefish *Coregonus maraena*. Moreover, we measured the transcript abundance of genes coding for 15 mechanoreceptive channel proteins from a variety of mechanoreceptors known in vertebrates. The overall expression patterns indicate the presence of the entire repertoire of neurons, glial cells and receptor proteins on the RNA level. This quantification suggests that the adipose fin contains considerable amounts of small nerve fibers with unmyelinated or slightly myelinated axons and most likely mechanoreceptive potential. The findings support a previous hypothesis about the innervation and potential flow sensory function of the adipose fin. Moreover, our data suggest that the resection of the adipose fin has a stronger impact on the welfare of salmonid fish than previously assumed (Koll et al., 2020).

Conclusion

Our data suggests that the adipose fin is fully innervated by small nerve fibers with, most likely, mechanoreceptive potential. Neurons, glial cells, and receptor proteins seem to be present on the RNA level. This supports the hypothesis about the adipose fin as a flow sensor (Reimchen & Temple, 2004; Buckland-Nicks, 2016). Our data accelerate the discussion about the use of adipose-fin clipping. The adipose fin is a criterion for the choice of suitable sexual partners (Westley et al., 2008) and, it contributes to the swimming efficiency (Templ & Reimchen, 2008). Thus, the resection of the adipose fin tissue seems to be a less suitable method, particularly from an economic point of view regarding sea ranching and large-scale aquaculture in the future.

Introduction

The awareness of mycotoxin-related issues in the aquaculture industry has been increasing, accentuated by the increased inclusion levels of plant meals in aquafeeds. Mycotoxins are secondary metabolites produced by fungi, often found in agricultural products, used to feed livestock, and pose a health risk to both livestock and consumers. Fumonisin (FB) and deoxynivalenol (DON) are among the most frequently detected mycotoxins at high levels in fish feed (Gonçalves et al., 2020). These mycotoxins can potentially cause problems in fish farms, with significant economic losses such as mortality, reduced productivity, higher susceptibility to diseases, etc (Koletsi et al., 2021). The effects of different contamination levels of dietary mycotoxins FB and DON on growth factors and health parameters in gilthead seabream (*Sparus aurata*), were presently assessed.

Materials and methods

Gilthead seabreams (3.40±0.5g) were transferred to the Aquaculture Laboratory facilities, University of Thessaly from a commercial fish farm, and randomly placed in 21 glass aquariums (125L, 30 fish/aquarium). The mycotoxins Deoxynivalenol (DON, Cayman Chemical) and Fumonisin B1 (FB, Cayman Chemical) were dietary administered at different contamination levels to the experimental fish. Six experimental diets in triplicate were applied: DON-A (300ppb), DON-B (2000ppb), DON-C (5000ppb), FB-A (5ppb), FB-B (10ppb), and FB-C (40ppb). The control group (CTRL) was fed with mycotoxin-free diet. Water quality parameters were systematically monitored and the water temperature was kept stable at 21 ± 1°C. Fish were fed *ad libitum*, 6 days a week, for 7 weeks. Throughout the experiment, the amount of food consumed and mortality were daily recorded. Fish were fasted for 24h before sampling and were killed by overdose of anesthetic. Total length and total weight were measured and growth parameters were calculated for each treatment. Blood samples were collected from the caudal vein and haematological (haematocrit-HCT, red blood cell-RBC, and white blood cell-WBC) and immunological parameters (complement, anti-protease, myeloperoxidase, alkaline phosphatase, and ceruloplasmin activities), were assessed. Liver samples were collected for the determination of hepatic lesions through histological analysis. Data were analyzed by one-way ANOVA, followed by Tukey's post hoc test at a significance level of $P < 0.05$, using the IMB SPSS Statistics version 26 statistical program. The experimental protocol was approved by the Research Ethics and Ethics Committee of the University of Thessaly.

Results and Discussion

High concentrations of mycotoxins in DON-C and FB-C treatments caused significantly lower food consumption compared to other treatments. Similarly, significantly lower mean weight, mean length, and total biomass increase, were also recorded. In groups FB-A and FB-C, significantly lower mean weight was also estimated, compared to the control group. In DON and FB-A treatments, significantly higher FCR was calculated, while significantly lower SGR was estimated in the DON-B, DON-C, FB-A, and FB-C treatments, compared to the control group. Reduced food intake and limited growth have also been observed in salmon and carp after administration of deoxynivalenol, at similar concentrations (Bernhoft et al., 2018). Also, in the case of gilthead seabream, the dietary administration of FB affected growth parameters (Goncalves et al. 2020). Both mycotoxins affected the examined haematological and immunological parameters. A significantly lower haematocrit was observed in the DON-C group compared to the control group. Differences were observed in the blood cell counts, however, this was not statistically confirmed. Increased myeloperoxidase activity and ceruloplasmin activity were observed in DON-A and DON-C groups and decreased hemoglobin and alkaline phosphatase concentration in the DON-B group. FB addition showed significantly increased myeloperoxidase and ceruloplasmin activities in the FB-B and FB-C

(Continued on next page)

treatments and a tendency towards decreased alkaline phosphatase activity at all doses tested. None of the mycotoxins tested affected significantly the complement-mediated antibacterial activity or the anti-protease activity of the serum. The myeloperoxidase activity is proportional to the production of peroxide, a potent ROS that may provoke oxidative stress in the fish cells. The ceruloplasmin activity indicates some inflammatory response, while the alkaline phosphatase activity is linked to the anti-inflammatory response. Histopathological examination of the liver from the control group showed normal structure in the liver parenchyma and hepatopancreas. Both DON and FB groups showed mild (DON-A, DON-B, FB-A, FB-B) to extensive (DON-C, FB-C) pathological lesions, such as mild degenerative changes of hepatocytes, with graded hydropic and fatty degeneration, as well as early necrotic changes, with nuclear pyknosis and shrinkage. Mild congestion of the hepatobiliary blood vessels was also observed while the pancreatic cells appeared normal. Liver changes have also been confirmed in the case of deoxynivalenol administration in trout (Gonçalves et al., 2018). In conclusion, the dietary addition of DON and FB showed a dose-dependent negative effect on gilthead seabream growth and health.

Introduction

Fish, like other vertebrates, are susceptible to viral infections that cause huge losses to aquaculture. An important disease in the aquaculture sector is caused by the Spring viraemia of carp virus (SVCV) belonging to the *Rhabdoviridae* family, which includes some of the most important viral pathogens in aquaculture (Leong et al., 2008). SVCV is a virus with negative polarity single-stranded RNA genome encoding 5 proteins: 3 -´ Nucleocapsid protein (N)-phosphoprotein (P)-Matrix protein (M)-Glycoprotein (G)-RNA-dependent RNA polymerase (L)-5 ´. Common carp is the main hosts of SVCV and highly susceptible to infection. In European Aquaculture, SVCV causes losses up to 4000 tons annually (Fijan et al., 1999) Fish viruses are harmless to humans and are therefore a risk-free research tool. In addition to its importance in the aquaculture sector, SVCV is easy to grow in carp cells, where a number of interferon-related genes have been identified, thus making this virus a suitable candidate for the study carried out in this work.

Verteporfin (VTPF) is a derivative of benzoporphyrin, extracted from the mugwort plant (*Tanacetum parthenium*), that is used for the treatment of age-related macular degeneration (Wang et al., 2016) as a photosensitizer. Evidence has been found for the action of VTPF on signaling pathways related to the innate immune response. Specifically, Verteporfin has been identified as an inhibitor of YAP activity which is a central effector of the Hippo signaling pathway responsible for regulating organ size and tumorigenesis (Feng et al., 2016). Many immunodeficiency symptoms, including periodic bacterial and viral infections, are associated with deficiency of Hippo signaling, implicating its crucial role in immune modulation (Harvey et al., 2013).

Our goal in this study was to analyze the effect of VTPF in EPC cells infected (SVCV) or immunostimulated (poly I:C), to determine the cell antiviral status under those conditions.

Results

The overall objective of this research was to study the role of Verteporfin, a compound used in the treatment of cancer and degenerative diseases, on the immune response in *Epithelioma papulosum cyprini* (EPC) cells. First, the toxicity of the compound was evaluated using the EPC carp cell line observing that up to 2 µM VTPF is not toxic and a protective effect of VTPF against SVCV was seen at concentrations between 0.5-1 µM when VTPF was present during infection.

In plaque reduction assays, pretreatment of cells with VTPF led to the inhibition of SVCV at 4dpi, but not statistically significant. Addition of the compound at the beginning of the infection (0 h) did not produce inhibition. However, in qPCR experiments inhibition of SVCV N gene RNA synthesis at 24 hpi after VTPF pretreatment, and at 72 hpi under VTPF during the infection (0 h) was observed.

In teleost fish it has been shown that *ifitm* (interferon-stimulated transmembrane protein) genes respond when cells are treated with the synthetic double-stranded RNA poly I:C (a molecule that stimulates the interferon pathway). Our results corroborate this: poly I:C treatment increased 3 to 5-fold the expression of *ifitm1* and *ifitm5*, but also other genes related to the innate immune response such as: *isg15* (interferon 15kDa-stimulated gene) and *irf3* (interferon regulatory factor 3) that were stimulated 2 and 5-fold, respectively. As for the pretreatment of the cells with VTPF, there was an increase in the expression of *ifitm*1, but to a lesser extent *irf3* and *isg15*. It can not be ruled out that other interferon-modulated genes are affected by VTPF treatment, as has been observed in other fish cell lines (Zhang et al. 2021).

In summary, we have shown VTPF antiviral activity against SVCV in both RNA synthesis and cell survival experiments, but not in plaque formation assays. The double treatment of poly I:C + VTPF exerted the highest antiviral activity against SVCV. When cells were treated with VTPF a stimulation of innate immune response occurred.

Introduction

There is continued pressure to intensify aquaculture production to fulfil market needs. The expansion of the industry and increased diversity of materials used to build and maintain open, and recirculating aquaculture systems (RAS) have paralleled the development of synthetic polymers over the last decades (Astudillo et al., 2009). Synthetic materials offer greater strength and durability than natural fibres for the construction of ropes, infrastructures, and pipes, whilst often also being less costly and easier to handle. All plastic material within an aquaculture site is maintained and controlled for chemical degradation, biofouling and corrosion, and regularly inspected to ensure strength and stability. Broken and fragmented equipment as well as debris released from intense use however are sources of plastic emission from aquaculture operations at a local and global level, whilst accurate estimations of their contribution remain unknown (Lusher et al., 2017).

The project ASTRAL (All Atlantic Ocean Sustainable, Profitable and Resilient Aquaculture) focuses on integrated multi-trophic aquaculture (IMTA) farming, aiming at defining, supporting, and promoting this type of sustainable aquaculture production across the Atlantic area. To estimate the environmental sustainability, the fingerprint of different IMTA production systems is needed. ASTRAL is looking at the challenges related to the release of microplastics from aquaculture operations in both open and recirculating systems as well as quantifying the marine derived sources of plastics potentially impacting the IMTA labs. A monitoring plan was designed and applied at selected IMTA labs, using a novel sampling equipment able to preconcentrate large volumes of seawater onto appropriate filtering membranes.

Materials and Methods

Three sites were selected within the present study: A) the coastal open multi-trophic aquaculture facility located in Port-a-Bhuiltin (Scotland) managed by the Scottish Association for Marine Science. Being productive throughout the year, the farm aims at adding shellfish (native oysters, king scallops) to traditional seaweed production; B) the coastal open multi-trophic aquaculture facility located in Bertraghboy Bay (Ireland), managed by the Marine Institute. The farm aims at introducing new species combinations and C) The onshore partially (50 %) recirculating multi-trophic aquaculture facility "Buffeljags Abalone" located near the city of Cape Town, South Africa and managed by Viking Aquaculture. The farm aims at culturing a sub-tropical sea urchin species in temperate seas as well as integrating aquaculture of urchins with Ulva spp. and abalone. The occurrence of plastic fragments in different environmental compartments potentially affected by aquaculture production activities such as seawater and marine sediments was investigated at increasing distances from the open systems aquaculture facilities. The sampling grid was defined in relation to the site's location, and the direction and intensity of the main surface and sea bottom currents present at site. Three sampling sites were selected from each of the open systems. In the partial RAS system, sampling sites were selected in the water inlet, outlet, as well as in some selected areas inside the recirculating system (abalone & Ulva raceways). For the seawater collection a Compact Large Volume Microplastics sampling device was developed. A large volume of seawater is conveyed by a compact stainless steel pump unit to a cascade of two stainless steel filters of 10 and 300 μm mesh size where particles (including micron-sized plastic fragments) are trapped. After each sampling, filters can be easily released from the small portable filter holder unit (fig.1) and accommodated on pre-cleaned glass petri dishes of appropriate size, sealed, kept in cold and dark conditions prior to the sample preparation and analysis steps. The sediments were collected by means of a Van Veen grab device. The first 0 to 5 cm sediments layer was collected for analysis. The extraction and purification method for all samples included a combination of a multistep enzymatic-strong alkali-oriented incubation followed by density-based separation to extract plastic fragments from digestates. Extracted samples were analysed first by μ-FTIR (Fourier Transform Infrared) microscopy and finally by GCMS-pyrolysis technique.

(Continued on next page)

Figure 1 - Large Volume Microplastics sampling device operating at Bertraghboy Bay sampling site.

Results and Discussion

The preliminary evaluation of the seawater samples shows the occurrence of 27 different polymer types. Among them the most recurring ones were polyethylene (PE), polystyrene (PS), polypropylene (PP), ethyl vinyl acetate (EVA), polycarbonate (PC), polyurethane (PU), (polyvinyl chloride) PVC and polyamide (PA66). The observed fragments were mapped against the IMTA lab inventory of polymers used in their daily operation. The sites targeted as reference in the study showed a similarly representative pool of polymers but with different accumulation levels. The preliminary results point out a complex distribution of polymers which hamper the interpretation of the source of microplastics in the aquatic environment. The ongoing work will contribute towards an improved understanding of the complexity, introduction, and potential emission of synthetic polymers in open and recirculating IMTA systems that will contribute towards the improved sustainability of modern aquaculture systems.

Introduction

Spices, particularly pungent spices (activators of Transient Receptor Potential Vanilloid receptor 1, TRPV1), have long been known to positively influence metabolism, improve energy balance (reduce adiposity) and digestion, especially of fats (Srinivasan, 2005; Westerterp-Plantenga et al., 2006). A multitude of effects, including hypolipidemic and hypocholesterolemic activities, increase of fat oxidation, stimulation of bile acid synthesis and bile secretion, and stimulation of digestive enzyme activities, have been well established in mammals. Therefore, the active principles of many spices are considered excellent nutraceuticals. However, these effects have been little explored in fish. On the other hand, in the context of the need to reduce levels of fish oils in fish diets, alternative oils rich in saturated fatty acids (SFAs) and minimizing tissue deposition of 18:2n-6 have been advocated, especially for salmonids (Fonseca-Madrigal et al., 2005). However, these oils have the potential to affect lipid metabolism and digestibility. Having this in mind, the objective of the present study was to test the potential of spices to improve performance and enhance metabolism of rainbow trout fed high lipid diets with a standard oil composition or, alternatively, enriched in SFAs.

Materials and methods

A 100 days trial was performed with 4 groups of rainbow trout (start weight: 61.9±8.9g) in 4 replicate 500L tanks. Fish were fed isoproteic and isolipidic diets (42.5% crude protein and 27.2% crude fat) with either a standard (STD) composition of added oils (7.38% fish, 7.38% soybean, 7.38% rapeseed and 2.46% linseed oils) or a more saturated (SAT) composition (4.92% fish, 4.92% soybean, 4.92% rapeseed and 9.84% palm oils). Two control groups were fed one of the basal diets (CTR-STD or CTR-SAT) and two treatment groups were fed the same diets supplemented with an encapsulated mixture of spices oleoresins at 0.075% (SPI-STD or SPI-SAT). At the end of the growth trial, a lipid digestibility study was performed, and 8 animals per treatment were sacrificed and samples were collected for fillet composition, liver and intestine histological and gene expression (by qPCR) analysis, and bile and liver bile acids (by HPLC) analysis. Results were analyzed by two-way ANOVA considering the effects of "Diet", "Treatment" and their interaction. Values shown in graphs are means ± standard error of the mean (SEM).

Results and discussion

A significant improvement of body weight (BW) was observed at day 72 when diet was supplemented with SPI ($P<0.05$), but at the end of the trial only a trend was noticeable ($P=0.08$ for the comparison CTR-SAT *vs.* SPI-SAT, +5.5% BW in the later treatment). A significant interaction was found for feed conversion ratio (FCR), which was only significantly improved with the addition of SPI in SAT diets (t-test $P=0.01$, -12.7% in SPI-SAT *vs.* CTR-SAT). No significant effects were found in perivisceral fat level or hepatosomatic index but scores of lipid accumulation in hepatocytes, assessed histologically, were significantly reduced by the SPI additive in both diets. No changes were observed in histological scores of lipid accumulation in enterocytes but the average size of lipid droplets was noticeably reduced. Fillet proximate composition was not significantly affected, albeit % lipids was numerically reduced by SPI supplementation.

Lipid digestibility was not significantly affected, although a slight numerical increase (+1.4%) was observed in the SPI-SAT compared to the CTR-SAT treatment.

Analysis of gene expression in liver indicated several genes that were significantly affected by SPI supplementation (i.e., "treatment"), including genes involved in lipogenesis, β-oxidation, and their regulation (PPARα), as well as genes involved in bile acid synthesis and transport. Similar results were observed in intestine. However, results of bile acid concentration in liver and bile were highly variable (no significant changes).

(Continued on next page)

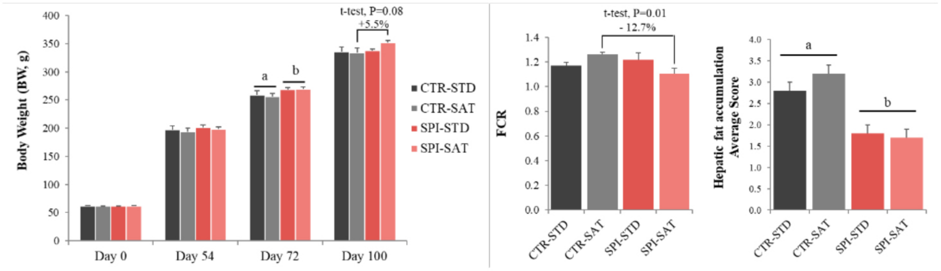

Fig. 1. Fish BW during the growth trial (a), FCR (b) and hepatic accumulation scores (1-5) (c) at the end of the trial.

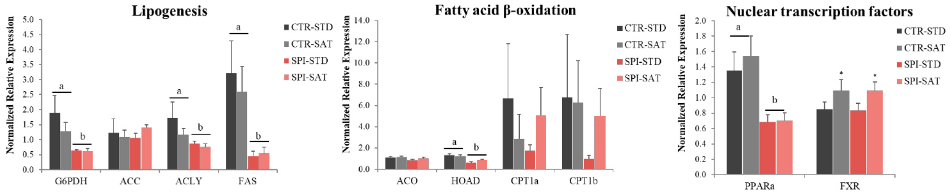

Fig. 2. Hepatic expression of lipid metabolism genes, assessed by qPCR. Different letters denote P<0.05 for "Treatment" and asterisks for "Diet" factors.

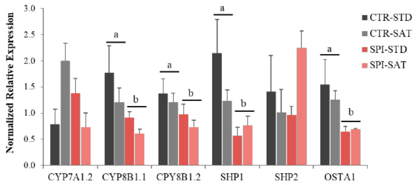

Fig. 3. Hepatic expression of bile acid synthesis genes, assessed by qPCR. Different letters denote P<0.05 for "Treatment" and asterisks for "Diet" factors.

In conclusion, present results confirm the hypotriglyceridemic effect of spice oleoresins in trout, denoted by a lower lipid accumulation in hepatocytes. Such effect has been well demonstrated in mammals for pungent spices, which prevent the accumulation of fat in liver by enhancing triglyceride transport. As in mammals, a strong activation of fatty acid metabolism was observed. Part of the hypolipidemic and hypocholesterolemic effects of spices is attributed to an enhanced cholesterol turnover to bile acids through activation of bile acid synthesis enzymes. This has also been observed in the present study. Metabolic effects were independent of basal diet formulation. However, noticeable improvements in fish performance (growth and especially FCR) were only seen in the more challenging CTR-SAT diet containing higher levels of SFAs.

ALTERNATIVE ASSESSMENT OF FISH AND SHRIMP GUT HOMEOSTASIS AND PERFORMANCE: AN EX-PLANT MODEL TO WEIGH THE EFFECTS OF FUNCTIONAL INGREDIENTS

Gonçalves, A.T.[1,2]* ; Jacinto, R.[2]; Dias, J.[1]

1. SPAROS, LDA., Área Industrial de Marim, Lote C, Olhão, Portugal
2. GreenCoLab- Associação Oceano Verde, Universidade do Algarve, Campus de Gambelas, Faro, Portugal

Introduction

Gastrointestinal tract homeostasis is key for animal health, and in aquaculture, fish and shrimps are frequently challenged with conditions that disturb gut functional stability (e.g. water quality, stressors, antinutritional factors). Assessing gut condition upon an insult is a central task to develop and test novel ingredients with damage mitigation properties. *In vivo* trials are the classical approaches; however, the *in vivo* simulation of gut homeostatic disruption might present ethical barriers, and the time frame required for these types of assessments is long. There is here an opportunity to introduce alternative approaches, thus, the aim of this work was to standardize and implement a fish and shrimp gut *ex vivo* based model to evaluate intestinal homeostasis regulation by novel ingredients, targeting in particular the intestinal immune and antioxidant response and epithelium integrity for permeability regulation.

Material and Methods

An ex-plant culture of intestine was performed for both fish and shrimp to assess acute disruption and potential mitigation by functional ingredients. Juvenile gilthead seabream (*Sparus aurata*) and whiteleg shrimp (*Penaeus vannamei*) were chosen as models and after standardization steps (e.g., medium choice, incubation time), a panel of selected genes was assessed to enrich the model with a cost- and time-effective quantification of the gut health status. The panel included genes related to immune (e.g. *cox2*, *IgM*) and antioxidant response (e,g, *cat*, *gpx*), but also related to epithelium integrity (e.g. *tjp2*, *cldn12*). To evoke a response representative of dysregulation, different insults were included as proxies. Here we simulated a bacterial infection (lipopolysaccharide), an oxidative damage (hydrogen peroxide), exposure to a toxic compound (dextran sulfate sodium) as well as to an antinutritional compound (soy saponin). The expression of the panel genes was assessed and response to insults was compared with the response to several functional ingredients (e.g. algae), including commercially available ones (e.g. medium chain fatty acids, butyrate).

Results and Discussion

The intestinal ex-plant culture represents an alternative tool to screen the potential of ingredients as a gut homeostatic dysregulation mitigators or protectors. In this study we observed a differential response to the different insults that during the acute phase could be representative of the main effects exerted on the gut mucosa. The effects of the lipopolysaccharide in the anterior intestine were evidenced by a strong upregulation of *cox2* and *IgM* among others, indicating activation of the immune response. On the other hand, soy saponins response was associated with an upregulation of the gene coding for pro-inflammatory enzyme (*cox2*), the glutathione peroxidase (*gpx*) and catalase (*cat*), indicating an immune and antioxidant response that was expectable through the action of this antinutritional compound known to promote intestinal inflammation in fish. Soy saponins also triggered an increase in the expression of genes related to the tight junctions' complex (e.g. occludin) in both intestinal sections, as a compensation for a possible disruption. These and other results allowed to categorize and separate the tissue's response to the different insults and served as standards for grading the response to functional ingredients. Here we identified algae immunostimulatory potential, and medium chain fatty acids buffering of epithelium integrity through the regulation of tight junction's related genes. Regarding shrimp intestinal explant, an evident immune response was recorded after incubation with lipopolysaccharide, showing its potential for further nutritional studies. These promising results gave ground to a wider exploration of this alternative tool for functional ingredients assessment. The gene panel is under expansion to unravel the underpinnings of the intestinal homeostasis regulation. Further, since one of the main assets of the ex-plant approach is the ability to reveal a fast response to the stimuli, further studies are in place to evaluate synergies and antagonisms between functional ingredients and its dosages. This will allow a fine tuning of the functional ingredients to include in a formula considering the target feature of the diet that will be tailored (e.g. stress mitigation, immunostimulation).

Introduction

Aquaculture production continues to grow steadily within the food production sector, but one major drawback to its sustainable growth and profit is the emergence of infectious diseases. There is a current need for finding alternative vaccination methods since most commercially available vaccines are injectable, which require laborious work and can cause stress-related mortalities in the fish. Immersion and oral vaccination seem to be the most suitable options for antigen mass delivery. In particular, oral vaccination through the incorporation of the vaccine in the fish feed would reduce fish stress, vaccination costs and is suitable for not only juvenile and adult fish but also larvae stages (1). *Bacillus* spores are the ideal candidates for oral antigen delivery, since its resistant structure allows not only the survival to harsh conditions of the gastrointestinal tract but the incorporation into the fish feed (2). Surface display of antigens has already been applied with promising results for developing oral vaccines for fish, in particular by using *Bacillus subtilis* spores to display immunogenic proteins from virus and gram-positive bacteria (3,4), but to date, this technology has not been applied to fight fish diseases caused by gram-negative bacteria.

In this work, we used *Bacillus subtilis* 168 spores as vehicles for the delivery of four immunogenic proteins, and its protective potential was evaluated in increasing the survival of zebrafish larvae challenged with *Vibrio anguillarum*, *V. parahaemolyticus, Aeromonas hydrophila*, *Edwardsiela tarda* or *Photobacterium damselae* subsp. *piscicida*. The potential of one vaccine candidate for vibriosis was also evaluated in European seabass.

Materials and Methods

Animal experiments and handling were approved by the Animal Welfare Committee of the Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), performed by trained scientists (with FELASA category C), and carried out in a registered installation (N16091.UDER), in compliance with the European directive 2010/63/EU for the care and use of laboratory animals.

Four immunogenic proteins were tested in this work: OmpK, an outer membrane protein shared by several *Vibrio* spp., Php_0080, a lipoprotein found in the membrane of *Photobacterium damselae* subsp. *piscicida*, FlgD, a flagellar protein from *Edwardsiela tarda* and GAPDH, an outer membrane protein used for developing polyvalent vaccines. The genes encoding these proteins were amplified and cloned into p1CSV-CotY-N and p1CSV-CotY-C plasmid vectors (5), resulting in C-or-N-terminal fusions to the crust protein CotY. The integration of the translational fusions in the *B. subtilis* 168 chromosome resulted in the congenic derivatives strains: CRS220 (CotY-H6-OmpK), CRS221 (H6-OmpK-CotY), CRS226 (H6-Pdp_0080-CotY), CRS227 (H6-GAPDH-CotY), CRS228 (CotY-H6-GAPDH), CRS229 (H6-FlgD-CotY), CRS230 (CotY-H6-Pdp_0080) and CRS231 (CotY-H6-FlgD). Spores of the parental strain *B. subtilis* 168 and its congenic derivatives were produced and purified following standard procedures, and the display of each target immunogenic protein was assessed by western blot. The vaccination potential of the antigen-displaying spores was evaluated in zebrafish larvae at 28ºC, distributed in 6-well plates (10 larvae per well) containing egg water. At 6 days post-fertilization (dpf), larvae were exposed for 2h with 10^8 CFU mL^{-1} of each recombinant spores suspension. At 9 dpf larvae were challenged by immersion with 3×10^8 CFUs mL^{-1} of *V. anguillarum*, 1×10^8 CFUs mL^{-1} of *V. parahaemolyticus*, 8.5×10^7 CFUs mL^{-1} of Ph

(Continued on next page)

damselae subsp. *piscicida*, 1×10^8 CFUs mL^{-1} of *E. tarda* or 1×10^{10} CFUs mL^{-1} of *A. hydrophila*. Cumulative mortalities were registered between 16 and 24h and each experiment was carried out 3 times. The protective potential of OmpK-displaying spores was also evaluated in European seabass. Triplicate groups of juveniles were fed diets that incorporated 1×10^9 spores Kg^{-1} feed of either CRS220 (OmpK-diet) or from the parental *B. subtilis* 168 strain (CTR) for 30 days. Sixty fish fed each diet were challenged by intraperitoneal injection with $1x10^6$ CFU/fish of *V. anguillarum*. Fish injected with PBS were included as a control, and fish survival was followed for 7 days. Survival curves were plotted using the Kaplan-Meier method and pairwise comparisons between treatments were performed with a nonparametric log-rank test, at 0.05 significance level, in GraphPad Prism version 9.

Results

Zebrafish survival upon challenge with *V. anguillarum* and *V. parahaemolyticus* increased in magnitudes of 50 to 90% respectively, when previously vaccinated with CRS220 (CotY-OmpK) spores. Survival significantly increased when larvae were treated with CRS230 and CRS231 and challenged with *Ph* subsp. *piscicida* and *E. tarda*, respectively. Larvae treated with spores from CRS228 (CotY-GAPDH) significantly increased survival upon challenge with *A. hydrophila*, *E. tarda* and *Ph* subsp. *piscicida*, showing the polyvalent potential of GAPDH-carrying spores. Further, European seabass fed diets containing OmpK-carrying spores increased survival by 30% when challenged with *V. anguillarum*.

Conclusions

These results confirm the potential of antigen-displaying spores as immersion and oral vaccines in zebrafish larvae, a model organism, and European seabass, an economically important aquaculture species.

Introduction

The main source of omega 3 long chain polyunsaturated fatty acids (n-3 LC-PUFA), such as eicosapentaenoate (EPA) and docosahexaenoate (DHA) in aquafeeds is fish oil, which is currently a limited and finite source. Nutritional programming that induces long-term consequences on animal metabolism and physiology, such as biosynthesis of LC-PUFA (Lucas, 1998), could be adopted for sustainability. Previous studies have confirmed that the pathway for EPA-DHA synthesis was upregulated in Atlantic salmon populations first-fed vegetable-based feeds during a 3-week stimulus (Vera *et al*., 2017), combined with improved growth rate and food conversion efficiency (Clarkson *et al*., 2017). Thus, the present research evaluated if nutritional programming changes triggered by an early nutritional intervention are still prevalent after 16 weeks and whether a new challenge will enhance the tissue net production of EPA and DHA as a booster.

Material and Methods

In the present trial two types of diets were applied to salmon from first feeding (initial weight 0.15 g): a marine diet comprising mainly fish meal and fish oil (EPA+DHA 26% total fatty acids; TFA), or a vegetable-based diet containing plant proteins and vegetable oil (EPA+DHA 5.9% TFA). As shown in figure 1, at the first feeding "stimulus phase", three experimental groups (300 fish/tank, n=3) were fed either with a vegetable-based diet for one or two weeks (V1 and V2, respectively or the marine diet (M) individually to provide stimulus as a program. Afterwards, all experimental groups were fed M diet until the end of 16th week (marine phase) before all treatments were transferred back to the vegetable-based diet for 6 weeks (challenge phase). Fish were sampled and tissues collected for lipid analysis (liver, brain, eye, gills, intestine and muscle), gene expression (liver), as well as histology (liver and intestine) at the end of the marine and challenge phases.

Results

The challenge diets reduced the n-3 LC-PUFA contents, as expected, in the total lipids of all tissues ($p<0.05$). On the other hand, the difference of the n-3 LC-PUFA amount in the total lipid between treatments in all of the tissues were insignificant ($p>0.05$) for both stages. Similarly, the n-3 levels in tissue polar lipid were not clearly influenced by treatments ($p>0.05$) but a significant decrease in n-3 levels after challenge was observed ($p<0.05$). In liver, V1 showed a significant up-regulated expression for fatty acid desaturase and elongation of very long chain fatty acids than V2 only at the end of the challenge ($p<0.05$). On the other hand, the transcription factors sterol regulatory-element binding proteins 1 and 2, liver X receptor as well as peroxisome proliferator activated receptor alpha and gamma, were significantly down-regulated in V2 ($p<0.05$). The regulation of lipid metabolism related genes, fatty acid synthase, acyl-CoA oxidase and carnitine palmitoyltransferase I shared the similar pattern as M > V1> V2 at the end of the challenge phase ($p<0.05$). The percentage of the hepatic vacuolization in group V2 was significantly higher than group M for both stages ($p<0.05$). In the anterior intestine, V1 showed the slightly lower amount of goblet cells after marine phase ($p>0.05$) which became significant after challenge ($p<0.05$).

Discussion

The decrease of EPA, DHA and n-3 LC-PUFA in tissues after challenge can be explained by the diet change. Comparing the individual fatty acid content between the total lipid and polar lipid of tissues indicates the deposition preferences of LC-PUFA from the intake or endogenous production. Also, the less impacted fatty acids after challenge suggest their functional priority. In the present study, the relatively stable content of DHA in liver may be the result of high involvement for structural significance such as membrane formation (Sargent *et al*., 2002). In addition, EPA and DHA could be endogenously biosynthesized from their precursor 18:3n-3 (Tocher, 2003), as confirmed by the gene expression results. Compared with vegetable diet challenge phase, the different early stimulus periods had rare impact on the fatty acid composition. However, further molecular analysis indicated that several LC-PUFA biosynthesis regulators showed to be up-regulated in V1, while the down-regulation found in most transcription factors in V2 group suggested a negative influence of the two-weeks stimulus.

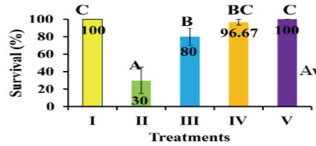
In shrimp farming viral diseases produce important economic losses. The use of prophylactic methods as natural additives wthout inmmune resistance and environmental problems were proben. Medicinal plants powder, yeast and *B. licheniformis* were used in the survival in the digestive and immune systems of *P. vannamei* challenged against *V. parahaemolyticus*.

Four bioassays were carried.Postlarval white shrimp stage were used to analyze the digestive and immune-related genes expression by RT-qPCR.

The combination of MP in the food and *B. licheniformis* in the water (3 x 106 CFU / L) significantly improved the survival of *P. vannamei* challenged with *V. parahaemolyticus*. *B. licheniformis* inoculated in the water, did not alter the expression of the trypsin digestive gene.

B. licheniformis in the water decreased the expression of the SOD gene (related to the immune system), which plays an important role as an antioxidant, decreasing the concentration of superoxide anion, the product of the phagocytosis process. *B. licheniformis* in the water did not alter the expression of the genes of the immune system penaeidine4 and lysozyme. The mixture of MP added in the feed and *B. licheniformis* in the water prevent the AHPND in *P. vannamei* cultivated in the laboratory.

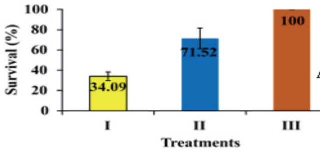
Bioassay 1. Medicianl Plant (MP) powder added to feed every 2 d and two concentrations of *B. licheniformis* in the water after 7 d were evaluated.



CL$_{50}$: 180,000 UFC/mL.
Average media weigth = 0.56 g

1) Control (-); II) Control (+); III) MP 4 g/kg c/2 d + Vibrio CL$_{50}$; IV) BL 1 x 10^{6} UFC/L c/7 d + Vibrio CL$_{50}$; V) MP 4 g/kg c/2 d + BL 1 x 10^{6} UFC/L c/7 d + Vibrio CL$_{50}$.

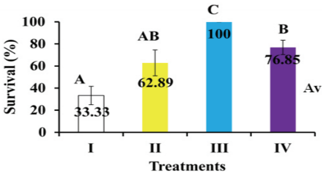
Bioassay 2. Best results with MP and *C. parapsilopsis* were added to feed after 2 d and *B. licheniformis* in water after 3 d.



CL$_{50}$: 105,000 UFC/mL.
Average final weigth = 0.344 g

I) Control (+); II) MP 4 g kg^{-1} c/2 d + BL *2 x 10^{6} UFC L^{-1}* 3 d^{-1} + *Vibrio* CL$_{50}$; III) MP/2 d^{-1} + BL *3 x 10^{6} UFC L^{-1}* 3 d^{-1} + *Vibrio* CL$_{50}$.

Bioassay 3. The yeast added to feed each 2 d and *B. licheniformis* in water after 3 d were analizaed.



CL$_{50}$: 63,000 UFC/mL.
Average final weigth = 0.173 g

Control (+) ; II) Yeast 2 g kg^{-1} 2 d^{-1} + *Vibrio* CL$_{50}$; III) BL 3 x 10^{6} UFC L^{-1} 3 d^{-1} + *Vibrio* CL$_{50}$; IV) DKT 3 g kg^{-1} 2 d^{-1} + *Vibrio* CL$_{50}$.

Bioassay 4. The yeast in two different concentrations and *B. licheniformis* in the water. All four bioassays were challenged against *V. parahaemolyticus*.

Introduction

Water treatments and therapeutants applied in recirculating aquaculture systems (RAS) are complicated by potential impacts on critical nitrifying bacterial populations in biofilters (Noble & Summerfelt, 1996), specifically reduced oxidation of total ammonia nitrogen (TAN) and nitrite-nitrogen. Hydrogen peroxide (H_2O_2), while considered environmentally benign due to non-toxic end-products (Block, 1991), is known to disrupt biofiltration when applied at therapeutic concentrations in RAS (Fredericks, 2015). Previous research has assessed low-dose H_2O_2 applications in RAS to avoid biofilter impacts (Møller et al., 2010; Pedersen et al., 2012); however, the ability for RAS producers to use therapeutic or disinfection-level H_2O_2 concentrations in culture tank static bath treatments, followed by decomposition of H_2O_2 prior to resumption of recirculating water flow through biofilters, would be advantageous. We therefore sought to assess H_2O_2 decomposition using a novel enzymatic product following static bath applications of H_2O_2 at both therapeutic- and disinfection-level concentrations.

Materials and methods

Two single-day experiments were conducted to assess the effectiveness of a new catalase enzyme product, BioRas® Balance, in the decomposition of H_2O_2 into H_2O and O_2, applied as a static bath at either therapeutic- or disinfection-level concentrations. The first trial (Trial 1) employed simulated static bath treatments for bacterial gill disease in replicated culture tanks, with live fish present, followed by application of BioRas® Balance in a range of concentrations to assess dose-response decomposition of H_2O_2 over time. Trial 2 was a similar dose-response experiment, but employed disinfection-level H_2O_2 concentration with no live fish present. *Trial 1*. Diploid Atlantic salmon *Salmo salar* were received as fertilized eggs and hatched onsite using a temperature-controlled incubation system, and then cultured to market-size in freshwater RAS. To begin the study, 216 fish (5 kg mean weight) were stocked randomly into 12 replicated partial recirculating aquaculture systems (PRAS). Each PRAS consisted of a 5.0 m^3 dual-drain tank, a gas conditioning column with counter current forced air ventilation, and a low head oxygenator (LHO) with a sump. A 0.4 horsepower pump, located in the sidewall box of each tank, continuously recirculated 379 L/min of water. Biomass densities at the start of the experiment were approximately 20 kg/m^3. PRAS were operated at a 90% recirculation rate (on a flow basis), and under these conditions typical water quality parameter values for both studies were as follows: temperature (14 °C), pH (7.8), alkalinity (277 mg/L), CO_2 (4.5 mg/L), TAN (0.2 mg/L), and total suspended solids (1.0 mg/L). Following acclimation, 60-minute static bath tank treatments were carried out, simulating therapeutic treatment for bacterial gill disease (100 mg/L H_2O_2 applied for approximately 60 minutes' duration). BioRas® Balance was then added to the culture tanks to create concentrations of 1.5, 2.5, 5.0, and 10.0 mg/L (target concentrations were selected based on previous unpublished research); each tank was randomly assigned one of these BioRas® Balance concentrations, for a total of three replicates per treatment concentration. Following the addition of the catalase enzyme, water samples were collected and H_2O_2 concentrations analyzed at 10 minute intervals, until H_2O_2 concentration within a given tank was less than 0.5 mg/L. *Trial 2*. The second trial was carried out to simulate a typical disinfection event using a higher concentration of H_2O_2 (i.e., 250 mg/L initial target concentration). Dosing of H_2O_2 and BioRas® Balance, as well as H_2O_2 concentrations assessments, were carried out in an identical manner to the procedures used in Trial 1. The only major differences with Trial 2 were that i) water continued to recirculate within the PRAS (as opposed to a culture tank static bath), and ii) no fish were present in the culture tank. Initial and final H_2O_2 concentrations during the pre-catalase, disinfection phase were 261.0 ± 15.3 mg/L and 244.9 ± 14.1 mg/L, respectively.

(Continued on next page)

Results

In both trials, enzymatic decomposition of H_2O_2 followed a dose-response relationship, catalyzing a first order decay reaction. First-order decay constants and kinetic reaction formulae for each BioRas® Balance application concentration were calculated using least-squares regression of the log-transformed H_2O_2 concentration data; reaction rate constants calculated for Trial 1 were in close agreement to those calculated in Trial 2, indicating that the reaction rate constant may be independent of the initial concentration of H_2O_2. Overall, the results of these experiments are encouraging for RAS farmers who may require utilizing H_2O_2 at concentrations that would normally compromise biofilter nitrification processes. Under the conditions of our studies, BioRas® Balance was effective at quickly reducing H_2O_2 to safe concentrations, in either post-static bath therapeutic application or post-system disinfection scenarios.

OPTIMISING CAPTIVE BRED BALLAN WRASSE (*Labrus bergylta*) BROODSTOCK PERFORMANCE

Arthair Gordon

Address: Otter Ferry Seafish Ltd., Otter Ferry, Tighnabruaich, Argyll, PA21 2DH, United Kingdom
Email: arthair.gordon@stir.ac.uk

Introduction

Cleaner fish, such as ballan wrasse (*Labrus bergylta*) have proven to be an effective environmentally friendly alternative to chemicals, to control sea lice (*Lepeophtheirus salmonis* and *Caligus spp*) infestations in commercial Atlantic salmon (*Salmo salar*) aquaculture farming (Roth, 2000; Mordue & Pike, 2002; Rae, 2002). Otter Ferry Seafish Ltd. (OFS) started breeding ballan wrasse in 2009. The stocking densities over the past 13 years have not been consistent, with variations in sex ratio and total number of broodfish used per tank. Female broodfish also range in weight from 500g – 3,000g. A collaboration between the Institute of Aquaculture (IoA) at University of Stirling, and Otter Ferry Seafish Ltd., is experimenting in optimising captive bred ballan wrasse broodstock performance.

The aims of this experiment are to prove what stocking density is the most productive, and whether female weight influences productivity. Due to competitive behaviour amongst both males and females, it is hypothesised that a lower stocking density is more productive than at higher stocking densities, and that heavier females produce more eggs, and therefore are more productive, than smaller ones.

Methods

Over a 12-week period, broodfish were stocked into varying size cohorts and allowed to naturally spawn. The ratios were female 20:5 male, female 25:6 male, female: 32:8 male. Each ratio was triplicated.

Over another 12-week period, broodfish were separated into three different size cohorts and allowed to naturally spawn. The treatment sizes were: 520g – 750g, 750g – 1,100g, 1,100g – 2,400g, and mixed sizes. Males were of random sizes. Each treatment was triplicated.

	Female 20:5 Male	Female 25:6 Male	Female: 32:8 Male
Egg Factor (average)	4.5	4.8	4.4
Fertilisation (percent)	58.5	43.6	52.6

Figure 1: the egg productivity (factor) and fertilisation (%) for stocking densities: female 20:5 male, female 25:6 male, and female 32:8 male.

Egg Productivity	Mixed	520-750g	750-1100g	1100-2400g
Biomass (g)	56619	39650	55696	82322
Av	3.7	1.7	3.6	4.2
Sd	3.7	3.2	4.5	4.7
Fert 24h (%)	Mixed	520-750g	750-1100g	1100-2400g
Av	48.8	65.5	57.1	51.8
Sd	40.5	33.3	34.3	35.2
	Mixed	520-750g	750-1100g	1100-2400g
Total larvae	884000	563000	1064000	1562500

Figure 2: egg productivity (factor), fertilisation (%), and total number of larvae hatched for the four female size cohorts: mixed, 520-750g, 750-1100g, and 1100-2400g.

(Continued on next page)

Results

The number of eggs produced are expressed as a factor where 1 = 12,000 eggs. The results for the stocking density trial are depicted in figure 1 below.

Although the medium stocking density produced the greatest number of eggs (4.8), because its fertilisation was so low (43.6%), the lowest stocking density was the most productive has it had a far higher fertilisation rate (58.5%).

The results of the female size trial are summarised int Figure 2 below.

It was concluded that the largest female broodfish (total biomass of 82,322g) are the most productive as they produce the greatest volume of eggs (egg factor 4.2) and consequently the biggest quantity of larvae (156,2500).

CONSUMERS' VALUES-ATTITUDES-BEHAVIOUR (VAB) TOWARDS CONSUMING SEAWEED FOOD PRODUCTS: THE EFFECT OF PERCEIVED NATURALNESS, UNIQUENESS, AND BEHAVIOURAL CONTROL

F. Govaerts* and S.O. Olsen

*Nofima, Norwegian Institute of Food, Fisheries and Aquaculture Research; 9-13 Breivika, PO Box 6122, NO-9291 Tromsø, Norway
florent.govaerts@nofima.no

Introduction

Seaweed is a food resource with a neutral environmental impact, as its cultivation helps capture CO_2 and helps the global production of O_2. Therefore, seaweed's cultivation helps counter global warming and is good for capturing and storing CO_2 in the long term; thus, it can be considered a pro-environmental source of food. Seaweed is also of nutritional interest, as most species contain protein, are low in lipids, and low in calories. Seaweed is also known for being rich in iodine, antioxidants, vitamins, and minerals (Mabeau & Fleurence, 1993; Roohinejad et al., 2017).

The consumption of seaweed has been cultivated and consumed in Asia for centuries. In other Western countries, seaweed cultivation is receiving increased interest for both its nutritional and environmental qualities. However, few studies have focused on the factors influencing consumers' behavioural tendencies towards seaweed food products. This study aims to fill the gap by investigating the antecedent of consumers' attitudes and consumption of seaweed food products in Norway. An extended version of the value-attitude-behaviour (VAB) theory is used as a conceptual framework to study seaweed consumption from a social dilemma perspective: hedonistic values and perceived uniqueness versus biospheric values and perceived naturalness.

Materials and methods:

This study uses a representative sample of Norwegian consumers (N = 426). Structural equation modelling was used to test the hypothesis.

Results:

Our results showed that attitude significantly affected the consumption of seaweed food products and that perceived behavioural control positively moderated the attitude–consumption relationship. Perceived naturalness and perceived uniqueness are associated with attitudes towards seaweed. Biospheric values directly influence attitude, while hedonistic values are indirectly related to attitude through uniqueness.

Beyond the theoretical contributions, this study will help the seaweed industry develop its marketing strategy by promoting its naturalness, healthiness, and pro-environmental attributes. Marketers should also make efforts to encourage consumers to associate seaweed with pleasure. Finally, since seaweed food products are perceived as unique, seaweed food products can be positioned as luxury products. By extension, the findings can be used to promote seaweed to policymakers and investors. The European seaweed cultivators remains small, new and requires more private investment and public support to develop. Therefore, promoting seaweed uniqueness and naturalness and emphasizing positive biospheric consequences are ways to influence policymakers and investors positively.

The development of ecosystem models in coastal marine waters containing fish farms has matured to the extent that predictive modelling can be applied to dissolved and particulate waste dispersal, benthic deposition and diagenesis, and the spread of pathogens. These model results are critical to both siting and ongoing monitoring of fish farms. Nonetheless, systematic application of these models to fish farm management is less common, i.e. modelling capability and results are neither widely available or user-friendly. Drawing on decades of model development, we have developed a Windows-based application known as FINS (Farming in Natural Systems) to integrate multiple carrying capacity criteria into aquaculture decision support (Figure 1). FINS is effectively a GIS framework allowing a marine spatial planning approach to management in terms of cage density and location. The following models are included for carrying capacity: (a) Particulate deposition and mapped footprints, (b) sediment diagenesis including sulfides, (c) nutrient plumes, (d) disease risk, and (e) chlorophyll depletion (bivalve culture). Due to the overall forcing of marine environments with circulation via wind and tides, numerical circulation models are the foundation of ecosystem models. We utilize FVCOM as the physical platform to enable diffusion-advection of particles and solutes, and include its particle tracking module to create numerical experiments with respect to non-conservative pathogens such as sea lice. Although all of the component models in FINS are fully developed and groundtruthed, several steps remain including the establishment of carrying capacity thresholds, and integration into the software platform. Among the models, disease risk requires further consideration of epidemiological criteria associated with location of multiple farm sites. A targeted project of the Atlantic Fisheries Fund and the province of Nova Scotia will lead to completion of the FINS framework and extension to multiple sites. Compilation of GIS, bathymetry, river flow, wind fields, and other data is proceeding as input to application to multiple sites in Nova Scotia based on aquaculture development priorities. A calibrated FVCOM model is required for each new location. Although each case study is site-specific, FINS can be developed for any site worldwide.

E-mail: luca.grosso@alumni.uniroma2.eu

Introduction

Polyculture of mussel and sea cucumber species is highly attractive since both these organisms have important economical and environmental value. Mussel farming provides more than 1/3 of EU aquaculture products, being one of the most spatial-extended industrial production of mollusk in Europe (Tamburini et al., 2020). On the other hand, the sea cucumbers are considered luxury seafood, especially in Asian countries (Purcell et al., 2016). Moreover, mussel and sea cucumber co-culture potentially doesn't need external food input resulting an environmentally friendly alternative as a high-quality protein source. Mussels, in fact, are filter-feeders able to feed on natural primary production from the water column, without other food supplies (Tamburini et al., 2020). They represent a fundamental organic material connection between the bottom and the water column, by settling organic matter on the seabed. This organic biodeposit could be an attractive food source for deposit feeder sea cucumbers, which are able to ingest sediment and organic material, playing an important role in cycling and energy flow in benthic ecosystems (Purcell et al., 2016). Although the suitability of mussel and sea cucumber polyculture have been investigated in Indo-Pacific (Slater et al., 2007; Zamora et al., 2016), there is no investigation for Mediterranean species. Hence, for the first time in the present study, an Integrated Multi-trophic Aquaculture among Mediterranean species of sea cucumbers (*Holothuria tubulosa* and *Holothuria polii*) and mussels (Mytilus galloprovincialis) was investigated.

Materials and Methods

During the Spring of 2020, a IMTA experiment was carried out at Ittimar Soc. Coop. mussel farm, a *Mytilus galloprovincialis* long-line submerged productive system (South of Adriatic Sea, Italy). Specimens of *H. tubulosa* and *H. polii* were collected along Apulian coast and sorted in two size classes (small size: 40-100 g; large size: 100-200 g). For each species, representative specimens of both size classes were placed in 20 seabed cages beneath the long-line mussel farm at a density of 670 g/m^2. The suitability of *H. tubulosa* and *H. polii* to use *M. galloprovincialis* waste as the sole food source was evaluated in terms of survivorship and somatic growth performances over four-month experiment.

Results

At the end of the experiment, both *H. tubulosa* and *H. polii* showed high survival, respectively of 94 % and 92 %. Instead, in terms of growth performances, high differences emerged between the two species and the two size classes tested. *H. tubulosa* showed higher growth than *H. polii*, respectively of 6.07 % and -25.37 %. When comparing growth performances among size classes, the highest SGR % was achieved in small *H. tubulosa* specimens (0.09 % day-1), which resulted significantly higher than the value obtained in large ones (0.01 % day-1) (Fig. 1). Both these values, however, were higher than those achieved in *H. polii*, which gained negative somatic growth in both size classes (SGR of -0.26 % day-1 and -0.45 % day-1 respectively for small and large specimens).

Discussion

The present study evaluated for the first time on European species the potential of integrated aquaculture between sea cucumbers and mussels. This polyculture is potentially able to increase energy-use efficiency inside mussel farms, promoting productivity increase and rearing diversification with new commercially important species. Furthermore, these results clearly indicate the different compatibility of *H. tubulosa* and *H. polii* in polyculture with mussels, highlighting that these two sea cucumbers have different feeding behaviors and culture requirements. In fact, Boncagni et al. (2019) observed that *H. tubulosa* and *H. polii* present species-specific use of the same resources that would allow their co-existence in the same benthic ecosystems. This partial degree of niche segregation, which could be related to the differences in digestive physiology (e.g in terms of intestinal microbiota) and feeding specialization in microhabitat (different sediment layers), potentially explained the better suitability of *H. tubulosa* for polyculture with Mediterranean mussel *M. galloprovincialis*. However, we hypothesize that the high rearing density of *H. tubulosa* in the present study could have mitigated its growth performances. Hence future investigations are needed to define the optimal rearing density of this sea cucumber species, to be adopted as extractive species in association with commercial farms of *M. galloprovincialis*.

Introduction

As the global human population grows and wild fish stocks decline, fish farming and production has become the fastest growing area of food production, achieving a steady growth of 8.4% since the 1970s (FAO 2016). For this, a profound understanding of fish physiology is crucial for successful and sustainable aquaculture production, especially in terms of animal welfare. To achieve this, fishes are presently the subject of a large number of studies where they are exemplarily exposed to different abiotic parameters in order to investigate their physiological stress responses to temperature change (aspect of global warming) or environmental pollution (aspect of ecotoxicology). Furthermore, fishes are also used in animal experiments for the understanding of diseases and tests of medicinal treatment. Already in 1962, the first fish cell line was established by Wolf & Quimby to study these factors. Since then, the number of fish cell lines has increased to about 900 cell lines, reflecting the scientific interest in these species (https://web.expasy.org/cellosaurus/). Although the possibilities of in vitro models have greatly improved, live fishes remain a popular model for animal research. In the statistic of animal experiments, they are second, being surpassed only by rodents and accounting for 14% of all animal experiments in the United Kingdom and 16% in Germany. Altogether, the number of fishes used in research has increased by 54% from 2015 to 2019 (https://speakingofresearch.com/, BMEL.de).

It has already been shown that cell lines can be useful tools for studying the effects of various biotic and abiotic factors, such as temperature changes (Schäfer et al., 2021) and virus-host pathogen interactions and pathogenesis (Noguera et al., 2017). Now, the goal of our work is to establish and to evaluate cell lines from several economically important fishes such as Atlantic sturgeon (*Acipenser oxyrinchus*), rainbow trout (*Oncorhynchus mykiss*), whitefish (*Coregonus mareana*), and Atlantic salmon (*Salmo salar*) as potential in vitro models for fundamental aquaculture-related research.

Methods

Cells were isolated from different fish species and tissues by dissection with simultaneous enzymatic digestion (e.g. trypsin or collagenase). Specific cultivation environments were applied for each fish cell line. Hereby, temperatures below 22°C were usually taken for cold water species, while warm water species cell lines were treated with temperatures of 25°C or above.

After the successful establishment, fish cells exhibited unhindered growth/proliferation due to their telomerase activity, so that their cells can be produced in very high numbers for a wide variety of studies.

Results

We have succeeded in establishing well proliferating cell populations from a variety of fish species that have been passaged and propagated over several years. Hereby the cells exhibited a uniform cell morphology with increasing numbers of passages. Tests on the Atlantic sturgeon and whitefish cell lines demonstrated differences in the physiological reactions in between the species, exemplarily in the responses to both temperature changes and environmental toxins (Grunow et al., 2021).

(Continued on next page)

Cell isolation of fish larvae from several species including trout, salmon, whitefish, sturgeon, pikeperch, and zebrafish resulted in spontaneously contracting cell (SCC) aggregates (Grunow et al., 2011, Grunow et al., 2015). Characterization of the cells revealed fully developed cardiac muscle and endothelial and fibroblast cells that were electrically and mechanically connected (Grunow et al., 2012, Grunow et al., 2011). The autonomic contraction of SCC is stable over time and resembled the heart beat frequency of fish. This in vitro model is suitable to study cardiac specific fish viruses, such as Infection Salmon Anemia (ISA) or Salmonid Alpha Virus (SAV). Supportively, analysis of viral infection by qPCR revealed that SCCs can be infected with different SAV (F93-125, MS 4640, and F97-220) and ISAV (ISA 390-98) isolates (Noguera et al., 2017, Noguera et al., 2021).

Discussion

Fishes present an outstanding biodiversity possessing wide ranges of evolutionary adaptions to various environmental circumstances. Consequently, species possibly react very differently to external influences. The establishment of cell lines from different fish species is therefore important to detect species-specific peculiarities. In the recent years, we demonstrated that in vitro models are a bioethical and cost-effective tool to study the effects of changing climatic factors or the interaction between host and viral pathogens. Our future goal is to establish stable cell lines from a broad taxonomic range of fish species and to answer the question in which ways suitable in vitro tools can replace in vivo models.

GILL HEALTH IN MARINE FISH AND BENEFIT OF FUNCTIONAL FEED AS PART OF THE HOLISTIC MANAGEMENT STRATEGY

Jinni Gu*, Victoria Valdenegro, Iannis Karacostas, Elena Planas Callao, Stelios Tsekouras and Elisabeth Aasum

The gills of teleost fish are essential for the gas exchange and play an important role in regulation of mineral ions and pH of blood. Gills are also the primary organ of excretion of nitrogenous waste. As one of the main mucosal immune barriers in fish, gills are the first line of defense against all kinds of biotic and abiotic insults. Insulted gills often manifest epithelial hyperplasia/hypertrophy, inflammation, degenerative changes, and circulatory disturbance. When the insults are persistent, pathologies can exacerbate to clinical gill diseases with macroscopic lesions, which indicates that gill function is seriously compromised. Impaired gill function has broad impacts on the fish health including loss of appetite, insufficient oxygen exchange, low-stress tolerance, susceptibility to the secondary infections, and increased mortality.

In marine environment, most of fish production occurs in open or semi-open systems. Gill diseases associated with infectious and non-infectious agents are one of the major health challenges in the farmed fish worldwide.

Similar to complex gill disease (CGD) observed in farmed Atlantic salmon during the seawater phase, the gill disease with multifactorial etiology and non-specific histopathological changes is commonly seen in marine fish in the sea cages. As part of the complex gill disease, infestations of hematophagous monogenean gill parasites, *Sparicotyle chrysophrii, Sciaenacotyle panceri,* and *Zeuxapta seriola*, in gilthead sea bream (*Sparus aurata*), meagre (*Argyrosomus regius*), and yellowtail kingfish (*Seriola lalandi*), respectively, are considered as one of the biggest obstacles for increasing their production in the sea. Histopathological lesions and mechanical blockage of water flow and gas exchange in the gills cause the severe detrimental impact on fish health. If fish are left untreated, the parasites cause not only growth impairment, but also mortality associated with anemia and secondary infection.

Formalin and praziquantel are the most common treatments for gill parasitic diseases. These treatments are not only expensive and labor dependent but also highly stressful for the fish. The secondary effects on development of resistance to anti-parasitic treatment and environmental pollution have raised concerns in the public. Furthermore, all these treatments are not able to prevent the re-infections.

Elimination of above-mentioned gill diseases in the open system is “Mission impossible”. The exchange of parasitic agents between the wild and farmed fish is unavoidable. Mitigation efforts should focus on holistic preventative control strategy. In addition to optimizing the farming practices and environmental hygiene, functional feed concept should be part of the control strategy.

With aim to combat gill diseases in marine species, an extensive field experiment was executed, trials with monthly sampling in two marine fish species, Sea bream (45-155 g) and meagre (75-600g), and in two Mediterranean countries during 2020-2021. Blood parameters, gill histology and growth performance were evaluated, which provided an insight on how growth and welfare were affected by compromised gills and the beneficial effects of functional nutrition. Holistic control strategy with incorporation of functional feed is a potential solution for control of gills diseases.

INCLUSION OF BLACK SOLDIER FLY MEALS IN PACIFIC WHITE SHRIMP DIETS: EFFECTS ON GROWTH & HEALTH PERFORMANCES

Introduction

For several years, feed manufacturers are searching for new sources of proteins to respond to the growth of the sector and the challenges of sustainable development. At the same time, more than 30% of the world agricultural production is wasted (unsold or expired products, by-products of agri-food industries). Recommended by the Food and Agriculture Organization of the United Nations (FAO), insects make it possible to valorize food waste (bioconversion). The black soldier fly (*Hermetia illucens*) represents a particularly adapted resource to feed fish or shrimps because it is natural, safe, sustainably produced and has a good nutritional quality and potential positive effects on the health.

The objective of the study carried out in the facilities of IMAQUA (Merelbeke, Belgium) between December 2021 and January 2022 is to evaluate zootechnical performances and health protection on juvenile shrimps (*Penaeus vannamei*) by replacing fishmeal with defatted black soldier fly meal (IM) sourced from different Insect Bioconversion Units (IBU) in comparison to a conventional feed (CTRL).

Materials and methods

Three IM produced by three IBU were incorporated in pelleted feeds as replacement material from 27% to 66% of the fishmeal compared to the CTRL. These feeds have been given to 720 Pacific white shrimps from 0.93 grams to 9.86 grams (42 days of trial). The shrimps were divided per group and in triplicates (60 shrimps per tank). The feed distribution was done automatically 6 times a day. The groups of shrimps received the respective diets at the predetermined percentages of their initial mean body weight and expected daily growth. This was adjusted daily according to the expected growth and observed mortality and feed consumption per group.

After the growth trial, 30 shrimps per treatment were transferred to individual tanks for an Acute Hepatopancreatic Necrosis Disease (AHPND) challenge (10 days). The inoculation of the bacterial agent was done by immersion. Shrimps were then monitored twice a day for clinical signs of disease and mortality.

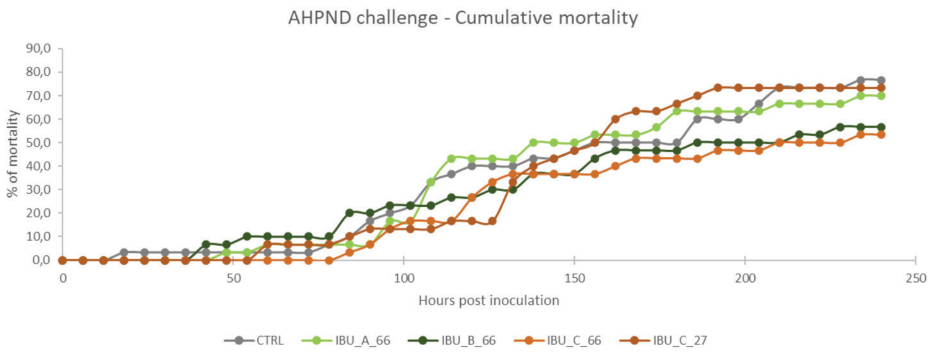

Figure 1: Graphic overview of the results collected during the AHPND challenge

(Continued on next page)

Results

All results of the growth phase were positive, and the CTRL was validated. Although not significant, an increased final weight (and related weight gain) was observed in all treatments where fishmeal was replaced with IM in comparison to the CTRL. The AHNPD challenge showed expected results for the CTRL with a final mortality of 76.7%. Although not significant, there was a clear trend of decreased mortality at the highest IM inclusion rates compared to the CTRL (Figure 1). Also, onset of observed mortality in all IM groups have been delayed in comparison to the CTRL.

Conclusion

These results suggest 1) a positive impact on growth performance in shrimp at all inclusion rates, and 2) no significant difference between the 3 IBU. It therefore seems possible to replace a significant portion (up to 66%) of fishmeal by IM as this ingredient meets the nutritional needs of shrimps as mentioned by other authors (Mastoraki *et al.,* 2020) who did similar studies on juvenile Baltic prawns. Other studies that used insect meal as fishmeal replacement in shrimp feeds observed the same type of results with a high palatability among diets containing BSF meal (Cummins *et al.,* 2017) and no effects on color and firmness of the shrimp fed with different proportions of mealworm meal (Panini *et al.,* 2017).

This study suggests that although the insect sector is relatively recent, good quality IM (nutritional properties, functionalities) could already be achieved and industrially produced by certain suppliers, using different farming and processing technologies.

As well, reinforcing previous observed tendencies, results obtained suggest that inclusion of IM under certain conditions has potential to improve shrimp resistance to certain pathogenic agents (AHNPD). Further research will be necessary to have a complete picture on how to correctly produce and apply IM in feeds for protecting shrimp against AHNPD. Three components of IM have been identified in the literature as having a potential on health improvements: chitin, lauric acid and antimicrobial peptides (Gasco *et al.,* 2018).

Current microalgae production systems are mainly based on suspended cultures using large volumes of water such as in raceway ponds and photobioreactors. The relatively low cell density or biomass concentration observed within these planktonic-based systems requires energetic expenses for culture agitation, and for biomass harvesting and dewatering. Therefore, an innovative technology has been developed and patented by the inalve company to further enhance productivity at reduced costs, overcoming the drawbacks of conventional systems. Created in 2016, inalve produces microalgae and formulated products used as live feeds for the aquaculture industry. Indeed, microalgae are required during the first-feeding of fish larvae, either for direct consumption or indirectly as food for living preys. Based on Rotating Algal Biofilm (RAB) cultivation, the process does not spend energy to mix the culture, and harvesting is simply carried out by scraping the attached biomass with minimal energy demand. This gentle harvesting procedure allows to produce a concentrated algae paste (15-20% DW) with high cell viability and long shelf-life conservation (>50% alive cells after one month at 4 °C). Therefore, the poster will describe the advantages of the microalgal biofilm production system developed by inalve and the use of the produce microalgae and formulated products by marine hatcheries as feedstock for rotifers, copepods and shrimp larvae.

Sulphur (S) and selenium (Se) are chemically similar. Once Se is taken up, it substitutes S in S-containing amino acids. This study investigated the effect of S on selenite accumulation in the microalga *Nannochloropsis oceanica*. [0-28 mM] S concentrations and selenite concentrations of 0 and 30 μM were tested. S concentrations of ≤ 3 mM led to decreased cell growth whereas cultures with ≥ 4 mM were not growth limited. Se accumulation increased up to 8-fold when using S ≤ 2 mM and decreased with S 28 mM. The average relative abundance of organic Se species was selenomethionine (SeMet) 98.2%, selenocystine ($SeCys_2$) 1.4% and selenomethyl selenocysteine (SeMeSeCys) 0.4%. Total fatty acids were not affected by S limitation or Se presence. This is the first study on the effect of S on selenite accumulation, organic Se speciation of *N. oceanica* and its potential as an organic Se-enriched food/feed ingredient.

PRO HEALTH FEED TO MITIGATE SPARICOTYLOSIS EFFECTS IN CAGED GILTHEAD SEABREAM (*Sparus aurata*): PRELIMINARY RESULTS

A. Musmanno[1], S. Colak[2], M. Kolega[2], M.L. Fioravanti[1], C. Viroli[1], M. Berrettini[1], D. Mejdandžić[2], R. Baric[2], G. Bignami[1], A. Di Biase[3], A. Gustinelli[1]*

e-mail: andrea.gustinelli2@unibo.it

Introduction

Sparicotylosis is a parasitic disease caused by *Sparicotyle chrysophrii*, a blood-feeding gill fluke of gilthead sea bream *Sparus aurata* currently considered as one of the most relevant limiting factors in sea bream Mediterranean mariculture. *S. chrysophrii* has a direct transmission between fish, producing eggs able to spread in the water attaching to the gills host or entangling sea cages nets and hatching the oncomiracidia, ciliated infective larval stage able to actively reach the host. Life cycle of the parasite is strongly influenced by environmental factors, *in primis* temperature. *S. chrysophrii* can be responsible for worsening growth performance and, in the case of massive infections in more susceptible fish, even mortality. Currently, there is a lack of therapeutics both effective and cost-effective, environmentally friendly and authorized in the European aquaculture. In this context, the development of feasible and sustainable control tools such as the use of specific functional feeds is deemed an optimal option as they could combine direct effects on the parasite with positive effects on host immunity and growth, always when administered in the context of proper health management practices. Among the additives identified for the formulation of functional feeds with anti-parasitic action, caprylic acid is considered a promising compound and has been proven to be effective at a concentration of 200 mg/kg b.w. in reducing quantitative parameters of *S. chrysophrii* infection (Rigos et al., 2013) mainly if integrated with MOS and iron (Rigos et al., 2016) and when administered since the early stages of infection. Therefore, in the framework of the EU H2020 Project NewTechAqua (https://www.newtechaqua.eu) and following the results of preliminary lab feeding tests, two functional feeds (Feed A and Feed B) with a mix based on herbs extracts, essential oils, fatty acids (caprylic acid, Feed B double dosage than Feed A), complex of vitamins B (originated from yeast - *Saccharomyces cerevisiae*), iron (chelate of amino-acids) and zinc (chelate of amino-acids) were selected for a field trial on caged sea bream in order to verify their effects on Sparicotylosis mitigation and growth performance.

Material and methods

In January 2021, 60000 gilthead seabream juveniles (mean weight 3g) were seeded in 6 cages (9x5x5m) and divided into 3 experimental groups: 2 cages fed with Feed A, 2 cages with Feed B and 2 cages with standard commercial feeds considered as control group. Samplings were carried out monthly from February to November 2021 collecting hematocrit and biometrical (length, weight) and environmental (oxygen and temperature) data. Parasitological and histological analyses were performed in order to assess quantitative infection data (prevalence, mean intensity, MI, and mean abundance, MA) and related gill pathology during the whole trial. A generalized linear model for the mean abundance of *Sparicotyle* was developed, assuming a negative binomial distribution for the parasite count in each cage. Such model extends the Poisson one, which is commonly used for count data, allowing to manage the issue of overdispersion (i.e. a variance notably larger than the mean) detected in the data. After including all the biometrical and environmental information in the starting model, the best combination of variables independently associated with the abundance of parasites was selected via forward stepwise procedure. Following a similar procedure, a linear model for the average fish weight in the cages was fitted applying the logarithmic transform to fix heteroscedasticity issues, thus leading to a log-normal model.

	coefficient	exponential	standard error	95% C.I. (exp)	p-value
intercept	5.724	-	-	-	-
temperature (°C)	0.090	1.095	0.025	(1.039; 1.153)	2.91×10^{-4}
age (days)	0.007	1.007	0.002	(1.004; 1.011)	2.99×10^{-5}
condition index (g/cm^3 × 100)	-2.203	0.110	0.981	(0.013; 0.875)	2.48×10^{-2}
feed B (yes/no)	-0.333	0.716	0.125	(0.563; 0.915)	7.46×10^{-3}

Table 1: estimated coefficients, together with their exponential (for interpretation purpose), standard error, 95% confidence interval (of the exponential) and p-value for the model for the mean abundance of *Sparicotyle*.

(Continued on next page)

Results and Discussion

During the trial the MI values ranged from 1.09 in K4 (March) to 8.05 in K1 (July), and the MA values from 0.12 in K1 and K4 (March) to 7.70 in K1 (July). The peak of MI and MA values were observed in July (5.10 and 4.54), followed by August (3.04 and 2.28) when temperatures reached the highest values of 23.9 and 25.8°C, respectively, confirming the role of temperature in parasite load modulation.

Four variables were selected for the negative binomial model, which proved to be adequate according to the goodness-of-fit test (p-value = 0.218), with a pseudo-R^2 of 0.75. According to the coefficients estimated for such model (reported in Table 1), a direct proportionality of the parasite abundance with the water temperature and the time elapsed from the trial beginning is confirmed, as well as its inverse relation with the fish size in terms of condition index. Furthermore, while no significant difference between Feed A (single dose of CA) results and those of the control group has been detected, Feed B (double dose of CA) proved to be a protecting factor reducing the mean abundance of *Sparicotyle* by about 38.4% with respect to the control feed and Feed A at the same temperature, age, and condition index.

The log-normal model fitted almost perfectly the weight data, explaining 99.1% of the variability; not surprisingly, the model resulted adequate according to the test, with a p-value close to 1. The feed not being included in the model after the stepwise forward procedure indicates that there is no significant difference between the three feeds in terms of fish weight when controlling for time elapsed, hematocrit, oxygen concentration, water temperature and mean intensity of the infection, which are the variables selected (estimates not reported here). Focusing on the intensity, which is highly correlated with the abundance (r = 0.985), this variable was confirmed to be a risk factor for weight loss, reducing the average weight in the cage of about 6.3% for each additional parasite per infected fish (for fixed values taken by the other quantities).

In conclusion, we confirmed the caprylic acid's anthelmintic effectiveness when administered at the proper dosage in limiting the course of infection and mitigating the effects of Sparicotylosis in farmed gilthead seabream when administered since the introduction of fish into cages and before high levels of parasitic infection are established. Feed B could therefore represent an effective prevention tool to reduce the impact of Sparicotylosis on farmed gilthead seabream, albeit further steps would require its administration during a normal production cycle, to confirm these promising experimental results. The preliminary results achieved in this study will be implemented by further analyses to associate the collected data with histopathological studies on gill environment during Sparicotylosis occurrence.

E-mail: guterres.bruna@furg.br

Introduction

Harmful algae blooms (HABs) are characterized by a massive proliferation of phytoplankton organisms, which provide a myriad of adverse effects such as large-scale marine mortality, economic impacts in coastal regions and consequences to aquaculture industries. Climate change has affected HAB frequency and severity on a global scale. In this scenario, machine learning may be an invaluable tool in helping society adapt to the effects of climate change through reliable HAB monitoring and early detection.

Plankton data sets are usually imbalanced and reflect natural differences within the environment. For minority classes, there may not be enough data to properly represent this variability, preventing AI models from gaining a full understanding of these classes (Kerr et al., 2020). The present work employs state-of-the-art Deep Learning (DL) models to support HAB monitoring applications within the Atlantic area.

Materials and Methods

A unified benchmark database covering publicly available phytoplankton images has been built through a data integration pipeline (Guterres et al., 2021) considering target phytoplankton genera from Integrated Multi-Trophic Aquaculture (IMTA) farms from Brazil, South Africa and Scotland. Classic convolutional neural networks architectures are trained for phytoplankton classification. Best individual models serve as a baseline for investigating state-of-the-art methods for class imbalance classification of target phytoplankton organisms. The following approaches have been evaluated to best support climate resilient solutions on HAB monitoring:

- Two-phase Learning (2PL) combines the Random Under Sampling technique with transfer learning. The model is first pre-trained using threshold data and then fine-tuned using original unbalanced datasets (Buda et al., 2018).
- Dynamic Sampling (DS) dynamically changes the class distribution of the training samples. Initially, the number of samples of each class equals the average number of samples. For every other iteration, the number of samples of each class is calculated based on the F1-Score from the previous training round (Johnson et al., 2019).
- Threshold Moving may be implemented on already trained models to improve classification results. It adjusts the decision threshold of a classifier during the test phase. Considering neural networks estimate Bayesian *a posteriori probability*, the output y for class i implicitly corresponds to for a given datapoint x. The correct class probabilities can be obtained by dividing the network output for each class by its estimated prior probability (Buda et al., 2018).
- Deep collaborative models (ensemble) may harness the limited understanding of individual models to provide a collective and more accurate classification specially for minority classes. It is a heterogeneous ensemble of DL models which grants a substantial performance improvement regarding other state-of-the-art approaches (Buda et al., 2018).

Results and Discussions

MobileNetV2 was selected as baseline model for further DL modeling since they provided best results among other architectures (NasNet, Resnet and VGG16). They are also targeted towards embedded and resource constrained environments. Table 1 depicts performance results within state-of-the-art approaches for phytoplankton classification.

All investigated methods have improved classification performance compared to the baseline architecture. Collaborative deep learning model showed promising results. It enabled the combination of other state-of-the-art approaches towards reliable phytoplankton and HAB monitoring. Threshold moving has provided outstanding performance compared to other investigated approaches.

Conclusions

The present work investigated state-of-the-art approaches to class imbalance classification, considering target phytoplankton organisms within the Atlantic area. Deep collaborative models and threshold moving may be key methods towards climate resilient solutions for HAB monitoring since they can be employed upon latest DL models and architectures.

Introduction

The common ragworm *Hediste diversicolor* is an omnivorous, burrowing polychaete with a broad tolerance to environmental conditions such as temperature, salinity and oxygen levels. This nutritious annelid has received a great deal of attention lately for its potential as an extractive species in IMTA systems to recapture high-value compounds from fed aquaculture particulate side streams (sludge) and its suitability for subsequent utilisation as a novel, omega-3 rich aquafeed ingredient (Wang et al., 2019). It has recently been shown that this species has the capacity for endogenous production of omega-3 long-chain polyunsaturated fatty acids (Kabeya, et al., 2020), however it is yet not understood how environmental cues affects this ability. We conducted two sets of experiments to assess the combined effects of diet, temperature and salinity on growth, survival and total body fatty acid composition in *H. diversicolor* juveniles.

Materials and Methods

Polychaetes (*H. diversicolor*) were collected from Leangen Bay, Trondheim, Norway (63°26′24.5″N, 10°28′27.7″E). To investigate the effects of diet and temperature on growth, survival and fatty acid (FA) composition of *H. diversicolor*, worms were fed mixes of solid biogas digestate (SBD) and salmon aquaculture sludge (SS) along a 4-step feed gradient ranging from pure SBD to pure SS, and a 5-step temperature gradient ranging from 5.8 to 17.1 °C, for 15 days, using fish feed as a control (Experiment 1). A second experiment was conducted to investigate the effects of salinity and temperature on the same variables. Here, the worms were fed the diet which yielded the highest growth rates in the first experiment (33:66 % SS:SBD) along 5-step salinity and temperature gradients ranging from 5 to 40 ppt and 7.7 to 17.9 °C, respectively, for a duration of 28 days. In both experiments, worms were fed isonitrogenous diets equalling 30 % of the worms' total body nitrogen per day (Wang et al., 2019). Both experiments were conducted in a temperature gradient table (modified after Thomas et al. (1963)) using a 18h:6h light:dark cycle. Worms (n=7-8) were stocked in glass beakers (800 mL) containing an eight cm thick layer of sand and sand- and bagfiltered (1 μm) seawater from the Trondheim fjord collected at 60 m depth. The worms were allowed to evacuate their guts in clean seawater for minimum 4 hours before each sampling and weighing. Water exchange and feeding was conducted every second day. Data analyses were performed using the inbuild statistical package of SigmaPlot v. 14.5.

Results and Discussion

In the first experiment, the highest specific growth rate (SGR) was found for worms fed a 33:66 % mix of SS:SBD (SGR= 0.025) at 14.7 **°C**. Growth was found to be significantly influenced by temperature (two-way ANOVA; $p<0.001$) and not by diet (two-way ANOVA; $p>0.05$) (Figure 1A). Growth was only positively related to temperature up till 14.7 °C, whereafter SGR declined. The proportions of SS and SBD in the diet showed no significant effects on SGR within temperatures. Survival was high for all treatments combined (88±13 %), and both temperature and diet had significant effects on survival (two-way ANOVA; $p<0.001$ and $p>0.05$, respectively); mortality increased with increasing temperature, whereas feed type did not have such a pronounced, yet significant, effect on survival. In the second experiment, the highest specific growth rates (≤0.015) were found for worms maintained at high temperatures (≥14.3 °C) and high salinities (≥35 psu) (Figure 1B). Survival averaged 80.5±16.2 % for all treatments and was, opposed to growth rate, not significantly affected by neither salinity (One-Way ANOVA, Holm-Sidak *post hoc*; $p>0.05$) nor temperature (Kruskal-Wallis One Way Analysis of Variance on Ranks; p= 0.380).

No temperature- nor salinity-driven segregation patterns could be identified in the FA profiles of the worms, however a clear diet-driven segregation was found between worms fed lipid-rich fish feed (control) and lipid-poor SS and SBD diets (data not shown). Hence, our results indicate that the major influence on fatty acid composition in *H. diversicolor* is diet. We here demonstrated that short-term (≤4 weeks) alterations of environmental parameters have neglectable effects on the lipid profile in wild caught *H. diversicolor* juveniles (Villena-Rodríguez, A. et al., *in prep*, data not shown).

(Continued on next page)

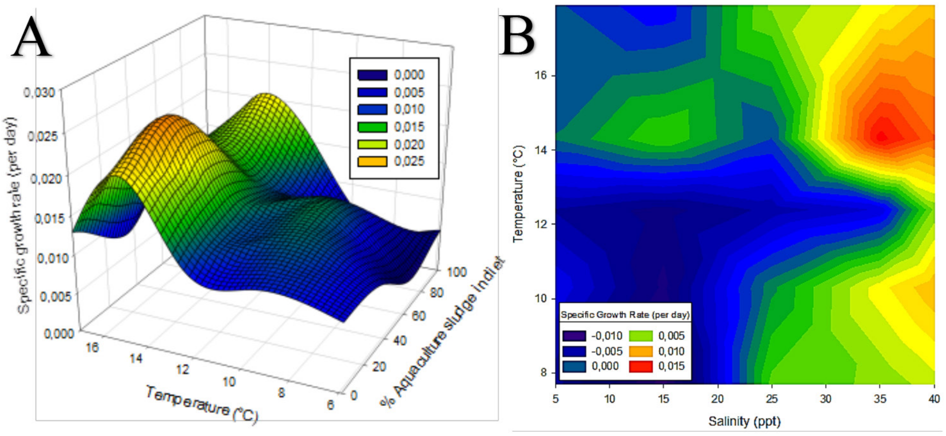

Figure 1. Specific growth rate (SGR) for *H. diversicolor* fed different ratios of solid biogas digestate (SBD) and salmon sludge (SS) at different temperatures over a 15-day period (A), and *H. diversicolor* fed the same diet at different temperatures and salinities over the course of 28 days (B).

PHYSICAL PLASMA FOR DECONTAMINATION IN AQUACULTURE

V. Hahn,[1*] M. Balazinski,[1] M. Schmidt,[1] K.-D. Weltmann,[1] T. von Woedtke[1,2] and J. Kolb[1]

Clean water is an essential good although its preservation and supply can be very challenging. This includes the sustainable management in production processes and especially aquacultures. An efficient remediation of aquacultural water should reduce freshwater consumption and thereby costs as well as ensures healthy products. The utilization of physical plasma has been proven as efficient method for water remediation with inherent advantages (Malik et al. 2001). In particular, the formation of reactive oxygen and nitrogen species (such as ozone, hydrogen peroxide, nitrite, nitrate and hydroxyl radicals) provides effective means for the inactivation of microorganisms and the degradation of pollutants (Lu et al. 2016; Banaschik et al. 2018; Hahn et al. 2019). Respective processes are supported by the emission of electromagnetic radiation i.e. ultraviolet light and strong electric fields.

In this regard, plasma can be applied for the inactivation of microorganisms and viruses. An inductively-limited discharge (Schmidt et al. 2017) was used for the treatment of the T4-bacteriophage (virus, DSM4505; host microorganism: *E. coli* DSM613) and the multidrug-resistent microorganisms *Klebsiella pneumoniae* (DSM109397) or methicillin-resistent *Staphylococcus aureus* (MRSA; DSM 18827). The examined test objects were inactivated by up to six orders of magnitude depending on the exposure time after plasma treatment. In addition, the pollutant bisphenol A was transformed by 34% in preliminary experiments. Interestingly, reactive species that are provided by plasma can be preserved by freezing the plasma-treated liquid. With respect to aquaculture this might offer another possibility for the extended shelf life of fish or shrimp by the inhibition of microbial growth for the storage on frozen plasma-treated water i.e. ice.

Thus, plasma is suitable for the removal of microbial and chemical contaminants and thereby improves water quality and production processes in aquaculture.

Introduction

Mussel *Mytilus galloprovincialis* Lamarck, 1819 is an important commercial mariculture species and powerful bio-indicator commonly used to monitor spatial distributions and temporal trend of pollutants in costal and estuarine areas (Hamer et al., 2008; Pavičić-Hamer et al., 2016). More recently, behavioural markers are applied to assess changes in the health status of mussels and ecosystem in response to different threats, and as a part of biological early warning systems (BEWSs) (Borcherding, 2006). Mussel valve movement (gaping) is widely recognized as an integrative measure of physiological functions such as respiration, feeding and excretion, which can change under stressful conditions in response to a deteriorating environment and as a defence reaction to external stimuli e.g., touching or shading, the sudden approach of a predator (Cameau et al., 2018).

In the summer 2021 and 2022, during monitoring of the intensive ascidian tunicate invasive species *Clavelina oblonga* Herdman, 1880 fouling occurrence at shellfish farm locations in the Lim Bay (NE Adriatic Sea, Croatia), the presence of unusual numerous individuals of the free-living Turbellaria flatworm *Imogine mediterranea* (Galleni, 1976) was determined (Figure 1A,B). It was previously established that *I. mediterranea* feeds on the commercial mussels and oysters (Gammoudi et al., 2017). With following experimental setup (Figure 1C), we answer raised question: Does the flatworm feed only on weakened-death mussel in *C. oblonga* fouling "sods" or can attack healthy mussels also?

Materials and methods

Under laboratory conditions (2 x 40L tanks with aeration and throughflow sea water) 6 acclimated mussels (meat yield 19.4 +/- 0.5%) were connected to Valve Gaping Mussel Monitor (VGMM). Two mussels were used as control and 4 mussels were exposed to 12 flatworm specimens for 3 days (Figure 1C). After acclimation, mussels were monitored 2 days to check normal valve gaping rhythm as a proxy of their filtration and resting activity. Mussel VG was measured by frequency of 0.5 Hz using magnets and Hall sensors fixed on mussel shells connected to microcontroller Arduino Uno and notebook (Figure 1D,E).

Results and Discussion

Analysing and comparing VG results before and during mussel exposure to flatworms, including controls, it was possible to observe mussels VG normal daily rhythm (> 70% time filtrating with valve open > 50%, with 1-5 resting periods valve open < 20% and occurrence < 30%), behaviour changes control vs exposed mussels (stress), the time of flatworm attack, following mussel response during predation and as well as mussel death time (30 h after exposure and 26 h after flatworm attack) (Figure 2).

Flatworm *I. mediterranea* is very likely an extremely opportunistic species i.e., it uses an abundance of food due to the poor mussels condition provoked by the presence of *C. oblonga* fouling, but also can feed on healthy mussels. Such a numerous invasive predator could pose an additional threat to shellfish farms in the Istrian County. According to our field observations and mussel VG results in framework of projects (BlueBio 2020 MuMiFaST and Istria County 2021/2022), there is huge potential of VGMM application for *in*/*ex situ* mussel behaviour and health monitoring as indicator of normal VG behaviour (mussel filtration function), suitable environmental conditions, extreme conditions (CC), fish predation, presence of diseases, including toxic phytoplankton blooms.

CULTURING THE SEA CUCUMBER *Holothuria forskali* IN INTEGRATED MULTITROPHIC AQUACULTURE (IMTA) OFF THE WEST COAST OF IRELAND, A BIOREMEDIATION STUDY

P. Hynes[1]*, J. Downes[1], C. Hannon[2]

[1]Marine Institute Ireland, [2]Atlantic Technological University Ireland
Paula.hynes@marine.ie
Jamie.downes@marine.ie
colin.hannon@gmit.ie

This study aims to culture sea cucumbers *Holothuria forskali*, carrying out field trials at Lehanagh Pool IMTA Marine Research Site. This involves maintenance of sea cucumber stock, field measurements - monitoring of benthic conditions and nutrient profiles, to develop and test structures for the containment of sea cucumbers under salmon pens. It will provide data on the feasibility and value of sea cucumbers grown under aquaculture structures, how much waste they can eat or remove and assess their use as a food source. Biochemical tracers such as stable isotopes will be used to show a trophic link between sea cucumbers and the fish farm.

Method

Sea cucumbers have been placed in cages on the sea floor and in lantern nets at a low stocking density suspended from a rope 5m above the seafloor near and around salmon pens to trial whether they consume and grow on the waste from the farm above. Evaluation of seeding and harvesting sea cucumbers where fish faeces have built up for site remediation is carried out. This valuable and sustainable site remediation service is followed by sea cucumber utilisation as human food and novel compound resource.

This study was set up at the Marine Institute IMTA research site Lehanagh pool, Bertraghboy Bay, Connemara, County Galway, Ireland. The area is situated on the west coast of Ireland in a sheltered bay. The sediment type is typically muddy and sandy. A small-scale experimental IMTA site where salmon smolts (*Salmo salar)* are reared in sea pens. The site is comprised of 3 polar circle cages (50 m circumference and 8 m deep) at a water depth of 21 m. The site is managed according to organic farm standards, with no prescription medicines or antifoulants used. Sea cucumbers *Holothuria forskali*, Sea urchins *Paracentrotus lividus*, European lobsters *Homarus gammarus*, King Scallops *Pecten maximus* and different species of seaweeds *Alaria* sp. and *Saccharina sp*. are also cultured on this site. Sediment traps have been developed and grab samples taken for Total Organic Carbon, Total Nitrogen and Total Phosphorus and sent for analysis. The salmon are fed a standard commercial organic diet. Water quality is routinely monitored for chemical and biological parameters.

Results

Preliminary results show – Figure 1. Average weights of *H. forskali* at higher stocking density, 100% survival in October in all lines, in March 83% survival in North line and 100% survival in South lines. Animals did well in higher stocking densities. Losses in average weight are possibly due to animal mortalities. Control lines 100% survival in October, 66% survival at March weigh in.

Figure 2. Average weights of *H. forskali* at lower stocking density 100% survival in all lines. In October 50% survival in North lines. Control line 100% survival. The losses in average weights are possibly due to animal mortality.

Figure 3. Temperature data between July 2021 and April 2022 the data is normal for the time of year with a dip in winter time below 9ºC temperatures are beginning to rise now so expect to see further growth in animals.

Conclusions

This may be due to where the animal was in life cycle when caught, no way of knowing age of animal, only by how they look when putting into cages. Weather exposure could be an issue, possibly lack of food over the winter.

Introduction

Microplastics (MPs) are recognised as emerging contaminants in the marine environment, and are suspected to affect aquaculture production. Bivalves, such as oysters, are low-trophic organisms that are relatively exposed to microplastics due to their sedentary living and high filter-feeding capacities. There are limited studies focusing on assessing depuration efficacy in commercially grown species, although it is estimated this number will grow given the global efforts to identify and quantify microplastic pollution. This study investigates microplastic depuration efficacy in two commercially grown oyster species, the Pacific oyster (Magallana gigas, n=50) and the European flat oyster (Ostrea edulis, n=50) collected from the West coast of Ireland.

Materials and methods

A depuration set up was run in a temperature-controlled facility (~10 °C). Five depuration treatments were assessed control, 24, 48, 72 and 96-hours (with ten individuals (n=10) per treatment) for each oyster species. A 10% potassium hydroxide (KOH) solution was used to digest the organism (Δ 40 °C for 24-hours). After digestion, the resulting digestate was filtered using a vacuum pump filtration system using glass microfibers filter membranes (Whatman GF/C, Ø = 47 mm, pore size 1.2 μm), under a laminar flow, to minimise airborne contamination. Filters were observed under a stereomicroscope and subsampled for polymer (109 out 539) characterisation using the micro-Fourier Transformed Infrared Spectroscopy. A forensic approach to cross-contamination was applied to minimise all potential particles from clothes and daily use.

Results

Microplastics concentrations prior to depuration in *M. gigas* were 0.6 MP g^{-1} edible tissue and 0.4 MP g^{-1} for *O. edulis*. Significant reduction in MP concentrations after a 96-hour depuration period were measured: 0.2 MP g^{-1} for *M. gigas* and 0.1 MP g^{-1} for *O. edulis,* respectively. Moreover, there was no significant correlation between microplastic concentrations and weight of edible tissue of oysters. Microplastics were mainly fibres, with the main colours being blue, black, red and transparent. Polymer identification from the subsample analysed revealed more than 51.6% of fibres were natural fibres, with the remaining (48.6%) varying synthetic fibres, including Nylon.

Conclusion

The results from this preliminary depuration study showed that increasing depuration time to 96-hour can significantly decrease the concentration of microplastic in edible tissues of selected oyster species. These findings align with other depuration studies showing reduction in microplastics concentrations in bivalves species, however the novelty in our results relies in the fact of using two species, with a large sample size (N=50 per species) and for a longer period of time than conventional laboratory assays (t=96h). These results also contribute to provide information to aquaculture producers and policy makers on how to reduce microplastic exposure in products that are destined for human consumption.

EFFICIENT USE OF RESOURCES IN AQUACULTURE: NEEWA – NETWORK FOR GENERATING ENERGY WITH HYDROPOWER IN EXISTING WATER SYSTEMS

Harvey Harbach*, Manuela Wimmer*

*University of Hof, Institute for Water and Energy Management (iwe), Alfons-Goppel-Platz 1, 95028 Hof, Germany
harvey.harbach@hof-university.de

Current problem and state of knowledge
With the Green Deal, the European Union has committed itself to be climate neutral by 2050. The aim is to no longer release any net greenhouse gas emissions (1). In order to achieve this goal, it is essential to increase the share of renewable energy in final energy consumption. In this way, by 2030, this share of all energy in the EU is expected to increase to 32% (2). These goals are also implemented at national level as part of the climate protection program 2030 (3). In addition to wind power, biomass and solar energy, electricity generation from hydropower offers another option for decentralized electricity generation from a renewable source. In many places, the possibilities of hydropower are probably not exhausted due to legal hurdles or a lack of technical know-how, despite its advantages. The advantages can be seen in particular in 100% clean and base load energy with low production costs. The focus here is on the greatest challenge, the ecological compatibility, which describes the influence on the environment of the power plants, which are mostly installed in natural ecosystems such as rivers. The primary goal is to be able to rule out effects such as endangering fish stocks, as well as negative influences on the surrounding riverbed and its flora. Technological possibilities are insufficiently known, and political education makes expansion more difficult. Technological solutions are also anchored in special machine construction, which excludes series certification and thus results in expensive certification costs for each individual system.

Subject and goals of the project
There is great energy potential in the wastewater from sewage treatment plants, sewer networks and aquacultures, which has not yet been tapped due to a lack of knowledge transfer and, in addition, a lack of research (4). With these systems, energy flows for the realization of hydropower and its advantages (see "Current problem and state of knowledge") can be used profitably, excluding ecosystems. The water used for the processes is withdrawn from the ecosystem in these procedures. In this way, using hydropower within these production systems eliminates the environmental impact, which is the main negative aspect of hydropower.

The aim of this project is, in addition to networking and the exchange of all potential actors from the entire value chain, to bring the participants together from the point of view of knowledge transfer and to train them with regard to opportunities and possibilities. The regular exchange within network meetings and knowledge transfer events provides information on new technologies and the combined use of application processes.

The network is intended to promote the use and further development of existing and new technologies for the use of hydropower in combination with heat exchangers through regular exchange. Another goal of the project is to develop an online decision-making tool and make it available to interested parties through the exchange and central compilation of obstacles and problems of hydropower in order to make a decision on the use of hydropower within your production processes outside the ecosystem enable. In particular in the areas of small-scale hydropower, these are only insufficiently available. These initial findings have already been gained through guided interviews as part of the project. The guide or decision support tool makes it easy to understand the approval process and the necessary steps. The results of the project are published in various places to strengthen a neutral, scientific representation of hydropower in Germany. The aim is to disseminate information about the use of hydropower in anthropogenic water systems in Germany in order to support the exploitation of this clean and sustainable energy potential.

Own preparatory work and previous activities in the field
The Institute for Water and Energy Management, founded in 2015 at the Hof University of Applied Sciences, is an interdisciplinary laboratory of the Engineering Faculty. The institute is currently working on the projects "Development of fully biodegradable growth bodies in aquaponics with the release of nutrient additives for biological water treatment" (ZIM, 2021-2023) and "Network for generating energy with hydropower in existing water systems". (ESF, 2021-2022) by Dr. Harvey Harbach and a team of scientists.

Financing and duration of the project
The planned duration of the project is 18 months. This project is funded by the European Social Fund (ESF) with 417,000 euros.

IN VITRO ANTIPARASITIC EFFECTS OF SOME HERBAL EXTRACTS ON CILIATA, *Cryptocaryon irritans* THERONTS

B. Harmansa Yilmaz*, F. S. Secer, M. A. Tunar and H. Yavuzcan Yildiz

Ankara University, Faculty of Agriculture, Department of Aquaculture and Fisheries, Ankara, Turkey
E-mail: harmansa@ankara.edu.tr

The ciliate protozoan *Cryptocaryon irritans,* which causes white spot disease in fish, is recognized as one of the most dangerous pathogens in cultured marine fish. Since herbal products have less adverse impact on the environment and fish in comparison to chemical treatments, their use in aquaculture against diseases has increased. In the present study, anthelmintic effects of onion (*Allium cepa*), ginger (*Zingiber officinale*), garlic (*Allium sativum*), radish (*Raphanus raphanistrum*) and pomegranate (*Punica granatum*) extract solutions were investigated *in vitro* against *C. irritans* theronts (infective phase). In the experiments, *C. irritans* theronts were subjected to the herbal extract solutions with 100, 50, 25, 12.5, 6.25, 5 and 1% concentrations for 20 minutes. At 100% concentration, 100% cumulative mortality was observed in 1 minutes with pomegranate, radish and garlic extract solutions, whereas corresponding cumulative mortality caused by onion solution was 50% and by ginger solution was 70% in 1 minutes. At the lowest concentration, 1%, tested, 100% cumulative mortality was observed in 20 minutes with pomegranate extract application. No parasite mortality in 20 minutes was observed after tests with onion, ginger and garlic extracts at 1% concentration. *In vitro* results revealed that all solutions had dose and duration dependent antiparasitic effects against *C. irritans* theronts.

OVERVIEW OF THE AQUACULTURE SECTOR AND MSP PROCESSES IN THE MACARONESIAN SEA BASIN

R. Haroun[1*], A. Abramic[1], C. Andrade[2], N. Nogueira[3] & S. Kaushik[1]

1 Research Institute ECOAQUA, Univ. Las Palmas de Gran Canaria, Spain
2 Centro de Maricultura da Calheta, Madeira Government, Portugal
3 Secretaria Regional de Mar e Pescas, Direção Regional do Mar, Madeira Government, Portugal
E-mail: ricardo.haroun@ulpgc.es

Introduction

The Macaronesian Sea Basin includes the Portuguese archipelagos of Azores and Madeira and the Spanish archipelago of Canary Islands, which are located in the Central Eastern Atlantic Ocean. In these archipelagos maritime-based activities constitute the backbone of the local economies, with coastal tourism, cruise tourism, shipping and fisheries identified as playing a pivotal economic role. In the last decades, marine aquaculture is assuming a relevant position. The growing trend of cage production for finfish species, such as seabream (*Sparus aurata*), European seabass (*Dicentrarchus labrax*), Amberjacks (*Seriola* spp.) and Meagre (*Argyrosomus regius*) is mainly connected to favourable climatic conditions (e.g., annual stable and high mean sea temperature and short photoperiod variation throughout the year) together with the competition for land space. After the implementation of regional regulations for aquaculture by regional Governments, which include the allocation of marine space, mariculture production is expected to grow in the coming years, On that sense, Madeira published the Plan for Management of Marine Aquaculture of Madeira (2016), the Canary Islands adopted the Regional Plan of Management of Aquaculture (2018) and the Azorean administration is also engaged in the establishment of the sector through the development of a legislative framework for licensing the location of aquaculture production areas and identification of species allowed in the Azores (2016); in all three archipelagos, these initiatives are promoted from tax benefits for investors. The development of aquaculture in Macaronesia entails several concerns about its environmental interactions that needs to be addressed to foster the long-term sustainability of the sector.

Aims

In this contribution we shall present the state of the art on MSP implementation together with the environmental pressures and impacts related to the marine finfish aquaculture in the Macaronesian Sea Basin. Strategic planning and application of technical standards for aquaculture systems to mitigate potential environmental impacts will provide fundamental information to spatial planning processes, ensuring that this and other maritime activities will have access to clean, healthy and productive marine waters.

IT'S GETTING HOT IN HERE; EXPLORING THE EFFECT OF HEAT TREATMENT ON SPAT AND HALF-GROWN OYSTERS (*Crassostrea gigas*)

Eva Hartog[1 *], Lotte Niemeijer[1], Bas van den Berg[1], Demian Zwaan[1], Jacob Capelle[2]

[1]HZ University of Applied Sciences, Edisonweg 4, 4382NW, Vlissingen, The Netherlands
[*]email: e.hartog@hz.nl
[2]WMR - Wageningen Marine Research, P.O. Box 77, 4400 AB Yerseke, The Netherlands

Oysters (*Crassostrea gigas*) are in volume after mussels the most important cultivated shellfish species in the EU. In the Netherlands, off-bottom techniques were initiated in 2010 due to high losses by the oyster herpes virus (Ostreid herpesvirus 1; OsHV-1) and predation by the Japanese Oyster drill (*Ocinebrellus inornatus*) on subtidal culture plots. Off-bottom cultivation takes place in the intertidal areas and typically results in oysters with fast growth and high meat quality due to a higher food quality and food availability higher in the water column. While the implementation of such cultivation systems could reduce the mortality caused by the oyster herpes virus and predation of the Japanese Oyster drill, heat exposure of the oysters increased in off-bottom cultivation. Recent summers showed long periods of increased solar radiation compared to 10 years ago. Prolonged sun radiation exposes the oysters in off-bottom systems to temperatures even higher than 40°C. Climate change increases this risk. Heat stress can result in higher mortality amongst oysters and reduce harvest yield for off-bottom cultivation.

In 2020 the European Marine and Fisheries Fund project "*Oyster yield improvement through knowledge transfer and monitoring*" was initiated. The goal of this project is to optimize oyster farming and it should lead to efficiency improvements in sustainable oyster cultivation. As part of this project, a study on the effect of heat exposure on survival of spat and half-grown oysters was carried out. The aim of this study was to investigate the overall mortality rate caused by prolonged exposure to radiation heat of 40 degrees Celsius.

The experiments were carried out at HZ University of Applied Sciences in a climate-regulated room set to a default temperature of 20^{o}C which represents the average Dutch summer water temperatures over the last ten years. During the treatments oysters were exposed to air. Heat radiation was simulated with a heat lamp (EXO Terra Intense Basking Spot PT2140 150-Watt S30).

Two size classes were tested: 1. oyster spat (2n), 13.76 mm (±1.70) was acquired from the Hatchery '*Roem van Yerseke'* and 2. half-grown oysters (3n), 15,6 gr (± 3,03) fresh weight were acquired from the off-bottom location '*Hooge Kraaijer, Delta Ostrea B.V.*' originating from the Hatchery '*France Naissian*'. Triploid oysters were used to prevent spawning, that maybe initiated by a sudden rise in water temperature. Experiments were carried out during winter and spring.

During the experiment, the oysters were exposed to heat radiation for 2 hours a day.

Based on the average inundation of 20% for off-bottom cultivation sites in the Oosterschelde, the Netherlands. Simultaneously, a control was carried out in which oysters were exposed to air at the default temperature of 20^{o}C. After the treatments, the oysters were held in aerated saltwater, set at 20^{o}C. Four consecutive runs were carried out with both oyster spat and half-grown oysters. The number of living oysters was counted before and after treatment. Dead oysters were removed. To simulate a prolonged summer period each run was continued for 12 days or until all oysters died.

An example of survival over time is shown in Figure 1, for the control and exposed (lamp) oysters for the different size classes.

Results are still processed and will be shown and discussed during the presentation.

COMMERCIALISING YOUR POND: DON’T GET CAUGHT BY LEGAL DISRUPTORS!

Katherine Hawes

Principal Solicitor, Aquarius Lawyers

marketing@aquariuslawyers.com.au

Introduction

Most aquaculture farmers usually work with professional researchers, equipment suppliers, specialists, technology providers, water specialists, feeding companies and other famers to name a few when they set up their farm. This is irrespective of whether the ‘fish’ farm being commercialised is land or ocean based. am aquaculture business.

The question is when it is time throughout that process for either aquaculture professionals or farmers to engage with business experts to manage: your risks, protect your assets and meet your regulatory and compliance requirements. This presentation will take aquaculture professionals and farmers through the commercialization process and outline touchpoints with a business and legal professional.

Aquaculture Farm Start-Ups

Whether you are just starting out or been in business for a while, we have a checklist for you about ensuring your future generations are looked after by you minding your business. We give practical advice on making sure the majority of what you do is protected by both upstream and downstream agreements.

If you employ people, there are a myriad of things today to consider. Some of the key ones are some standard terms and conditions of employment, terminations, management of social media and now of course ensuring you are protected in a pandemic.

If you are engaging with scientists your agreement should specify who is responsible for doing what and who owns what at the end of a trial or experiment. Protecting your intellectual property is paramount to keeping your business safe.

Aquaculture Farm Growth

As you hit critical mass and your business expands, success means your customer expectations change and there is nothing like a great customer service charter and agreement to ensure that both your expectations are aligned.

At this point you will also potentially engage with fish brokers who are always looking for product. Cover yourself with a well thought our Supplier Agreement. We will be explaining what is critical in these types of agreements, particularly if you are entering the export market, for your business.

The logistics of getting product to market on time and within standards also comes into play. In this scenario it is important to understand the delineation of responsibility for the product as it moves from the farm to the fish market and on to the customer.

Growth can also mean new relationships. You may want to partner, move into a joint venture or sell your business. A business and legal professional can not only work up the agreements you will need but they can be instrumental in monetizing your business and working with your Accountant.

Advances in Farm Techniques

Aquaculture is one of the fastest growing food production industries. However, there are issues that can be managed with the addition of technologies. These technologies require special consideration in agreements to address issues such as using the product to standards, warranties and guarantees, the product is ‘fit for purpose’ and works in your ponds, to name a few.

(Continued on next page)

New Technologies

This paper will also spend some time on how robotics, blockchain and AI can assist in commercialising your business. While these technologies are fantastic for not only managing your ponds, blockchain means that you can implement smart contracts to assist with the majority of your external relationships that get product to market.

It will explore when a farmer work in experiments and trails with product and technology providers.

Outcomes from this Presentation
Understand the legal framework that your aquaculture business operates within
Gain insight into relevant legislations to protect your assets and intellectual property
Become experienced at knowing when to put Terms and Conditions into your business
Prevent disruption to your business through legal disputes.

OPPORTUNITIES AND CHALLENGES FOR UPSCALED GLOBAL BIVALVE SEAFOOD PRODUCTION

David F. Willer*[1], Richard J. Nicholls[2], and David C. Aldridge[1]

[1] Department of Zoology, University of Cambridge, Cambridge, UK
[2] Nomad Foods Europe Limited, Lowestoft, UK
Email: dw460@cam.ac.uk

Summary

Slow growth in the bivalve mariculture sector results from production inefficiencies, food safety concerns, limited availability of convenience products and low consumer demand. Here we assess whether bivalves could meet mass-market seafood demand across the bivalve value chain. We explore how bivalve production could become more efficient, strategies for increasing edible meat yield and how food safety could be improved through food processing technologies and new depuration innovations. Finally, we examine barriers to consumer uptake, such as food allergen prevalence and bivalve preparation challenges, high- lighting that appealing and convenient bivalve food products could provide consumers with nutritious and sustainable seafood options—and contribute positively to global food systems.

This abstract is based upon our recent publication in *Nature Food*, alongside unpublished data from research we have been carrying out with leading academics and global food companies. Please see Willer, D. F., Nicholls, R. J. & Aldridge, D. C. Opportunities and challenges for upscaled global bivalve seafood production. Nat Food 2, 935–943 (2021).

Benefits of unfed bivalve mariculture

To assess the sustainability and nutritional merits of bivalves relative to a current mass-market seafood, we compare bivalves with cod and Alaska pollock, alongside tuna (yellowfin and skip- jack). These wild-caught fish are already a proven resource and will continue to be a key component of consumer seafood, but supply is limited and global food companies are interested in how alternatives for filling the demand gap, such as bivalves, directly compare. In depth sustainability and nutritional analyses will be presented in the oral presentation alongside visual illustration.

Production

We discuss three key challenges to upscaling bivalve production: providing adequate volumes, maintaining sustainability, and ensuring food safety. We outline the emerging opportunities to tackle these challenges. These include new bivalve breeding approaches, feed technologies and grow-out practices; shell valorisation, the use of new species and sustainability regulations; and new depuration approaches including antimicrobial peptides, bacteriophages and chelating agents. We present several figures, including Figure 1, which outline the potential for production increases.

Food Processing

Bringing bivalve-based foods to the mass market will require creating bivalve products that can be easily and safely stored, distributed and purchased by consumers. We discuss the key challenges and opportunities in producing the major types of bivalve food products: fresh in-shell products, frozen de-shelled products, and cooked processed products. These are briefly outlined in Figure 2.

Consumer Uptake

We consider the key barriers to driving increased consumption of bivalves by the mass market and discuss the key opportunities to meet these challenges. We present the results of a consumer survey carried out with Europe's largest frozen food company (Nomad Foods) which can help us understand how to increase mass market demand. These results are compared with other global studies.

Conclusion

Demand for seafood is growing at double the rate of the global population, requiring nutritious seafood to be delivered to this mass market while avoiding damage to ecosystems through overfishing or poorly managed aquaculture. We discuss how through new innovation across production, food processing, and consumer uptake, bivalve shellfish can help meet this consumer demand.

(Continued on next page)

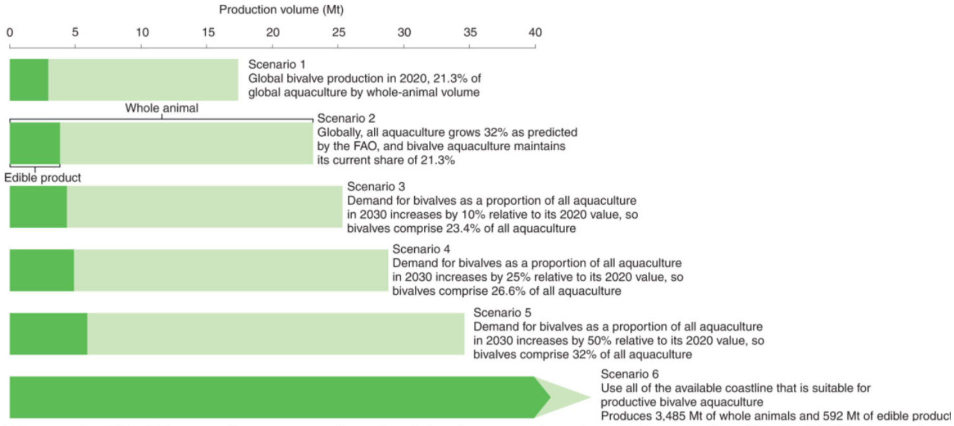

Figure 1. Six illustrative scenarios for bivalve production. Figure details in Willer et al. *Nature Food* 2021.

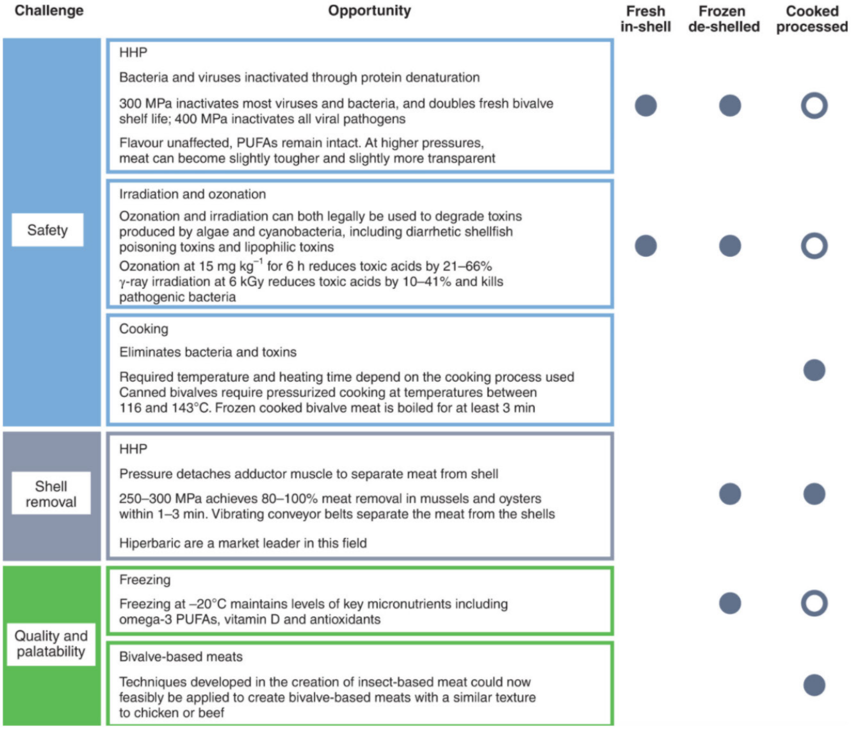

Challenge	Opportunity	Fresh in-shell	Frozen de-shelled	Cooked processed
Safety	HHP Bacteria and viruses inactivated through protein denaturation 300 MPa inactivates most viruses and bacteria, and doubles fresh bivalve shelf life; 400 MPa inactivates all viral pathogens Flavour unaffected, PUFAs remain intact. At higher pressures, meat can become slightly tougher and slightly more transparent	●	●	○
	Irradiation and ozonation Ozonation and irradiation can both legally be used to degrade toxins produced by algae and cyanobacteria, including diarrhetic shellfish poisoning toxins and lipophilic toxins Ozonation at 15 mg kg^{-1} for 6 h reduces toxic acids by 21–66% γ-ray irradiation at 6 kGy reduces toxic acids by 10–41% and kills pathogenic bacteria	●	●	○
	Cooking Eliminates bacteria and toxins Required temperature and heating time depend on the cooking process used Canned bivalves require pressurized cooking at temperatures between 116 and 143°C. Frozen cooked bivalve meat is boiled for at least 3 min			●
Shell removal	HHP Pressure detaches adductor muscle to separate meat from shell 250–300 MPa achieves 80–100% meat removal in mussels and oysters within 1–3 min. Vibrating conveyor belts separate the meat from the shells Hiperbaric are a market leader in this field		●	●
Quality and palatability	Freezing Freezing at −20°C maintains levels of key micronutrients including omega-3 PUFAs, vitamin D and antioxidants		●	○
	Bivalve-based meats Techniques developed in the creation of insect-based meat could now feasibly be applied to create bivalve-based meats with a similar texture to chicken or beef			●

Figure 2. Key opportunities for producing fresh in-shell, frozen de-shelled and cooked processed bivalve products. Figure details in Willer et al. *Nature Food* 2021.

ENZYME ACTIVITY AND PLASMA NUTRIENT VARIATION DEPENDENT ON FEEDING TIME IN ATLANTIC WOLFFISH (*Anarhichas lupus*)

I. Hedén*[1,2], J. Roques[1,2], J. Hinchcliffe[1,2], M. Langeland[2], E. Jönsson[1,2], K. Sundell[1,2] and H. Sundh[1,2]

[2] Swedish Mariculture Research Center (SWEMARC), University of Gothenburg
Box 463, 405 30 Gothenburg, Sweden
Contact: ida.heden@bioenv.gu.se

Introduction

Atlantic wolffish (*Anarhichas lupus*) has been proposed as a cold-water species in aquaculture [1]. However, in order to explore the commercial farming potential of the species, we need more knowledge about its nutritional and digestive physiology, nutrient requirements and feeding protocols for optimal growth and welfare. Previous studies in fish on protein digestion, including a few on Atlantic wolfish, show that the enzymatic activity of intestinal trypsin and chymotrypsin is well correlated with growth, and feed conversion efficiency [2–4]and of 6°C induced the variant TRP-2*92 ($p<0.01$. Digestion leads to nutrient uptake and increased plasma concentrations of amino acids, glucose and lipoproteins. Plasma amino acid and glucose concentrations of fed Atlantic wolffish has not been measured. In other fish species dependent on feeding strategy and intestinal morphology, digestion of protein and amino acid uptake result in increased free amino acid plasma concentration short after feeding [5]. Further, lipase activity and fat absorption have not been examined in Atlantic wolffish. Free fatty acids (FFA) plasma concentration is known to vary between species and have seasonal and circadian variations [6,7].

The aim of the current study was to gain knowledge about the diurnal and nocturnal activity of digestion of protein and lipids in Atlantic wolffish.

Material and method

Atlantic wolffish juveniles were kept in re-circulating water systems with artificial seawater at 10˚C, and artificial 12:12-h light-dark photoperiod. The fish was fed in excess to visual satisfaction once a day for 4 weeks in the morning (MF) (8 am), or evening (EF) (8 pm) (Skretting Amber Neptune grade 2.0, Skretting, Stavanger, Norway). The fish were fasted 24 h before sampling. On the sampling day, the fish were fed once and after 30 min, uneaten feed was collected. Sampling of chyme, intestinal scrapings and plasma started 1h post feeding with subsequent sampling after 7, 13, 19 and 25 h for each feeding regime. Intestinal enzymatic activity of trypsin, chymotrypsin and lipase as well as plasma profiles of free amino acids (FAA), free fatty acids (FFA) and glucose were measured.

Results and conclusion

In both feeding groups, there was no difference in trypsin and chymotrypsin activity in the proximal mid-intestine over time (Fig 1 A and B), whereas there was higher of chymotrypsin activity in the distal mid-intestine in MF fish 1 h post feeding (not shown), and lipase activity remained un-changed during the whole experimental period (not shown). In MF fish, there was a decrease in trypsin and chymotrypsin activity in the proximal mid-intestine after 19 h that was correlated with a drop in hepatic total FAA concentration and glucose, suggesting that the fish goes into a digestive resting state during the dark cycle (Fig. 1 C and D). This effect was not seen in EF fish that had sustained enzyme activity and high plasma FAA, and glucose concentrations through the experimental period.

In conclusion, Atlantic wolffish has a higher and more stable trypsin and chymotrypsin activity along with increased plasma FAA and glucose plasma concentration if they are fed in the evening compared to if they are fed in the morning. Since feeding time influence the digestive ability and nutrient uptake over time after an ingested meal this information could be used to optimize the feeding strategy for Atlantic wolffish. Future studies should aim for examining the long-term growth effect under different feeding regimes and continuous feeding.

(Continued on next page)

*Figure 1. IMPROVING MICRODIET FORMULATION FOR TWO FLATFISH SPECIES: SENEGALESE SOLE AND ATLANTIC HALIBUT

João Henriques[1]*, Maria Morais[1], Wilson Pinto[1], Walter Olsen-Ryum[2], Børre Erstad[2], Jorge Dias[1] e Luís Conceição[1]

[1] SPAROS, Lda. Área Empresarial de Marim, Lote C, 8700-221 Olhão, Portugal.
Email: joaohenriques@sparos.pt
[2] Sterling White Halibut AS, Hundsnesveien 205, NO-4130 Hjelmeland, Norway.

Introduction

Flatfish species such as Senegalese sole and Atlantic halibut are target species for European aquaculture diversification due to its high market value and excellent consumer acceptance. Aquaculture development of these species partially relies on optimization of feeding and nutrition, especially at early development stages. Although significant progress has been made on microdiet quality, feeding regimes and zootechnical procedures for Senegalese sole (Pinto et al., 2018), little R&D work has been conducted to improve microdiets for Atlantic Halibut larvae and post-larvae. Atlantic halibut poses difficulties on accepting inert microdiets (Hamre et al., 2019) which can lead to increased mortalities and depressed growth rates. Therefore it becomes paramount to carefully formulate and produce microdiets with suitable nutritional and physical properties, as well as increased attractiveness targeting the early developmental stages. This work presents two trials which were conducted to evaluate the effect of several microdiets with varying protein sources on the growth performance and survival of Senegalese sole and Atlantic halibut.

Material and methods

The trial with Senegalese sole aimed at identifying the preference for a specific protein source and comprised three dietary treatments: MIX (mixture of marine and plant-based ingredients), KRILL (krill meal) and SQUID (squid meal). Microdiets were introduced in the feeding regime of Senegalese sole postlarvae at 27 days after hatching (DAH) and kept for nearly 6 weeks (68 DAH). Sole postlarvae were reared at an initial density of 3000 fish/m^2 in triplicate flat-bottom tanks (8 L), set in a partially-closed recirculating aquaculture system. Sole were sampled at 27 DAH, 51 DAH and 68 DAH. The second trial was performed also to determine Atlantic halibut's preference for a main protein source. Three dietary treatments were used: MIX, SQUID and KRILL. Atlantic halibut postlarvae were reared for 35 days, from 97-132 DAH and were kept in triplicate flat-bottom tanks (2x2m). Sampling occurred at 97, 115 and 132 DAH. Both trials comprised the analyses of Relative Growth Rate (RGR), Feed Conversion Ratio (FCR) and Survival. Eye migration, pigmentation quality and liver histology were also evaluated in the Atlantic halibut trial.

Results

At the end of the sole trial, no differences were found on dry weight amongst the 3 treatments (Figure 1). In addition, there were no differences in RGR (9-9.4%), FCR (0.96-1.08) and survival (57-66%). On the other hand, Atlantic halibut group fed on the Squid diet showed significantly lower wet weight (figure 1) and also the lowest total length ($P<0.05$) at the end of the trial. There were no significant differences in RGR (3.02-3.77), FCR (2.3-3.3) and survival (>77%).

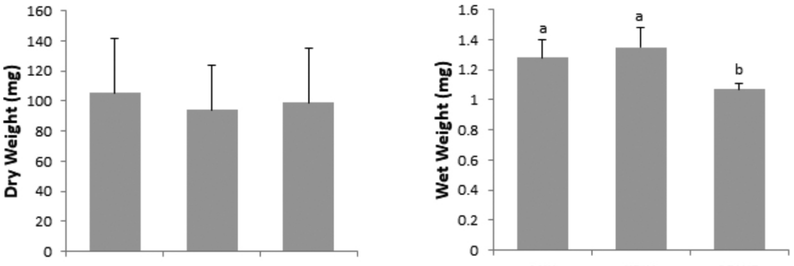

Figure 1. Dry weight of Senegalese sole (left) and Wet Weight of Atlantic halibut (right) fed diets with different protein sources – Mix (mixture of marine and plant-based ingredients), Krill (krill meal) and Squid (squid meal). Results are expressed as means ± standard deviation. Different lowercase letters indicate significant differences between the dietary treatments ($P<0.05$).

(Continued on next page)

Discussion and Conclusion

There is scope to keep testing novel feed formulations which can promote growth at early development stages of emergent aquaculture fish species such as Senegalese sole and Atlantic halibut. The present results show that sole performed well on all tested microdiets, regardless the protein source. The Relative Growth Rate (RGR, up to 9.46 % day^{-1}) is satisfactory although slightly behind the 12-13 % day^{-1} achieved nowadays during weaning. Such high RGRs are only possible due to the intensification of R&D efforts on microdiet optimization for Senegalese sole in the last decade (Pinto et al., 2018). On the other hand, Halibut seem to have a preference for diets with a mixture of marine and plant-based ingredients (MIX) or krill meal (KRILL). Both diets resulted in improved growth performance when compared with the diet with squid meal (SQUID). Interestingly, both species have different feeding behaviours; whilst sole is a typical passive bottom feeder, Atlantic halibut shows a high swimming activity especially after metamorphosis (Kristiansen et al., 2004), being a more proactive feeder. Overall the results obtained on microdiet preference for both species and also the distinct feeding behaviours suggest that diet formulation and physical properties should be tailored to each species in order to improve attractiveness and maximize growth performance.

CHROMOGRANIN A AS STRESS MARKER IN FISH

Introduction

Chromogranins belong to the granin family, soluble acid proteins which are expressing in several endocrine, neuroendocrine and neuronal cells. They are stored in secretory granules and released together peptidic hormones, neurotransmitters or amines as response to a range of stimuli (D'amico et al., 2014). The chromogranin A (CgA) has recently reported as stress marker in superior vertebrates (Srithunyarat et al., 2018). Its higher stability in blood than catecholamines, not being submitted to circadian rhythms and easier analysis and preservation make them a remarkable candidate for stress markers based on the SAM (sympathetic-adreno-medullar) axis reactivity (Martínez-Miró et al., 2016).

Although the proprieties of peptides derived from chromogranins acting as cardiac stabilizers have been studied in fish, their relationship to the stress response has been not described in any work yet (Imbrogno et al., 2019). In this sense, it has been reported that these peptides show cardio-inhibitors effects in teleosts and use several strategies for the cardiac control, despite its biological meaning still remains unclear.

The objective of this work was to study the chromogranin A variation for stress in fish, aiming at determining if those proteins could be a suitable stress marker, mainly for chronic stress conditions.

Material and methods

The experimental cultures were carried on 900 L circular tanks (0.65 m radius) integrated in a close water system. Meagre juveniles were purchased from MARESA (Ayamonte, Spain) and submitted to an acclimation period for two weeks. After fish were initially sampled for body weight (181.5±15.1 g) and total length (37.3±0.88 cm).
Chronic stress culture: It consisted of two treatments, stressed (CS) and control (CT) for 6 months. The CS groups were submitted to confinement and netting/chasing stress.

Acute stress challenge: After completing the chronic stress culture, all remaining fish from the control groups were kept in the same non-stressing conditions for15 days. Then 10 fish were netted and exposed to air stress for 3 minutes, and sampled after 15 minutes.

Fish were sampled at the end of the experimental chronic stress culture (6 months) and the air stress challenge for blood, tissues and biometry. Plasma glucose, proteins, lactate and cortisol were determined, as well as brain and head kidney cortisol and chromogranin A.

Results and discussion

Acute stress

Plasma lactate and cortisol increased significantly after stress although glucose and proteins remained stable (Fig. 1A, 1B). As plasma cortisol, kidney cortisol after stress was significantly higher (Fig. 1B). Kidney CgA decreased significantly in the stressed fish though brain CgA did not change between statuses (Fig. 1C).

Chronic stress

Several biometric parameters varied between treatments significantly (Table 1). They were significantly lower in chronically stressed fish. Plasma stress markers did not change significantly (Fig. 2A, 2B). Kidney cortisol increased in stressed fish (Fig. 2B). Both brain and kidney CgA concentrations decreased in stressed fish (Fig. 2C).

Only kidney CgA and cortisol kept the same variation pattern in both stress types. Although cortisol concentrations in plasma and tissues have been widely studied, the tissue CgA concentrations related to stress have not still reported in fish. Initially, the depletion of kidney CgA could be considered as a chronic stress marker.

Introduction

Gill diseases are an important challenge for Atlantic salmon (*Salmo salar*) aquaculture worldwide. Complex gill disorder (CGD) is a multifactorial and multiaetiological condition that is thought to be a consequence of the interaction of a number of factors including environment, management practices and pathogenic microorganisms. The main infectious agents associated with cases of CGD in Atlantic salmon are *Candidatus* Branchiomonas cysticola, *Desmozoon lepeophtherii* and salmon gill poxvirus (SGPV) (Herrero et al. 2018)pathogenic organisms and farm management practices. None of the three principal agents purportedly associated with CGD (Desmozoon lepeophtherii, salmon gill poxvirus or Candidatus Branchiomonas cysticola. The individual roles and possible interactions between these pathogens have not yet been fully elucidated and studies on infectious gill disease agents in Scottish aquaculture, other than *Neoparamoeba perurans*, are scarce. In the absence of *in vivo* or *in vitro* experimental models, prospective longitudinal studies can help to clarify any associations between exposure to a potential aetiology and the development of disease.

Material and methods

A prospective longitudinal study was designed to investigate the infectious dynamics of the putative pathogens of CGD for one year, starting from the late freshwater stage of the production cycle and continuing through the subsequent marine stage. The protozoan *N. perurans*, which causes a specific disease known as amoebic gill disease (AGD), was also included in the monitoring of the study. The relative loads of the four pathogens, estimated using real-time reverse transcriptase polymerase chain reaction (RT-rtPCR) Ct values, were correlated with a semi-quantitative histological gill scoring system derived from the samples. Generalised additive models (GAMs) were used to represent changes over time in the Ct values of the different infectious agents in the gills of salmon at the various sampling timepoints in the two farms, and to represent the variation of the gill score across time and farms. Linear regression models were used to study the possible associations between gill score and different explanatory parameters such as variations in the pathogens' loads, environmental and farm management factors.

Results and discussion

The two marine farms screened in this study were positive for the three main pathogens associated with CGD by RT-rtPCR, which shows that the detection of *D. lepeophtherii*, *Ca.* B. cysticola, and SGPV are common in marine Scottish salmon farms. *Ca.* B. cysticola and *D. lepeophtherii* were the most prevalent agents, whilst SGPV was detected irregularly throughout the study. In addition, *Ca.* B. cysticola and SGPV were first detected in the late freshwater stages of both populations suggesting that these pathogens were carried from the freshwater to the marine farm.

In the marine phase, Farm B showed significantly higher gill scores compared to Farm A ($p< 0.05$). Farm A experienced minimal to mild unspecific gill changes during the study whilst fish in Farm B had gill pathology characterised by AGD lesions and low to occasionally moderate vascular, proliferative and inflammatory pathology, from late summer until early winter. Gill score was significantly higher during the autumn on both farms compared to other seasons ($p< 0.05$). The strong link between the gill score and seasonality may indicate that water temperature is an important risk factor in terms of gill health compromise. In this study, the load variation of SGPV was not significantly associated with changes in the gill score ($p> 0.05$) and typical pathology associated with SGPV was not detected. As fish seemed to be first infected during the freshwater stage, it could be that the virus becomes latent and can be re-activated at a later stage, for example during episodes of immunosuppression, contributing to the gill pathology. An increase in *Ca.* B. cysticola load was associated with an increase in the gill score ($p< 0.05$) when only Farm B was used in the statistical analyses. *Ca.* B. cysticola was shown to be associated with gill pathology by *in situ* hybridization, for CGD events occurring in the absence of visible epitheliocysts, showing that the effects of the bacteria can be easily overlooked by common histological methods (Gjessing et al., 2021).

(Continued on next page)

In this study, the inflammatory and necrotic cell reaction in the gills was not marked (changes associated with *Ca*. B. cysticola), and the low level of epitheliocysts detected in the histopathology suggests the bacterium was not a major cause of the gill disease present in Farm B although it could have contributed to some of the changes present. Higher loads of *D. lepeophtherii* were significantly associated with an increased gill score in Farm B ($p < 0.05$) but not in Farm A ($p > 0.05$), and characteristic *D. lepeophtherii*-type microvesicles were minimal and not significant in the gills of fish examined from both farms, which suggests the significant associations could be the result of the parasite developing in more affected gills (with higher gill score) rather than *D. lepeophtherii* being a causative agent of the gill pathology observed. An increase in *Neoparamoeba perurans* loads was significantly associated with an increase in gill score ($p < 0.05$) on both farms and an outbreak of amoebic gill disease was one of the main causes of the gill disease observed in Farm B.

When using only Farm B in the linear model, parameters such as a lower number of days since last net cleaning and a lower number of days since the last hydrogen peroxide treatment were significantly associated with an increase in the gill score ($p < 0.05$). *In situ* net-pen pressure washing cleaning of the nets and the mechanical trauma caused during the treatments performed likely contributed to the gill damage observed in Farm B (Østevik et al., 2021, 2022).

MARINE INGREDIENTS FOR FEED FOR AQUACULTURE: AN ANALYSIS OF CERTIFICATION AND SUSTAINABLE SOURCING

Introduction

Global fish production peaked at about 171 million tonnes in 2016, with aquaculture representing 47 percent of the total and 53 percent if non-food uses (including reduction to fishmeal and fish oil) are excluded (FAO, 2020). Global aquaculture production (including aquatic plants) in 2016 was 110.2 million tonnes, with the first-sale value estimated at USD 243.5 billion (FAO, 2018). The total production included 80.0 million tonnes of food fish, 30.1 million tonnes of aquatic plants as well as 37,900 tonnes of non-food products (USD 214.6 million). EU aquaculture accounts for about 20% of fish and shellfish supply in the EU and directly employs about 70,000 persons. EU aquaculture accounts for about 20% of fish and shellfish supply in the EU. Despite COVID-19 complications like high level of absenteeism at work sites, transportation difficulties, limited capacity for diagnostic tests for COVID-19, and an increase in operating and logistics costs mainly, global production has been increasing between 5% to 7%.

Despite the diversity of aquaculture, the EU aquaculture production is largely concentrated on a few species, the most important being mussels, salmon, seabream, rainbow trout, seabass, oysters, and carp. Looking at the diversity of species but also the farming method, we see a high dependency on feed for salmon, seabream, rainbow trout, seabass, and carp.

On the other hand, Industry more and more has been attacked by the media specifically because of the environmental and sustainable impact that this is producing. At the same time, there is a very close relationship and synergy with fisheries because it is a fact: The aquaculture industry will not exist without feed and marine ingredients mainly. Marine ingredients include essential proteins, fats, vitamins, and minerals that are important for farmed fish, and are also passed on to humans when they eat farmed seafood. Growing global production from aquaculture, as envisioned by the United Nations' Food and Agriculture Organization in its recent "State of World Fisheries and Aquaculture 2020" report, will require additional feed and a greater demand for marine ingredients use of marine ingredients in aquafeed will not decline soon,

Feed companies are becoming more sophisticated in using the nutritional and physical properties of materials, but the growth in marine ingredients derived from byproducts still needs more focus, currently, more than one-third comes from the byproducts of wild or farmed fish processing, but there is potential for greater innovation. Feed manufacturers already regard them less as a commodity and more as a strategic ingredient in feed made from a wider variety of feed components. According to the FAO forecast, by 2050, it will be necessary to triple protein production to support the development of 10% annual aquaculture production. Arable land is limited and stocks of fish are strained. It is necessary to find additional resources rich in protein in a market of 9 billion euros. Alternative ingredients with similar nutritional value profile, and from marine origin should be a solution, and if it is possible to produce it in a sustainable manner

Methods and Materials

A key part of our methodology is to compile and review current aquaculture certification programs and schemes certifying marine ingredients and feed for aquaculture. How they are addressing the marine ingredients for feed in the supply value chain and the interdependency among aquaculture and fisheries certification programs. A full reference list will be shared during the presentation of this paper.

The scope of the paper and gap analysis include aquaculture and fisheries certification programs associated with shrimp production. A case study of different alternative marine ingredients has been reviewed and valuated. Therefore we have tried to examine these sequentially and have attempted to produce an assessment list for considering at the moment of assessing a new feed marine ingredient and/or alternative – decision making. Whilst we have provided an overview of the marine ingredients for feed in aquaculture and alternatives sources, we have not examined this in detail as several global feed producers may have done in the private sector.

(Continued on next page)

Results and Conclusions

A stairs process approach will be shared as well as reflections in the European feed marine ingredients and 8 steps to consider for feed ingredients design. The right certification scheme for your ingredients and feed seems to end in only one certification program – Marin Trust. Reflections of the important requirements are part of the conclusions.

Beyond certifications, the feed producers should start to develop an assurance model that includes KDEs for a continuous evaluation of the feed ingredient composition, origin, nutritional value, food safety, quality, sustainability, and labor conditions of workers in the supply chain.

WIND-WIN: A MULTI-USE CONCEPT FOR INTEGRATING NON-FED AQUACULTURE WITH OFFSHORE WIND ENERGY GENERATION

G. Hill*, E. Costa, O. Luthman, M. Hanstén

Nord University
E-mail: griffin.hill@nord.no

Introduction

Off-shore marine environments are often portrayed as new frontiers for development by international organizations such as the EU and the UN (European Commission, 2017, FAO, 2017). The expansion of marine exploitation is set to reduce stresses on limited terrestrial environments through the sustainable harnessing of untapped resources at sea, to use technological advancements and to maximize social benefits whilst minimizing social resistance (WorldBank, 2017). While new technology makes these resources more accessible than ever, stakeholder engagement and regulatory expediency are critical to realizing the full potential of development in this arena. A framework providing accessibility for stakeholders as well as predictability for investors has the potential to accelerate development. To increase transparency and to reduce the areas of conflict, Marine Spatial Planning (MSP) has become a commonly used tool to plan and consider different claims and stakeholder positions (Qiu and Jones, 2013). MSP has also become a staple in Blue Growth initiatives that are aimed at enabling and nudging states towards expanding marine development. Presented here is a scalable framework for successful implementation of coupled offshore aquaculture and renewable energy, as well as a case study in the Baltic Sea, one of the most eutrophicated environments in the world.

Case study: macroalgae cultivation in the Baltic Sea

In Europe, the potential for both micro- and macroalgae cultivation is slowly being recognized and encouraged as a powerful tool in the face of urgent challenges, including climate change, food and energy security and social prosperity. Although the number of seaweed farmers is increasing, the majority of the biomass still comes from foraged wild seaweed. With the growing market for bio-based products and the increased knowledge of how to utilize seaweed, there is huge potential throughout the whole supply chain for creating an industrial-scaled macroalgae industry in Europe. The potential global seaweed market value is estimated at € 9.3bn by 2030, creating some 115 000 jobs while improving the environmental state of our oceans (Vincent et al., 2020).

With its low temperatures and brackish waters, the Baltic Sea is home to a unique set-up of marine species, including some 450 macroalgae species. The low salinity level hinders the cultivation of the more conventional macroalgae species, nonetheless, there are a number of species that are of interest, both based on their properties as well as from an economic perspective. Furthermore, seaweed is considered a promising protein for food, feed and the bio-based economy (van den Burg et al., 2020). These include, but are not limited to, the brown algae *Fucus vesiculosus* (bladderwrack), red algae *Furcellaria lumbricalis* and green algae *Ulva lactuca* (Sea lettuce) and Ulva intestinalis. At the present time, there are small-scale pilot projects studying the potential of macroalgae cultivation in the Baltic Sea whereas wild seaweed is commercially foraged only in Estonia and Denmark.

Implementation framework

The Wind-Win project framework is a tool to create and identify a network of actors benefiting from the multi-use concept both on a local and international level. The concept combines identification of local partners, expert technical analysis of aquaculture production elements, as well as developing infrastructure both onshore and offshore including job opportunities and business incentives. Special emphasis is placed on developing the necessary associated onshore hatcheries and nurseries in synergy with local industries based on the circular economy model. Introducing a multi-use approach of ocean space, combining aquaculture and offshore wind, provides a unique opportunity to leverage local tourism to bring awareness about both sectors.

(Continued on next page)

Methodology

An array of methods from diverse disciplines are employed to assess the viability of offshore multi-use development. As achieving stakeholder engagement is a major challenge for projects of this scale, significant attention was given to developing an adaptable outreach strategy including branding approaches and local market development. Technical requirements for operations including tradeoffs between single and multi-use facilities are provided alongside conceptual designs and review of technological developments contributing to feasibility of projects within the framework. Furthermore, a Strengths, Weaknesses, Opportunities and Threats (SWOT) analysis is included as a means to preemptively identify specific elements likely to influence the outcome of the project.

Conclusion

New legislation and heightened incentives have generated momentum towards a transition to green energy in Europe (European Commission, 2021c). The war in Ukraine has only stressed this need further and many states are pushing for a quicker transition to clean energy, more specifically wind (Tollefson, 2022). The development framework proposed here aligns with the Green New Deal and Blue Growth initiatives that emphasize energy, especially through off-shore wind farms to expedite growth in this sector as well as facilitate the de-eutrophication of European Waters (European Commission, 2019, 2022). As a resilient, low impact addition, seaweed farming is a perfect candidate for multi-use in a variety of habitats (Wever et al., 2015, Bak et al., 2018). The planned expansion of windfarms in offshore environments is driving a multi-use interest. The Wind-Win framework and associated Baltic Sea case study provide the structure for rapid implementation of this promising partnership between green energy and blue growth.

Introduction

The spotted wolffish, *Anarhichas minor,* is a promising species for coldwater aquaculture (Foss *et al.,* 2004; Le Francois *et al.,* 2021). The nutritional requirements may not be fully met in captivity, which can result in health issues such as tooth loss and neprocalcinosis (Foss *et al.,* 2004; Béland *et al.,* 2020). Previous studies have shown the potential of marine and plant based alternative protein sources in wolffish diets, with no negative effects on growth and stress markers such as plasma cortisol, glucose and lactate (Knutsen *et al.,* 2019[a,b]). Whereas, other more recent investigations imply no significant effects on intestinal barrier function and nutrient uptake by alternative marine protein sources (Hinchcliffe *et al.,* in prep). However, health issues like kidney stones and tooth loss remain (Béland *et al.,* 2020; Le Francois *et al.,* 2021). Little attention has focused on mussel meal as a potentially beneficial ingredient in aquafeeds for wolffish. Blue mussels have protein and amino acid content similar to fishmeal and can act as both a dietary protein source (Vidakovic et al., 2016; Langeland et al., 2016) and feed attractant for fish (Berge and Austreng, 1989). Moreover, the shell of mussels (BMS) can act as a source of minerals such as calcium and phosphorous, that are essential for health (Flik and Verbost 1993). Its potential benefit for maintaining bone density and reducing kidney stone levels is yet to be investigated for any fish species. The aim of the current study was to investigate the inclusion of mussel meal and shell in marine and plant based on-growth diets for spotted wolffish in a 30 week feeding trial. With specific objectives to:

1. Establish effect of plant based ± BMS *vs.* marine based diets ± BMS on growth performance and plasma health and welfare markers of spotted wolffish
2. Establish effect of experimental diets on gut barrier function and nutrient transport using Ussing chamber technology
3. Compare neprocalcinosis and bone density in diets using CT scans.

Material and methods

For the study, 600 fish 104g ± 15.18 (mean weight ± SD) were randomly distributed into 12 PE-coated fiberglass tanks (1200 L), triplicate tanks (50 fish/tank) were allotted to a treatment, and fed one of 4 experimental diets. 1) **MC**: 60% fishmeal, 20% blue mussel meal. 2) **MS:** 61.7% fishmeal, 20% blue mussel meal with shells. 3) **PC**: 30% fishmeal, 20% pea and soy protein concentrates and 20% blue mussel meal. 4) **PS:** 30.9% fishmeal, 19.5% pea and soy protein concentrates and 20% blue mussel meal with shells. At the start, middle and end of the feeding trial, weights and lengths of all individual fish were recorded. At the end of the experiment, liver weights for hepatosomatic index were measured and blood was sampled for plasma growth and appetite hormones, IGF-1 and ghrelin; stress parameters such as cortisol, glucose, lactate, ion content and acid-base balance and nutrient parameters such as FFA (n=12 fish/group). Ussing chambers were utilized to characterize gut barrier function and nutrient uptake in fish fed the different diets (n= 12 /group). Finally, we collected whole body of fish for chemical composition, tooth and bone structure and kidney stone quantification (n = 12 fish/group).

Results and discussion

At the end of the trial, fish showed a final weight that was approximately 5 times higher than their initial weights (Table 1). Overall, fish fed the plant-based diet with mussel meal (PC) and shell (PS) were the strongest performers; the final SGR of the fish fed these diets were significantly higher (0.65 ± 0.01 %/day) relative to fish fed the MC diet (0.60 ± 0.01 %/day). While the final weight of the group PC was significantly higher than the MC and MS treatments (522 ± 7.4 g *vs.* 462 ± 5.8 and 463 ± 8.4 g, respectively). In contrast, no significant differences were found for plasma IGF-1 which ranged between 12-14 ng/ml in all treatments. A significant increase in HSI was found in marine based diets relative to plant-based diets (4.53 ± 0.13 *vs.* 4.04 ± 0.13). Plasma FFA concentrations have been measured but pend further investigation to ascertain consequences on lipid metabolism from the marine based diets. In addition, other hormones related to appetite

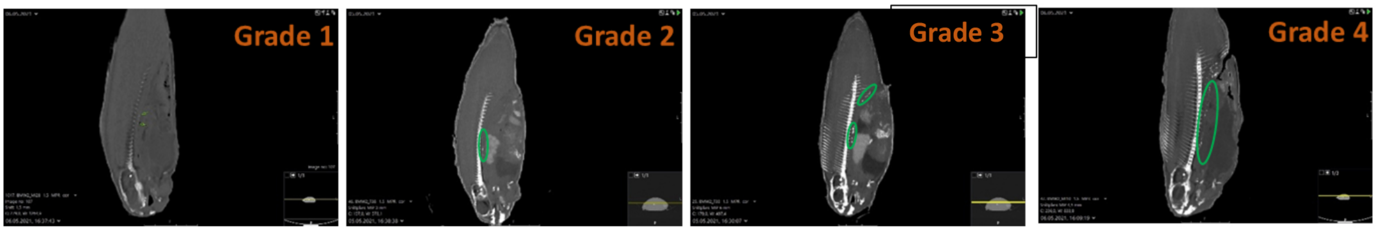

Figure 1. Kidney stone scoring system used in the present study

and stress/welfare, ghrelin and cortisol, are under current analysis and will be discussed further with data ascertained for ionic-balance and acid-base balance. Preliminary results from the neprocalcinosis scoring (Fig1) indicated no significant differences between the experimental diets, suggesting no clear evidence on the effect of diet on kidney stone formation. Bone density also did not differ significantly between the experimental diets. Kidney stone and bone density may well be correlated in spotted wolffish and this is pending further investigation that will be discussed along with the gut barrier function and nutrient uptake from the Ussing chamber methodology.

In conclusion, the present experiment shows the potential of plant-based protein sources, for the emerging spotted wolffish aquaculture sector with no significant impacts on growth or welfare observed. The preliminary data shows no clear evidence thus far on the effect of diets on kidney stone formation in spotted wolffish.

Introduction

The European lobster (*Homarus gammarus*) has been the subject of aquaculture research for the last 150 years, due to both the wild fishery and cultural value of the species. Since the middle of the 20th century, increasing anthropogenic pressure has led to a severe decline in wild fish and shellfish stocks, including *H. gammarus,* with some fisheries yet to recover. *H. gammarus* is amongst the most exclusive shellfish products worldwide, and whilst management measures have been implemented to safeguard stocks, *H. gammarus* aquaculture is an increasingly credible approach to help to secure sustainable lobster supply. Historically, this has been achieved by relatively small-scale release of hatchery reared juveniles. Until recently, commercial attempts at farming have not been viable, mainly due to cost prohibitive technical challenges. At present, there are several promising approaches to overcome bottlenecks hampering commercialisation of lobster aquaculture. This talk will summarise the new husbandry and nutritional advancements in *H. gammarus* culture from experiments performed at Swedens fiest pilot scale lobster hatchery over the last 5 years. Additionally, likely directions for both sectors in the coming decades are summarised, knowledge gaps identified, and the societal support required to achieve further potential will be highlighted.

Material and methods

This presentation will summarize data taken from a series of juvenile lobster exoeriments that took place between 2017-2022 at Kristineberg research station, Sweden. In general, gravid female lobsters were donated from commercial fishermen operating in Gullmarsfjorden, Sweden, and delivered directly to the Sven Lovén Centre, Kristineberg, Sweden during September- October 2015 and September-October 2016. During preparation for experimental periods, lobsters were individually maintained in opaque 40 L perforated boxes with a 8:16 L:D photoperiod, immersed in a flow-through system, incorporating “deep” water pumped to shore and originating from ca. 33 m depth. Temperature fluctuated with season but with a minimum and maximum 6-16°C. For hatching, up to three ripe adults were removed and placed in an experimental facility for preparation of the experiments. Hatching systems were matched to ambient water conditions, and temperature was gradually increased and temperature was gradually increased. For the experiment 1 larvae were fed a wet feed, dry feed and conspecific treatment in communal and individual reared cells to ascertain the degree and importance of larval cannibalism in lobster nutrition. In experiment II, Pandalus borealis, was used as a reference diet, with four additional diets: isocalorific and isonitrogenous commercial fishmeal, experimental shrimp meal, herring meal ± supplements, or mussel based feeds based on the nutritional profile of larvae from experiment I, in order to test the potential of alternative protein sources and added supplements in juvenile on growth diets.

Results and discussion

Experiment 1 underlines the impact of cannibalism on survival and nutrition in H. gammarus larviculture.Analysed H. gammarus zoea 1 composition, identified deficiencies in ash and carbohydrate in lobster feeds. This suggests a need for a species-specific, formulated dry feed for H. gammarus larviculture. This experiment represents the first investigation of H. gammarus larval composition and dietary requirements and highlights decreased growth potential associated with providing nutrition solely from generic commercial feed. In experiment II, the high survival and growth, low incidence of moulting problems and high availability of waste shrimp material, suggest that non-heat-treated shrimp products are a promising feed ingredient for post-larval European lobsters.

In conclusion, this presentation has highlighted the technical, nutritional and practical innovations that have taken place over the last two decades that have allowed European lobster hatcheries to proliferate throughout Europe. However to reach a sustainably produced plate sized product that can contribute towards a local nutritious food production systems, further innovations revolving around improved feeds for all life stages, technical and ecological scale ups, systemic support and regulations and improving welfare practices are needed.

CUMULATIVE IMPACTS OF CLIMATE CHANGE AND INCREASED AQUACULTURE PRODUCTION IN A NORWEGIAN FJORD

SS. Hjøllo*, JM. Aarflot, L. Falconer, S. Gao, E. Ytteborg, MD. Skogen

Introduction

The Norwegian coastal marine ecosystem is highly productive due to nutrient release from land, high incoming solar radiation (in summer) and a blend of mixing and stratifying processes in the water column. Nitrogen (N) and especially phosphorus (P) are essential elements and often the limiting factors for phytoplankton growth. However, eutrophication through N and P enrichment from human activities can stimulate the growth of algae and change the structure and function of the phytoplankton community. A planned 5-fold increase in aquaculture production will further add nutrients to the coastal systems. In addition, global climate change will impact coastal systems in a number of ways, and cumulative impacts from climate change and human activities are to be expected. Several climate pressures to the Norwegian coastal ecosystem are already in play: surface temperatures have increased by 0.7-1.3°C and increased runoff from land has contributed to increased light attenuation and "darkening" of the Norwegian coastal watermasses. Thus, the main objective of the study is to investigate the cumulative impacts of climate change, coastal water darkening and eutrophication from fish farming on lower trophic level production in a coastal ecosystem, exemplified by the Hardangerfjord at the west coast of Norway.

Methods

A coupled 3D physical, chemical and biological high resolution ocean model for plankton and nutrient cycling has been applied (Aksnes et al. 1995; Skogen et al. 1995, Albretsen et al. 2011). Five different experiments have been performed to project both the isolated and combined impacts of fish farming (nutrient release), darker water (increased light attenuation) and climate change (temperature increase) on the timing (onset of spring bloom) and amount of phytoplankton production for the example years 2018-2020.

Results and Discussion

Depth integrated modelled net annual primary production for the reference simulation without any stressors is 117 $gC/m^2/year$, with spring bloom starting at March 13. Adding estimated present day nutrient release from fish farming does not change the timing but increases the production slightly (5%), while increased temperature accelerates the spring bloom by 3 days and reduces the productivity by only 1%. The combined effect of present-day fish farming and temperature increase is 4% increase in production and 3 days earlier spring bloom, while the largest change in production is seen from the combined effects of a 5-fold increased fish farming together with temperature increase. This causes a major increase in production (20%) and 3 days earlier spring bloom. Reduced light levels, however, have an opposite effect on timing and delays the spring bloom by 4 days, and reduces the production by 6%. The cumulative net effects of all three pressures (increased fish farming and temperature, reduced light in the water column) are no change in spring bloom start, though the primary production in the area still increases by 9%

Our results suggest that eutrophication from increased fish farming in the Hardangerfjord will increase the primary production levels in the fjord substantially, though the total effect might be dampened by coastal water darkening. The ecological consequences for a future fjord are, nevertheless, largely uncertain. One potential effect is that increased amounts of phytoplankton may stimulate zooplankton growth and thus provide an extra food resource for fish. However, both temperature increase and reduced light levels are expected to shift the phytoplankton community towards smaller sizes, which may alter the dynamics and energy transfer between phytoplankton and zooplankton. Furthermore, other studies have shown how the combined effect of eutrophication and reduced water clarity can lead to ecological regime shifts, going from fish- to jellyfish-dominated ecosystems. These potential consequences should be addressed by future studies to enhance our understanding of how coastal ecosystems might be affected by a changing climate and growth in the coastal aquaculture sector.

Conclusion

In the Hardangerfjord, increased nutrients from a 5-fold increase in farming activities in a warming climate can induce an as high as 20% increase in primary production. The accumulated effect of higher temperature, darker water and increased nutrient loads will altogether result in a 10% increase in primary production. The ecological effects of the changes remain to be studied.

Introduction

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most frequent and most common pharmaceuticals used in medicine due to their analgesic, antipyretic, and anti-inflammatory effects. Their use on daily basis resulted in NSAIDs have a leading position among the pharmaceutical contaminants present in the aquatic environment. Even so, their complex mechanism of toxicity for fish is not fully understood. We selected rainbow trout (*Oncorhynchus mykiss*) as an ideal model to examine the impact of two NSAIDs – diclofenac (DCF) and ibuprofen (IBP). The aim of our study was to test toxicity via dietary exposure of environmentally relevant concentrations (2 μg kg^{-1}) of these drugs together with exposure doses of 100× higher (200 μg kg^{-1}), including their mixture (combination of 2 μg kg^{-1} DCF and 2 μg kg^{-1} IBP). Here, we present the results of oxidative stress markers and gene expression.

Materials and Methods

We performed a test in accordance with OECD 215 methodology (Fish Juvenile Growth Test) in which DCF, IBP and their mixture were incorporated into commercial feed pellets. A total of 144 individuals were divided into control and five experimental groups fed by DCF in c = 2 μg kg^{-1} (DCF2) and 200 μg kg^{-1} (DCF200); IBP in c = 2 μg kg^{-1} (IBP2) and 200 μg kg^{-1} (IBP200), including their combination, i.e. DCF in c = 2 μg kg^{-1} mixed with IBP in c = 2 μg kg^{-1} (DCF2+IBP2). The experiment lasted six weeks and ended by taking the biometric data, blood and samples of tissues for subsequent laboratory analyses. Hodkovicova et al. (2022) refer in detail all of the methodological and statistical procedures of sample and data processing.

Results and discussion

The kidneys, liver and gills were discovered to be the most severely affected tissues in our experiment and in all of them, the outbreak of reactive oxygen species (ROS) was observed. In posterior kidney, the environmentally relevant DCF concentration caused an increase in the catalase (CAT) activity – an enzyme which major function is to eliminate hydrogen peroxide as one of the ROS representatives. In liver, marker of lipoperoxidation (TBARS), increased in DCF2 and IBP200, as well as in DCF2+IBP2 combination. Regards gills, we confirmed the decreased glutathione peroxidase (IBP2, IBP200 and DCF2+IBP2) and CAT activity (DCF200). In general, ROS can oxidise cellular macromolecules, i.e. lipids, proteins and DNA, and provoke cell death.

The heat shock protein 70 (*hsp70*) is a commonly used marker for assessing the impact of environmental pollutants and its mRNA levels are known to increase in response to various types of stress. *Hsp70* is also an important factor in protein function, maintaining cell homeostasis, and affecting cytokine production. Regards *hsp70* expression, the environmental concentration of IBP caused an increase in the anterior kidney and liver. In gills, the *hsp70* expression increased in both tested concentration of IBP.

In conclusion, due to changes in activity of antioxidant enzymes, we assume that the toxicity of NSAIDs in rainbow trout manifests itself mainly through their effect on the function of mitochondria. Damage of mitochondria can lead to increased ROS and cell death; consequently, the ROS increase can provoke a proteotoxicity that reflected by *hsp70* increase in kidney, liver and gills. We kindly invite you to take a look at our poster and our study results (Hodkovicova et al., 2022), where the detected changes are presented in a comprehensive overview.

Figure 1. The *hsp70* mRNA expression and the catalase (CAT) activity in tissues of *O. mykiss* after six weeks of oral exposure to diclofenac and ibuprofen in concentrations 2 and 200 μg kg^{-1} (DCF2, DCF200; respectively IBP2, IBP200); including their mixture (DCF2+IBP2). Significance was stated with different letters of superscript (n= 8).

NMR-BASED METABOLIC PROFILE IN MUSCLE OF JUVENILE TURBOT (*Scophthalmus maximus*) FED WITH PLANT AND ANIMAL PROTEIN SOURCES

C. Hoerterer[1]*, J. Petereit[1], G. Lannig[1], C. Bock[1], B. H. Buck[1, 2]

[1] Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Am Handelshafen 12, 27570 Bremerhaven (Germany)

Email: Christina.Hoerterer@awi.de

Introduction

The reduction of the environmental footprint of diets for farmed fish that are nutritious but at the same time economically and environmentally sustainable has become a high priority (Naylor et al. 2021, Glencross et al. 2020). Turbot (*Scophthalmus maximus*), a high-value species in Europe, has a high potential for sustainable production and is suitable for diets with novel ingredients. Although alternative feed ingredients such as insect meal or processed animal protein have no or little effect on growth and feed performance, nutritional status indicators were negatively affected at low inclusion levels (Hoerterer et al. 2022). Using ^{1}H-nuclear magnetic resonance (NMR) spectroscopy, this study examined the diet dependent effects on the metabolic response in muscle tissue of juvenile turbot after the fish were fed with different diets formulations including plant and animal protein sources.

Material and Methods

In a 16-week feeding trials with 750 juvenile turbot (20 ± 0 g), two formulation concepts were tested against a commercial formulation (CTRL). The alternative formulation concepts were based on replacing 20 % of fishmeal with insect meal and fermentation biomass. Furthermore, sustainable terrestrial plant proteins (NoPAP) or processed animal proteins (PAP) replaced the soybean content in the CTRL (see figure 1). The metabolic profile of a perchloric acid extract of the muscle and liver tissue of N = 45 juvenile (n = 15 per diet) was generated using ^{1}H NMR spectroscopy (Rebelein et al., 2018). A Partial Least Squares - Discriminant Analysis (PLS-DA) of the metabolic profiles was performed to identify differences between the formulation concepts using MetaboAnalyst 5.0

Results and Discussion

The comparative approach revealed that metabolites associated with growth and energy allocation showed different levels in the muscle of fish fed with the alternative formulation concepts (NoPAP and PAP) and the commercial formulation (CTRL). Creatine levels were highest in fish from the CTRL group indicating fast energy provision in the body and good muscle growth. Furthermore, taurine levels were highest in muscle tissue of fish from the PAP group indicating that the dietary taurine (supplemented with 0.5 % in NoPAP and PAP) was metabolised better than in fish from the NoPAP group (see figure 2).

In general, the results from the ^{1}H NMR generated metabolic profiles and following PLS-DA indicated that metabolites such as taurine, creatine, acetate and glutamine are diet-dependent in muscle tissue of turbot and that the NoPAP and PAP formulation concepts might affect the taste and consistence of muscle tissue of the final consumable product. More insight on the diet dependent effects on the energy allocation in turbot will bring the analysis of the liver of the juvenile turbots. Sensory analysis of the filets might confirm the NMR-based metabolite findings in the muscle.

APETITE REGULATED FEEDING BY AUTOMATED FEED WASTE MONITORING IN CLOSED AQUACULTURE SYSTEMS (CAS)

A.B. Holan*, B. Skjelstad, Y. Ulgenes, T. Kristensen, A. Selle, R. Zamiri, T. Solvang

Scale Aquaculture AS, Beddingen 16, 7042 Trondheim, Norway
Email: astrid.holan@scaleaq.com

Introduction

In precision feeding (PF) the feeding is automatically regulated by the appetite of the fish. In closed aquaculture systems (CAS), landbased and sea based, there is a physical barrier between the fish and the surrounding environment, which enables development of technologies for appetite regulated feeding. By monitoring uneaten feed in the waste drain, information about the appetite is obtained. This information can then be used to regulate the amount of feed that should be added to the tank at any time.

Automated feeding is an important step towards sustainable aquaculture as it has a great impact on many different aspects of the industry.

In CAS almost all suspended solids originate from added feed, either directly as uneaten feed or indirectly as feces. A smaller portion by mass comes from biofilm shedding and biofloc (dead and living bacteria) (Timmons et al., 2018). In terms of water treatment efficiency and water quality stability, controlling the solids tightly through PF is very important. High levels of suspended solids increase heterotrophic bacterial growth, which in turn can reduce TAN removal efficiency in RAS and deteriorate water quality (Chen et al., 2006). It has been stated that suspended solids in RAS should be kept below 15 mg/l (Thorarensen and Farrell, 2011).

In terms of growth, feeding according to appetite can improve the feed conversion ratio (FCR) because of the reduced underfeeding. This directly impacts the production capacity as well as the predictability for the farmer. Feeding according to appetite also improves the fish welfare as feed will be offered whenever the fish is hungry.

Furthermore, PF is an important step by reducing wasted feed in the industry and reducing the cost for the farmer as less feed is lost. Feed is also the main contributor to CO_2 emission in aquaculture. Controlling the feed will therefore also reduce the CO_2 footprint.

The results from PF will be significant as the production will be more predictable and less risky, and potentially enable industry growth in CAS.

Method

A system for Precision Feeding (PF) and feeding according to appetite is under development. The technology is based on a patented camera-based sensor system mounted in the waste drain. The camera monitors feed waste, and the observations are interpreted to build predictive models and system simulations that can be used for regulation of feeding, either as decision support or as fully automated actuation.

Monitoring wasted feed in CAS can be a challenge as the color of the water can be dark and the number of particles and level of turbidity high. The camera-based sensor system for monitoring feed waste needs to operate under these challenging water quality environments. Under these conditions the camera needs to see the difference between feed and faeces. For that the camera needs to be highly light sensitive and the external light needs to have the correct wavelength and positioning (angle).

Several tests have been conducted in different experimental conditions, both in research recirculating aquaculture systems (RAS) with fish and in test labs without fish.

Results

The experimental systems were successfully achieved. The results are under investigation and will be presented at the conference.

Introduction

Plastic pollution is a global problem caused by an excessive use of this material, high resistance in environment and poor waste management. One of the most common type of plastic polluting the environment is polystyrene (PS), which commonly contains flame-retardant, hexabromocyclododecane (HBCD), in high percentage. In general, oral ingestion of MPs can cause mechanical damage and obstruction of digestive tract and particles < 600 µm are able to cross intestinal barriers, enter the blood stream and can be transported to tissues. While in vertebrates, the toxicity of HBCD has been extensively studied with discovered reproductive and developmental toxicity, neurotoxicity, mutagenicity, as well as endocrine disrupting effects, the mechanism of toxicity is not fully clarified in fish to date. This study was focused on the analysis of genes via gene expression, which will be the basis for further analyses.

Materials and methods

The experimental part of the study was carried out in accordance with Fish Juvenile Growth Test (OECD 215) in duplicate. A total of 144 *O. mykiss* juveniles were divided to control and groups exposed to 2%PS (in size 200-300 µm), 1%HBCD and mixtures of 2%PS+ 0.1%HBCD and 2%PS + 1%HBCD of daily feed intake. The experiment was terminated after six weeks. For gene expression analysis made by quantitative real-time polymerase chain reaction method, the samples of liver, skin and cranial intestine (n=10 per group) were processed according to Hodkovicova et al. (2021). Selected genes were interleukin 8 *(il8)*; catalase *(cat)* and cytochrome P450 1a3 *(cyp1a3)*.

Results and discussion

During the experiment lasting, the expression of *il8* decreased in the group exposed to 2%PS-MPs in the liver and cranial intestine (Figure 1).

Cytokine *il8* is produced mainly by monocytes to recruit neutrophils as well as trigger cytotoxic effect in site of infection. Hodkovicova et al. (2021) observed *il8* up-regulation in the liver and cranial kidney of rainbow trout exposed to polyethylene MPs. In this case, uncontrolled proliferation with potential to participate in chronic diseases can occur. Our study showed the opposite results, i.e. - *il8* down-regulation by 2%PS, which can affect the immune system by limitation of neutrophil function (Wang et al., 2017). This demonstrate the various effect of different types of MPs and need for further investigations. In addition, in liver tissue the expression of *cat* increased at 2%PS. In the skin, the expression of *casp3* increased in 2%PS + 0.1%HBCD, *cyp1a3* increased in 2%PS + 0.1%HB CD, also in 2%PS + 1%HBCD in compared to control. The results are expressed in figure 2.

Catalase is antioxidant enzyme and marker of oxidative stress that breaks down hydrogen peroxide into oxygen and water. Increased *cat* expression is likely a response to toxic stress triggered by PS-MPs and serve to neutralize the increased reactive oxygen species production (Kumari et al., 2014). Cytochrome 1a3 belongs to P450 superfamily of enzymes which catalyse oxidative, peroxidative, and reductive xenobiotic metabolism. In addition, combination of PS and HBCD caused up-regulation of *cyp1a3* in skin by which we hypothesize that molecular detoxifying mechanisms was activated (Bertucci et al., 2020). In summary, prolonged weakening of liver, intestine and skin can cause severe health disruption and increase fish mortality. Histopathological examination and analysis of oxidative stress will be made to verify our hypothesis for mechanism of toxicity provoked by PS and its common additive, HBCD.

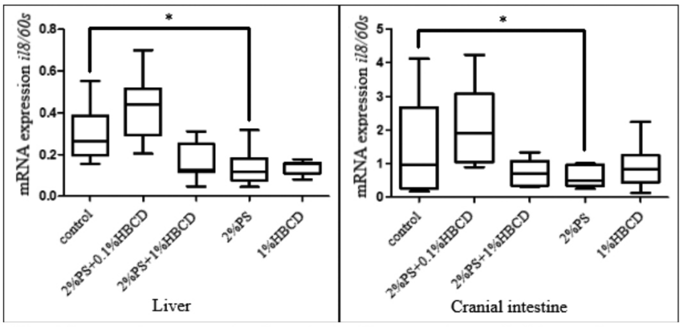

Figure 1. Significant decrease in the *il8* in liver and cranial intestine. Results with significance are marked with * ($p<0.05$).

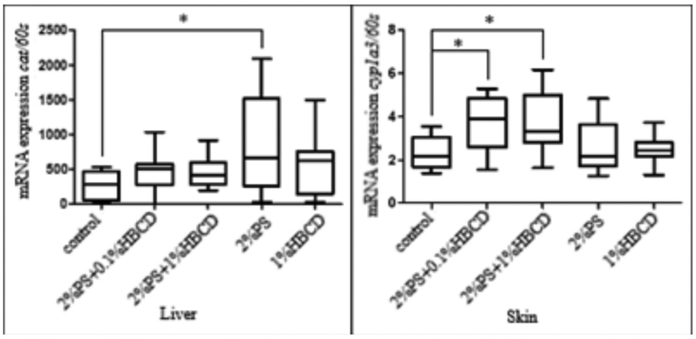

Figure 2. Significant differences in the expression of *cat* in liver *cyp1a3* in skin. Results with significance are marked with * ($p<0.05$).

Introduction

Epinephelus marginatus (Dusky grouper) is an endangered species with great potential for aquaculture in Brazil (Rodrigues-Filho et al., 2020). On the other hand, when kept in captivity, this hermaphrodite protogynous species presents reproductive dysfunctions, reducing the success of its large-scale rearing (Moreira et al., 2019). Nowadays, we are designing specific *primers* for this species to perform rtPCR and analyze the gene expression of the main components of the Hypothalamus-Pituitary-Gonads (H-P-G) axis to better understand the origin of these reproductive dysfunctions in captivity animals.

Material and Methods

In the present study, two groups were considered during the reproductive period and outside of the reproductive period: animals raised in captivity (G1 – as experimental group) and animals sampled from natural environment (G2 – as control group). Brain, pituitary, and gonads of fish from both groups at different moment were sampled for gene expression study. We analyzed the gene expression of brain aromatase (*cyp19a1b*), and the *gnrh* (three distinct forms), both in the brain; gonadotropins (*fshb* and *lhb*) were analyzed in the pituitary; and several genes involved in the sexual differentiation and steroidogenic pathway (such as, *sox9, dmrt1, amh, foxl2, 20β-hsd,* and *cyp19a1a*) were also analyzed in the gonads. Additionally, the genes *ef1α* and *cog5* were used as endogenous references for the analysis of the relative expression of target genes. The samples were processed to conventional PCR for DNA amplification of their respective target genes. Then, using primers developed and patterned for other species of *Epinephelus* genus, we sequence the DNA from PCR products by DNA Sequencing – SANGER. For brain (*gnrh* 1, 2, and 3 and *cyp19a1b*) and gonads (*sox9, dmrt1, amh, foxl2, 20b-hsd,* and *cyp19a1a*), we are designing by sequencing the DNA fragment that bounds to the primers and testing new specific primers for *E. marginatus*. Moreover, gonadotropins, *fsh* and *lh*, and *ef1a* have been already performed and apparently were specific for *E. marginatus* by our research group.

Results

It is expected that the results of this study will show whether the endocrine disruption observed in animals kept in captivity is due to changes in the gene expression of neurohormones, neurotransmitters, gonadotropins, and gametogenesis regulators, which coordinate the H-P-G axis. Additionally, these primers will be specific for this species, and it is the first time that they will be described for *E. marginatus*. In Figure 1 we presemt the first results of conventional PCR for these H-P-G gene target of *E. marginatus*.

Final considerations

Previous studies conducted by our research group suggest that *E. marginatus* presents reproductive dysfunction when kept in captivity (Rodrigues-Filho et al., 2020), mainly in the gonadal maturation of females. In these previous studies, it seems that dysfunctions in the gene expression of different targets of the H-P-G axis must occur, primarily in gonadotropins expression (Garcia et al., 2013). All this information is important to improve the artificial reproduction of *E. marginatus* through controlled breeding programmers, considering the threatened situation of this species, that requires immediate recommendations to be taken, to avoid the extinction of this important species. Additionally, these results may support future studies on Brazilian aquaculture of marine teleost species.

STARCH – AN ANTINUTRITIONAL FACTOR FOR YELLOWTAIL KINGFISH *Seriola lalandi*?

Introduction

Yellowtail kingfish (*Seriola lalandi)* is a fast growing fish species. One of the challenges of farming yellowtail kingfish in recirculating aquaculture systems (RAS) is their poor faecal quality, also referred to as 'diarrhoea-like' faeces. Poor faecal quality hampers the faecal solid removal, causing high concentrations of total suspended solids (TSS) in the water. This affects the animal health, system performance and environmental eutrophication negatively (Reid et al., 2009). A study with juvenile white sturgeon (*Acipenser transmotanus*) by Hung et al. (1990) implies that starch level can negatively affect osmolality, water reabsorption and thus potentially faecal characteristics. Therefore, the current study investigated whether the inclusion of starch induces a poor faecal quality in yellowtail kingfish. This was done by comparing faecal quality and production of yellowtail kingfish fed diets varying in starch inclusion and diet type.

Materials and Methods

The effect of starch inclusion (0% // 20% gelatinized wheat flour) on faecal waste production and quality of yellowtail kingfish was investigated for two diet types (marine // plant-based) over a 36-day experimental period. Diets were formulated according to a 2 × 2 factorial design. Each dietary treatment was tested in three replicate tanks, which were stocked with 21 yellowtail kingfish (mean initial weight 53 g). Fish were fed restrictively ($23.75\ g/kg^{0.8}$, expected FCR 0.9) twice a day. For each tank, nutrient digestibility and faecal recovery by settling was measured.

Results

Both the inclusion of starch and plant-ingredients negatively affected the nutrient digestibility, thus resulting in an increased faecal waste production (g organic matter/kg feed intake) ($p < 0.001$; Figure 1a). The faecal quality of yellowtail kingfish fed 0% starch diets was not poor (not-diarrhoea-like; Image 1) as fish excreted faecal pellets and short strings. However, faecal waste collected from fish fed 20% starch diets was classified as diarrhoea-like. Fish fed the 0% starch diets had the highest faeces recovery (%) by settling compared to the diets without starch inclusion ($p < 0.001$; Figure 1b). Consequently, the non-recovered amount of faeces (g organic matter/kg feed intake) at the 0% starch diets was on average 65.5% lower compared to the 20% starch diets ($p < 0.001$, Figure 1c).

Conclusion

Excluding starch from the diet of yellowtail kingfish reduced the faecal waste production and improved quality (not diarrhoea-like), ultimately resulting in a lower amount of non-recovered faeces compared to 20% starch diets. Thus, excluding starch from yellowtail kingfish diets will result in a reduced TSS load in RAS, ultimately improving animal welfare, system performance and reducing the environmental eutrophication. Moreover, this findings offer new possibilities for other finfish species with a poor faeces quality such as Atlantic salmon (*Salmon salar*).

Results

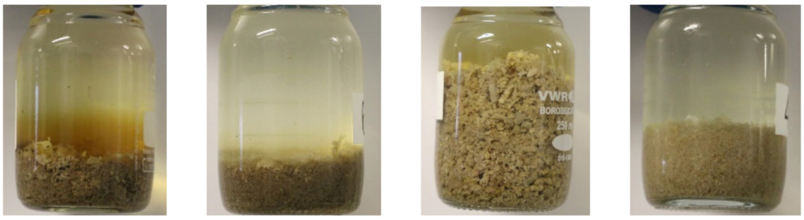

Image 1. *Collected faeces of yellowtail kingfish fed the marine 0% starch, marine 20% starch, plant 0% starch and plant 20% starch diets (left to right) restrictively for 36 days.*

Introduction

The need for conservation of genetic resources of fish leads to a continuous development of methods in reproduction. Cryopreservation of gametes offers a solution for the long-term preservation of these resources. In fish, however, only sperm can be cryopreserved which puts the application of these methods in disadvantage. To overcome this problem, a set of methodologies have been developed for the cryopreservation and transplantation of germline stem cells (GSCs) such as spermatogonia and oogonia for the surrogate production of gametes (Yoshizaki et al., 2011). In the present work, we describe the results of 7 years of experiments on the cryopreservation and interspecific transplantation of salmonid GSCs.

Materials and Methods

The studies have been carried out in Slovenia and Hungary. Brown trout (*Salmo trutta m. fario*), grayling (*Thymallus thymallus*) and rainbow trout (*Oncorhynchus mykiss*) were used as donors of GSCs whereas the hybrid tiger trout (*S. trutta m. fario* × *Salvelinus fontinalis*) as well as diploid and triploid rainbow trout were used as recipients.

Brown trout ovarian tissue was vitrified in varying concentrations of methanol, dimethyl-sulfoxide (DMSO) and propylene glycol (PG). Isolated GSCs of brown trout and grayling were transplanted into diploid and triploid rainbow trout larvae whereas those of the rainbow trout were transplanted into larvae of the hybrid tiger trout. Colonization of the recipient gonads as well as incorporation of donor-derived GSC-s was verified using fluorescent microscopy, molecular biology and histology.

Results

Vitrification of salmonid ovarian tissue using needle-immersed vitrification (NIV) on acupuncture needles using 3 M DMSO and 3 M PG as cryoprotectants resulted in up to 40% survival of cells and qualitatively and quantitatively unaltered follicles (Lujić et al. 2017). Transplantation of brown trout and grayling GSCs into diploid rainbow trout recipients resulted in successful colonization of 26-28% of the recipient gonads. This was verified by fluorescent microscopy and the presence of donor-specific molecular markers 2 months post-transplantation (Lujić et al. 2018). In the trials using the hybrid tiger trout as a recipient, one male individual has reached sexual maturity 22 months post-transplantation and produced sperm that was used to fertilize rainbow trout eggs. The resulting progeny was verified to be 100% rainbow trout using sequencing of species-specific DNA fragments. On the other hand, hybridization resulted in very high mortalities (up to 95%).

Transplantation of brown trout and grayling spermatogonia into triploid rainbow trout recipients was conducted in the form of 3 independent trials in Slovenia and Hungary. The recipients failed to reach sexual maturity and were sacrificed 3 years post-transplantation. Their gonads were underdeveloped and typical of triploid fish. Brown trout- and grayling-specific fragments of the mitochondrial DNA control region, however, were amplified in all three trials in the gonads of several recipients.

Discussion

The results of our studies have shown the importance of finding the appropriate combination of donor and recipient in salmonids. It is clear that brown trout and grayling GSCs were capable of colonizing the gonads of rainbow trout recipients, however, in triploid individuals they remained in a dormant or semi-dormant state and did not undergo gametogenesis. Our findings are in contrast with those of Hattori et al. (2019) who were able to obtain donor-derived sperm and eggs from triploid rainbow trout recipients following transplantation of Atlantic salmon (*Salmo salar*) spermatogonia. The hybrid tiger trout was able to produce donor-derived sperm, however, its use as a recipient was compromised by the high mortality of the hybrids. In addition, some tiger trout males are known to produce sperm which further complicates their utility as recipients.

IMPACTS OF CLIMATE CAUSED SALINITY INSTRUSION ON EARLY DEVELOPMENT AND GROWTH PERFORMANCE OF STRIPED CATFISH

Farzana Hossain* & Md Shahjahan

Laboratory of Fish Ecophysiology, Department of Fisheries Management, Bangladesh Agricultural University
Mymensingh-2202, Bangladesh
E-mail: farzana29828@bau.edu.bd

Introduction

Climate changes induced salinity intrusions in the coastal areas are cause for serious concern in tropical and subtropical countries (Rabbani et al., 2013). Efficient management of brackish water environments is needed to overcome the climate-caused obstacle. Striped catfish (*Pangasianodon hypophthalmus*) is a popular freshwater aquaculture species. Its growth rate is high and grows well in higher density and this fish can survive in a wide range of environmental conditions. Embryos and larvae are very sensitive to any changes during all stages of fry production (Akitas et al., 2004; Shahjahan et al., 2017; Rahman et al., 2020; Ashaf-Ud-Doulah et al., 2021). So it is important to examine the influence of salinity on embryonic and larval specimens to understand the likelihood of survival, growth, and physiological stability of this species throughout their life cycle in coastal aquaculture systems. The present investigations may provide insights into the optimum salinity level for successful egg incubation and early development, which might be helpful to produce fingerlings in brackish water for the sustainable coastal aquaculture of this species and can potentially be used as a candidate species for aquaculture in slight brackish water areas of Bangladesh as it can tolerate definite range of salinity.

Materials and methods

Striped catfish embryos and larvae were exposed to seven salinities (0, 2, 4, 6, 8, 10 and 12 ppt) in triplicate. Fertilized eggs (n= 300) and larvae (n=300) were exposed in different salinities. The number of dead embryos and larvae were counted at 24 hour and 48 hour of salinity exposure respectively. Hatching rate and larval mortality were recorded. Malformations of embryo and larvae were observed under digital microscope and images were snapped. To know the salinity effects on growth performance of striped catfish (*Pangasianodon hypophthalmus*) firstly, median lethal concentration (LC_{50}) of salinity for striped catfish was determined and then the fish were exposed to three salinity conditions (4, 8 and 12‰) and a control (0‰). Fish were counted and weighed at 7, 14, 28, and 56 days after start of salinity exposure. Growth performance and feed efficiency were determined by evaluating a number of growths and nutrient utilization indices, such as, weight gain, percent weight gain, specific growth rate (SGR) and feed conversion ratio (FCR).

Results

A considerable survivability of embryos was recorded up to 6 ppt. Mortality of embryos significantly increased at 8 and 10 ppt and 100% mortality was displayed within 12 h of exposure at 12 ppt. The rate of hatching was significantly reduced at 8 and 10 ppt. Different types of deformities were highest at 10 ppt. Similar to embryo, a considerable survivability of larvae was recorded up to 6 ppt and 100% mortalities were found within 24 h of exposure at 12 ppt and deformities were highest at 10 ppt after 48 h of exposure (Figure 1). Within 24 h of exposure about 80% yolk-sac of the larvae was absorbed at 8 and 10 ppt while 30-50% yolk-sac was absorbed at 0 to 6 ppt. Growth rates in terms of length and weight were higher at 0, 2 and 4 ppt, and moderate at 6 and 8 ppt. Salinity levels from freshwater to 8‰ showed optimal conditions with high survival rate and good growth performances of fish in terms of weight gain and specific growth rate (SGR). Interestingly, the lowest food conversion ratio (FCR) was found in 4‰ group.

Conclusion

Salinity is among the most important environmental factors that influence the physiological processes of aquatic organisms. Overall, the current findings define the limits in order to optimize hatchery procedures for culture of this species in low saline brackish water and revealed that striped catfish might be suitable fish species for culture in the brackish water containing salinity up to 10‰.

EFFECTS OF MULTI-SPECIES PROBIOTICS ON GROWTH AND GUT HEALTH OF NILE TILAPIA

Md Kabir Hossain* & Md Shahjahan

Laboratory of Fish Ecophysiology, Department of Fisheries Management, Bangladesh Agricultural University
Mymensingh-2202, Bangladesh
E-mail: kabir39284@bau.edu.bd

Introduction

Aquaculture is considered as one of the most competitive and promising sectors for providing income and nutritional security to human, as demand for animal protein from fish is growing globally (Mohapatra et al., 2012)T 2 (BF+Bacillus subtilis and Lactococcus lactis. Although the sector has achieved remarkable improvement, in recent time the income of this field is declining because of huge feed costs that account for over 70% of total production expenses (Hossain et al., 2020, Nguyen et al., 2020). Use of probiotics may be an ideal approach for better feed utilization and growth enhancement in fish reducing the feed cost as well as substituting use of antibiotics (Allameh et al., 2017). Thus, the goal of this study was designed to see the effects of multi-species probiotics in water on the growth, and intestine, liver and muscle morphology in the Nile tilapia.

Materials and Methods

Tilapia fingerlings (5.95 ± 0.07 g) were stocked and evenly distributed into three replicates separated into three treatment groups, each providing probiotics at concentrations of 0, 0.5 and 1.0 mL/L in water for 8 weeks. After completion of the trial, growth factors (weight gain, % weight gain, specific growth rate, hepato-somatic index, and viscera somatic index), feed utilization parameter (feed conversion ratio), gut microbiota, and intestinal, liver and muscle morphology were examined.

Results

The experiment revealed dramatic growth and feed utilization in the fish reared with multi-species probiotics compared to control group. Total viable count (TVC) and total lactic acid bacteria (LAB) count increased substantially in the fish gut provided with multi-species probiotics. The morphological improvement of intestine includes increased intestinal length, width, and area of the villi, lamina propria and abundance of goblet cells were observed in the probiotics treated fish (Figure 1). The livers of treated fish showed irregular shaped nucleuses turned into regular shaped and reduced spaces between liver tissues. Increased number of nucleus, diameter of muscle fiber, hyperplastic muscle fiber was also found from morphological observation from the multi-species probiotics applied fish compared to control group. The study indicates administration of multi-species probiotics can be an important growth promoter for Nile tilapia.

Conclusion

Multi-species probiotics administration in water demonstrated supreme growth and feed utilization of Nile tilapia through enhancing gut microbial content, and gut, liver and muscle morphology. Further investigation on probiotic is required to know the relative expression level of muscle developmental related genes, different enzymatic activity, disease resistance and which types of response is occurred due to probiotic exposure on host species. Furthermore, which types of bacterial strain are responsible for specific improvement for specific organ is needed for multi-species probiotic.

THE CASE FOR LAND-BASED BIVALVE FARMING

Broderick J. House*[1,2], David Willer[1,2], David Aldridge[1,2]

Department of Zoology[1], University of Cambridge, UK[2]

David Attenborough Building, Pembroke St, Cambridge, UK CB2 3QZ
Bjh63@cam.ac.uk

Abstract

Current estimations suggest that over 2 billion people world-wide suffer from a micronutrient deficiency (MND), which may increase with global population size, unless current food practices change. As agricultural land is limited, and common farming practices have had detrimental consequences over the years on the environment and human health, the development of novel farming techniques has become vital. A novel onshore aquaculture approach for marine bivalve molluscs offers considerable promise for easing these global challenges. Here we explore their potential value to food security by comparing oyster, mussel, and clam nutrient profiles against top Finfish, Crustacea, and agricultural livestock nutrient profiles; reveal the gap for onshore marine bivalve farming; and set the grounds for the development of urban sourced marine bivalve aquaculture, which promises to address MNDs whilst mitigating the current human health risks associated with consumable bivalves.

Global Bivalve Production is Not Represented in Landlocked Regions

Mapping global bivalve edible weight (Figure 1) from the latest FAO fisheries and aquaculture report, 2022, reveals production of livestock is less than 1 Mt in landlocked countries. With current marine bivalve aquaculture being limited to coastlines, this confirms that there is untapped farming potential onshore within geographical locales where no coastal farming is possible. If marine bivalves are to deliver on their promise of being blue foods capable of addressing current global food security challenges and MNDs, then urban aquaculture must adapt to support the growth of marine bivalves for their ultimate consumption and possible remediation for the proportion of the population they currently do not reach. However, to allow such a system to be viable, there must also be high gross margins which are led by consumer demands. For this reason, the top produced mussel, oyster, and clam were also identified (Figure 1) to allow for an understanding of what bivalve livestock would be best to rear within an urban marine bivalve aquaculture facility.

Potential for Urban Aquaculture of Marine Bivalves

The development of a marine bivalve aquaculture system that could be implemented within the city environment, without the need for the ocean, would allow marine bivalve production to be expanded. This expansion would not only bring with it the introduction, and increased availability of a highly nutritious food source to currently excluded geographical locales (Figure 1), but such a system could also bring many benefits including MND amelioration, increased food safety, production of high value by-products, poly-culture, and the foundation to expand marine onshore aquaculture as a whole (Figure 2). However, inputs such as electricity, feed, and maintenance for an onshore facility could result in higher start-up and overall costs compared to current marine bivalve farming, which is solely ocean based (Figure 2). Though, with the development of such a system, there also comes the need for optimization to help unlock its benefits while keeping costs as low as possible for both the facility and consumer.

Conclusion & Future Directions

The present work reveals a large gap in global geographic access to fresh marine bivalves, and thus their promising role in addressing current population MNDs as well as being a highly nutritious food source. The development of a novel urban marine bivalve aquaculture system will not only set the groundwork for its translational use towards addressing global food security, but also aid in addressing fundamental questions that are still unknown in bivalve mariculture, and MND reduction within the human population.

Future work includes optimizing bivalve growth, decreasing bivalve related health hazards, optimizing sustainable feed, and expanding micronutrient fortification capabilities within an artificial setting. Elucidation of these methods will make possible the development of scalable technologies that will allow onshore urban marine bivalve aquaculture to gain consumer trust around bivalve consumption and deliver the nutritional promises marine bivalves have to offer.

(Continued on next page)

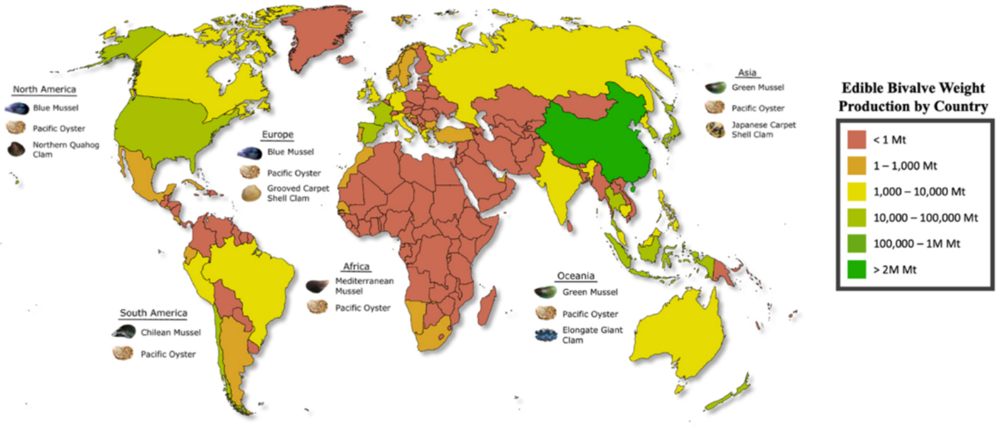

Figure 1: **Global production of edible bivalve meat and top produced oyster, mussel, and clam species.** Mapping of global edible bivalve production suggests landlocked regions and extreme temperatures lower bivalve production. Analysis of production for oysters, mussels, and clams based on continent shows ubiquitous production of the pacific oyster, with the top mussels being the green and blue mussel, and no consistent species of clam.

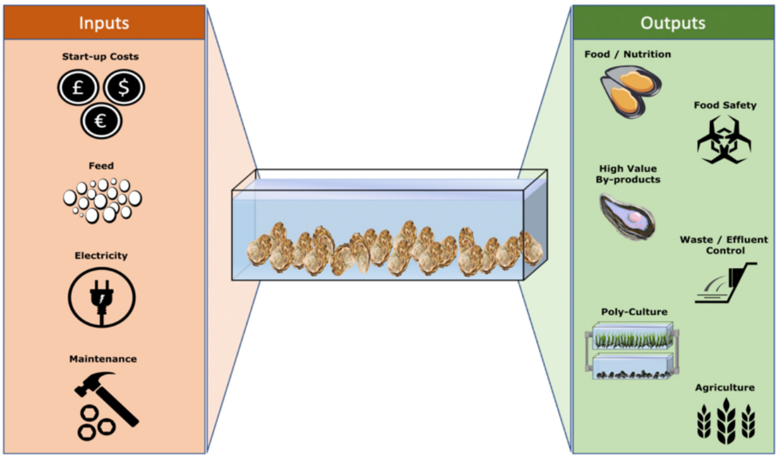

Figure 2: **Urban marine bivalve aquaculture schematic**. Development of a marine aquaculture system that can rear marine bivalves to market size requires a full understanding of the inputs required, compared to its outputs. Though there are many outputs compared to the designated inputs, the revenue produced by identified outputs must be larger than the cost of the inputs if such a system is to be successful at being a disruptive solution.

IMPACTS OF DIETARY C/N RATIOS ON WATER QUALITY IN RECIRCULATING AQUACULTURE SYSTEMS

Xiaoyu Huang*, Sanni Leea Aalto, Johanne Dalsgaard, Per Bovbjerg Pedersen

Introduction

In recirculating aquaculture systems (RAS), good water quality needs to be maintained to ensure fish health and stable production. However, to fulfill the nutrient requirements of fish in different life stages, the proportions of carbohydrate, lipid, and protein in fish feed are continuously adjusted, which leads to different dietary C/N ratios. As fish waste excretion to some extend reflects the feed content, the amounts of C and N compounds sustained in water is expected to change as well. Indeed, dietary and water N contents are positively correlated in RAS (Godoy-Olmos et al., 2022), while the relationship between dietary and water organic matter (C) has not been examined. Undigested and non-retained dietary C and N, acting as macronutrients for microbes present in RAS, might potentially affect microbial water quality (abundance, activity, and community composition). Elevated C/N ratios in water caused compromised nitrification performance and unbalanced microbial communities in lab-scale biofilters (Michaud et al., 2014). Currently, the effects of dietary C/N ratios on water quality in RAS are still poorly understood. Such knowledge would provide foundation for cost-effective water management. The aim of this study was therefore to investigate the impacts of dietary C/N ratios on RAS water quality and microbiology at both biofilter and system levels.

Materials and Methods

COD was used as the proxy for organic carbon. By altering the proportions of protein, carbohydrate, and fat, four diets with different COD/N ratios (22.7, 24.7, 26.6, and 32.5) were formulated and termed LO (low), ML (medium-low), MH (medium-high), and HI (high) (Table 1). An 8-week trial was conducted in triplicate pilot-scale RAS situated at DTU Aqua, Hirtshals, Denmark. Each system consisted of a 500 L tank stocked with 7.31±0.04 kg of juvenile rainbow trout (*Oncorhynchus mykiss*), a moving bed biofilm reactor (MBBR) (75 L), and a pump sump (140 L). The fish in each RAS was fed 100 g/day with water renewal rate of 60 L/day (make-up water). Water samples were collected from the sump every other week, samples of biofilter elements were obtained at week 1, 4, and 8, and fecal samples were obtained by the end of the trial.

Results and Discussion

By the end of the trial (averaging weeks 6-8), the HI diet resulted in significantly lower system concentrations of nitrite (0.03±0.01 mg N/L), particulate organic matter (BOD_5, 4.89±1.16 mg O_2/L), abundance of particle-associated microbes, and microbial catalytic activity (H_2O_2 degradation k-value, 0.54±0.16/h), as well as better water clarity (9.23±2.15 NTU) than the other diets.

Overall microbial community structures in biofilter and system water did not differ between treatments, however, ammonia-oxidizing bacteria (AOB) were less abundant in biofilters with the HI diet than those with the other diets. The reduced AOB abundance was probably due to the reduced N excretion from the HI diet, leading to less substrate for nitrifying bacteria. Biofilm communities have been found to be less influenced by environmental changes such as water treatment (e.g. foam fractionation) (Aalto et al., 2022) and increase in organic carbon (Michaud et al., 2014).

Fecal COD/N ratios were subjective to dietary ratios (Table 1), which was in line with Letelier-Gordo et al. (2015). However, dietary and RAS water COD/N ratios did not correlate, mainly because water organic matter did not respond to dietary COD. Since water C/N ratios can affect nitrification performance and system microbiology, diets should be tested in RAS to examine the resulted nutrient ratios in water.

Table 1. C/N ratios of diets, water (n=6), and feces (n=3) (mean ± standard deviation): Kjeldahl N in feeds and feces, and total dissolved N in water. All units are mg O_2/mg N. Lowercase letters indicate statistical differences from the other groups.

Parameter	LO	ML	MH	HI
Dietary COD/N	22.7	24.7	26.6	32.5
Water BOD_5/N	0.11 ± 0.02^{b}	0.18 ± 0.06^{a}	0.17 ± 0.07^{ab}	0.11 ± 0.02^{b}
Water COD/N	0.72 ± 0.12^{b}	0.95 ± 0.18^{ab}	1.02 ± 0.17^{a}	0.83 ± 0.09^{ab}
Fecal COD/N	27.90 ± 1.67^{b}	35.45 ± 2.10^{a}	33.00 ± 2.09^{ab}	37.75 ± 3.29^{a}

(Continued on next page)

Conclusion

This is the first study to investigate the impacts of different dietary C/N ratios on RAS water quality. Based on the results, dietary C/N ratios could affect physicochemical water quality, microbial activity, and abundance of particle-associated microbes, while microbial community composition in system water and biofilter biofilms were not affected. Dietary and water C/N ratios did not correlate, probably because organic matter was used or incorporated in the biofilm.

Recirculating aquaculture systems (RAS) have lower water consumption and lower nutrient discharge to the environment than the traditional flow-through systems, making them environmentally sustainable fish-producing systems. However, waste management still need to be improved to reduce environmental impact. Partial nitrification combined with anammox (PNA), which combines the anammox with the partial nitrification, is currently applied for nitrogen removal from wastewater with very high concentrations of TAN, and is characterized by reduced requirements for aeration, no need for addition of carbon source, lower sludge production. In this study, we investigate the potential for adapting the PNA process to RAS relevant conditions with low TAN concentrations, to seek out an economical atlernative to solve the nutrient discharging problem of RAS. A continuous PNA moving-bed bioreactor (MBBR, 14L) was started up by applying active AnitaMox carriers, which originated from wastewater treatment plant treating wastewater with approximate 1000 mg TAN and 3000 mg COD per liter. The PNA-MBBR was fed with synthetic water (10 mg/L TAN and 15 g/L COD,) with a hydraulic retention time of 2 days at 20□. The PNA-MBBR showed an efficient nitrogen removal ability after around 4 weeks adaption. The TAN removal rate gradually increased from around 40% (week 5-week 10) to around 75% (week16-week 23) . After decreasing the inlet TAN to 5mg/l, the TAN removal rate has been stable around 90% for 6 weeks with an outlet concentration of TAN at below 0.1mgl/L (0.08±0.03mg/L). No nitrite accumulation was observed during the whole trial. This experiment demonstrated that the PNA process can be applied for removal of nitrogen at RAS relevant TAN concentrations. Bacterial and archaeal biofilm microbiomes of bio-carriers will be characterized by high-throughput DNA sequencing of 16S rDNA amplicons, and the results will be presented at Aquaculture Europe 2022.

UTILISING SALMOSIM, AN IN-VITRO SIMULATOR OF THE GUT OF ATLANTIC SALMON *Salmo Salar* TO ASSESS A MANNAN PREBIOTIC FOR FERMENTATION INTO VOLATILE FATTY ACIDS BY THE SALMON MICROBIOME

J. L. Humble*, R. Kazlauskaite, C. Heys, J. Sweetman, P. Lyons, S. Connelly, W.T. Sloan, M. S. Llewellyn

Introduction

The aquaculture industry is rapidly expanding and is challenged with improving the gastro-intestinal health of farmed salmon in the face of disease outbreaks and issues arising from novel aquafeed formulations. Prebiotics are non-digestible food additives that improve gut function and overall health by stimulating the growth of commensal microbial species. Mannan oligosaccharide (MOS) prebiotics are known to improve the gut morphology of rainbow trout by modulating microbial communities[1]respectively. The control treatment consisted of a standard commercial diet, and the MOS treatment consisted of the control diet supplemented with 0.2% MOS. Morphology of the anterior and the posterior intestine was examined with light and electron microscopy. Light microscopy demonstrated increased gut absorptive surface area in the subadult MOS group. Additionally, electron microscopy revealed an increase in microvilli length and density in the subadult MOS group compared with the control (P < 0.05. Volatile fatty acids (VFAs), the end products of anaerobic fermentation of non-digestible fiber, are known to exert multiple functional benefits on the host such as maintenance of intestinal barrier integrity[2]. Recently, we presented an *in-vitro* gastrointestinal tract model of the farmed Atlantic salmon called SalmoSim[3]welfare, and the environmental sustainability of the aquaculture industry. There is still a lack of knowledge surrounding the importance and functionality of the teleost gut microbiome in fish nutrition. In vitro gut model systems might prove a valuable tool to study the effect of feed, and additives, on the host's microbial communities. Several in vitro gut models targeted at monogastric vertebrates are now in operation. Here, we report the development of an Atlantic salmon gut model, SalmoSim, to simulate three gut compartments (stomach, pyloric caecum, and midgut. We demonstrated that the major genera from the salmon gut can be maintained within *in-vitro*, and the microbial community composition and nutritional biochemical products proliferate in SalmoSim as they do in real fish when faced with a changes in diet[3]welfare, and the environmental sustainability of the aquaculture industry. There is still a lack of knowledge surrounding the importance and functionality of the teleost gut microbiome in fish nutrition. In vitro gut model systems might prove a valuable tool to study the effect of feed, and additives, on the host's microbial communities. Several in vitro gut models targeted at monogastric vertebrates are now in operation. Here, we report the development of an Atlantic salmon gut model, SalmoSim, to simulate three gut compartments (stomach, pyloric caecum, and midgut. Here we deploy SalmoSim to assay BioMOS (a commercially available prebiotic) for production of VFAs by anaerobic fermentation.

Method and materials

SalmoSim is comprised of bioreactors where physical and biochemical parameters (pH, oxygen levels, temperature, peristaltic flow rate and addition of biofluids) are maintained to ensure similarity with the gut compartments of real salmon[3]welfare, and the environmental sustainability of the aquaculture industry. There is still a lack of knowledge surrounding the importance and functionality of the teleost gut microbiome in fish nutrition. In vitro gut model systems might prove a valuable tool to study the effect of feed, and additives, on the host's microbial communities. Several in vitro gut models targeted at monogastric vertebrates are now in operation. Here, we report the development of an Atlantic salmon gut model, SalmoSim, to simulate three gut compartments (stomach, pyloric caecum, and midgut. Here, the microbiomes of pyloric caeca of adult farmed Atlantic salmon were sampled and pre-grown for 20 days to establish stable communities. A sterilized solution of ground fish meal was pumped through a bioreactor simulating the stomach then pumped into three bioreactors simulating the pyloric caeca. The pre-grown microbial communities of three salmon were inoculated into the pyloric caeca bioreactors and subjected to an static growth period of four days, followed by continuous flow pre-treatment phase of 5 days, then a 20 day BioMOS treatment phase, and finally a wash out phase of 6 days (Fig 1). Samples were taken at three time points during each phase (nine sampling time points in total).

Thirty milliliters of digest culture was taken and centrifuged at 5000 rpm for 10 minutes. The supernatant was filtered through the Costar SpinX centrifugation tube filter and VFAs were analysed by gas chromatography at MS-Omics (Denmark). A linear mixed effect model was used to determine if VFA concentrations were statistically different between the phases. The pelleted material was subjected to DNA extraction and next-generation sequencing as described previously[3]welfare, and the environmental sustainability of the aquaculture industry. There is still a lack of knowledge surrounding the importance and

(Continued on next page)

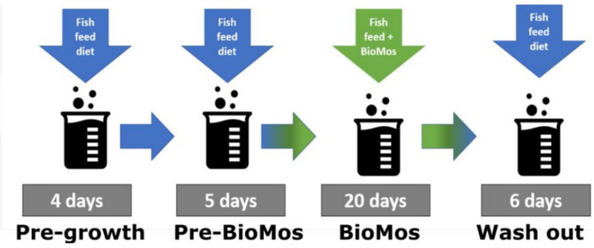

Figure 1. Visual representation of the phases of MOS prebiotic inclusion in fermentation.

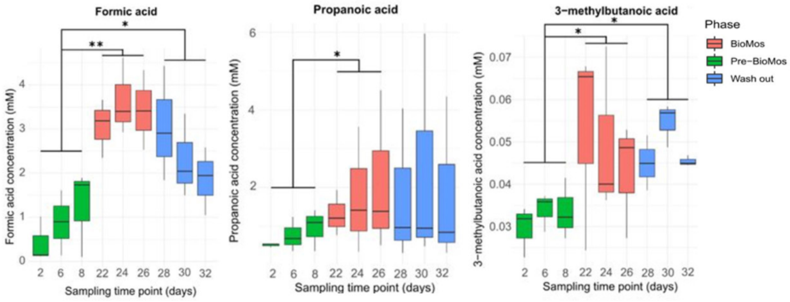

Figure 2. VFA response in SalmoSim pyloric caeca to MOS addition and washout

functionality of the teleost gut microbiome in fish nutrition. In vitro gut model systems might prove a valuable tool to study the effect of feed, and additives, on the host's microbial communities. Several in vitro gut models targeted at monogastric vertebrates are now in operation. Here, we report the development of an Atlantic salmon gut model, SalmoSim, to simulate three gut compartments (stomach, pyloric caecum, and midgut using Illumina HiSeq amplicon sequencing of the 16S V1 rDNA locus. Pearson correlation coefficients between the operational taxonomic units and concentrations of VFAs were calculated.

Results

Inclusion of the MOS increased the concentrations of the VFAs formic acid (p=0.001), propionic acid (p=0.037) and 3-methylbutanoic acid (p=0.024) whose levels correlated with increasing abundances of principally anaerobic microbial genera (*Fusobacteria, Agarivorans, Pseudoalteromonas, Myroides*). Concentrations of the VFAs 2-methyl-propanoic acid, butanoic acid, sulfurous acid, pentanoic acid, 4-methyl-pentanoic acid, hexanoic acid and heptanoic acid were unchanged by the inclusion of MOS.

Discussion

Here we assess a commercially available MOS prebiotic's effect on the production of nutritionally important VFAs by microbial flora native to farmed Atlantic salmon pyloric caeca. Interestingly, we found the MOS stimulated the production of formic acid, salts of which are often supplemented into the diets of farmed pigs to promote growth and protect from pathogens[4]. Dietary sodium propionate has also been shown to increase weight gain, increase carcass protein content and modulate immune function in European seabass[5]. Our results indicate BioMOS is a credible candidate prebiotic capable of promoting the synthesis of beneficial VFAs via the farmed salmon's native gut flora and our NGS sequencing results select genera of bacteria associated with increases in VFA production.

THE CAUSES OF STURGEON POPULATION DECLINE, IN LOWER DANUBE

T I Ionescu, I V Petrescu-Mag

Faculty of Management and Technological Engineering, Doctoral School of Engineering Sciences Oradea University, Oradea, Romania
E-mail: tudor.ionescu@sturgeons.eu

Introduction

The special importance of Danube River is given by the fact that it represents the habitat for 6 of 26 sturgeon species: Beluga Sturgeon (Huso huso), Russian Sturgeon (*A gueldenstaedtii*), Starry Sturgeon (*A. stellatus*) and European Sturgeon (*A. sturio*), Sterlet sturgeon (*Acipenser ruthenus)* and Ship Sturgeon (*A. nudiventris*). All these species are critically endangered or some of them even probably extinct from Danube and Black Sea. Worldwide, the captures of sturgeon had the same drastic decreasing trend in the last century, as in Romania. In 1978 the fished quantity worldwide reached at 32 thousand tonnes and in 2016 decreased to only 2.2 thousand tonnes (FAO, 2018; Ionescu, 2019).

Materials and methods

The data related to the sturgeons commercial catches of are very few, we found data in old books, difficult to obtain and in database archives that are not available online. We studied and analyzed in 3 years all the specific literary sources but also the fishery databases and we found valuable data about Romanian sturgeon fishery, which have scientifically processed and interpreted, resulting very pertinent conclusions.

Results

In the seventeenth century, near Silistra (Danube, km 375), every day were caught 70 big beluga, (Decei, 1976) and, in comparation, in the year 2004, in all Romania, were commercial caught only 100 specimens. Analysing the commercial catches data, we can conclude that after a century, the Russian sturgeon commercial catches decreased with 99.7%, from 10 570 specimens (145 000 kg) in 1903–1904 to only 28 specimens (555 kg) in 2003–2004. In the case of the Beluga sturgeon, the number decreased with 97%, from 4 254 specimens (230 000 kg) in 1903–1904 to just 111 specimens (11060 kg) in 2003–2004 (Antipa, 1909; Manea, 1980; MPADR, 2006; Ionescu, 2019). The situation is also confirmed by caviar production, quantity decreased from 17 tonnes/year to 3.4 tonnes exported/average/year (Daia, 1926; FAO, 2018; Ionescu, 2019).

The Danube sturgeon population was affected by many factors like: overfishing, habitat loss, poaching, spawning site alteration, pollution, dikes, chemical changes of Danube stream water, alien species etc. We analysed the first three causes because we consider them to be the most important, with clear evidence.

Sturgeons commercial fishing, that was practiced in the last centuries without a sustainable vision, directly affected the sturgeon spawners and subadults. This was possible because of the legislation gap, due to which this activity turned into overfishing. As an example, from 1896 to 1974, the Romanian legislation stipulated too small minimum catch size of sturgeons.

For Beluga sturgeon the minimum catch size, regulated by law from 1896, was 100 cm (approx. 5–6-year-old) standard length and in 1974 increased to 170 cm. Analysing commercial catch data, it appears that before 1974, for 80 years, more than 80% of beluga caught commercially, were sub-adults (Beluga sturgeon reaches sexual maturity at an average age of 15 years). For Russian sturgeon, the minimum catch size, regulated by law from 1896, was 80 cm (approx. 6-year-old), after 80 years increased to 140 cm. Analysing the same data, in the case of this species, over 50% specimens, caught commercially, were sub-adults (Russian sturgeon reaches sexual maturity at an average age of 13 years).

Reaching sexual maturity is a primary condition of the species to ensure a sustainable population and this type of overfishing has produced consequences that is difficult to recover.

Habitat loss by blocking migration corridors and destroying the spawning sites is the second major cause that has directly affected the Danube Sturgeons. On Danube River the biggest obstacle for sturgeons is the Iron Gates I (1972) and Iron Gates II (1984) dams. The construction of the IG I (Km 942) and IG II (Km 863), blocked the migration corridor, reducing the migration with 64 %.

Iron Gates it wasn't just a crossroads for sturgeons, there were the best spawning sites, which now are permanently lost (IG I dam accumulation lake). In 1726, Marsigli describes that in the Iron Gates area, 50–100 Beluga were caught every day, near Adakaleh Island (Marsigli , 1726). Antipa also described that sturgeon are mainly reproduced in the Iron Gate cataract. At the beginning of the twentieth century, in spring, fishermen caught in this area very largest specimens of sturgeons, with a lot of amounts of caviar (Antipa, 1909).

The first and only complete study of benthic fauna from Danube cataract (km 955-1042) was realised between 1958-1960 (Popescu & Prunescu, 1961). The structure of the substrate, in this sector, was composed of boulders, gravel, coarse sand, fine sand to muddy-sandy. This structure is the ideal substrate for sturgeons spawning grounds but also for hatching, pre-development and sturgeon growth in the early stages. For example, beluga fingerlings switch to active feeding at the size of 2-4 cm and in the first stage the main food consists of tubular worms. After 3-5 cm, gammarids begin to appear in the food structure after 8 cm the larvae of chironomids and fish (Leonte, 1959). The structure of the benthos was composed by tubular worms, Gammaridae and Chironomide larvae (Popescu & Prunescu, 1961). There were many spawning sites in this area but there was also a nursery for sturgeon fingerlings, before migrating downstream to the Black Sea. Loss of these sites directly affected natural productivity and is a major cause of sturgeon populations decline, which is unfortunately irreversible.

The third major cause is poaching, which continues to cause losses of Danube Sturgeons wild populations. The poaching phenomenon was encountered in Romania, especially after the fall of communism, when the chaotical transition allowed illegal fishing and trade. The poaching persisted also after 2005, when the Romanian law banned the sturgeon fishery, and it has become more complex and harder to stop. Most of those who catch sturgeons illegally are commercial fishermen, targeting other species (eg carp), but, intentionally or not, bycatch sturgeons, because the fishing gear and method are the same. It is hard to identify this activity because they have all the legal documents for commercial fishing, transformation into poachers is made by keeping the sturgeon specimen and trafficking it on the black market. There are also fishermen who fish for scientific purposes and whom, through this cover and the negligence of the authorities, manage to traffic sturgeon specimens, especially females, which normally must be monitored, tagged and released back into the wild. In recent years, 477 adult sturgeons have been monitored by scientific fishing and tagged and of them, 91% are male (M.A.D.R., 2021), in the context in which the sex ratio is aproximativ1: 1.

Discussions

Many efforts are made for sturgeon conservation, from a general ban, stoking programs, improved legislation, enforcement to awareness, but nevertheless, there are still causes which need to be resolved.

In this context, after hundreds of years of overfishing, irrational fishing, habitat destruction, poaching and other causes that have affected Danube sturgeon populations, recovery will be slow, difficult and it will require a lot of involvement.

IMPROVED HEALTH STATUS OF ATLANTIC SALMON (*SALMO SALAR*) DURING SMOLTIFICATIONS AFTER REPLACING FISH OIL WITH ALGAL OIL

Introduction

Atlantic salmon farming is regarded one of the most profitable and successful aquaculture industries, especially for Norway, Chile and Canada (Asche et al., 2013). To keep the production cost low, salmon feed industry has gradually shifted from marine to terrestrial plant ingredients (Aas et al., 2019). However, the use of such ingredients can have negative effects on the growth performance and health status of the fish. Therefore, microorganisms and their extracted oil, are likely to be more suitable and sustainable ingredients for the near future, due to several factors such as vitamin and mineral content, good amino acid profile, sterols, folic acid, nicotinic acid, and the capability for producing omega-3 LC-PUFA fatty acids and especially DHA (Taelman et al., 2013, Kousoulaki et al., 2013). This fatty acid is crucial for the growth, physiology and disease resistance for both fish and humans.

Materials and Methods

The trial was performed at LetSea, Dønna Norway, with the aim to evaluate the potential of *Schizochytrium* oil (*Veramaris* - VMO), partially or total replacing the fish oil. After the acclimation period, fish were randomly distributed to 9 fiberglass tanks, 200 fish/tank. There were three different dietary treatments, in triplicate, with three levels of *Veramaris,* 0% VMO, 50% VMO and 100% VMO. After 49 days of feeding, weights were recorded and various samples were collected and preserved for further analysis, such as histomorphometry of the intestines and gills, expression selected genes in the gills, and assessment of the welfare status. Fish were also assessed for saltwater tolerance in 33 ppm saltwater after the feeding period.

Results

The results have so far showed that fish fed the 50% VMO diet tended to have higher growth performance. No fish mortality was observed in fish moved to salt water. Algal oil appeared to improve the height of the intestinal folds, both in distal and anterior part, although no significant changes were observed among the treatments. Gill morphology, and gene expression involved in immunity are underway.

Conclusions

The present study has revealed so far that using of algal oil can improve the growth of fish and intestinal fold height in Atlantic salmon. Further analysis of gill morphology and gene expression involved in immunity will help to explore the physiological functions and immune responses during smoltifications when algal oil is used in the diet.

THE IMPORTANCE OF CHOOSING THE RIGHT ORGANIC ACIDS BLEND FOR AQUACULTURE FEED

Dr Dafna Israel

Research manager and animal nutrition expert at Phibro Aqua

The quest for the best performing feed additive is a major mission in the aqua feed world. There is a variety of useful additives that raise the crucial debate regarding the selection of the best option. Acidifiers are functional feed additives with acidic properties. There are many organic acids available to the animal feed industry, including formic acid, acetic acid, propionic acid, lactic acid, fumaric acids, citric acid, sodium formate, butyric acids, sorbic acids and malic acids and the question is: how to choose the appropriate and most beneficial acid blend. Many factors need to be taken under consideration such as technological and nutritional aspects to achieve a unique blend that will able to be incorporated in aqua feed and offer the best solution.

FEEDING SEABREAM IN SUBSTITUING FISHMEAL AND FISH OIL BY FRESH MUSSEL AND FEED BASED ON VEGETAL RESOURCES

Introduction

Feeding seabream (*Sparus aurata*) on a sustainable fish feed implies to find alternatives to the use of fish oil and fishmeal in the diet. It means that attention must be paid to substitute long chain poly-unsaturated fatty acids (LC-PUFA) and essential amino acids from fish oil and fishmeal, with other sources, in order to maintain growth performances. Seabream is a predator for shellfish and is able to crush the shells, once the size is suitable. The area of Charente Maritime (France), is known to produce oysters and mussels. A part of the production, out of calibration, is discarded whereas it could be a suitable source of nutrient for gilthead seabream. Thus, to propose a sustainable diet, based on local resources, a formulated feed based on vegetal resources, supplemented with fresh mussels (*Mytilus edulis*) out of calibration was tested. In order to test the interest of this approach, two trials were carried out in the facilities of the Lycée de la Mer at Bourcefranc-le-Chapus (France): (i) An indoor experiment was conducted on small size gilthead seabreams in order to check the relevance of the experimental diet on rapid growth rate individuals without any other potential natural sources of nutrient; (ii) An outside second experiment was performed in which the experimental feed was delivered to larger seabreams in fishpond.

Materials and methods

Indoor experiment

The experiment lasted for seven weeks. The gilthead seabream were bought in a commercial hatchery at a mean weight of 6.7 g (± 1.3 g). At the beginning of the experiment, they were stocked at a density of 1.5 kg/m^3 in 3 tanks of 1.6 m^3 (342 to 345 fish per tank). The three tanks were associated in a single recirculating aquaculture system (RAS). The water circulated by air-lift and was maintained to a constant temperature of 21±1°C. Water was renewed at a rate of 2 m^{3}water per kg of feed distributed. In each rearing tank, a different diet was delivered 6 days a week: (i) the "control" diet (C), corresponding to a commercial feed (Neo Start, Le Gouessant), specific to pre-growing marine fish (including marine ingredients); (ii) the "vegetable" diet (V), corresponding to an experimental formulated feed composed only of raw materials from plants. This experimental feed was formulated based on: (1) absence of marine ingredients; (2) use of raw materials only from European production; (3) without synthetic amino acids; (4) limitation in the use of refined products; (5) a protein/fat rate similar to the commercial feed; (6) and use of an attractive compounds to foster feed intake (Actipal HP1-S1. Dianaaqua); (iii) the "mussel" diet (M) corresponding to the formulated feed V (five days a week), supplemented with fresh flesh (shells were removed) from discarded mussels, on the basis of gross energy content one day a week. The mussels were purchased from a close aquaculture farm.

Outdoor Experiment

The outdoor trial was performed twice in 2020 and 2021, from early June to early October. The gilthead seabream were bought in a commercial farm, from an indoor controlled environment. At the beginning of the experiments, the fish had a mean weight of 200 g and were stocked at a density of 3 individuals/m^2 in a single earthen pond of 410 m^2. The fish feed was formulated on the same basis than in the previous experiment and adapted to the requirement of 200g seabreams. The formulated feed was delivered five days a week, supplemented with discarded whole fresh mussels on the basis of gross energy content one day a week.

For indoor and outdoor experiments, fish were weighed at the beginning and the end of the experiment, and at intermediate dates. During the experiments, the quantities of feed distributed were recorded. In each experiment, proximate composition of diets, mussels and whole body were analyzed and their fatty acid profile determined, at the beginning and at the end of the experiment.

(Continued on next page)

Results

Indoor experiment

At the end of the experiment, the mean weight of fish from the C (23.1 ± 4.3 g) and M (23.1 ± 5.2 g) treatments were not significantly different, whereas they were significantly lower in the V treatment (15.5 ± 3.6 g) ($p<0.05$). The survival rate was slightly higher in C and M (99.7% and 99.4% respectively) than in V (98.0%). Feed Conversion Ratio (FCR) obtained for C, V and M were 1.00, 1.84 and 0.99, respectively. For M, The FCR, including the mussel, calculated on the basis of the formulated feed at 97.3% dry matter (DM).

A total of 5 182 g DM of feed were delivered in C, 5 057 g DM in V and 5 240 g DM in M (composed of 4 708.5 g DM of feed V and 531.5 g DM of mussel flesh). The quantities of total protein delivered in each treatment were 2 891 g for C, 2 781 g for V and 2 906 g for M, and the quantities of total energy delivered were 110 MJ for C, 122 MJ for V and 116 MJ for M. During the experiment, the lipid content of the fish increased, with a higher level in V and M (11.87% and 12.15% respectively) than in C (9.38%), at the end of the experiment. But, the proportion of EPA (Eicosapentaenoic acid) and DHA (Docosahexaenoic acid) in the body lipids was lower in V (1.31% and 2.10%) and M (1.82% and 2.21%) than in C (9.20% and 10.78%, respectively), at the end of the experiment. The retention rates in lipids and protein were similar between C (69% and 30% respectively) and M (70% and 29% respectively) but lower for V (45% and 16% respectively).

Outdoor Experiment

Similar growth performances were observed between the trials carried out in 2020 and in 2021 with a final mean weight of 352.4 g (± 59.4 g) and 363.8 g (± 72.1 g) respectively. The survival rate was similar too with 94% and 95% respectively. The FCR obtained were 1.90 and 1.76 respectively, calculated on the basis of mussel with the same dry matter than the formulated feed. During the experiment, the mean lipid content of the fish increased, from 13.8% to 17.5%, but, the mean proportion of EPA and DHA in the body lipids decreased from 3.9% to 1.8% and from 7.1% to 3.5% respectively. The retention rates in lipids and protein were 16% and 18% respectively.

Discussion-Conclusion

For both types of experiment, fish fed with formulated feed supplemented with fresh mussel exhibited growth performances similar to that from fish fed with commercial feed. Survival rates observed were over 90%.

If the protein content in fish remained stable during the experiments, the lipid content increased. The balances between saturated and polyunsaturated fatty acid, and n-3/n-6 FA ratio decreased with the use of the vegetable diet, and the supplementation with mussel did not allow to maintain the proportions of PUFA.

The use of the proposed feeding strategy has to be confirmed on longer periods and/or included in a global feeding strategy along the fish rearing cycle, including phases of feeds of different PUFA levels. This study shows that it is possible to propose new feeding strategies, based on the use of available nutritive sources in territories.

CARRYING CAPACITY AND SPATIAL VARIABILITY OF THE CULTIVATED *Saccharina latissima* IN A DUTCH COASTAL BAY: A MODELING ASSESSMENT

H.M. Jansen*, L. Jiang, L. Blommaert, O.J. Broch, K.R. Timmermans, K. Soetaert

Introduction

Kelp cultivation receives increasing interest for its high-value products and ecological services, especially in Europe and North America. Before industrial kelp farming in marine ecosystems continue to scale up, evaluation of the site-wide production relative to ecological carrying capacity (CC) of the identified system is essential (Jiang et al 2022). Furthermore, prior studies have demonstrated large spatial variability in the yield and chemical composition of the cultivated *S. latissima*, even within small coastal bays. Hence main drivers of the spatial variability must be investigated to offer insight into farm-site selection and optimize production.

Methods

For the purpose of evaluating ecological and production carrying capacity, a mechanistic kelp model was developed and applied for hypothetical numerical experiments of expanding the farming area in a Dutch coastal bay (the Eastern Scheldt, Figure 1), where cultivation of *Saccharina latissima* (sugar kelp) is emerging. The kelp model was implemented within a three-dimensional hydrodynamic–biogeochemical model to account for the environmental interactions. The model captured the seasonal growth dynamics of *S. latissima*, as well as its carbon and nitrogen contents measured at the Eastern Scheldt pilot sites. A total of two types of scenarios were run in this study: the baseline scenario representing the current pilot sites and idealized scenarios increasing the farming area hypothetically by 1%, 3%, 10% and 30% of the total bay area, respectively, where farm locations were uniformly distributed not considering any potential (physical) conflict with other user functions.

Using the same a pre-validated hydrodynamic-biogeochemical-kelp model, we examined the spatial variability and investigated the main drivers in *S. latissima* growth dynamics in 40 hypothetical farms spread throughout the bay. Meanwhile, the Eastern Scheldt, renowned for mussel and oyster culture for decades, serves appropriately as a prototype for studying the reciprocal effects between (co-cultivation of) shellfish and farmed *S. latissima*.

Results & Discussion

The model results suggest that expanding the kelp farming area to ~1–30% of the bay (representing ~3.4–75 kt harvest dry weight in the 350-km2 bay) had the potential to weaken the spring bloom (Figure 2), and thereby affected the coexisting shellfish culture in the bay. Competition between *S. latissima* and phytoplankton mostly occurred in late spring for nutrients (dissolved inorganic nitrogen). The ecological CC should be weighed according to these negative impacts. However, the production CC was not reached even when farming ~30% of the Eastern Scheldt, i.e. harvesting totally 75 kt dry mass, given that the simulated overall *S. latissima* production kept increasing with the farming activity.

S. latissima yield in the deeper and better flushed western compartment more than doubles that in the eastern compartment, which is found to be driven primarily by temperature. Model results furthermore suggest that *S. latissima* benefits from co-cultivation with shellfish, since nutrients excreted by shellfish replenish its nitrogen reserve and fuels a relatively high growth rate in the nitrogen-depleted late spring.

Our modelling approach can be applied to other systems for *S. latissima* cultivation and assist in assessing CC and environmental impacts. We also discuss the possible further improvements for assisting in seaweed farming practice.

Introduction:

Parasites are ubiquitous in aquaculture and can have devastating effect with serious socioeconomic, ecological, and welfare consequences. Of these, monogenean parasites are of particular problem as the conventional treatment for this infection, application of organophosphates is no longer permitted due to its neurotoxic effect, leaving no treatment option for this disease, which induces high morbidity and mortality due to skin and gill lesions associated with the attachment of the parasite to the fish.

In the past years there is a trend in aquaculture of moving away from chemical to natural treatments, *i.e.* alternative strategies for disease control and natural treatments effective in eradicating fish parasites and safer to public health and the environment.

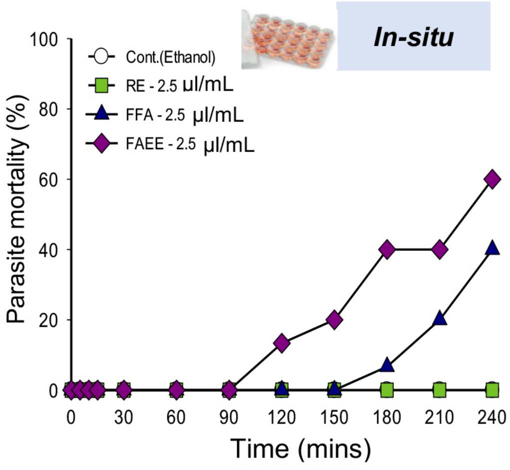
Our previous research had demonstrated that an extract produced from the diatom *Phaeodactylum tricornutum* was effective against fish monogenean parasites. *P. tricornutum* is a potent photosynthetic marine diatom, which is commercially produced for high value nutraceuticals, such as LC-PUFA and fucoxanthin. Its extracts also have been shown to have antibacterial properties, mainly associated with fatty acids liberated from glycerolipids during cell treatment and extraction.

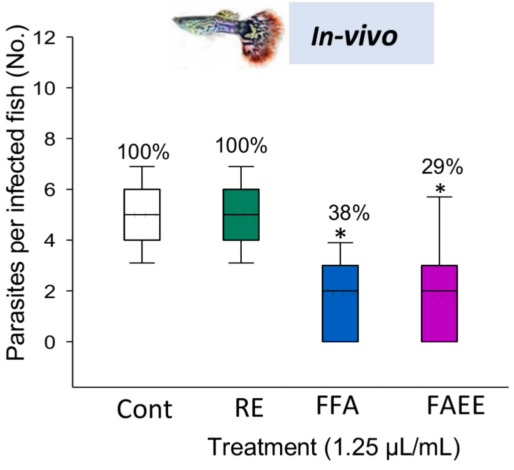
To further develop a sustainable and cost-effective treatment for aquaculture, the use of residue material from commercial *P. tricornutum* production was explored.

Methods:

Gyrodactylus turnbulli, a monogenean parasite affecting guppies (*Poecilia reticulate*) was used. As infection is high on the guppies' tail fin which is transparent, direct observation of live fish and tail clips is feasible. Residue material of *P. tricornutum*, which was produced as a source of fucoxanthin, was obtained as dry powder from a commercial producer. Several extracts and preparations were tested, including Ethanolic residue extract (RE), free fatty acids (FFA) produced from this residue extract (RE) and fatty acid ethyl esters (FAEEs), produced directly from the *P. tricornutum* residue powder. These preparations were initially tested *in situ*, using infected tail clips, followed by *in vivo* testing.

To characterize the active ingredients, the extracts and preparations were analyzed by thin- layer chromatography (TLC), GC, followed by direct examination of pure compounds with potential anti-parasitic toxicity that were identified by these analyses.





(Continued on next page)

Results:
All extracts and preparations were effective against the parasite, but FAEE fraction was the most effective *in situ* and *in vivo* (Fig 1). FAEE can be easily produced by a single step, direct transethylation of the algal residue powder. The active ingredients included FAEE of EPA 16:0, 16:1 and 14:0.

The research presents the potential utilization of *P. tricornutum* residue as a source for natural treatment against *G. turnbulli* and potentially other monogenean parasites.

INFLUENCE OF TEMPERATURE AND DIET QUALITY ON LARVAL PERFORMANCE OF *Palaemon serratus*

jean-bapstiste.baudet@univ-lehavre.fr

Introduction

The pink shrimp, *Palaemon serratus*, is a commercially valuable species distributed along the European coast. It lives for 2-5 years and females can weigh up to 13 grams (Huxley, 2011). Although aquaculture trials were attempted in the 1970s and 1980s (Campillo, 1979; Rodriguez, 1981), this species is not commercially produced today. Due to its size and the temperature of the environment in which it naturally lives, *P. serratus* is an ideal candidate for extensive European marine shrimp farming.

Here we focus on the performance of the larval phase of *P. serratus* under controlled conditions. Temperature determines the duration of larval development by influencing the number of larval moults and the duration of intermoult (Gonzalez-Ortegon and Giménez, 2014). This temperature-mediated plasticity has consequences for juveniles, with size at metamorphosis decreasing with increasing temperature (Baudet et al., in press). Conversely, larval survival increases with temperature (Reeve, 1969). The rate of metamorphosis of *P. serratus* larvae is very low at temperatures below 15°C (Reeve, 1969). However, the larvae of this species are released into the environment between April and July, in areas where the water can be between 10 and 15°C. We believe that the poor larval performance obtained in the laboratory in cold water is due to the poor diet used. Indeed, artemia nauplii contain little of the polyunsaturated fatty acids necessary for membrane fluidity in cold water (Sorgeloos et al., 2001).

In this study, we compared the larval performance of *P. serratus* at three temperatures (14, 18 and 22°C) by feeding the larvae three diets of more or less rich artemia. We hypothesise that larval survival increases with diet richness and temperature. The interaction of these two factors should have synergistic effects on larval survival. We also expect that diet richness will increase growth rate, regardless of temperature.

Materials and methods

We collected 5 ovigerous *P. serratus* females which we isolated in the laboratory. Upon hatching of each brood, 9 groups of 52 larvae were incubated in 9 conical vessels of 500 mL. These were then incubated in 3 waterbaths at 14, 18 and 22°C respectively (3 vessels of each brood per waterbath).

To test the influence of the fatty acid richness of the diet on larval development, we prepared the following 3 diets (from the poorest to the richest): unenriched metanauplii I (24h after hatching), nauplii I (at hatching) and metanauplii I enriched for 24h with microalgae rich in polyunsaturated fatty acids. Each vessel was fed the same diet every day, *i.e*. 10 artemia per mL. We therefore had 45 containers each containing 52 larvae (5 females x 3 temperatures x 3 diets). The larvae were observed during the water change 3 times a week. When they metamorphosed into juveniles (morphological and behavioural criteria), they were removed for weighing and stored individually at -80°C. Their lipid profile was then analysed.

We will test the effects of temperature and diets on larval metamorphosis rate, development time and weight of metamorphosed larvae. For this purpose, we will use mixed-effects models to consider that for each model, the larvae used at different temperatures were from the same females.

Results and Discussion

The experiment started in May 2022 and is currently not completed. The analysis of these and the discussion will be presented at the conference.

Introduction

Because the life cycle of the European eel *Anguilla anguilla* is not yet closed in captivity, the aquaculture industry depends on wild caught juvenile glass eels that are grown to marketable size. In our facilities, larvae are produced on a regular basis but they die without feeding exogenously. High mortality and deformity rates are often observed during the first week after hatching. Therefore, there is an urgent need to increase egg and larvae quality to produce larvae that can grow, survive and metamorphose into glass eels. In an earlier study (Jéhannet et al., 2021), we compared the transcriptome of larvae at 1 dph, of batches that survived less than 3 days post hatch (dph) *vs*. batches that survived for at least a week to understand the reasons behind the mortality rates during the first week after hatching. Our results suggested that larvae that die early suffered from microbial infections because the expression of genes related to inflammation and host protection were up-regulated when compared to gene expression in viable larvae. Therefore, in this study, we tested the effects of antibiotics (rifampicin and ampicillin 50 mg.l^{-1}) and egg surface disinfection treatment (povidone iodine 25 ppm), alone or in combination, on hatching success, larvae survival and deformities in larvae from wild and feminized eels.

Materials and methods

Eggs were stripped from wild eels (N=5) and from eels that were feminized during the young elver stage (N=12). Eggs were collected in dry bowls and each individual batch was mixed with the sperm of 6-8 males. Gametes were activated by adding seawater and placed in 5-L beaker containing artificial seawater kept at a water temperature of 18°C and a salinity of 36 ppt under dark conditions. Within 2 hours post fertilization (hpf), floating eggs were collected from the 5-L beaker with a sieve and weighed. From the weighed eggs, 63 g of eggs were equally distributed over twenty-one 1,800 mL beakers containing the various treatments (Table 1). Eggs were (i) placed in three beakers containing artificial seawater as control (C); (ii) placed in three beakers containing artificial seawater supplemented with antibiotics (A2); (iii) disinfected for 5 mins, rinsed three times and placed in three beakers containing artificial seawater (D2); (iv) disinfected, rinsed and placed in three beakers containing artificial seawater supplemented with antibiotics (AD2) and (v) placed in nine beakers containing artificial seawater until similar treatments but at10 hpf. At 10 hpf, eggs that were previously kept under control conditions were (i) placed in three beakers containing artificial seawater supplemented with antibiotics (A10), (ii) disinfected, rinsed and placed in three beakers containing artificial seawater (D10); (iii) disinfected, rinsed and placed in three beakers containing artificial seawater supplemented with antibiotics (AD10). When females gave less than 63 g of eggs, treatments were applied in the priority order as shown in Table 1. For each treatment, hatching success, larvae survival and the type of deformities observed were recorded.

Results and discussion

Of the twelve feminized eels that were stripped, five of them gave larvae that survived up to 5 dph. All five wild eels that were stripped gave larvae that survived until 21 dph. In the controls for treatment, eggs from the wild eels had significantly higher hatching rates (8 %) than the eggs from the feminized females (1 %). In the controls, larvae from the wild females significantly survived longer (4 ± 1 dph) than the ones from the feminized females (1 ± 2 dph). These results show that wild females produced eggs and larvae of higher quality than the feminized ones. Antibiotic treatment doubled the larval survival period but the effect was only significant *vs*. eggs that were disinfected, not *vs*. the controls. As variations were high, we are currently increasing the number of observations. Among the abnormal larvae from feminized and wild eels, larvae were often curved. Larvae that hatched later than 80 hpf were more curved than larvae that hatch before 60 hpf suggesting that curvature is related to delayed hatching. Also other abnormalities such as notochord deformities (Fig. 1), pericardial oedema and head emaciation were frequently observed. Although our results show that antibiotics increase the early larval survival in European eels, sustainable methods aiming for antimicrobial control and increasing larvae survival are being developed.

COLLAPSING COASTAL GOVERNABILITY – GOVERNING UNSTABLE OBJECTS IN NORWEGIAN SALMON AQUACULTURE

D. Jensen*

Norwegian College of Fishery Science, UiT – The Arctic University of Norway, 9019 Tromsø (Norway)
E-mail: daniel.jensen@uit.no

Introduction

Evolving economies and technologies in the coastal space outline a situation related to governance where the ability to govern is becoming increasingly wicked. Governability, a term coined by Kooiman et al. (2008, p.3), relates to the "overall capacity [within a governing system] to make something governable". In relation to the ongoing intensification of anthropogenic marine activity and the pursuit for sustainable solutions, the need to reflect upon governability becomes highly relevant. It is thus unfortunate that current approaches to marine governance do not seem to appropriately deal with the unwanted outcomes of the ever more closely integrated socio-techno-ecological systems (Glaser & Glaeser 2014). On one hand, coastal spaces are seen as areas of opportunity, growth, and development. While on the other hand, many coastal areas remain a breeding ground for intense conflicts of interest, causing severe deterioration of marine ecosystems (Glavovic 2013).

With the theoretical lens provided by Evolutionary Governance Theory (EGT) and a poststructuralist approach, this paper investigates how innovative technology unfamiliar to the governing system feeds into the escalating wicked situation of conflicting discourses within sustainable development, and how technology thus challenges the governability. EGT has proven useful when studying emerging relations and patterns, and in this case the theory has been applied to show how and why governability is collapsing.

The paper explores the issue of collapsing governability through relating to a case in Norwegian salmon aquaculture where a type of innovative technology seeks to contribute to sustainable development. The technology in question is a dynamic aquaculture installation called Havfarm 2 (HF2). With its dynamic features, the installation will have the possibility to move around to always maintain optimum farming conditions, but also to adapt to other (industrial) activities making use of the same space. However, issues of governability arise as the governing system does not know how to govern a dynamic installation primarily because aquaculture is seen as, and regulated as, a physically stationary activity. The relevant research question, thus, becomes: "How is the governability of coastal areas challenged by innovative aquaculture technology?".

Methods and materials

The case of HF2 was chosen because it illustrates what happens when technology development reaches a point where it breaks with what the governing system is familiar with, and thus challenges the governability of the system. Following constructivist traditions, the methods of document analysis (Asdal & Reinertsen 2020) and process-tracing (George & Bennett 2005) have been made use of when analyzing gathered data. With an abductive and iterative approach, the research question has been explored by gathering data from governmental documents, reports, white papers, and news articles that relate either directly to developments concerning HF2 or salmon aquaculture development in Norway in general. The latter to situate the events relating to HF2 in a larger perspective. Retriever Atekst (Norwegian news database) and governmental websites are the databases used to find material.

Theoretical framework

EGT understands governance as the result of the evolution of many elements, such as actors, institutions, knowledge, and discourses, as well as technology. In established academic literature, EGT has proven useful to understand the specificity of coastal governance and the possibilities of a coastal governance better adapted to challenges that arise through intensified use of the sea (Van Assche et al. 2020). Through mapping governance paths and shifting roles of knowledge and narrative, the theory offers concepts that help understand how HF2 becomes an unstable object that is challenging the governability of the governing system.

(Continued on next page)

Results and Discussion

The acquired data tells the tale of what happens when technology exposes the lack of governability within a governing system, and why it happens. The governing system of Norwegian aquaculture is not constructed to handle the type of governmental dynamism necessitated by HF2 because the technological solution it represents comes across as unknown to the governing system. The evolution of actors, institutions, knowledge, and power have led to emerging governance paths over the past years that indicates a governing system that seeks to develop the industry with use of other technologies than dynamic aquaculture due to lack of governing capacity for such a technology.

The absence of suitable governing arrangements, regulations, and knowledge about what dynamic aquaculture implies has resulted in an ever-evolving web of politics, stakeholders, resistance, and sciences that is reducing the governability of the governing system. This outlines a reality where governability is collapsing in its attempt to govern an object that represents instability, i.e., unknown technological solutions.

What this case study ultimately shows is that the governing system and its institutions are integral for technology to work as intended. Even though technology, isolated, might represent a contribution to sustainable development, the technology is nothing without supportive policies and regulations. Hence, this paper argues that sustainability is not something that is achieved through technology, but that sustainability is a continuous process that is advanced through the necessary constant performativity of policies and politics.

REGULATION OF AQUACULTURE PRODUCTION

Frank Jensen, Rasmus Nielsen and Henrik Meilby

Department of Food and Resource Economics
University of Copenhagen
Rolighedsvej 23-25
1958 Frederiksberg C
Denmark

Since the late 1980s, global capture fisheries' production for human consumption has stagnated, whereas the output from aquaculture has increased rapidly. Today, aquaculture deliver nearly 50% of the fish used for human consumption worldwide. However, food production from aquaculture generates a number of negative externalities, including nutrient discharges, implying that management may be necessary. However, to a large extent, current governmental regulation is undertaken by using command and control instruments, with limits on water use as an example, and these instruments are considered economically inefficient. Therefore, the purpose of this paper is to study the economically optimal regulation of aquaculture production. The time between releasing and harvesting fish (rotation time) is an important decision variable for aquaculture producers, and we use rotation time as a regulatory variable. By drawing on ideas from the forest economics literature, we construct basic models for a private and social optimum, assuming an infinite time horizon. Furthermore, we explicitly introduce the quality of fish into our basic models and show that an optimal marginal tax is equal to the marginal damage costs (with respect to time) in the current and all future rotations (a dynamic Pigovian tax). We also discuss the implications for the regulatory recommendations of relaxing several assumptions in the basic models, such as the time when costs are incurred, differences between the social and private revenue functions and differences between the private and social discount rates.

FLEXIBLE POLICY INSTRUMENTS TO ENCOURAGE EXTERNALITY ABATEMENT TECHNOLOGIES IN SALMON AQUACULTURE

Andreea L. Cojocaru, Frank Jensen*, Kamila Kulmambetova, Bård Misund, Rasmus Nielsen, Ruth B. Pincinato, and Ragnar Tveterås

Section for Environment and Natural Resources, University of Copenhagen, Denmark
E-mail: fje@ifro.ku.dk

Aquaculture has been identified as a food sector that holds potential to grow sustainably to provide important sources of protein and essential micronutrients to an increasing global population, while maintaining a low environmental footprint relative to other food production technologies. Simultaneously, there is a shift in society's priorities with the threat of climate change taking a much more prominent role. In Norway, the political consensus is that an increase in salmon aquaculture production from today's 1.5 million tonnes to 5 million tonnes is desired by 2050 but only if achieved in an environmentally sustainable manner. Paradoxically, this ambition comes at a time when conventional open cage salmon aquaculture operations globally have been experiencing limited growth in production due to environmental challenges.

In response to a range of negative externalities, but also driven by the need for a higher degree of control over the production environment, salmon producers in Norway have been heavily investing in new technologies that hold promise of externality abatement. These technologies range from onshore production to closed and semi-closed containment systems and offshore open production systems. Although the range of negative externalities in salmon aquaculture is broad, we focus the discussion on regulating a single externality, namely sea-lice. This choice is motivated by sea-lice being an externality central to the regulatory framework in Norway, but also by the need to maintain clarity in the discussion, as a system with several regulatory instruments can quickly become complicated. Norway, like other salmon producing nations, has designed its regulatory measures to control the spread of this parasite through command-and-control measures

Unlike command-and-control instruments which offer no incentives to address externalities beyond the standard set by a related piece of regulation, economic incentives encourage behaviour through price signals rather than through explicit instructions. Economic incentives promote investments in new technologies by directly imposing a price on the externality. A result from regulatory economics is that a tax on pollution and a subsidy to abatement ultimately lead to the same level of pollution. Investments in new technologies that reduce the sea-lice problem are by nature dynamic. We propose and discuss feed-in-tariffs as a dynamic subsidy that encourages investments in new technologies. We present lessons-learned from Germany and Spain where these tariffs have been successfully used to promote investment in renewable energy production and draw parallels to the Norwegian salmon aquaculture setting.

The choice of discussing dynamic subsidies in the context of a single externality is equivalent to accepting that other externalities in salmon aquaculture production remain unregulated and that a subsidy to sea-lice reduction may have a less desirable effect on the other externalities. In practice however, several externalities may arise simultaneously (e.g., sea lice infestation and genetic pollution). Possible regulatory solutions may be to apply feed-in-tariffs to each externality separately, prioritizing the most important externality, or using an index of several externalities.

EVALUATING TWO METHODS OF INCORPORATION OF THE HALOPHYTE *Salicornia ramosissima* IN WHITELEG SHRIMP DIETS (*Penaeus vannamei*): SURVIVAL, GROWTH AND FEED EFFICIENCY

Introduction

To sustain the growth of the aquaculture sector, it is of paramount importance to study and develop efficient diets with alternative raw materials. Ingredients traditionally used in aquafeeds, such as wheat, are increasingly scarce and costly given the growing demand´s to supplement human and animal nutrition. The production of halophyte plants for human consumption, such as *Salicornia ramosissima,* is increasing as they have the ability to grow in saline soils or be irrigated with seawater allowing the utilization of unexploited resources. Additionally, these are known for their richness in bioactive secondary metabolites which can have health promoting effects for the consumer (e.g., phenolic compounds). However, the tender green tips of Salicornia are the only part sold as food, being essential to value the remaining plant material wasted. The principles of circular economy, where waste is recovered and utilized to create added value, are increasingly important, being applied to economical relevant areas, including the aquafeed industry. The whiteleg shrimp (*Penaeus vannamei*) is the most produced crustacean species worldwide. However, feed associated costs are significant, making the identification of more economical and sustainable formulations essential for the success of shrimp farming. Therefore, the current study aimed at evaluating the potential of incorporating *S. ramosissima* biomass in diets for juvenile *P. vannamei*. For this purpose, shrimp survival, growth and feed efficiency performances were assessed in two different experiments: Experiment 1 (dried non edible biomass) – inclusion of stems (SS) and leaves and seeds (SL) at 5% and 10% inclusion levels, replacing wheat; Experiment 2 (green protein rich extract) – supplement diets with *S. ramosissima* extracts at 0.1% and 1% inclusion levels.

Methods

Experiment 1: Five experimental diets were tested (5 replicate tanks each): a commercial like diet (Control), two experimental diets containing *S. ramosissima* stems at 5% and 10% inclusion levels, replacing wheat (SS5 and SS10, respectively), and two containing *S. ramosissima* leaves and seeds at 5% and 10% inclusion levels (SL5 and SL10, respectively). In this trial, the inclusion of *S. ramosissima* replaced Wheat in the same proportion. Whiteleg shrimp juveniles (mean wet weight 6 g) were kept at around 28 ºC and fed *ad libitum* for 55 days. At the end of the trial, shrimp were weighted and counted for growth performance and survival determination. Experiment 2: Three experimental diets were tested (6 replicate tanks each): a commercial like diet (Control), two experimental diets containing *S. ramosissima* extracts at 0.1% and 1% inclusion levels (SE 0.1% and SE 1%, respectively). Whiteleg shrimp juveniles (mean wet weight 1.6 g) were kept at around 28 ºC and fed *ad libitum* for 30 days. At the end of the trial, shrimp were weighted and counted for survival, growth and feed efficiency performances.

Table 1. *Salicornia ramosissima* biomass (Experiment 1) and extracts (Experiment 2): Initial and final weight, relative growth rate (RGR), feed conversation ratio (FCR), feed intake and survival of whiteleg shrimp juveniles fed the experimental diets for 55 and 30 days, respectively.

	Experiment 1 (Biomass)					Experiment 2 (Extracts)		
	Control	SS 5	SS 10	SL 5	SL 10	Control	SE 0.1%	SE 1%
Initial weight (g)	6.1 ± 0.0					1.6 ± 0.0		
Final weight (g)	17.6 ± 0.4	18.1 ± 0.5	18.1 ± 0.4	18.1 ± 0.4	18.3 ± 0.3	5.6 ± 0.4	5.9 ± 0.3	5.5 ± 0.3
RGR (% day-1)	2.0 ± 0.0	2.0 ± 0.1	2.0 ± 0.1	2.0 ± 0.0	2.0 ± 0.0	3.9 ± 0.2	4.1 ± 0.2	3.8 ± 0.2
FCR	3.1 ± 0.2^{a}	3.6 ± 0.2^{b}	3.7 ± 0.1^{b}	3.6 ± 0.2^{b}	4.0 ± 0.1^{c}	2.2 ± 0.1^{a}	2.6 ± 0.1^{b}	2.6 ± 0.1^{b}
Feed intake (% ABW d^{-1})	5.3 ± 0.3^{a}	6.2 ± 0.2^{b}	6.4 ± 0.2^{b}	6.3 ± 0.2^{b}	7.1 ± 0.2^{c}	8.8 ± 1.1^{a}	10.9 ± 0.5^{b}	$9.8 \pm 0.7^{a,b}$
Survival (%)	96.7 ± 1.5	97.1 ± 2.4	98.2 ± 2.6	96.0 ± 2.7	97.8 ± 1.5	97.7 ± 5.0	99.2 ± 1.7	98.5 ± 2.1

SS: Salicornia steams; SL: Salicornia leaves and seeds; SE: Salicornia extract. Results expressed as mean ± standard deviation (n = 5 experimental units). Different superscript letters indicate statistical differences ($P<0.05$) between treatments in a One-way ANOVA.

(Continued on next page)

Results and discussion

No statistically significant differences in growth performance and survival were observed among treatments (Table 1), suggesting that the inclusion of *S. ramosissima* biomass and extracts, at least in the forms and levels tested, did not compromise the adequacy of the diets. Nevertheless, shrimp fed diets containing Salicornia ate significantly more to achieve the same weight as those fed the Control, with this effect being more prominent in the SL10 and SE 0.1% diets (of each experiment, respectively) which produced significantly higher FCR and feed intake values than the remaining diets (Table 1).

Conclusion

Data from Experiment 1 and 2 indicate that *S. ramosissima* biomass and extracts, respectively, can be included in diets for juvenile *P. vannamei* with no detrimental effects on growth performance or survival. The inclusion of *S. ramosissima* stems in whiteleg shrimp diets (Experiment 1) seems to be preferable over leaves and seeds, which is the ideal scenario for adding value to halophyte production and potentially reduce shrimp feed formulation costs. Additionally, the valorization of a residue contributes to the principles of circular economy. The shrimp feed SE 0.1% diet (Experiment 2) exhibited the best results for final weight, RGR and survival, however without statistically differences for remaining treatments. The effect of these diets on the immune status of the species is being studied and will be presented in future works.

UTILIZATION OF SEASONAL FISH IN THE FORMULATION AND DEVELOPMENT OF FISH PRODUCTS TO IMPROVE FISH CONSUMPTION AND INCREASE THE UTILIZATION OF FISH BIOMASS

H. Jia, A. Tomčala, J. Mraz

Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Institute of Aquaculture and Protection of Waters, University of South Bohemia in Ceske Budejovice, České Budějovice, Czech Republic

Introduction

Fish are rich in highly digestible proteins, vitamins, minerals, omega-3 fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) (Jia et al., 2022). Those are essential nutrients for the human body and are important to improve the daily human diet. However, fish consumption is very low in the Czech republic because of high prices, complex preparation, and food prejudices (Voráčováet al., 2018). Processing of fish is also very low (about 11%), and most fish in the market are sold alive, chilled, or frozen carcasses and fillets. There is a low diversity of fish products. The sale of freshwater fish produced in the Czech Republic is also very seasonal, and most fish is consumed during Christmas. Thus, the consumer is not very motivated to buy freshwater fish, given the laboriousness of their processing, the presence of bones, and the relatively narrow range of available fish products. This study aims to develop new fish products and fish recipes to increase the diversity of fish products and increase fish consumption. Furthermore, the development of fish products and recipes might also change human eating habits to improve health and increase the utilization of fish biomass to avoid losses.

Materials and methods

The local professional chefs designed six new fish products and 11 fish recipes for fish dishes in our processing plant. During the product and recipe development, non-/fillet parts of the fish body were preferentially used to utilize better the fish biomass, such as fish fillets, filleting skeletons, and fishtails. The new products and recipes were analyzed for nutritional composition and microbial stability, and then they were presented to the consumers and had a sensory evaluation in the restaurant.

Results

All the newly developed fish products and recipes are shown in Fig.1. According to nutritional analyses, almost all fish products and recipes were rich in protein and fat content (Table.1). Especially, P2, R5, R7, and R9 had significantly higher DHA+EHA content (>100 mg/100 g) than other products and recipes; and the ratio of n-6/n-3 is higher than 4 in P4, P5, R1, R2, and R10. Hence, almost all products and recipes displayed excellent lipid quality, which has good advantages for human health, excluding R10 because its salt content was more than the limited standards (1.7g/100g), 1.9 g/100g.

Apart from nutritional evaluation, the quality and safety are very important to be monitored during the storage; furthermore, stability is regarded as the main criterion for product selection during storage. Hence, fish products' microorganisms, TBARS, and peroxide values were analyzed. The results presented that almost all fish products had good stability during the storage for three months, excluding the smoked carp with lard because of the mold, as shown in Fig.2. Moreover, the other five new products were recommended and applied finally.

On the other hand, sensory evaluation is crucial to presenting delicious food to consumers. Here, the main criterion for selecting sensory evaluation was the overall impression criterion in sensory evaluation, with a minimum threshold value of 65%. Almost all fish products and recipes had good feedback from sensory evaluation because of their good taste, aroma, and gastronomic pleasure, as shown in Table.1. The sensory scores in P4, P5, and R7 groups were more than 80%, even more than 90% in R9 and R10 groups. Conversely, the Carp miso soup recipe was discarded because of the lower sensory evaluation value (65% <).

Fig.2. The change of TVC in fish products during storage (4°C).

Table 1. The nutritional composition and the content of fatty acids, sensory scores, and material prices of fish products and dishes.

	P1	P2	P3	P4	P5	P6	R1	R2	R3	R4	R5	R6	R7	R8	R9	R10
Proteins (%)	12.2	11.8	10.2	9.5	13.1	13.1	9.6	8.9	5.6	1.8	15.4	13.9	14.0	14.0	12.3	19.2
Fat (%)	19.2	15.8	14.5	39.0	61.8	49.3	7.6	19.7	5.9	0.5	5.8	21.8	6.6	13.9	7.3	8.3
NaCl (g/100g)	1.4	0.5	1.2	1.5	2.1	1.5	1.2	0.9	0.5	0.8	0.7	0.8	0.3	0.9	1.2	1.9
EPA+DHA mg / 100g	78.5	121.8	56.5	87.2	21.5	46.0	17.0	82.0	53.0	32.0	320.0	65.0	300.0	77.0	323.0	85.0
n-6/n-3	2.2	2.5	2.2	4.9	5.4	2.2	8.8	4.9	2.7	2.4	3.1	2.1	2.2	3.6	3.2	4.2
Sensory score (%)	76.4	74.8	77.6	73.6	80.5	83.2	65.5	77.7	73.6	75.9	69.0	69.3	88.6	65.0	90.9	93.6
Price -material (€)	1.30	1.31	1.05	1.36	1.72	1.74	0.56	2.10	2.69	1.44	2.36	5.36	4.49	5.10	3.34	3.69

From the economic point of view, the prices of these new products and recipes were acceptable for consumers. This study achieved utilization of the unpopular parts of fish, such as fishtails and filleting skeletons. Especially, smoked carp in oil, carp blood pudding, ravioli, and poached pike achieved utilization of the unused fish biomass and decreased the losses of the fish biomass. The authors encourage the fish factories and restaurants to develop new fish products with the other tissues and organs (like fish skin, fins, tails, heads, liver, and gonads) to increase the diversity of fish products and produce the new products with the low prices for the enhancement of fish consumption and improving the eating habits of humans. Apart from the above advantages, the utilization of fish biomass can produce economic fish products and even avoid the cost of handling unused fish parts.

NUMERICAL MODELLING OF A TYPICAL MARINE OPERATION SCENARIO IN AQUACULTURE, WITH RIFLEX AND SIMO IN SIMA WORKBENCH

Jingzhe Jin, Robert Indergård, Halgeir Ludvigsen, Biao Su

SINTEF OCEAN, Trondheim, Norway
Email: jingzhe.jin@sintef.no

Introduction

Aquaculture of Atlantic salmon in coastal and offshore locations is an operation intensive industry. This paper first gives a brief overview of the most typical marine operations in the aquaculture industry. With the aquaculture industry developing toward offshore locations and the need to ensure efficient and safe operations, being able to predict the operation performance in planning phase and to monitor and assist the actual operation in real-time becomes more and more important.

To meet these needs, the paper focuses on a typical lifting operation over the side of a standby working vessel with onboard crane and establishes a numerical model for the complete system using RIFLEX and SIMO in the SIMA workbench. The working vessel is moored to the mooring system of the cage. The hydrodynamic performance of the cage -vessel system and the connection line tension during the lifting operation is evaluated in irregular wave and current conditions. At the end, the performance of the cage-boat system during the lifting operation will be summarized for different sea states and weather directions.

The cage and standby working vessel system and numerical modelling

A scratch of the cage – vessel system including the cage's mooring system is illustrated in Figure 1.

In this paper, the operation scenario of one service boat moored to a fish cage is numerically simulated. The simulation is performed in SINTEF Ocean's Integrated Simulation Environment, SIMA.

Fish cage and its mooring system model is made in RIFLEX in SIMA. RIFLEX solves the nonlinear hydrodynamic/structural responses of slender marine structures in a sea environment using FEM method. Special net elements in RIFLEX are applied to model the fish nets. In addition to standard cross section input parameters such as mass, volume, stiffness, damping and hydrodynamic force coefficients, fish net elements also require special input parameters such as solidity ratio, current velocity reduction coefficient and net width specification. The floater and bottom ring of the cage are modelled using beam elements. The bridle lines, frame lines and mooring lines are modelled using bar elements.

Hydrodynamic coefficients for the service vessel are calculated by WAMIT, which are then imported to SIMO inside SIMA and further integrated into the RIFLEX model of the fish cage to perform coupled SIMO-RIFLEX simulations. SIMO is a program to perform frequency and time domain hydrodynamic response analysis of rigid bodies in a sea environment, it can also be used to perform the same type of analysis for multi-body system and marine operations.

The service vessel is moored to the cage by four mooring lines: two connected to the cage floater and two connected to the buoys. The connection lines are modelled using bar elements in RIFLEX.

Numerical simulation

Static analysis is performed in current condition. Dynamic analysis is performed in irregular wave and current condition. Hydrodynamic interaction between boat and cage is so far not considered and uniform current filed is assumed. Wind load is not considered in this work. The simulations to be performed are summarized in Table 1.

Numerical simulation of operation scenario provides useful information for the planning and execution of corresponding marine operations. It can for example estimate the time window for a particular operation. Through digital twin of onsite measurement, the numerical model can be tuned to give as accurate prediction as possible, the numerical model can also be used to give real time visualization of the system response by reading in onsite measurement data in future.

E-mail: sandra@ipma.pt

Introduction

Cerastoderma edule is widely exploited and supports important commercial bivalve fisheries throughout its geographical range, particularly in Atlantic Area of Europe. However, the synergistic action of fishing pressure coupled with the rapid growth rate, short lifespan and huge mortality by diseases of *C. edule* leads to large inter-annual fluctuations in stock abundance and periodic recruitment failure. The development of cockle aquaculture and restocking programs could be an efficient fishery management strategy in order to rebuild stocks. To achieve this purpose, cockles aquaculture was tested, by transplanting juveniles from natural cockle beds to growth in different culture systems.

Material and methods

Two different outdoor culture systems were tested: in intertidal shellfish plots in a bivalve production park (37°01’25’’N; 07°48’41’’W) and in a suspended structure in earthen ponds tanks used for fish production in polyculture (37°01’54’’N; 07°49’17’’W) in Ria Formosa lagoon, south of Portugal. Juveniles from natural cockle beds of Ria Formosa with an initial size of 19 ± 2mm and 2.2 ± 0.7g by weight were used in all trials. Survival, growth (biometric measures - length, width, thickness and weight) and condition index (Walne & Mann, 1975) were monthly evaluated. Two different expected final densities were tested in both systems: 2 and 3 kg.m^{-2}. For each density, the experimental area of intertidal shellfish plot was composed by 6 squares 1x1m and half of the squares were protected with a plastic net with a grid 5x5mm to avoid predation. In the earthen ponds, two different containers for suspended cockle culture hanging from a cable (long-line) with floaters, set side by side alternating the two different densities were tested: rigid mesh bags and circular perforated (1 cm mesh) trays with 40 cm in diameter and 10 cm in height. Theses trays were piled, allowing comparison of culture at two depths (20 and 40 cm).

Results and discussion

The on-growing experiments carried out in intertidal shellfish plots showed that net protection against predators increased survival between 15 and 20 % in the first month after restocking. The *C. edule* juvenile’s length growth rate was 60 μm per day in a mean period of 4 autumn/winter months, when the water temperature and food were lower. In general, the low density showed the best results. In this conditions and without net, biomass yield was around 1,400 g.m^{-2} and individuals reached maximum values of 25.71±2.94 mm of mean length and 5.31±1.38 g of mean fresh weight. At the end of the experiment, the cockles condition index showed similar values for all the tested rearing conditions.

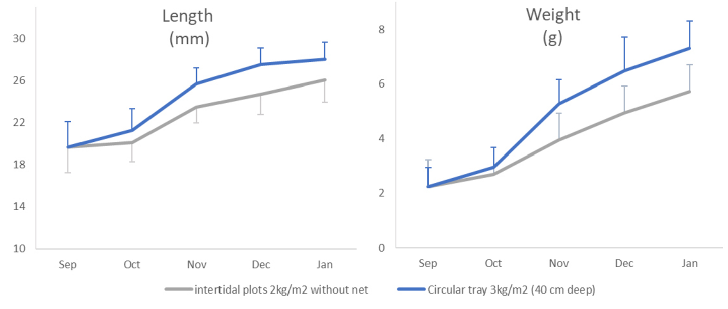

Figure 1 – The best growths of *Cerastoderma edule* juveniles (length and weight) in intertidal shellfish plots vs suspended culture.

(Continued on next page)

Growth of cockles reared in suspended culture was significantly better than the growth of cockles reared in intertidal shellfish plots. In the same period, length growth rate of cockle reared in the circular trays at 3 kg.m^{-2} can reach 85 μm per day (27.83±1.69 mm length and 6.92±1.30 g of weight at the end of the experiment). In rigid mesh bags, growth was slower (25.22±1.91 mm length and 5.29±1.05 g of weight in 3 kg.m^{-2} density at the end of the experiment). Biomass yield in circular trays and bags varied between 1300g.m^{-2} and 1900 g.m^{-2}, and the effect of density and depth of rearing were not substantially significant. Condition index of cockles reared in suspended culture was substantially higher and best results were found in November for cockles reared in circular trays placed at 40 cm of depth within the higher density.

The high cockle's growth found in suspended culture compared with intertidal shellfish plot culture may be explained by the highest input of organic nutrient that can exist in polyculture ponds due to the addition of fish food. On the other hand, in this ecosystem, cockles were continuously immersed with constant food availability which can be advantageous, compared with the intertidal plots where cockles are exposed to long periods of immersion. In spite of achieving greater growth increments in the culture in earth ponds tanks, cockles presented shell deformations resulting from the lack of sediment. However, these shell deformations do not increase mortality.

Results showed that was possible to attained commercial size in few months with high densities, in both rearing systems. In conclusion, juvenile's cockles reared in intertidal shellfish plots and in a suspended system in earthen ponds are both viable. The supremacy obtained of individual's growth in the suspended culture is undermined by deformations that can decrease the quality of the product and create obstacles to their sale directly to the consumer. So, this product can be forwarding to cannery industry or proceeded food without shell and cockles reared in intertidal plot is more targeted to fresh consume.

Background

Aquaculture production in Norway has grown immensely in terms of quantity and value compared to other developed nations in the last decade [1]. This tremendous growth depends directly on fish feed and fish health along with other best management practices contributing to fish welfare. Also, chemical compounds used in aquaculture have increased concomitantly and have been used widely for feed and health management. However, a further increase in aquaculture should occur in a sustainable manner without harming the environment or posing a threat to biodiversity and consumer safety. This can be achieved by replacing synthetic compounds, such as the antioxidant (eg. ethoxyquin) and antibiotics with natural, efficient, non-toxic alternatives identified among bioactive compounds from plant-based sources.

In the present study, we have screened 339 extracts from various plant parts of different varieties of 9 herbs (*Artemisia annua*, *Achillea millefolium*, *Rhodiola rosea*, *Mentha piperita*, *Oreganum vulgare*, *Humulus lupulus*, *Leuzea carthamoides*, *Rosmarinus officinalis*, *Portulaca oleracea*) grown in Norway for antioxidant (AO) property and antimicrobial (AM) activity against the Atlantic salmon pathogens, *Aliivibrio* spp. *Moritella* spp. and *Tenacibaculum* spp. The selected pathogens mainly cause ulcerative disease in salmonids, which is among the main reasons for reduced welfare and increased mortality in on-growing salmon in Norway [2]. Furthermore, intensive farming conditions can lead to increased bacterial and parasitic diseases, which in turn lead to huge losses in farmed fish [3]. The objective of this study was first to assess the bioactivity of herbs produced in Norway based on evaluation and comparison of the antioxidant and antimicrobial properties of the plant extracts, and second to select the potential phytogenic compound or whole extract that revealed the best properties to be included as an additive in fish feed.

Methods

The herbs were grown in open field or in green house in Norway. The extracts were prepared by successive extraction with three different extraction solvents: dichloromethane (DCM), ethanol and water. The commonly used antioxidant methods, ABTS and Folin Ciocalteu, were used to measure the antioxidant capacity of the extracts. Agar disc diffusion assay was used to test the susceptibility of bacterial strains to extracts. Tested strains were grown in two different growth media mimicking external sea water environment and internal tissue of salmon. Extracts that revealed the highest AO and AM activities were tested in salmon skin cells *in vitro* (keratocytes) and cytotoxic activity assessed.

Results

Among 9 herbs studied, *Origanum vulgare*, *Artemisia annua*, *Humulus lupulus* and *Rosmarinus officinalis* had an interesting effect on AO and AM properties. The DCM extracts of the selected plants revealed particular inhibition of the salmon pathogens. However, the extracts were found to have a lethal effect on salmon keratocytes in a dose-dependent manner. Therefore, further studies are required to fully understand its suitability as a natural additive in fish feed and its impact on fish. Our study also indicated that the bioactivity may be caused by a combination of compounds present in the whole extracts, which cannot be obtained using purified individual compounds from the same plant.

Conclusion

The results from screening of Nordic herb extracts using salmon pathogens and salmon keratocytes show a great potential in selecting a suitable herbal extract/compound that can be used in the salmon farming. Moreover, plant extracts or individual bioactive compounds may have additional benefits other than AO and AM activities, but might also show adverse effects.

Introduction

Bivalve mollusks are sentinel animals sensitive to the quality of aquatic environments (Pereira et al., 2014). Variations in physico-chemical parameters or presence of contaminants may lead these animals to change their behavioural patterns (Newton et al., 2007). Since oysters and mussels open and close their valves to perform physiological activities, the stress promoted by environmental factors may affect shell movement patterns (Hartmann et al., 2016).

By understanding the behaviour of bivalve mollusks, it becomes possible to employ them as biosensors for water quality conditions. In integrated multi-trophic aquaculture (IMTA), these organisms have commercial value and may take part in the chain as filtering animals (Crab et al., 2012). This work proposes to assess the behaviour of *Crassostrea gasar* oysters in IMTA environments containing biofloc in order to evaluate its application as a biosensor in aquaculture sites.

Materials and Methods

An experiment employing *C. gasar* oysters in biofloc water from shrimp breeding tanks was performed. The setup comprised instrumented animals disposed inside water tanks and an electronic acquisition system to log behavioural readings.

Oysters were instrumented with neodymium magnets and Hall Effect sensors, each fixed to opposing valves. The attachment of the respective devices was made using epoxy resin and cyanoacrylate glue for achieving greater resistance during tests. A 3-core cable was used to connect each sensor to the acquisition system and provide power (5V).

Water tanks (100 L) were employed as recipients for the animals. A nylon net was fixed at half height within the tanks to hold oysters in order to avoid their contact with sediments. Three biofloc concentrations and a control were tested (control, low - up to 100 mg/L, medium - between 100 to 200 mg/L, high - above 200 mg/L). Proposed concentrations were based on the range for optimized shrimp growth (Gaona et al., 2017). Each test tank contained four instrumented oysters. Temperature was controlled during the experiment and all tanks were connected to a continuous recirculation system to avoid precipitation of particulate matter. The experiment was performed in triplicate.

The acquisition system was composed of two multiplexing boards connected to an Arduino MEGA microcontroller. This system logged data at 2 Hz rate to an SD card as CSV files. After pre-processing, data was obtained as the percentage of valve opening for each animal. The experiment was performed in triplicate throughout a 28-day period. Figure 1 depicts the experimental setup.

Results and Discussions

Behavioural data from 28 days of recording were split into 4 weeks. Every 120 readings were grouped into a 1-minute value. Data analysis proceeded observing minute data frequency for every week. Statistical analysis was performed using ANOVA with 5% confidence level. The control group presented higher overall average opening amplitude than all three biofloc concentrations. This observation shows the particles may stress the bivalves, promoting longer closed shell periods.

In the second and third experimental week, the opening frequency showed significant differences among groups. Higher frequency of open periods was observed for the control group when compared to biofloc groups, especially at high concentration. Higher concentrations recorded longer closed valve periods. By the third week, low and medium groups presented similar opening frequencies when compared to the control.

Conclusions

The assessment of oyster behaviour in biofloc environments was observed over several weeks. Results show behavioural pattern variations with increasing particle concentration. Significant stress was observed at the highest concentration tested when compared to other groups. This behaviour may provide a feasible biosensor based on bivalve mollusks for IMTA environments.

Introduction

Highly polymorphic fragments of DNA, such as microsatellites, can be used to prepare genetic profiles of fish that could be used for breeding and gamete banking. These profiles can be used to identify individuals that are as different as possible and in management of the genetic variation in gamete banks.

Maintaining high genetic variation, expressed as high heterozygosity and allelic diversity, is crucial for populations viability of sturgeon fish and their adaptation to environmental changes. Conserving genetic diversity in broodstocks is important for conservation of all human-dependent fish species.

Identification genetic differences between sturgeons and optimization assemblage them in breeding pairs is very important for conservation biology and aquaculture of those species. If individuals are paired without knowledge of the genetic differences between them, they might be genetically similar, which would prevent optimal transfer of genetic variation from parental stock to their progeny. To help identify the best possible breeding pairs within and between breeding stocks and manage genetic variation deposited in gamete bank, Genassemblage 2.0 was constructed. The software is intended to be useful in the conservation of human dependent fish species (including sturgeons and paddlefish), the maintenance of genetic variation in broodstock, the production of juveniles for fish farming, and for educational purposes

Cryopreservation of gametes is used to protect the genetic resources of a fish population and to safeguard the level of genetic variability in the event of a catastrophe resulting in the extinction of the population. It is used for both endangered sturgeon species and economically valuable breeds and breeding lines.

The potential usefulness of cryopreserved gametes in protecting the genetic variability of sturgeons depends on the genetic diversity of the individuals from which the gametes were collected. The genetic diversity of a gamete bank can be managed if the genetic profiles of the gamete donors are known and a tool is available to process this information. To address this problem, we developed a tool that enables management of genetic variation in a gamete bank and added it as a new module for Genassemblage 2.0 software.

Material and methods

Genassemblage 2.0 is a free-of-charge Windows-based program. This software has four modules, which can be chosen by clicking on their respective bars. Its installer and a detailed user guide can be downloaded from the author's website. The software requires the use of MS Excel, version 2003 or newer and Microsoft .NET 4 framework.

An input file for Genassemblage 2.0 can be prepared in a MS Excel spreadsheet. Modules one and two described below use the same input file, but module three uses an slightly different input file than previous two. Details of constructing input files are given in user guide.

The module "Select best breeding pair" was designed for breeding individuals. The user can decide how many pairs to include in the set of best pairs. The suitability of pairs for breeding is evaluated by simultaneously comparing heterozygosity and percentage of weak heterozygotes expected in the progeny, as well as the number of different alleles that will be inherited by their offspring. In version 2.0, we have added the "*v* index", so that users can define the relative importance of the three indicators. To generate the results, we used the "Select best breeding pair" module and checked the fields for heterozygosity, percentage of weak heterozygotes and number of different alleles expected in the progeny. Using the *v* index, we defined the relative importance of the indicators as heterozygosity (0.40), share of "weak heterozygotes" (0.20) and number of different alleles (0.40). The number of pairs was set at four.

(Continued on next page)

The module “Select individuals for group spawning” is new in Genassemblage 2.0 and was intended especially as a help in breeding of fish. It enable to find a group males and females that, when bred together, will contribute the highest genetic diversity to the progeny. After clicking on the bar of this module, the user can indicate how many males and females to include in this set. In the example presented bellow we used this module to identify a set of two males and two females that will contribute the highest allelic diversity to their progeny. In the window of this module we chose “Number of alleles” as the primary indicator.

The module “Management of genetic variation in gamete bank” is based on allelic diversity across all loci included in genetic profiles. It calculates the overall number of alleles across all loci and indicates which samples should be used to obtain a target percentage of allelic diversity while using as few samples as possible. After the user loads the input file, the program will automatically calculate the number of alleles across all samples. In the line “minimum level of genetic variation”, the user should enter the percentage of total genetic variation deposited across all samples and loci that should be in the group of samples chosen by the software. In the example presented below, this value is 100%; as a result, all alleles included in the input file are included in the group of selected samples.

The details of calculations performed by those three modules are given in user guide.

Results

The results provided by all modules are presented in MS Excel files. In module “Select best breeding pair” they include four sheets: the expected heterozygosity in the progeny of each pair, the number of alleles that will be inherited by progeny of weak heterozygotes and the results of the *v* index. Based on this index, we found four pairs that were selected as optimal for breeding because their progeny have a high heterozygosity, low share of weak heterozygotes and high number of alleles.

The results of “Select individuals for group spawning” module indicated optimal group of males and females. Their progeny will inherit an highest number of alleles among all variants of male and female groups. Moreover their progeny will be highly heterozygotic.

The result file of module “Management of genetic variation include lists the alleles at each locus, and the alleles across all samples and loci. Transferring 100% of the allelic diversity detected in this group of samples can be done by using just a few samples across all included in the input file. Their names and genetic profiles are presented in the output file.

Conclusion

Genassemblage 2.0 identifies the set of parents that have the best values of genetic variation indicators. It indicates optimal sets of breeding pairs without using the same individuals more than once, thus reducing inbreeding risk. It can also select individuals for group breeding of fish to transfer the highest amount of genetic variation to the next generation. As calculations show, it is possible to use a fraction of the samples stored in a gamete bank and transfer the same number of detected alleles as when using all the samples. In this way, Genassemblage 2.0 can be in management of the genetic variation resources deposited in a gamete bank and can help in assemblage fish for breeding in fish farming and conservation of human dependent populations of sturgeons.

REUSABLE, RECYCLABLE AND SUSTAINABLE SEAFOOD PACKAGING FOR AQUACULTURE PRODUCERS

Y. Kailis and M. Delafosse

Disruptive Packaging
Unit 3, 7-15 Gundah Road, Mount Kuring-gai NSW 2080 Australia
yanni@disruptivepackaging.com.au

Introduction

Ocean pollution is affecting our marine environment in unprecedented ways. Eight million metric tons of plastics are dumped into our oceans annually, many of which take 500-1000 years to degrade. Polystyrene (EPS) boxes used to pack fresh fish are a key contributor to this due to significant volume and market share, combined with single-use behaviour and low levels of recycling capability amongst its users. Governments around the world enacting climate-change policy are beginning the process of outlawing EPS which has accelerated the adoption of new alternatives. The change to more sustainable packaging has been a case of the ‘chicken or the egg’ in terms of whether it has been led on the producer or customer end. In many cases, producers looking to follow through on ESG standards have adopted packaging that meets their internal environmental goals, while the customers and receivers of such stock including secondary processors, wholesalers and retailers have fast-tracked the process by demanding they receive products in recyclable, reusable and overarchingly sustainable packaging.

Our solution

Disruptive Packaging is an Australian inventor, manufacturer and distributor of sustainable packaging with the goal of addressing the aforementioned concerns. UNICOR is a revolutionary alternative to EPS and waxed cardboard with key environmental and performance benefits. The product has been engineered to be fit-for-purpose for the seafood industry taking into account multiple factors. First, UNICOR is 100% waterproof, leak proof and washable. Unlike cardboard alternatives, UNICOR stands up to the test of the wet nature of fish and can withstand any moisture exposure throughout the supply chain. Further to this, UNICOR strengthens in the cold chain as a result of its chemical composition by gaining greater rigidity. Additionally, UNICOOL is a strong insulator and has thermal properties that ensure that the integrity and quality of the seafood packed inside is maintained for good periods of time. Understanding that different species require different packaging solutions, UNICOR is fully customisable in shape, thickness, size and format (lid & base vs. single piece). Furthermore, a magazine quality print creates maximum brand exposure and gives customers a unique opportunity to use their packaging as a means of marketing. Finally, due to its flat packed nature, UNICOR eliminates the need for mass storage space and therefore reduces both warehouse and shipping costs.

UNICOR has been designed with sustainability and the environment at the core of its purpose. Unlike EPS, UNICOR is a vehicle that will help achieve key European objectives such as the Farm to Fork Strategy and European Green Deal. The product has been designed to directly address and eliminate the harmful effect EPS and waxed cardboard have on our oceans and planet. By being 100% recyclable, UNICOR supports the circular economy by ensuring no packaging ends up in landfill or the oceans as is the case with EPS. Its reusability due to waterproof properties allowing for washing means overall consumption of boxes by volume is reduced. Further to this, UNICOR is made up of at least 65% natural raw Earth elements that are sustainable in supply and, UNICOR does not contribute to deforestation. The carbon footprint of UNICOR is also significantly lower than its EPS and Cardboard alternatives by reducing overall CO2 emissions by 80%. Furthemore, the energy required for production is lowered by 25% and recycling by 92%.

Conclusion

If the Blue Economy is to truly be realised, action must be taken today to ensure our oceans are able to provide high quality seafood. Marine pollution puts this at risk and until harmful packaging such as EPS and waxed cardboard are eliminated, initiatives such as the European Green Deal and Farm to Fork Strategy will be at risk. Encouragingly however, the shift has already begun and aquaculture producers now have an alternative packaging option in the form of UNICOR that provides superior performance specially designed for seafood, as well as significant environmental benefits.

MICRO-RNA RECRUITMENT IN GREATER AMBERJACK'S (*Seriola dumerili*) DEVELOPMENTAL STAGES UNDER DIFFERENT REARING TEMPERATURES AND DIET CHALLENGES

Kaitetzidou, E*., Papandroulakis, N., Mitrizakis, N. and E. Sarropoulou

Institute of Marine Biology, Biotechnology and Aquaculture, Hellenic Centre for Marine Research (HCMR)
Heraklion, Crete, Greece
E-mail: ekaitetz@hcmr.gr

Introduction

The last decades, the greater amberjack (*Seriola dumerili*), has been considered a strong candidate as a newly introduced species in the farming industry. Principally, its high-quality meat, as well as its significant growth rate, high commercial value, and its cosmopolitan distribution, meets a lot of the aquaculture sector requirements. However, dysfunctions regarding greater amberjack's reproduction, egg survival and growth, limits the establishment of the species in the farming industry.

Among others, temperature shifts, as well diet variations have an impact on diverse physiological processes in teleosts, many of which are regulated by micro-RNA (miRNA). miRNAs, as a member of the epigenetics mechanisms, may alter gene expression -in this case post-transcriptionally- without altering the gene sequence. So, as to reveal the underpinning molecular processes of the critical period of embryo and larval development of greater amberjack, their miRNA repertoire under different rearing temperature, and different diet regime was searched in the current study.

Material & methods

Greater amberjack eggs were transferred to the HCMR Aqualabs facilities where they were kept at 20°C or 24°C. At the first feeding stage, larvae were further separated into two groups, one fed with rotifers and the other fed with copepods (Figure 1). Samples at a stage before first feeding and at the flexion and mid-metamorphosis stage were collected. Total RNA was extracted, and miRNA libraries were constructed and sequenced at an Illumina platform.

Results/ Discussion

The number of the sequencing reads for each condition ranged from ~10 to ~29 million reads. After trimming, the sequence length analysis revealed that most of the reads were 22 bp long (Figure 2), which is the mean length of miRNAs.

Principal component analysis located the replicates of the same condition close to each other. Searching the most abundant miRNAs, as well as the most differentially expressed miRNAs, showed higher variation between different stages reared under same conditions (temperature and diet). The later findings may indicate the strategic role of the miRNA in the fulfillment of the developmental processes, as well as the necessity of a specific miRNA repertoire for each developmental stage.

EVALUATION OF ECOLOGICAL STATUS AND FISHERY MANAGEMENT OF EUROPEAN PONDS: A META-ANALYSIS

L. Kajgrová*, K. Roy, Z. Adámek, P. Blabolil, R. Kopp, J. Mráz, O. Pecha, L. Pechar, J. Potužák, J. Vrba

University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, Institute of Aquaculture and Protection of Waters, České Budějovice 370 05, Czech Republic
E-mail: kajgrova@frov.jcu.cz

Introduction

Central European fishponds are shallow artificial water bodies of different sizes (<1 ha to several hundred ha) used for aquaculture (mainly fish production of common carp) since the Middle Ages. During the last century, farming in the fishponds has undergone intensification and diversification of fish production. Long-term excessive nutrient loads have modified biological processes such as primary production, nutrient utilization, respiration, or biogeochemical cycles. Overall biodiversity loss, excessive cyanobacterial blooming, and often hypoxia have been increasingly recorded in many fishponds. Such changes indicate progressing deterioration of fishponds with ultimate impacts on both fish production and freshwater environments.

Phosphorus (P) has been reported as the superior limiting nutrient in freshwaters that determines the status of water bodies and supports primary and secondary production. Yet in shallow P-rich lakes and ponds, denitrification has been recognized as significant nitrogen (N) loss driving phytoplankton from P to N limitation. The stoichiometric imbalance might be reinforced by internal P loading from anoxic sediments and driven by fish bioturbation. Ptacnik et al. (2010) recommended the dissolved inorganic N to total P ratio (DIN:TP) as the best indicator for inferring in situ N vs. P limitation from chemical data in nutrient-rich freshwaters. This study examines the current nutrient status of Czech fishponds to reveal their actual nutrient limitation. We hypothesized that the nutrient regime might vary on both temporal and spatial scales.

Material and methods

Our results covered 33 Czech fishponds from lowlands (<200 m a.s.l.; n = 6 ponds), moderate altitude (200–450 m a.s.l.; n = 19), and highland region (>450 m a.s.l.; n = 7). The ponds were monitored irregularly on a yearly basis from 2007 to 2021 (resulting in a total of 180 pond-year cases).
